[An engine rides easiest at the center of the boiler and hardest at the ends where the most oscillation takes place. More men are killed between the engine and tank in head-end collisions than in any other way, and this cab is easy to get out of without running the chance of getting pinched. It is cleaner and cooler, because there is no smoking fire door in the cab, and dust from the ash pan goes up behind it. A person used to a cab on rear of boiler would be surprised at the difference in view by being placed ahead and higher up; you can see across curves and on tracks to the left. Side rods once broken will get to the cab anyway if long enough; and this is a hard-coal burner, where the fireman spends most of his time in the cab ahead.]

The Cause of Slipping Again

Editor The Locomotive Engineer:

I have been much interested in the slip of drivers phenomenon. It has been claimed to have occurred on two prominent Southern roads recently, both of which twisted the axles and one broke both axles close to hub of driving wheels. Slipping, I think, is of two kinds, in which doubtless many get confused. As I understand it, when shut off, running down hill, drivers turn faster than is due to the engine's speed, which can be from two causes, over-counterbalancing or improper quartering. Badly put up side rods would produce the same results as bad quartering, as it would cause the engine to roll over a given point with a jerk, and with the aid of the counterbalance would slip. I remember two instances which have been remedied, one by quartering and the other by boring out side-rod brasses much larger than the pin.

In the other kind of slipping, or skidding, the engine is propelled by a heavy train down hill faster than wheels turn. I am sure an explanation is hardly necessary to the old and experienced engineer. It is, however, not understood by all that the plain slide valve will raise clear off the seat one-half to three-quarters of an inch when shut off, running thirty-five or forty miles an hour, if valve yoke will permit it, and whenever an engine falls back against the train, or if brakes were applied in front, it is because there is not enough space between valve yoke and valve to let the valve up and permit air to follow piston freely and without retarding effect. If any one doubts the above theory I would suggest that they would put a liner between yoke and valve, taking up the entire space, get her under good headway down hill and shut off, and I will venture that she will not roll down the side of a mountain. This, I think, was the trouble with Mr. Bosley's engine when he had to pull the lever back to center to relieve her. Another point which is very detrimental to an engine, and which causes nosing when shut off, is to have an eighth clearance on one yoke and one-half inch on the other, as is frequently the case where the seat or valve is faced off more on one side than the other. The objections we so often hear of to the balance slide valve are that they are given too little space between valve seat and balance plate, which gives piston no relief during the expansion period of valve travel, though such engine may have a relief valve. This engine will also fall back on train on a down grade, as if brakes were applied on the engine. D. O. SMITH.

Mobile, Ala.

[Side rods that produce a jerk at any one point of the stroke would increase friction and tend to retard rather than accelerate its speed, and boring their brasses out so as to free the rod would give the engine a better chance to slip ahead than it had before. Our correspondent makes a broad statement about the action of slide valves; if the reverse lever is put at or near full stroke when shut off, the valve opens the port before the piston starts back, and gives a full opening for air to follow until at least two-thirds of the stroke, while the other port is kept in communication with the exhaust for about the same length of time. It is the compression of air ahead of the piston after the port is closed that lifts the valve, but this in an engine running with the valves traveling full stroke is very slight indeed, the further back the lever is left the more the compression of air will occur, on account of the earlier closing of the port, and the valve will then be lifted. You can hear the valve raise and fall on the seat when the lever is left hooked up after shutting off, but it is stopped at once by dropping the lever into the corner. The cases of slipping distinctly state that the engines slip *ahead* while running down hill pushed by the train; no skidding surprises us, there are many things to help it, but what makes 'em slip ahead, overcoming friction, air resistance to the piston, etc.? That is the question.]

That Hoodoo Model.

Editor The Locomotive Engineer:

Say ! Talk about Barnum's circus , but for clean-cut fun of the vintage of '77 you should have been up to our division meeting last Sunday, when we unboxed one of those valve motion models whose stepmother you are supposed to be.

But let me commence at the beginning. Last winter, when the picture of the motion floated in with the L. E. I spotted it as just the sort of a thing *we* needed and *I* wanted, so the next Sunday I got up and proposed that the division set aside the necessary cash to get one. Two old plugs stood up and contested the right for the floor to ask what good the darn thing could do. I told 'em to help us understand the link motion.

Windy Brown said any man that knowed enough to run an engine knowed enough to set valves, or anything else I said he didn't.

Black Pete Yonder said we couldn't afford it (division has over a thousand cold dollars in the treasury). Then I proposed we go in halves with the firemen on it.

The chorus kicked, and High Water Wilks got up and said, in a sort of sneering way, that he would vote to buy a model boiler, and ask the firemen to practice on *that*, before they went into valve motion and other things "belonging to us" (the engineers, I suppose).

Then I asked High Water what *he* knew about firing; could he tell what was a fair amount of water evaporated for a pound of coal burned, and after he wouldn't answer I offered to bet $10 to 10 cents that he couldn't tell what steam was—and I'd leave it to the men present. But they were, as a body, opposed to any "school" in the division; didn't come there for that—but still they wouldn't tell what they did come for. The great objection was expense for a "fool thing like that."

I got my back up a little and I trapped 'em, first I asked them if there was anything new about the link motion—wasn't it just like a locomotive as near as could be ?

Yes, it was.

Wasn't it handy to get at, and so fixed as to see all the parts of the whole engine ?

Yes, but what good was it ?

Then I offered this communication, and the F. A E. read it.

Officers and Members of —— Div. No. —— B. of L. E.: If your division will purchase a Pedrick & Ayer valve motion model and open the packing case and set it up in open division, and there are any two members present who can set the valve to cut off *exactly* square for all points of cut-off, in both forward and back motion, I will pay for the model myself then and there. JOHN ALEXANDER.

They all sat as still as a Quaker meeting for a full minute, then Puffy Williams, an old machinist runner, got up and went over and whispered to Swifty Smith, shaking his head and jerking his thumb; but I got up, and, pretending mad, went for 'em hot. Accused them of knowing something once, but being so no-good as to forget it, and told 'em the firemen had ordered one of the models and was going to set it up at their annual ball and challenge the Engineers' Brotherhood to put up their best man to explain link motion against a fireman for a prize, and asked 'em who they'd send, or if they dared to send anybody?

Then Puffy Williams arose and sucked in about fourteen cubic yards of atmosphere and said :

Worthy Chief and brothers, I think Brother Alexander has misabused the scientific ability and mechanical sagacity of the other brothers present, and he ought to be suspended for ten months for unbecoming conduct, but just once in a while a blowhard gets took down ; now I propose that this division accept that paper of his and place it on record, and the F. A E. be requested to correspond with the makers about the model, with a view to getting one.

I wanted it ordered at once no use writing about it , we knew what it was like and what it cost.

But Puffy argued for the slower process, and ended by saying, lofty like, and with a patronizing look at Swifty, "and I think there is some engineers present in this here room that kin show our smart brother that they know as much about valve motion as the firemen—or him either."

As I was putting on my rubber coat out in the anteroom I overheard Swifty tell some of the fellows : "He's gettin' too dam smart, and we'll jest make him pay that $70 or expel him—that's all—he's a sucker anyway ; I saw him oiling around his motion work, and even the spring hangers, with a *squirt can* ; it's jest such suckers as him that's getting things down so fine a decent man can't run an engine any more." But I only laughed and went home.

Ever since then I noticed Puffy and Swifty both talking a good deal with old Silas Parsons, the man who sets valves, and watching him at work, but I kept away and said nothing.

Last Thursday the model came and I got a notice to be on hand at the division meeting—I was there.

The regular business was hurried, and we finally got to "unfinished business," and the chief ordered the opening of the crate and a recess of five minutes ; during this time all hands helped at the unboxing and setting up but me. I overheard Puffy whisper to Swifty to "look out that he don't get at that model and 'hoodoo' it." So I didn't even look.

Well, they finally got it all together, every man but myself gave it a few turns and called it a "cob-chopper," "feed cutter" or "sausage stuffer," and at last left it in front of the presiding officer, with the working side to the audience. With a show of making it legal and binding, the chief asked me if I was ready for the trial.

I told him yes, and went up and put $70 in the hands of the F. A. E.

Then the F. A E. read the resolution I had offered again, and suggested the appointment of judges.

I offered to leave it to the whole lodge, but they finally made the three first officers of the division judges.

The chief asked who would try and earn seventy dollars for the treasury by setting the valves of the model, and put on a postscript to his speech by saying that he "reckoned there wasn't an engineer there but what could do it."

It was worth two hundred dollars to the company, just the little posting up on valve motion most of 'em did while waiting for this model.

When he sat down, old Puffy and Swift got up with great importance and offered to try, and in each of their eyes I could see in letters of fire the old motto, "There is no such word as f-a-i-e."

Both took off their coats, and Swifty went out in the hall and brought in the road's standard tram, a package done up in a newspaper, and old Silas' dividers and scale. I suppose they wanted tools used to the work.

Puffy turned the wheel and Swift went down into the package and fished up a piece of thin Russia iron that Silas used to put down into the ports to "feel" the valve opening when putting tram marks on the stem.

But the port was not there in the model just as it was in the locomotive, and they could not get the tin between the valve and the port, so they whispered a minute, and finally the chief suggested that they merely look at the sharp lines on the edge of valve and port and set by them. They did so and made some prick punches on the valve stem.

Then Swifty smeared the front of the tire all over with chalk from the package—same chalk Silas used , it couldn't go wrong.

Then they started in to find the dead center. Swift held the wheel and Puffy did the dizzy work now, and they did pretty well, excepting that they were not particular which way they turned while approaching center marks, but that didn't matter much ; the model was neatly fitted and had very little slack, but they only took one end

Well, just here Swift discovered the instruction book tacked on the back, and proceeded to consult it, but the judges said it wa'n't fair and made him stop, although I offered to let him use it.

This got Swifty nervous and red in the face, and all he did after that was to offer suggestions and help muddle Puff, the latter stuck to his work, but it was plain he was getting mad ; then, to make matters worse, the boys commenced to offer suggestions.

The valves did not travel evenly each side of the seat, and Puff went for the eccentrics, and that changed the lead ; then he moved the blades, and that changed the travel, but didn't help the lead, and the boys guyed harder. Puff finally turned and announced with a red face that they could either shut up or set the pesky thing themselves ; they kept still.

He moved the reverse lever and tried again, but it didn't come out right , he got her pretty square in the corner, but she was a trifle "out" when hooked up, and finally he broke off the handle and half kicked the model over declaring it was "hoodooed."

The room was pretty full of men by this time, and they laughed heartily, but quit when I got up and asked for any one else to try it, as the offer was good to all.

One bright young fellow, who hadn't belonged but a couple of weeks, went up to the model and said he'd try, and asked to hear the resolution read, when he heard it he sat down and smiled.

"Won't nobody accept the offer and save the lodge $70 ?" asked the chief.

The young fellow suggested that the chief try it.

"I am a judge in this case, and it wouldn't be fair for me to do it," said he.

I was kind and offered him the chance, but he wouldn't have it, and some of the fellows commenced to itch for adjournment.

The chief called for volunteers, but none came, and at last he declared I had won.

Then I claimed the chance for a lecture, and I told them fellows they ought to be ashamed to not try and set the valves , they wanted me to do it myself, being I was so smart. You ought to have seen their eyes stick out when I owned up that I couldn't, and when I declared it was impossible to get them *exactly* square for all points forward and back they were interested enough to want to know why—that's progress.

In the discussion that followed every man present but Swift and Puffy virtually acknowledged that they didn't know much about link motion, and most of 'em said they wanted to learn.

Puff and Swifty declared they knowed how to set valves on a real engine, but that that model was "hoodooed," and no good.

Next Sunday we commence a regular discussion on valve motion, and when we have worn the interest out of that subject I hope they will see the necessity of tackling something else.

I suggest to the builders that they put a dingus of some kind on the model to hold the wheel still at any one place, so that one man can set valves; a clamp and thumb-screw on the shaft would be good.

Come up next Sunday and hear an illustrated lecture on link motion that will make your hair stand—I have agreed to tell all I know, and some things I only think, and let the boys ask questions —just for a starter.

Boston, Mass. JOHN ALEXANDER.

They Can't be Run for Fun.

With a full passenger list it costs about $25,000 a single trip to run such boats as the Normannia, City of New York, or Teutonic. It costs $1,000 a day for coal, $500 a single trip barely pays for the oil The salary list for a trip of eight days is a little over $2,000. The food and drink for crew and passengers of a recent trip of the Normannia cost $16,000. During the busy season these boats receive about $50,000 a trip in fares and freight receipts.

A remarkable invention has been made in Australia. Glass tubes project before the train, and if they are broken by an obstacle an electric movement is applied to the brakes, bringing the train immediately to a standstill.—*Ex.*

What a great help that will be—to set the brakes when two engines meet on the main line. Just like hanging a corpse to be sure it is dead.

The elevated roads of New York city are limited to 40,000 pounds in the weight of locomotives, and are having some thirty new engines built at Baldwin's with wrought iron drivers to keep down the weight. Their engines carry a heavy cast iron stack that it would seem easy to trade for a sheet metal one weighing about one-third as much.

CONTENTS.

The Chances for Economy in Running Locomotives.

Economy in operating locomotives is what every progressive motive power officer is seeking, some in one way, some in another.

The greatest chance for the exercise of economy is in the use of fuel, and the greatest number of tons of load transported the greatest number of miles to a ton of coal consumed has come to be the general gauge applied to test a road or an officer's accomplishment in locomotive economy.

Broadly speaking, this is a good test, but "circumstances alter cases," and there are quite a number of railroads in this country on which it does not pay to save coal by the use of "improvements," and if it could be proven that compound locomotives would decrease the fuel account fifteen per cent. it would not pay to adopt them. Where coal is worth less than one dollar a ton it don't pay to complicate anything on the locomotive to save it.

Where coal costs from five to fifteen dollars per ton it does pay to complicate almost anything to save it.

The Central Pacific road experimented many years with valve motion, and at last adopted one designed by A. J. Stevens, then Superintendent of M. P. This device is complicated, and costs more on the start and requires more running repairs than a common link motion; yet the road is running over sixty locomotives with this gear and find it pays slightly, all things considered—coal is worth more than ten dollars per ton there.

Everything that simplifies a locomotive with a gain, or even without a loss, should be adopted.

The best results we have heard claimed for the fuel economy of any compound locomotives in existence is twenty-two per cent., and perhaps ten would be a fair average, when the conditions are favorable to the compound. Now we must deduct from this gain the interest on excess in first cost and amount of running repairs over those of plain engines—extra parts mean extra cost of maintenance.

And so it is with every device invented to effect economy—its value depends upon its cost and maintenance over the old plans—if it is simpler and requires less care the amount less should be credited to it, if it costs more the amount should be deducted from the saving.

There is just one means of economical locomotive operating that is not covered by this rule; just one improvement from which there is no discount, no extra pieces, no extra maintenance, just one chance for clear gain, and that is in the improvement of the men on the locomotives—improvement by themselves.

The fuel economy that has been accomplished from this source is seldom less than ten per cent., and has often exceeded fifty per cent.

Every time there is a new device gotten up for "improving" locomotives the inventor or his agents go out with it and a picked man runs the engine. No possible chance to save is overlooked, and the result is a big showing—for which the device gets the credit.

A few years ago a feed-water heater was tried upon the Manhattan elevated road, a place where great care is taken to know just what the engines are doing, the returns from the trial were a surprise and the device got considerable credit; but the foreman of the shop was not satisfied, so he took the same engine, shut off her coal-saving heater and put a third man in the cab, with instructions to watch every opportunity to save *steam*, to, under no circumstances, let the pop lift, avoid unnecessary firing near terminals, etc., and the result was that the engine beat her "heater" record by eight per cent.—nothing but care and pains. Where coal is the cheapest thing to be had the care must be exercised in another direction.

There is scarcely a road in the country where there is not a very great difference in men about tire wear, and a man who is a "tire-grinder" is generally a grinder on everything else. Attention to the proper water line saves valves, seats, pistons, and cylinders. Intelligent use of what brains there are in your heads saves an awful bill in car repairs every year.

The more you think of the matter the greater the chance for economy in operating seems. We don't ask men on hurried runs to oil with a squirt-can or anything like that, sacrifice oil, coal or tire to make time, but use your brains; it will become a pleasure and make better enginemen of you.

On the P. R. R. the engineer and firemen each receive sixty cents per ton for all coal saved over a certain fixed rate—some of the boys haul in from $14 to $24 a month regular, others on the same runs have never won a premium. Which of these is the true engineer and fireman? We hope to see such a rule on all roads some day, where every man who *tries* will get paid for it, as he ought, and where the sluggard will not be considered an engineer because he is the older man or because he draws first-class pay, or does or does not belong to anything.

Neither the railroads nor the men can overlook the advantages and the chances for clear gain in improving the methods of the men upon our locomotives, instead of the locomotives themselves.

To the roads we would say, make it an object to the men to improve themselves—no library or bath-house, or vacation, or prize for the best, but a fair percentage of the gain made by each crew—it will pay the road well, without the payment of a royalty or the shopping of engines, for the improvement.

To the men we would say, *try;* don't be ashamed to show an interest in your work; it will tell in the long run, and be to your credit, and you will be in practice to reap reward when the sharing of profits of the results of economical working become universal, or strike your road.

We are not arguing against the adoption of compound locomotives or anything else; they will come and go on the natural rule of the "survival of the fittest," but the chance of improvement in locomotive engine running and firing will always be present. There may seem but little encouragement to try, but it will pay and will be soon noted, and credit given.

Engineers and firemen of America, you can show a better economy than any change in locomotives now contemplated if you will try. Try!

Some Lessons of the Strike.

The N. Y. Central road has paid its penalty for submitting to a strike—paid it in cash, charged it to profit and loss, and—forgot about it.

Some two thousand workingmen have just commenced to pay their penalties for going into a strike, and they are likely to suffer a long time to come—it is like purgatory; no one seems to know how long it will last.

Last month we blamed Mr. Webb for refusing to treat with Mr. Holland because he was not an employe of the road, and we still maintain that no road has a right to refuse to listen to the accredited representative of the men—to do so is to deny them the right to employ an attorney—something the roads always do.

Since last month, however, we have personally investigated several phases of the late trouble, and are now satisfied that Mr. Holland was treated very courteously at Mr. Webb's office; he did not present any evidence that he came from the men, and none was asked; he was not ordered out of the office, Mr. Webb simply refused to grant the demands of the strikers.

Mr. Hays got into Mr. Webb's office by presenting the card of a priest, and talked for some time before he announced that he had a letter of introduction from the priest—he could have got in by sending his own name.

A good many men had been discharged before the strike, no new ones were employed in their places, the road was simply reducing forces, and did what every individual among the strikers would have done—let out the men less useful, and those causing them the most annoyance.

Had the employes of the N. Y. Central come before the public in a contest for wages they would have had sympathy and support—the road does not pay the best wages.

One lesson, that it is to be hoped has been learned for all time by most of the men, is that there are bound to be fire-brands and reckless leaders in any organization, and where one little division or assembly has the power to call on a strike, trouble will surely come—it is too easy to strike in the K. of L.

Another lesson can be learned by reading the plain, sensible and manly arguments Mr. Powderly advanced in his letters to prevent the strike, and then comparing them with his actions after the strike took place, declaring that they would win if the men held out, and that it was a fight for the life of the organization, etc. This prevented many good men from getting their places back, and the life of the order was not at stake—the jobs of a few leaders like Lee were at stake.

Another lesson can be read, in letters about four feet high, in the plan proposed by Mr. Powderly for winning a big strike on this road when it was crowded with business during the World's Fair.

The officers of the federated orders came and investigated the trouble, and held a meeting to decide whether or no they would join the Knights A good many men thought they had no right to convene. We give the officers credit as shrewd advertisers of the use of federation. The Knights were alone, the other orders united, and while they sympathized with them they showed how their cast-iron rules deferred a strike to the last resort, and the unanimous consent of the bodies interested In the federation it takes four whole orders to cause a strike—one little assembly caused one on the Central.

No strike will ever be won on any railroad in this country by any one order if the road is disposed to fight. If all the orders unite there will be no strike, if either side is disposed to be half way fair.

The N Y Central strike is over. The officers of the road have done wrong if they have refused to meet every man who came to adjust a grievance—which the men allege they have done.

In the employment of Pinkerton men, before they tested the efficiency of the civil authorities in affording them protection, they committed a grave fault, if not a crime. There is redress for all loss where the civil authorities fail to protect property. Allegheny County (Pa.) paid the P R. R hundreds of thousands of dollars for damages to property during the strike of '77

The wrecking of trains since the trouble commenced will hurt the road a little in scaring away timid passengers, but the crimes will all be laid at the door of the order, and some one will go to the penitentiary. Any man who deliberately wrecks a train, for any cause whatever, deserves to go to the gallows; be is worse than a murderer.

During the Q. strike many divisions of the B L. E. would not pay the assessments to support the men, and the Knights complain of the same treatment in this strike—this shows that the sinews of the striking functions of organized labor suffer from partial paralysis, and the lesson should be learned in advance. When workingmen will not support other workingmen on strike it is a hungry time for the strikers.

Strikes and lockouts and labor disputes will be forever dead when laboring men can choose between the jobs they prefer, and a certain livelihood working for themselves; this may possibly occur when any man can occupy unused land; this may be a cure and may not—it is worth investigating, and our advice to laboring men far and near is to study some plan of relief and stop listening to the agitator, who thinks he can change human nature by force and make railroad officers or other human beings submit the discharge of employes to a committee of the employes themselves—or any one else.

Accidents crowd upon accidents. This year has been the worst in the history of the country, and the more miles of road we build the greater the slaughter. When business is poor, or only fair, the accident returns are bad enough; but a rush of business means that the crop of accidents will increase as the square, if not as the cube. In many of these fatal accidents some employe has blundered or was incompetent, and if the victim or victims were passengers the poor devil has been prosecuted or branded as a criminal. But in nine out of ten cases the victim was a railroad man, and the case is marked up in the company's books as an "incident of a trip" In every reported accident this year the writer has investigated it to the best of his ability, as a practical locomotive engineer, and gives it as his honest conviction that eight out of every ten fatal accidents would have been averted had the best and safest equipment been in use. The reckless rivalry among the roads to do the business at any price, causes them to pinch the dollars very close to pay fixed charges and dividends, and this leaves the operating and motive power officers no choice but to seek for equipment that "will do for the present," instead of putting in the best and safest known.

It has been proven that the different orders of railroad men pay out enough every three years in death and disability claims to equip the rolling stock of North America with automatic couplers and power brakes The companies are resisting the pressure brought to bear on them in this matter, under the plea of expense. Who ought to bear the burden of murder by their crude equipment—the companies or the men?

Promotions.

James Heron, one of the strong advocates of self-improvement for railroad mechanics, has been promoted from the Horton (Kan.) shops to be foreman of the boiler shops of the C., R I & P. at Chicago. Mr. Heron has been a correspondent and friend of this paper from the outset, and last year sent in more than one hundred subscribers; but we don't claim this caused his promotion—it was his work and study to cheapen and better boiler work

H. V. Rosing, chief draftsman of the Illinois Central road, has been promoted to be master mechanic.

A. J. Sovereign, of Brainerd, Minnesota, has been appointed assistant superintendent of the Fergus Falls and Black Hills division of the Northern Pacific. Mr Sovereign has been with the N P. a long term of years as an engineer. The roads of the Northwest seem to understand that practical men do best in positions of responsibility.

Books Received.

POOR'S HAND-BOOK OF INVESTMENT SECURITIES A Supplement to Poor's Manual of Railroads

This book is intended principally for bankers, brokers, and investors in railroad securities, and is invaluable to them, and of interest and assistance to railroad officials. It contains:

A table showing the range of stock and bond values at the leading stock exchanges of the country during the 12½ years, January 1, 1878, to June 30, 1890

A statement of all dividends paid by the railroad companies of the United States during the past eight years

A list of bond coupons payable each month in the year, with the places where same are payable.

A statement of the stocks and bonds listed on the New York Stock Exchange during the past 11½ years, January 1, 1879, to June 30, 1890.

A statement showing for the leading railroad companies (a) close of fiscal year, (b) time of holding annual meeting, (c) closing and opening of books; (d) place of holding annual meeting, etc , etc.

A statement showing by cities the location of all railroad general and transfer offices

The book contains 300 pages of closely printed matter, and is furnished in cloth or paper at $1.60 and $2 50 respectively

ASKED & ANSWERED.

(61) A. F Cook, Lilly Pond, Ga., asks:

1. Will four gallons of water furnish steam enough for a cylinder 1⅝ inch? 2. What is the most miles a locomotive ever ran? 3. What is the most load a locomotive ever pulled? *A* 1. Depends entirely upon how long you want to furnish steam to the cylinder 2. We do not know 3. No one knows

(62) Bonafide, Alexandria, Va., asks

If an engine's wheels be blocked on the scales, and reverse lever placed in center, will she weigh any more with the throttle open than when it is closed? *A.*—No; we once knew of a wager on this subject, and it was found that the valves leaked so badly as to have the effect of a blower, and this caused the pop to lift, and showed a slight increase of weight—because the escaping steam was doing work against the resistance of the atmosphere The engineer thought the increase of weight was due to filling the cylinders with steam, and argued that the steam escaping at the pop would tend to make the engine weigh less, as it took water out of the boiler

(63) Rotary, Windsor, Ont., writes:

If the cylinders of a locomotive could give out a steady, even, rotary movement to the wheels, we could do more work with a lighter engine; now what stands in the way of using a rotary engine on the axle of the drivers? I am well aware that every big mechanic in the country will say "boo" at you if you just say rotary, and class rotary engine designers with those who are working up perpetual motion machines; but is there a reason why they cannot be made as good or better than the reciprocating piston engine? *A*—Rotary engines have an advantage in that their work is more nearly constant, but they have inherent faults that, with our present knowledge of steam machinery, puts them behind the ordinary steam engine; in the latter the piston stops and starts at each end of the stroke, giving time to admit a volume of steam upon it, and cutting off the supply, leaving the confined steam to do its work by expanding; in the rotary the piston speed is constant, and the steam hasn't time to get to work, as it has to start in to do its work against a piston going from it at full speed; it becomes a sort of turbine wheel, and an almost constant stream of steam must be maintained to keep it in motion. Small rotaries are often used in places too cramped for the ordinary engine, but they are coal-pile killers.

New Plan of Signals.

Electrically-operated signals are a success and fast coming into use. A young inventor in New York has designed a signal of this kind where the semaphore is located in the cab, instead of on the line—breaking the circuit drops the signal to danger. It operates just as large signals along the track do, and it would seem to prevent a man from mistaking a signal for another track or siding for his, and, of course, can always be seen, regardless of fogs

In this device a bell is rung at every move of the signal, so that a man's attention is always directed to it. The inventor informs us that he has shown it to several signal men, and while they always declare against it, can offer no reasonable objection to the plan.

Ordinary signals are of a great deal of use to trackmen in their work, which his signal would not be, and we do not see how his could be made to signal for switches turned, but they could have signals of their own as now.

The report of Secretary and Treasurer E. V. Debs, to the Firemen's Convention, held on the 8th, at San Francisco, shows a healthy condition of the order. They have over 19,000 members in good standing, 435 lodges, and a credit of $60,000 in the bank. Grand Master Sargent recommended the order to build a Brotherhood headquarters in some central city, to cost not less than $150,000.

On some engines recently built in Glasgow, Scotland, for Government railways of the Argentine Republic, the blower pipe enters the side of the arch on a level with the high nozzle, and is bent around it, the end is plugged and the top of the bent pipe drilled full of small holes, it is claimed this makes a much more efficient blower than a plain nozzle.

The great tunnel between Sarnia, Canada, and Pt. Huron, Mich., under the St. Clair River, is opened through. The headings from the opposite sides met under the river within less than one inch of variation.

The recent convention of the Conductors' Brotherhood at Toledo, O., showed a very encouraging growth and enthusiasm. Grand Chief Howard is an old Brotherhood engineer, and an organizer of no mean ability.

Carpets in car aisles gather all the dirt and filth imaginable, as also does matting. What is the matter with an aisle floored with permanent colored linoleum? It is neat, clean and warm.

One of the new "Class P" engines, with Belpaire boiler, blew off her dome in Jersey City on September 10th Her mate, the 1,323, was illustrated in these columns last December

The article on side rods, in the correspondence department, has a good deal of sense in it. The cause of side rod trouble is no doubt as our correspondent describes it.

It is no credit to railroad managers of this country that they oppose the 24 hour system of running trains On the Canadian Pacific it is a perfect success.

Simple Lessons in Drawing for the Shop.

By Orville H Reynolds.

TWELFTH PAPER.

In Fig. 81 we have a side view of a spur gear, which we have sketched in our book, with the purpose of making a copy of it on the drawing board. The data we have filed for use on the drawing consists of the number of teeth, the pitch of teeth, breadth of teeth, diameter of hole, pitch diameter, etc.

Draw center lines *A B C D*; from their intersection *G* as a center draw a circle with the compasses, set to a radius of $\frac{3}{8}$", to represent the hole.

With the radius 1.91" on compasses draw pitch circle *E F*. Lay off below this pitch circle a distance equal to four-tenths of the pitch, which will equal, in this case, two-tenths of an inch (the pitch being $\frac{1}{2}$").

Outside of the pitch circle lay off a distance equal to three-tenths of the pitch, or fifteen hundredths of an inch. With these points as laid down for radii, describe two circles, the outer one representing the top of teeth, the inner one the bottom of teeth. The whole depth of tooth will therefore equal seven-tenths of the pitch.

Lay off outside of pitch circle another point, a distance equal to one-tenth of pitch, or five hundredths of an inch, lay off another point below the pitch circle, equal to five hundredths of the pitch, or twenty five thousandths of an inch. Taking on the compasses the distance from center *G* to the points laid down for a radius, describe circles *H I* and *J K* respectively.

Divide the radius of pitch circle into six equal parts; subdivide each of these parts into four equal parts and we have twenty-four points from which to draw lines through center *G*. These radial lines will be the center lines of the teeth.

It is unusual in shop practice to delineate all the teeth in a gear wheel, a few being enough to show what is intended; in this case we will show one-half of wheel. Lay off on pitch circle *E F*, from each side of center lines of teeth, a distance equal to twenty three hundredths of the pitch, to represent the thickness of tooth, which is to be equal to forty-six hundredths of the pitch, leaving the space between teeth equal to fifty four hundredths of the pitch.

Taking on the compasses a radius equal to the pitch of teeth, set them on the circle *J K*, and describe face of teeth, reversing the compasses, the opposite face of teeth are delineated in the same manner.

The compasses are to have the same radius for the flanks of teeth, which are described by placing the point on circle *H I* with the pencil, joining the faces just drawn at the pitch line; reversing the compasses the opposite flanks are drawn, as in the case of the faces. At the roots of the teeth draw small arcs.

This method gives a first-class wearing face for all pitches of teeth, with the advantage of a close approximation to accurate results.

Lay off each side center line *L M* half the breadth of face, and project from side view with the T square, the upper and lower teeth, also the keyway and diameter of hole. Section lining the view we have, it will appear as in Fig. 82.

If it were full edge view, and not a section, the teeth would be projected from side view, and look as shown in Fig. 83.

When toothed gearing is used to transmit motion from one shaft to another, whose axes are not parallel, bevel gears are employed. The teeth of such gears are not of an equal thickness, as on a spur gear, but are tapering, being largest on outer side, this taper being due to the angle of the teeth, which is found by drawing from the intersection of center lines of shafting, as shown at *A B*, Fig. 84.

When a drawing of bevel gears is intended for shop use, the time of the draftsman is again saved by condensing the operation into a section and half plan, also making an end view of one tooth, as shown in Figs. 85 and 86, the pitch and number of teeth being written on drawing.

After the angle has been found, as in Fig. 84, reproduce it in Fig. 85 by first drawing the center line *A B*, and laying off from it the pitch diameter as at *C*. From this diameter draw lines intersecting center line at *D*, and we have pitch line *G*, from which to lay off the teeth.

The faces *E F* and *E' F'* are drawn perpendicular to pitch line *G*. The breadth of tooth face *H* is next laid off and the inner end of tooth also made perpendicular to pitch line.

The depth of tooth can now be laid off on lines *E F* and *E' F'*, the same as in the case of Fig. 81, the whole depth to equal seven-tenths of the pitch, as before.

From the points just found draw lines to the center *D*, and we find that the outer ends of teeth are deeper than inner ends, caused by the lines radiating from center *D*, as referred to before.

Next, drawing diameter of hole for shafting, and then depth and diameter of hub, also thickness of web and rim, we have a section as shown, Fig. 85.

An end view of tooth can now be shown by projecting the three elements of the tooth—the top, the bottom and the pitch line perpendicular to line *E F*, and drawing a line parallel to *E F* for a center line; the tooth being laid off in the same manner as on spur gear Fig. 81. Specifying the number of teeth and giving diameter of both inner and outer pitch circles, as at *C* and *I*, the section is completed.

The outline of a half plan, having a few teeth shown, will serve to show more clearly the taper of the teeth. To make the plan we take on the compasses one-half of outer pitch circle, measured on line *C* from center line *A B*, Fig. 85; with this distance for a radius describe half circle from center line *A B* at any convenient point below the sectional view, as in Fig. 86.

Take on the compasses one-half of inner pitch diameter on line *I*, and from same center as before describe another semi-circle.

Tops and bottoms of teeth are also to be taken on the compasses from Fig. 85 and transferred to Fig. 86, in same manner as was done with pitch lines.

Dividers are then set to the pitch of teeth, and the whole or part of pitch circle spaced, as time or inclination may suggest; a few teeth shown will answer all purposes. Spacing done will represent the center lines of teeth, and these lines, drawn to the center from which pitch circles were described, show the difference between thickness of teeth at outer and inner ends.

The data furnished is usually sufficient for shop use in making the gears shown.

Should the student feel that more light is necessary to a better understanding of the theory of tooth curves, he is referred to what is probably the best and most comprehensive essay on the subject in any language, viz. "Odontics, or the Theory and Practice of the Teeth of Gears," by George B. Grant.

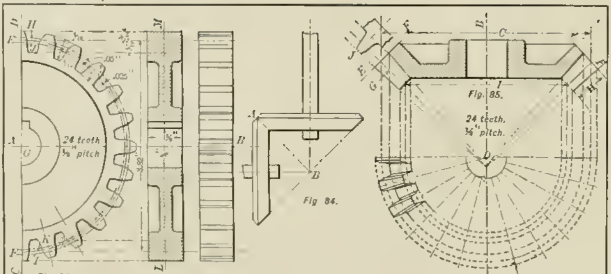

Fig. 81. Fig. 82. Fig. 83. Fig. 84. Fig. 85. Fig. 86.

SIMPLE LESSONS IN DRAWING.

The Erie road is talking of building a train of cars for suburban work, that will be without end platforms or steps; they will have a double door on each side of the car in the center, and the steps will be inside the door and inside the car; the bottom of the door will be some eighteen inches below the car floor. This plan will be cleaner, prevent draughts, prevent crowding on the platform and danger of falling off, and also prevent people from getting off on the wrong side. The car has two more seats than the ordinary coach

---

About three letters a month are received from young men asking the difference between a direct motion and an indirect motion locomotive. We have answered the question several times, but repeat. A direct motion valve gear is one in which there is no rocker employed, in which the eccentric moves the valve *ahead* when its wide side is ahead of the axle, and an indirect gear is one in which the valve is pulled *back* when the wide side of eccentric is ahead of the axle—the motion of the valve is just opposite that of the eccentric.

There are a few men in this country who do not worry about the exact hour that the pay car will strike town. John D. Rockefeller's yearly income is $6,831,000, or $18,715 per day. William W. Astor rakes in $8,612,500 per year, or $23,593 at sundown of each day. Cornelius Vanderbilt gets $5,566,000 yearly, or $15,249 at quitting time each day. While Jay Gould gets a salary of but $2,718,000 a year, or only $7,446 when the whistle blows. Moral: Insure in the — get rich.

There are several men under arrest in Troy, N. Y., for wrecking trains on the N. Y. Central. By the way these ex-employes and strikers have been shut up in the company's offices, and kept in the company of detectives, and from the company of their friends and counsel, it looks as if an attempt was being made to force a confession from men not guilty. We sincerely hope the guilty wreckers will be caught and sent to the penitentiary for life.

It looks now as if the D. L., & W. ferryboat "Bergen" with triple expansion engines and a screw at each end, would become the pattern for most boats of that class built in this country. The P. R. R. are building one on this plan, and several other roads contemplate a like action. The "Bergen" is the finest ferryboat afloat in American waters.

The Illinois Central recently invited its employes to invest in the stock of the company, and offered to let them pay for shares in installments of $5 or over—the company paying interest on the amounts paid until it equaled the market price of shares. It is reported that a large amount of stock has been taken by the men—they might do worse.

Don't think we have forgotten you when you see no reply in the next issue to requests to "Give us something on spring hangers," or "Please show up an elevated engine." There are 14,000 subscribers now, and all such requests are filed and given consideration in their turn.

The Webb compound locomotive costs about twice what a simple engine of the same power does.

A Crank-pin Test Gauge.

Mr. Allan McDuff, general foreman of the Burlington, Cedar Rapids & Northern Railway shops at Cedar Rapids, Iowa, describes and illustrates a very useful device of his invention, in the September number of the *National Car and Locomotive Builder*, as follows:

I find by practical experience that crank pins in locomotive driving wheels frequently get twisted in the pin hub from severe strains of service, and also that the pin hub itself sometimes becomes twisted from the same cause. Shrinking very heavy tires very tight on driving wheels sometimes distorts the crank-pin hub. Defects of this character are nearly always mistaken for a bent crank-pin, the result being that the pin is driven out, and a new crank pin put in without producing any improvement. Sometimes the old pin is put in the lathe and found true; then the machinist who judged the pin bent is blamed for careless measuring. The man is not generally to blame. The mistake made resulted from want of proper measuring tools. My experience is that the expense and delays resulting from misunderstandings about the real condition of crank-pins can be avoided by the use of this simple form of crank-pin testing apparatus.

The tendency of locomotives is to wear the crank-pins eccentric with the original center of the pin. This causes a very dangerous defect, yet it is very difficult to identify by the ordinary methods of testing crank-pins. I have found crank-pins from $\frac{1}{16}$ to $\frac{1}{8}$ inch eccentric from the true center of the pin, yet they were declared by skillful machinists to be all right. The journal was smooth and truly cylindrical, as found by calipering. In ordinary practice, pins in this condition are sent out with connections nicely fitted up, and those in charge cannot understand why the shearing of rod bolts follows, and keys enough are lost to pay for new crank-pins in six months. If an engine in this condition does not break a crank-pin or a side rod, it is more by good luck than good management.

The crank pin gauge hereby illustrated was designed to detect defects of crank-pins, and it performs the duty very successfully. The principle of the device is the making the crank-pin carry and control two marking points, which describe a circle on the crank pin hub, and on the end of the crank-pin, these circles supplying the means of showing whether or not the crank-pin is parallel with the axle, and how it stands in relation to its original center. Referring to the engraving, Fig. 1 shows a side elevation of the device as it appears when set on a crank-pin, and Fig. 2 is a transverse section of the gauge. The foundation of the device is a right-angle iron plate *A*, which presses on the crank-pin, and carries the marking connections. The marking rod *B* is held parallel with the crank-pin by suitable attachments. The tension rod *D* pushes the angle plate close to the hub of the crank pin, and *E* is a flexible strap which encircles the crank pin and holds the angle plate secure in its place. This gauge can be applied in a few minutes, and one revolution round the crank-pin will produce marks which demonstrate with geometrical accuracy the condition of the pin. If the circle described on the crank-pin hub is not concentric with the pin, the pin is not at right angles with the wheel. If the pin is worn eccentric from its original center, the degree of distortion will be shown by comparing a circle drawn on the end of the pin, by the testing gauge, with a circle drawn with dividers with the original center as a center.

McDuff's Crank pin Gauge.

An Act of Friendship.

John Alexander's story of the frontier "reminds" the writer, who is a well-known railroad man, of Denver, Col., of a story, for the truth of which he vouches, and writes:

Way back in the days of sixty-nine, the Kansas Pacific Railroad, in its race for the Rocky Mountain country, reached the then frontier stage station of Hugo. Here a short stop was made, during which sprung up a typical western town.

Money was plenty, gambling and dance houses on every corner. Several men had died with their boots on, of which little notice was taken. But one evening Big Ben, who had quit tiring to deal faro, was detected in a crooked game. This was a very serious matter then, as now, if found out. The law and order men who had been euchred, resolved that the welfare of the town demanded that an example should be made of the guilty party. So in the early part of the night a number of the leading citizens accompanied Ben down to the railroad bridge, where they *hung him*. A placard was attached to the body, warning all parties from interfering, on pain of similar treatment.

Among Ben's friends were two engineers, Mart Baird and Jack Vaulin, they had known him back in the States, and they agreed to show their friendship by according him a decent funeral.

A blanket in those days was considered a pretty good coffin, but the friends determined that he should have something better, and as near what he would have at home as they could give him.

If detected in removing the body it would be death to them. But they had been used to facing dangers, and towards midnight, when everything was still, *O no!* everything was in full blast, Mart and Jack started on their errand of friendship.

Between them they carried Mart's trunk—the nearest approach to a coffin in town. They soon reached the bridge, and cut the body down, but now an unthought of obstacle arose. The body would not go in the trunk. Mart, ever full of resources to help a friend, said, "Jack, you skip up to the 23 and git my hand saw." He was soon back, and in a short time they had Ben's legs *sawed off*, the body packed in the trunk, and he was then decently buried in his unmarked grave.

Mart quit the road, married a Mexican woman, secured a competency, and was shortly after killed by a Greaser, who envied him his success.

A few weeks ago, while at Los Animas, in a clump of bushes beside the Purgatory River (pronounced picketwier), I was shown the grave of poor Mart, waiting for the Caller. Jack, when last heard of, was running on an Eastern road, should this meet his eye, he will know that that night's work is still spoken of as the act of brave engineers.

Young men are constantly writing us asking that we answer through the paper where they can get a position as fireman. We cannot publish such letters; they are useless. Apply to the motive power officials of some railroad.

In some ten-wheeled passenger engines weighing 130,000 pounds, recently built by the Brooks Works for the Big 4 road, driving journals 8x10 inches carry 17,000 pounds each. Pretty heavy load for a fast engine.

During the past year the Switchmen's Mutual Aid Association received the sum of \$97,527.34 in dues and charter fees, and paid out \$92,331.86. Of this amount \$76,000 was paid on death and disability claims. \$76,000 will relieve lots of suffering—and there is lots to relieve.

An Efficient Car Replacer.

We don't know why the humped-back pieces of iron with a claw at one end and a plow clevis at the other were called frogs—probably because they looked as little like a frog as possible.

Just why they were carried on the back of tenders and in way-cars to put under derailed cars and engines we never could fully account for, as in an extended acquaintance with them we never knew one to stand up to business without injury to itself, nor did we ever see one that did not overdo its work when it did any—one end had to be above the rail, and when the tread of the wheel mounted that end it carried the flange above the rail, and the cramped and twisted truck would crowd it over the other side.

If from any cause the derailed car came back upon the track, and was pulled too far, the frog would derail other cars. The ideal frog or car replacer would seem to be one that will of itself furnish all the guides, frogs and blocking necessary to replace derailed cars—one that is capable of straightening a "slewed" truck, one that can be placed in position for a pull in either direction without danger of slipping, one that raises the flange of the wheel outside the rail higher than the rail, and only raises the inside wheel high enough to let the tread over the rail, and one that can be left in position without danger of derailing any rolling stock that passes over it.

These requirements seem to have been met in the Norwood replacer, shown herewith. This device consists of two cast-steel blocks or frogs, a wooden cross-bar, and a clamp and key for securing the outside block to the rail.

Fig. 1 is an inside view of the blocks, showing

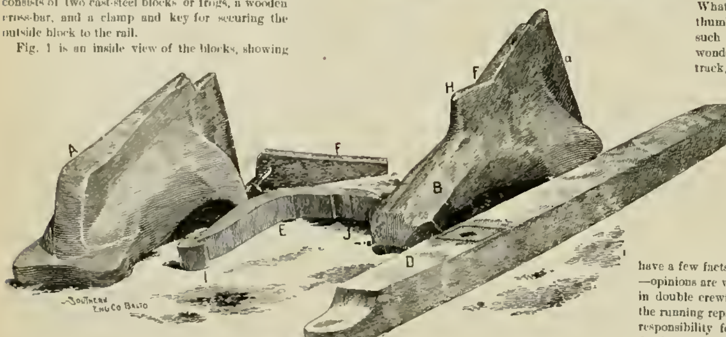

Fig. 1.

the brace for clamping and keying the pieces, and the key. Fig. 2 is an outside view of the blocks. Fig 3 shows the replacer in position, the wooden bar *D* holding the inside piece against the rail, and the clamp *B* and key *C* holding the outside piece up to its work. Any railroad man worthy the name can see how the wheels are guided by these blocks back to the rail. The dotted line shows an extension of the inside piece, by a short rail, to guide trucks that are a good way off, or badly slewed. Any railroader that has tried to slew trucks with a cramp stick, or by pulling against blocks between the rail and inside wheel, will appreciate this device.

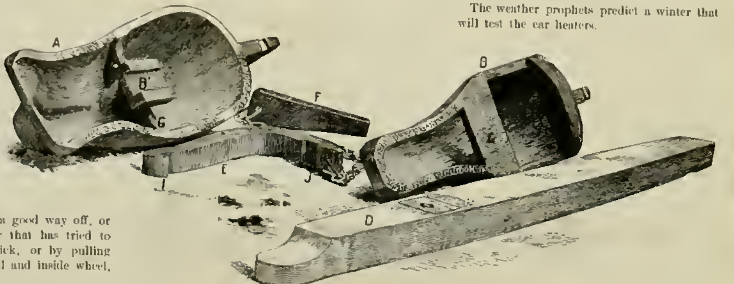

Fig. 2.

A very severe trial of this device has recently been made at Cincinnati, in which a consolidation locomotive was completely derailed and got on without outside assistance, in twelve minutes.

The five pieces comprising this rig weigh only 170 pounds, and can, if necessary, be carried by one man; there are no set-screws or small parts that can be deranged by use, they occupy no more space than frogs, and are of some use when you get off the track—which is more than can be said of frogs.

The Norwood Car Replacer Co., of Baltimore, Md., are putting this device on the market, and can furnish testimonials of prominent railroad men as to their efficiency.

A Hustler.

On July 30th the fastest long run on this continent was made by the limited train, No. 19, of the Michigan Central road. The run was over the Canadian division from Suspension Bridge, N. Y., to Windsor, Ont. The distance is 226.9 miles, and the heavy train covered the distance in the remarkable time of 224 minutes. This piece of track is the best racing ground in America, being level, straight, and kept up in extra good condition. Four miles of the run were made at the rate of 66.9 miles per hour.

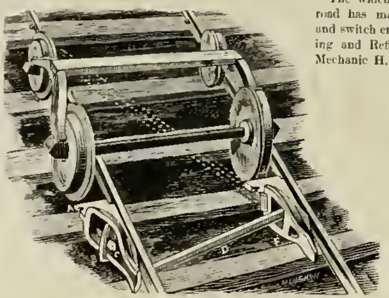

Fig. 3.

The Paris, Lyons & Mediterranean Railway has hit upon a new source of revenue. In future people who accompany their friends to any of the stations on that line to see them off will only be admitted on the platform on payment of a fee of one penny, in return for which they will receive a special ticket of authorization. The ticket is only available for one hour, at the end of which time another must, if necessary, be obtained. As this company is by far the largest railway undertaking in France, a nice little addition to its revenue is anticipated as a result of this new departure.—*Railway Engineer* (Eng.)

Almost every road in the country is buying cars, in orders of from 50 to 2,000. The number of freight cars in the country is something enormous, according to Poor's Manual, 1,060,164, and increasing at the rate of 60,000 per year. Some great improvement in loading and unloading cars, and in keeping them in service more, is badly needed. It is estimated by the competent car accountants on one of our big lines that the freight cars owned by that company are in motion less than one-fourth of the time.

The widening of the gauge of the D. & R. G. road has made it necessary to widen the yards and switch engines belonging to the Pueblo Smelting and Refining Co., at Pueblo, Col. Master Mechanic H. R. Jones has decided to sell the two saddle tank, six-wheeled, narrow gauge switchers; they are Rhode Island build, and Mr. Jones says he is loth to part with them, they are so satisfactory, but concludes that it is cheaper to sell them and buy new ones than to widen them out.

On a certain Eastern road hot boxes developed on leading trucks of three new engines fresh from the works of a leading locomotive builder. A run of thirty miles warmed them dangerously. The cause was found to be, trucks on all three, three-eighths of an inch out of square. What excuse is there for this rule of thumb way of treating a matter of such great importance? Is it any wonder that our engines jump the track, and that wheels run to the flange and ruin themselves? The day for this sort of carelessness ought to have gone by.—*Nat. Car and Locomotive Builder.*

We want to know something about the plan of running locomotives continuously, or chain-ganged. Now let's have a few facts and arguments for and against—opinions are worthless. What object is there in double crewing? Does it pay? How can the running repairs be kept up, and how shall responsibility for defects and breakdowns be fixed? Let us hear from all with experience.

The weather prophets predict a winter that will test the car heaters.

The Pennsylvania road are putting brake beams and shoes each side of all wheels in four-wheeled passenger coach trucks. This calls for sixteen brake shoes per car, but they wear only half as fast as when eight are employed, and are easier on the truck, as they "squeeze" the wheels, instead of trying to shove all four of them to the center of the frame.

Last year the average price paid for hauling freight in the United States was 970 of one cent per ton per mile, and passengers paid an average of 2.17 cents per mile fare.

H. K. Porter & Co. Locomotive Works, at Pittsburgh, Pa., have voluntarily reduced the hours of labor in their shops from ten to eight, pay to remain the same. This firm also distribute a large amount of money annually on the profit-sharing plan. It must pay them to have contented and interested workmen.

The old 17x24 8-wheelers on the N. Y. C. & H. R. haul an average of 35 loads each way between Buffalo and De Witt—304 miles for the round trip—and burn about seventeen tons of coal. The new 19x26 moguls haul an average of 45 loads, and only get away with 18 or 19 tons of fuel.

On the Great Western road in England the engineer and firemen get $2\frac{1}{4}$d., or $4\frac{1}{2}$ cents, American money, per mile; this is about as high as the average pay on Eastern roads in this country, but no comparison to wages paid in the West.

Last year the State railroads of Prussia earned $10,600 per mile. The Pennsylvania beat that—$16,000.

Last year the actual dividends paid on railroad stocks amounted to $82,110,198.

It cost almost 67 per cent. of the earnings to operate our railroads last year.

The Canadian railway system has increased from 7,596 miles in 1881 to 13,324 on June 30th, 1889 Of this mileage 9,505 are controlled under three managements the Government—1,363 miles, the Canadian Pacific—4,073 miles; and the Grand Trunk—3,179 miles, leaving 3,819 miles under other control. The earnings per mile are very low, $3,337; the only lines of large earnings being those between Buffalo and Detroit, which handled a heavy American traffic. Deducting these, the average earnings of the Canadian system are some $2,650 per mile. The train miles per mile of road have decreased from 3,760 in 1881 to 3,074 in 1889, because of the large mileage constructed in thinly populated districts The inhabitants per mile of road are 383, against about 400 in the United States.—*Ex*

The Johnson Railway Signal Co., of Rahway, N. J., are building the apparatus for completely interlocking and blocking the Erie yard at Jersey City, N. J., from the dock to Bergen hill tunnel. One of the towers will contain a fifty-six lever machine, the largest they have built

Our correspondent who asked how to get an engine in with both water hose pulled off, writes to say that he wants some one to tell how to get in alive, provided both goose necks are broken. Can any one tell him?

The Wisconsin Central are rebuilding some light eight-wheelers for suburban work, the frames will be extended back to carry the tank, and there will be one double truck under it, just like the engine truck and the same distance from the drivers. It will be a very neat and serviceable engine.

There are in the United States 1 5 miles of railroad tunnels, 17,042 miles of wooden bridges, 8,185 of stone, 11,838 of steel and iron, and 3,535 of combined wood, stone and iron, making a total of 40,600 miles of bridges.

There were 1,064 new locomotives put in service in this country in 1889.

BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

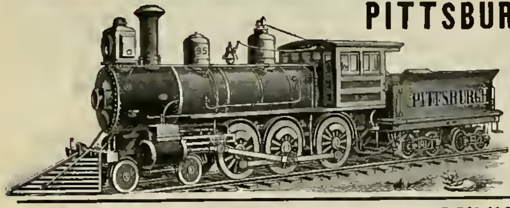
ANNUAL CAPACITY 800

LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable.

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, Etc.

BURNHAM, PARRY, WILLIAMS & CO., Proprietors, PHILADELPHIA, PA.



PITTSBURGH LOCOMOTIVE WORKS,

PITTSBURGH, PA.

Manufacturers of

LOCOMOTIVE ENGINES

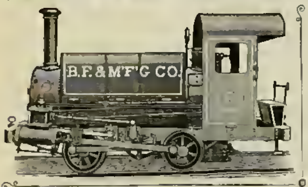
For Broad or Narrow Gauge Roads.

From standard designs, or according to specifications, to suit purchasers.

TANKS, LOCOMOTIVE OR STATIONARY BOILERS

Furnished at Short Notice.

WILSON MILLER, Pres. and Treas. D. A. WIGHTMAN, Supt.



J. & J. B. MILHOLLAND, 240 Fifth Ave., Pittsburgh, Pa.

EXPERT ENGINEERS, DESIGNERS AND BUILDERS OF

NARROW GAUGE LOCOMOTIVES,

WITH OR WITHOUT LINKS.

Very simple in construction, and adapted to STAND HARD WEAR and TEAR, and especially in the dirt and dust of Coal Mines.

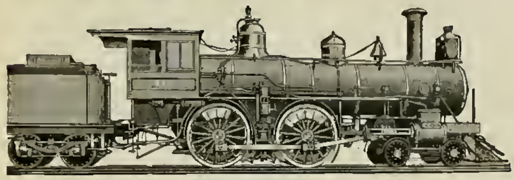
WIRE ROPE HAULAGES,

FOR COAL MINES AND TRAMWAYS.

Over 75 complete Wire Rope Haulage Plants in successsful operation.

PLANS AND ESTIMATES GIVEN ON APPLICATION

Inclined Plane Railway Plants a Specialty.



DICKSON MANUFACTURING CO.,

SCRANTON, PENN.

Locomotives of every style and size, Standard and Narrow Gauge, made to Standard Gauges and Templets. Also for Plantations, Mines and Logging.

SPECIFICATIONS ON APPLICATION.

JAS. P. DICKSON, Pres. WM. H. PERKINS, Sec. & Treas.
E. W. WESTON, V. Pres. JOHN DEVINE, Supt.

RICHMOND LOCOMOTIVE & MACHINE WORKS, RICHMOND, VA.

BUILDERS OF

LOCOMOTIVES

FOR EVERY VARIETY OF SERVICE.

MOTORS

for Street Railways, Tram Roads and Mines.

Also manufacturers for the Pole Road Locomotive Company of their efficient logging engines and cars.

H. K. PORTER & CO., Pittsburgh, Pa.

BUILDERS OF

Light Locomotives & Noiseless Steam Motors.

Send for New Illustrated Catalogue, containing information useful to every Locomotive Engineer or Railroad Man. **Mention this Paper.**

THE RICHARDSON AND THE ALLEN-RICHARDSON

BALANCED SLIDE VALVES.

Used by 140 Railroads. 4,000 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

MANUFACTURED COMPLETE FOR ANY LOCOMOTIVE.

Also Manufacturers of "RICHARDSON'S MODEL OF LINK VALVE MOTION."

Estate of F. W. RICHARDSON, Troy, N. Y.

THE STANDARD STEEL WORKS

PHILADA., PA.

Our PURE MOULDED "ROYAL" MAN-HOLE and HAND-HOLE GASKETS, being soft and pliable, conform themselves to rough or uneven plates, thereby making a tight joint in every case. Will not harden or blow out, and are recommended by Boiler Inspectors.

Gasket Tubing, Pure Tubing and Mould Work of every description.

METROPOLITAN RUBBER COMPANY,

649-651 BROADWAY, NEW YORK CITY.

WINTERTON METAL POLISH.

BEST POLISH AND QUICKEST CLEANER KNOWN.

Class A, for Hot Brass, Copper, Nickel, etc. Class AA, for Cold Brass, Copper, Nickel, etc. Class D, for Finished Iron and Steel.

Send 10 cts. for Samples. Try it.

Specially adapted for Locomotive Work.

W. W. CALLERY & CO., 36th & Butler St., PITTSBURGH, PA.

CORRUGATED COPPER GASKETS

For all Pipe Fittings and Unions, whether for Steam, Water or Air. Can be used wherever any gasket can be applied, with better satisfaction and greater durability than any other. **Will not leak, rust, stick, burn or melt.** All sizes and shapes, ⅛ to 42 inches. In use on N. Y. & N. E. R. R. and others. *Write for particulars*

U. S. MINERAL WOOL CO., 2 CORTLANDT ST., NEW YORK.

THE LOCOMOTIVE ENGINEER.
DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III, NO. 11. NEW YORK, NOVEMBER, 1890. $1.00 per Year or 10c. a copy.

The New York Air-brake.

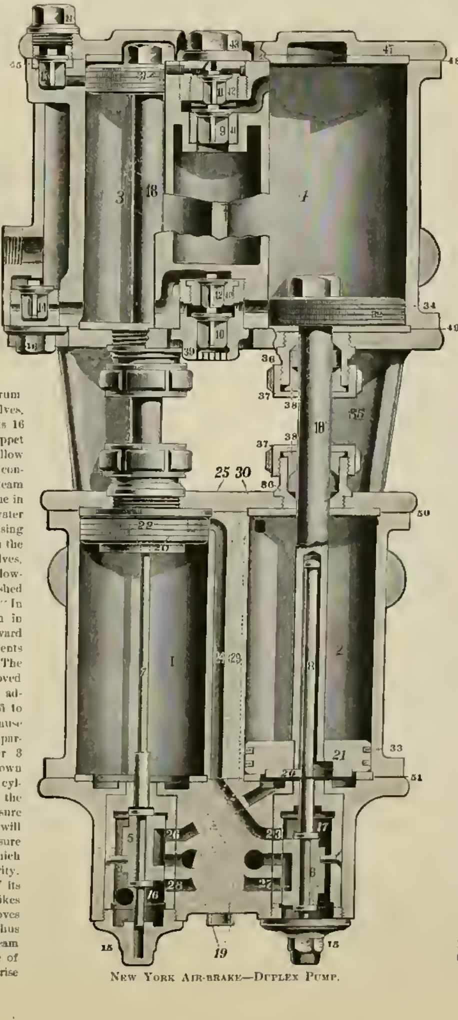
The New York Air-brake Company is a new corporation, formed principally inside of the Eames Vacuum Brake Co., who are now putting upon the market an automatic air-brake system, interchangeable with the Westinghouse, but having some new features, the principal parts being shown in our illustrations in this issue.

The air-pump is double, having at the bottom two five-inch steam cylinders, one of which moves an air piston 8" in diameter and the other an air piston 5" in diameter.

The large air piston pumps air from the atmosphere and delivers it under pressure to the smaller cylinder, which compresses it to the desired pressure and delivers it to the main drum.

The steam valves are plain slide valves, numbered 5 and 6, working in chests 16 and 17, and are operated by the tappet rods 7 and 8, extending into the hollow piston rods. The valve on one side controls the admission and exhaust of steam from the opposite cylinder, as is done in the well-known Worthington water pumps. This plan admits of the using of plain valves, and does away with the use of steam-actuated piston valves, common to other pumps. The following description of the action, furnished by the builders, will make it clear "In the position shown the air piston in cylinder 4 has completed its downward stroke and compressed its contents through valve 12 into cylinder 3. The plate 20 on steam piston 21 has moved valve 6 to its lowest position. This admits steam through port 23, 24, 25 to upper side of piston 22, and will cause the piston to descend and expel the partially compressed air in cylinder 3 through valve 14 and passage shown into the reservoir. Meanwhile, the cylinder 4 has become filled above the piston with air at atmospheric pressure through valve 9, and the cylinder 3 will be filled with air at atmospheric pressure through valves 9 and 11, both of which open inward and are seated by gravity. When piston 22 reaches the end of its downward stroke, the plate 20 strikes the tappet on valve stem 7 and moves valve 5 to its lowest position, thus uncovering port 26 and admitting steam through port 26 to the lower side of piston 21, thus causing piston 21 to rise and compress the air which is in cylinder 4 through valve 11 into upper part of cylinder 3. Just as piston 21 completes its stroke its plate 20 strikes the tappet on valve stem 8 and moves valve 6 to its highest position, uncovering port 27 and admitting steam through port 27 to the lower side of piston 22, causing the piston to rise and expel the partially compressed air in cylinder 3, through valve 13, into passage shown, and thence into the reservoir. While the pistons are compressing the air above them into the reservoir, the air cylinders below the pistons will be filled with air at atmospheric pressure through valves 10 and 12, ready for another cycle of operation

"The 5-inch duplex air-pump will, in a given time, compress as much air as the ordinary 8-inch air-pump, with the consumption of but 60 per cent. of the quantity of steam. The air valves are simple poppet valves, which seat by gravity, while the pistons wait, and therefore are not liable to pound themselves to pieces. All the parts of the pump have been made so as to be durable and easily accessible, steam and air valves may be examined by unscrewing plugs, without taking down the pump."



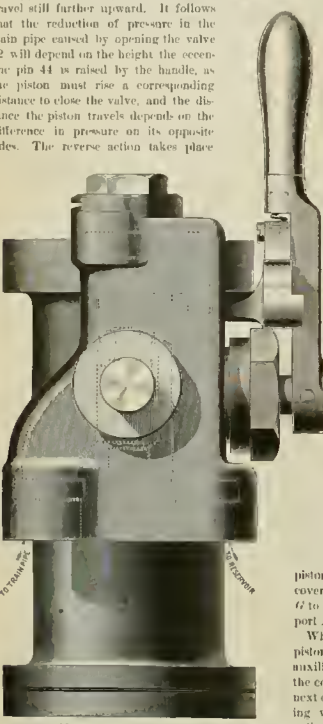
New York Air-brake—Duplex Pump.

The illustrations on page 202 show the engineer's valve, which is entirely new. The operating handle stands up perpendicular in the running position, and is pulled back for application, and pushed ahead for release.

The sectional view shows the side, and its operation is as follows:

The chamber above piston 32 is connected with the train pipe, and from it reductions are made to set the brake, the chamber below the piston is connected with the engine drum all the time

The space above valve 39 is also connected with the engine reservoir. Valve 39 regulates the flow of air from the reservoir to the train pipe Valve 42 regulates the discharge of air from the train pipe Lever 43, which is fulcrumed on eccentric pin 44, is for opening valve 42 Lever 49 is for opening valve 39, it is actuated by lever 48, by means of the slot and pin 48. The opposite end of lever 43 is controlled by piston 32. To apply the brakes, the handle attached to the spindle that carries the eccentric pin 44 is turned to the right, this raises the outside end of the lever 43, and with it valve 42, thus allowing air to escape from the train pipe. As the pressure is reduced above the piston 32, the reservoir pressure tends to raise the inside end of lever 43, and allow valve 42 to close, and stop the escape of air from the train pipe. If the eccentric pin is raised but a little, the piston will have to rise but little to close the valve; if it is raised higher, the piston will need to rise higher to close the valve, and consequently will allow more air to escape from the train pipe before the valve closes. This piston is made automatic in its action by means of the bell-crank 34 and spring 33. The pressure of the spring holds the piston down as long as the pressures on both sides of the piston are the same, but with a very short leverage on the bell-crank; the piston is connected with the bell crank with a much longer leverage, so that a very slight difference in pressure on the piston will allow it to start upward, but as it moves the piston, the piston leverage decreases and the spring leverage increases, until an equilibrium occurs and the piston stops; a further reduction on the upper side of the piston will cause the piston to travel still further upward. It follows that the reduction of pressure in the train pipe caused by opening the valve 42 will depend on the height the eccentric pin 44 is raised by the handle, as the piston must rise a corresponding distance to close the valve, and the distance the piston travels depends on the difference in pressure on its opposite sides. The reverse action takes place



ENGINEER'S VALVE—BACK VIEW SHOWING PORTS.

when the handle moves the eccentric pin downward. This action opens valve 39 and allows the air to pass from the reservoir to the train pipe, but as the piston descends in proportion as the pressure below it, the lever 40 will be drawn away from valve 39 as soon as the piston has descended a distance corresponding to the movement of the eccentric pin by the handle. Thus, by stopping the handle at any desired point, an excess pressure may be carried, more or less, as is desired

You will understand that when valve 42 is opened to reduce the air in the train pipe for a service stop, it remains open until closed by the action of piston 32, which closes the valve gradually and performs the same functions in preventing the concussion of air from the rear of train from releasing the forward brakes, that the equalizing discharge valve of the Westinghouse does.

The amount of braking done depends upon the distance the handle is moved; the engineer simply moves the handle and leaves it there, the reduction takes place at once, and the piston closes the exhaust valve automatically.

On page 203 will be found a sectional cut of their quick-action triple valve; for engines and tenders they use a plain valve—one without the quick-acting mechanism.

This valve is not far different in principle from the Westinghouse valve, but differs in detail.

Connections are made with the auxiliary reservoir, the brake cylinder and the train pipe, as shown in the illustrations, piston 2 actuates slide valve 4 and graduating valve 5. The stem 6 of valve 5 is arranged to slide in the stem of piston 2, so that valve 4 may be closed before graduating valve 5 is opened. The slide valve can remain stationary while the piston 2 returns part way and closes graduating valve 5, as the abutments that move valve 4 are farther apart than the length of the valve.

Air passes from the train pipe to the drip cup *A*, through port *D* to the cylinder *E*, moving the piston 2 to the location shown by the cut; this uncovers port *F*, and allows air to pass through port *G* to the valve chamber *H*, and through the upper port *B* to the reservoir

When the train pipe pressure is reduced the piston 2 moves its full stroke, first shutting off the auxiliary reservoir from the train pipe by closing the connection between passage *F* and cylinder *E*, next closing exhaust valve 4 and opening graduating valve 5, which will admit air to the brake cylinder. If the train pipe pressure is reduced but little, the pressure in the reservoir is soon reduced to less than the train pipe, and the piston 2 starts back and closes graduating valve 5 without disturbing valve 4, which is held with some force by the air pressure, and checks the return stroke when valve 5 is seated A further reduction in the train pipe would repeat the same action and apply the brakes a little harder If the train pipe pressure is reduced eight or ten pounds the graduating valve 5 will remain open and the brakes go full on, as for a service stop An increase of pressure in the train pipe will cause all the valves to move back to the position shown in the plate, thus releasing the brakes and allowing the reservoir to be re-charged.

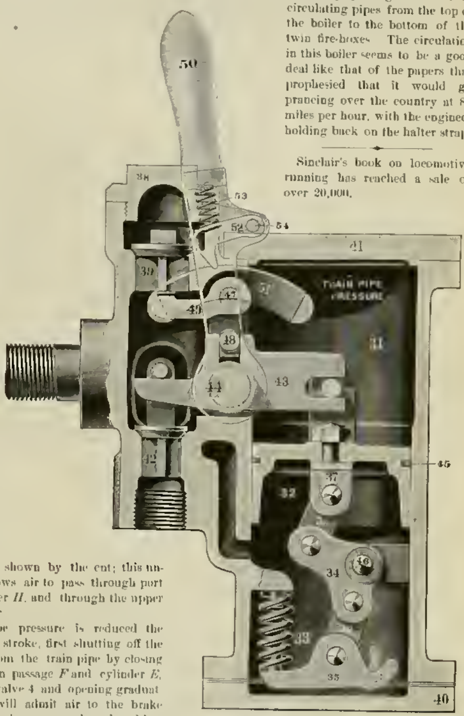
In all service stops the quick-action valves, shown below the triple, remain inoperative, but a quick reduction of 15 or 20 pounds in the train pipe pressure causes valve 14 (which is a piston exposed to reservoir pressure on one side, and train pipe pressure on the other side) to open and admit pressure through *K* above piston 17, which then opens valve 19 and allows air from the train pipe to pass check valve 21, and enter directly into the brake cylinder through passage *C*, thus quickly reducing train pipe pressure to actuate valves on succeeding cars, and at the same time applying the brakes with a greater force than would be possible if the brake cylinder received air from the reservoir only. An increased pressure in the train pipe causes all the valves to return to the position shown and release the brakes.

The mechanical details of this brake were worked out by Albert P Massey, mechanical engineer of the company. The preliminary tests have been continued over a long period of time, and the brake is actually at work on several roads. The address of the company is 115 Broadway, this city

---

Trouble having been found in the circulation of water in the boiler of the Strong locomotive on the Santa Fe, Supt. of Machinery, John Player, has improved it materially by putting a number of circulating pipes from the top of the boiler to the bottom of the twin fire-boxes The circulation in this boiler seems to be a good deal like that of the papers that prophesied that it would go prancing over the country at 80 miles per hour, with the engineer holding back on the halter strap.

Sinclair's book on locomotive running has reached a sale of over 20,000.



ENGINEER'S VALVE—SECTIONAL VIEW.

Reporting Work, and Kicking on Changes.

When you report work be sure that you know just what you want and the engine needs.

Don't repeat history for the four thousandth time by booking "valves faced" when the fact is that the valves are in good condition and the cylinder packing needs attention.

Men who ought to know better often make themselves ridiculous by such work—if work it can be called. We call to mind the case of a certain engineer running out of a city where a large locomotive works are located. The road had some new locomotives built and tried a different make of injectors than the "standard," the first one fell to the lot of this engineer, and before he went out he took occasion to kick about the new injectors—he was used to the other kind, and, besides that, the makers had given him a patent oil-can and nickel-plated torch. The new injectors somehow got water into the boiler all right until the fourth day, when they refused to work—much to the satisfaction of our kicker friend.

"I told you they wan't no good," said he, "now they are bucking and no one knows where to look for the trouble, with the old ones we had no trouble, these new-fangled things are built on the wrong principle."

The road had not yet accepted the engines, so the M. M. sent word to the superintendent of the works to come over. When he arrived and heard the complaint he asked for the engineer, to see if he could tell from the way the instruments acted where to look for the trouble.

No satisfaction could be got from the runner, he ended all his remarks with: "They ain't no good, and the way to fix them is to take 'em off and put on the old squirts."

The superintendent got a machinist to take down the steam valve and found coal in the combing tube and the delivery choked with it, then he took down the water hose and found no strainer there.

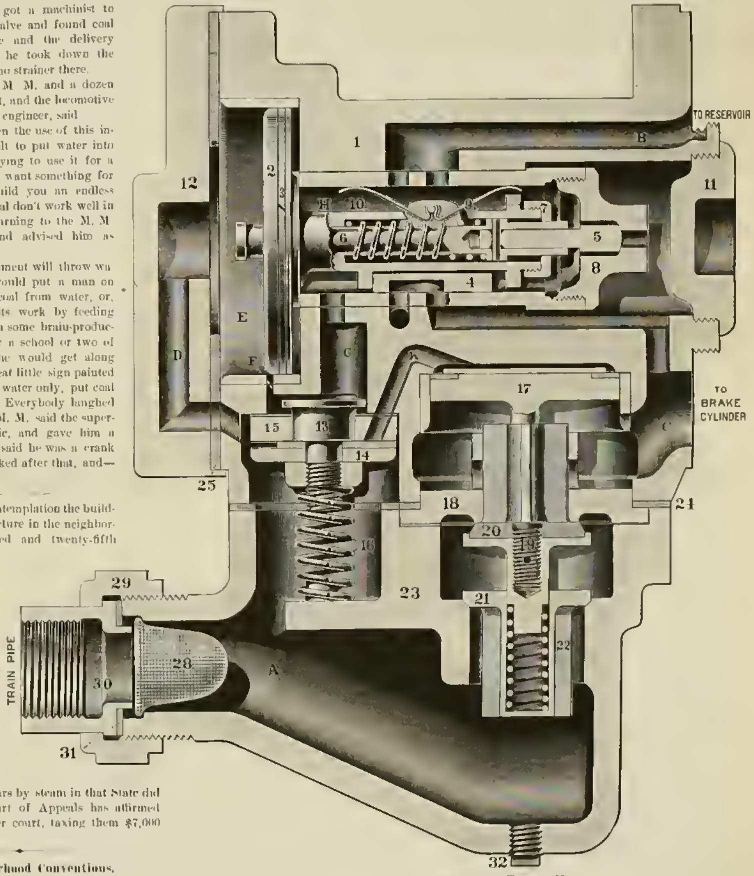
The kicker and the M. M. and a dozen other men were present, and the locomotive builder, turning to the engineer, said:

"You have mistaken the use of this injector, sir, it was built to put water into the boiler, you are trying to use it for a coal conveyor; if you want something for that purpose we'll build you an endless chain with buckets, coal don't work well in an injector." Then turning to the M. M. he bowed politely and advised him as follows:

"I think this instrument will throw water all right if you would put a man on to run it that knew coal from water, or, you might improve its work by feeding the man in charge with some brain-producing food, like fish—say a school or two of whales—or, perhaps he would get along with it if you had a neat little sign painted over it, reading, 'For water only, put coal in with the scoop.'" Everybody laughed but the kicker. The M. M. said the superintendent was sarcastic, and gave him a cigar, and the kicker said he was a crank—but the injector worked after that, and—this is a true story.

Jay Gould has in contemplation the building of a very fine structure in the neighborhood of One hundred and twenty-fifth street for the free use, as library, gymnasium, etc., of the elevated railroad employes. He could well afford to make this the best building of the kind in the city.

The N. Y., N. H. & H. runs less than fifty miles in the State of New York, and claimed that, in its case, the penalty for not heating cars by steam in that State did not count. The Court of Appeals has affirmed the order of the lower court, taxing them $7,000 in fines.



QUICK ACTION TRIPLE VALVE.

The Brotherhood Conventions.

The firemen convened this year at San Francisco, and the engineers at Pittsburgh. The reports of the officers of both orders show a flattering condition of the financial departments, and increased membership and new lodges seem to be the order of the day. The firemen increased the salaries of all their grand officers $1,000 per year, and unanimously re-elected E. V. Debs secretary, treasurer, and editor of the magazine.

At this writing, the engineers are still in convention, and the prospects of quite a scramble for the two grand offices to be filled, promising.

The agitation of the federation question is still an engrossing theme, but the anti's, so far, seem to be in the majority, headed by Grand Chief Arthur.

There was some pretty fair speaking indulged in at the opening exercises, the local dignitaries, as usual, told the boys how brave they were, how much more nerve it took to die with the hand on the throttle, and the eye on the rail, to the music of escaping steam, than to face a row of brass cannon, headed by a string band and a drum major—the railroad hero is a laborer until he is killed, then his role of hero is assumed. Chauncey M. Depew gave the boys a good speech, and they encouraged him with applause, but while he was telling how many hundred times the engineers had come to him to correct some wrong, and how quick he saw the point, and how quicker he granted the request, we were wondering how it is that so bright a man as he did not himself see the wrong first and apply the remedy, instead of waiting for the committee. When has a high official offered to change a thing for the benefit of the men until requested to do so? Would not a spirit of justice offer to correct a wrong when discovered, be it on the one side or the other?

There were many delegates at Pittsburgh who favored biennial sessions, as the firemen have, and some had figured up statistics going to prove that it cost the order $6 per minute to hold the convention—it takes a good many engineers running for three cents per mile to earn $6 per minute.

The committee of arrangements are to be complimented on the able way they handled the entertainment of this large body of men. Chairman F. K. Adams is especially worthy of praise for the way he introduced the speakers, and the way he did *not* inflict the audience with letters of regret, and his omission of flowery speeches of his own—he simply introduced the speaker by name and title, and turned him loose. Most chairmen take occasion to smuggle a speech of their own into the audience between each act. We never attempted to make but one speech, and then the chairman prefaced us by fifteen minutes of rot—some of the very things we meant to use—and as we bowed and waited for him to quit, we forgot our speech, age, name, and previous condition. The man wrote our oratorical obituary, and choked off another Clay or Webster from the halls of Congress.

The latest news from the convention is that the plan of general federation has been defeated. That the office of assistant to the Grand Chief has been created, and A. B. Youngson, of the Erie, elected to fill the place—the proper and graceful thing would have been to make the office appointive. T. S. Ingraham was re-elected F. G. E. The election of second grand engineer had not taken place.

The Woolf valve gear on engine 18, Manhattan elevated road, this city, has not done as well as was expected of it, nor as well as the link motion, therefore it goes.

The monthly pay-roll of the C. & N. W. is said to be $1,200,000.

New Form of Tender.

A correspondent who signs himself G. L. W., in the *Northwestern Railroader*, offers the form shown by the cuts for locomotive tenders. His plan has several advantages, and one or two disadvantages, but seems on the whole to possess considerable merit. Fig. 1 is a plan, and Fig 2 a side elevation of his tender, and make the construction plain.

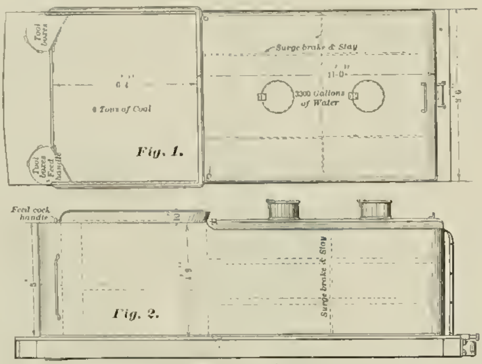
He proposes to make the coal pit the full width of the tender, and all in front with a flange around it alone. The water tank is located entirely behind the coal pit, and has round corners and a crowning top, this prevents the collection of coal and cinders there, and the consequent rusting out and pitting of the tank He has two manholes for taking water, to save too fine an adjustment in setting the engine at the tank.

The water valves are back of the coal pit, and operated by rods running through pipes along the sides of the flange.

Just why he should narrow up his gangway end of the pit to the old size and shape by that particular form of tool-box is not plain.

The fireman would certainly have more room in this form of tender; he would have no coal shoveling from the top of tank, no troublesome back deck to clean, and no water in his coal pit.

With this form of tank the area of water tank exposed to the action of the pitting compounds formed in wet coal, and the cutting action of large coal is reduced to a minimum. This plan places the weight of the coal all on the front truck, and most of the weight of the water on the back one; the coal is used out slowly, while the water goes fast and is often replenished. When near the end of a run that would nearly exhaust the coal, a tank of water would put an immense load on the back truck, and the front truck, being relieved of nearly all its load, would be high on its springs, with the chances in favor of pretty unsteady riding. One other possible objection is in the extra long goose-neck, and the danger of freezing; still, a heater is required on the shortest of them in freezing weather, and this plan has an advantage in that the goose-neck joint is behind the front truck, where it can be easily got at. If this form of tender should become popular, what is the matter with having the coal pit and the water tank two separate and distinct pieces, so that one could be taken off and repaired or replaced, regardless of the other? This would do away with all trouble with pitting and rusting tanks, do away with the necessity of taking coal off an engine to calk her water-tank, and would certainly be a cheaper tender to build than the present U form; the water tank could be easily kept painted outside, and it would be a simple, square box to build and brace.



A NEW TENDER DESIGN.

The Swinerton flat-spotted driving wheels have lost more friends. The second pair tried on the elevated had smaller flat spots than the first one—to stop the noise—but they were so small they didn't count, and the men did not know they were under the engine until told—and she slipped just the same. The project of lengthening all the station platforms, and hauling seven cars—five with the engine and two with the spots—has been abandoned. What next?

The Westinghouse Air-brake Co. have completed the removal of the entire plant from Allegheny City to their magnificent new shops at Wilmerding, Pa. The general office of the company will remain, as heretofore, in Pittsburgh, and the old shops will be occupied by the Fuel Gas and Manufacturing Co., another Westinghouse concern. The new shops are in full blast, and by their use the output is very largely increased, and it needs be, for the demand for power brakes was never greater.

Mount Clair Shops of the Baltimore & Ohio.

As is well known to most of our readers, the B. & O. was one of the pioneer roads of America. It used some of the earliest and crudest forms of locomotives, cars, tools and track appliances—and has not thrown them all away.

A MUSEUM.

Probably there is not another shop on the American continent that makes a nearer approach, on so large a scale, to a museum of antiquity than these same shops, located, as they are, within the corporate limits of the chief city of Maryland.

BIG, BUT SLEEPY

The B. & O. is a gigantic system, the owners of one of the most valuable and extensive franchises in the country, but comes a long way from being a model road.

Its lines reach from New York to Chicago, and, radiating from Baltimore, cover a vast extent of territory, the very heart of the coal, coke, iron and oil industry of the nation. In all, they own or control 2,954 miles of track, and pull 27,000 cars of their own, with 780 engines.

Before the war it was the best road in the Union, and its reputation then is still quoted by its friends. It is safe to say that, had this great property been in the hands of a progressive management, like the Pennsylvania, it would have been to-day a four-track, stone ballasted road from end to end of its main lines, instead of the single track, crooked, rough-and-ready line that it now is. Between Baltimore and Philadelphia they have a fine road bed, but west of Baltimore it is simply horrible, in comparison with other lines in the same field.

INADEQUATE APPLIANCES.

The most primitive of switch targets are used, and many of these are without lights. Accidents, especially to freight trains, are regular, and appalling in their magnitude. This is partly due to bad track, but more to bad equipment.

CALAMITY CARS.

They haul a class of coal cars carrying a twin hopper made of iron. These cars have no through sills, except the outside ones. No decent draft rig can be used. They have no continuous brakes, and you will see just as many in bad order, in a trip over the road, as you will in good. The hoppers freeze up in winter, and refuse to dump, and rough handling disables the dumping gear. You can see them by the half dozens with the draw-heads gone and chained together These cars have a peculiar rigid truck that materially assists in their destruction when they get off the track—a condition in which they seem to delight

THE SHOP BUILDINGS.

The Mount Clair shops are a series of old buildings, long in use as the big shops. Most of them are as dark as dungeons, and the older of them have basements partially lighted by side pits. There are, however, some new buildings

One of the latter is the office building, containing on the upper floor the testing department, the superintendent of machinery's office, and the

DRAWING-ROOM.

This room is the lightest, cleanest, best managed, and most modern department about the shops. It is under the charge of chief draftsman F. J. Cole, who has everything in good shape, and maintains a system in caring for his drawings and in the issuing of blue prints, which is done on the card system. The older drawings of this road were, unfortunately, long ago destroyed, but everything since 1850 is carefully preserved. Some of them are signed by M N. Forney, who, long years ago, was chief draftsman here.

A ROUND TOWER.

A short distance back of this building is a new round shop, for passenger car work. This building is not above five years old, but just why it was made in the shape it is no one seems to know. Its side walls are very high, and its great, dome roof rises at least fifty feet above the floor. All around the sides of the building are arranged heater pipes, but how such a building can be made comfortable in freezing weather is not plain. The tracks radiating from the center are none too long for coaches, and it seems to be rather an unhandy affair all around

THE PAINT SHOP,

for coaches, is located in an old building with a basement, the latter used as a paint and varnish storeroom. The paint shop is very dark and very illy ventilated, although some attempts have been made to improve this by conducting small tin pipes from the roof down to within a few feet of the car tops, where they flare out into bell-shaped hoods. These are too low. Light and ventilation could better be secured by using a transomed roof The fumes of fresh paint and varnish were strong enough to kill birds that happened to get into the building, and were shut in for the night, before the new ventilators were added.

THE MACHINE SHOP

and erecting shop are old, dark, and filled with ancient, infirm, crippled and decrepit tools. Here and there a modern tool is to be seen, but they are lost in the general air of age and decrepitude

FROM ANOTHER AGE.

Old chain-feed lathes are there, and at work, worn until the carriage looks like a scrap of stove plate, patched, scratched, jammed and bungled There are two large lathes of home manufacture that have stone beds and stone head-blocks. Their V's are slight strips of iron, laid on a granite block. We never knew before that the machine tool business reached back into the stone age.

CAMELS AND GRASSHOPPERS.

Most of the locomotives in the shops were no better or no more modern than the tools, still the road has a goodly lot of first-class engines. Old camel backs, without trucks, lagging or jackets, were in, getting extensive repairs. One grasshopper was being thoroughly rebuilt, and more of them are in use in the yard around the shop These engines were built in 1835, and their age and service is greatly praised here, and it is remarkable, yet it is not at all likely that there is an original piece in any of them. They look comical, walking around the yard with their grasshopper legs up in the air, their exhaust through an independent pipe, and the water tank setting straddle of the fire door.

PRIMITIVE FROGS.

In this large yard they use cast-iron frogs, with loose tongues, and no targets or levers to operate or hold them in place. The switchmen kick the tongues over with their feet, or pry them over with a stick, and then they are free to flop around under cars being moved across them, and spread trucks around in a promiscuous and careless fashion—a trick they play daily This form of frog belongs to the grasshopper engine age, and the road will probably discard them together—it wouldn't be right to part them now.

THE BOILER SHOP

has some new tools, and does better work than the average. A new shop is being fitted up for this department, that will have a crane and hydraulic riveting plant. In all their longitudinal seams they use a butt joint, and inside and outside welts. At the fire-door they flange the inside, or fire-box, sheet out enough to receive a line of rivets. The outside sheet is left straight, and the hole for the door about two inches larger than that in the inner sheet. To the outside of this sheet is riveted an angle iron ring, and to the angle iron a ring of square section, the rivets also holding a half-inch thick copper ring, extending from the outside to the inside sheet. This makes four joints instead of one, but it is claimed that it pays, as it is so easy to get the copper ring out for repairs.

NEW LOCOMOTIVES.

They are building a number of 21x26 consolidation engines here, the mates of others of the same size now in service. Baldwins are also building them some heavy passenger engines, with 21x24 inch cylinders. They will have 60-inch boilers, which is none too large for the cylinder. They turn out an average of four new locomotives per month, and repair four or five times that many.

IMPROVED GRATE ARRANGEMENT.

Shallow fire-boxes, with a decided drop in front, are extensively used here. This dropped front gives some 24 inches between the grates and the lower rows of flues, and the incline is provided with shaking grates, like the rest of the furnace, making it easy to maintain a clean fire ahead. Where axles come under ash pans, they put a lining of asbestos on the ash-pan to protect the axle from heat. The grates used are straight bars running across the fire-box, and having an open slot through the center. These give about 60 per cent. of opening, and do not cock and burn off so easily as finger grates.

A HEAVY TENDER TRUCK.

In some new tender trucks they will bolt independent cast-iron pedestals upon an upper frame. The faces of the pedestals will be chilled, and no machine work put on them, a floating box used. The frames will be extra heavy.

CONTROLLABLE RELIEF VALVES.

On freight engines they put a large plug cock in the steam chests and connect it with a lever like the cylinder cock lever. This is very useful when switching, as the engine can be reversed and the stop graduated by the amount of opening given to the plug in the chest, as it allows more or less compressed air to escape; not as good as driver brakes, but better than nothing. The cock can also be used as a relief valve when desired.

PONY TRUCK KINK.

They use a steel bush in the back end of the radius bar to pony trucks. This bush is held by a set-screw, and can be taken out and replaced in a few moments. This would seem a good practice to follow, as all roads using pony trucks have to upset the eye of radius bars more or less often.

PATCHING.

In the back shop we noticed a machinist fitting a half-inch brass plate on the side of a driving-box. The plate was the full size and shape of the box, and was held on by about fifteen tap bolts of brass or copper. No doubt a new set of driving boxes could be made for the money expended in doing a poor job of patchwork on the old boxes.

MAKING TEMPLATES.

Last winter a template room was established, and some nineteenth century mechanics put to work getting up templates for standard forms. This they are doing in a very thorough and substantial manner, yet the road would be better off and their work greatly simplified if a good many of the "standards" were scrapped.

ROUNDABOUT VALVE MOTIONS.

There are on the road a lot of eight and ten-wheelers known as the Perkins engines; they are improvements on the grasshoppers and camel backs, but they are peculiar—devilish peculiar. The ten-wheelers have a link motion employing two sets of rockers, and two extra connecting rods on each side—a sort of a back-action affair that there seems no very good excuse for, still they are accounted very fair engines, when a little aged they must have a wonderful amount of lost motion.

INGENIOUS SPECIAL TOOLS.

In one of the shops there is a very efficient oil tester, designed by a former chief draftsman; in the tool-room there are also a pair of machines of his design, for twisting and cutting wire for car seals, the work being done automatically and fast, before the invention of this machine, they used to make twisted wire seals by taking long strands of wire the length of the shop, and twist them by hand, cutting the lengths with a pair of shears.

SIDE RODS.

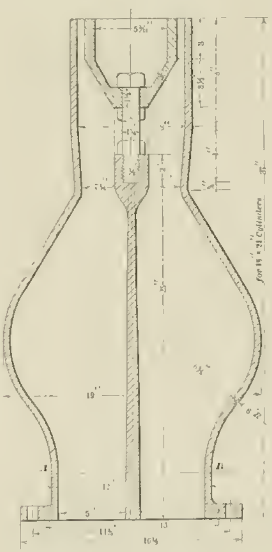
All kinds and shapes of side rods are in use here, but solid ended rods are put on all new 8-wheeled engines.

PECULIAR SPLIT ECCENTRIC.

On some classes of engines they use a split eccentric that carries a collar on its side; the halves are held together by bolts through lugs on this collar, a cheap but clumsy rig, and very efficient where there is room to get it in.

REFORMED CAMELS.

Engines for driving the shops have been built from time to time, some of them converted from



A., T. & S. F. NOZZLE.

camel backs that had been unfortunate on the road; these shops, in times past, also built many of their machine tools.

EASILY-HANDLED THROTTLES.

On engines where the boiler comes through the cab, a throttle arrangement is used where the stem goes down into top of boiler, and turns in its packing instead of sliding lengthwise, they are neater than any pipe arrangement to the dome, and handle better.

On cars they are using some M. C. B. couplers, but experience heavy brakage.

MODEL SWITCHERS.

They have recently turned out some heavy six-wheeled switchers, that are as neat and modern as can be found, they are handy and well proportioned, they weigh 100,000, and the weights on the forward and back wheels are within fifty pounds of balancing, no better examples of good design are to be found.

AN ICE TRUST.

In passing through the shop we noticed on a water-cooler a sign "For subscribers only"—the men have to pay for their own ice.

JUNK.

The yards of these big shops seem crowded full of material of little or no value except as scrap, and it looks at first glance as if little is sold, and there was enough on hand to buy a few new engines, if turned into cash.

ONE CHANCE LEFT.

Certain it is that the railroad world has grown clear past this shop, its tools, and much of its power. A change must come over the spirit of its dreams, or it will never be a half-way modern shop, it needs a clean-up, modern buildings, an exodus of ancient tools to the cupola, old engines to the scrap heap, the scrap heap to the junk shop, and a management with money, and energy, and ability to refit and reform; but they can't do this without expense, and perhaps nothing human will soon make a marked change; it will needs be something unusual—say an earthquake.

An Annular Exhaust Nozzle.

The accompanying cut shows a form of exhaust nozzle now being experimented with on the A., T. & S. F. As will be seen, it has a large chamber or reservoir in the pipe, and a spreading plug in the top. The size shown is the one used for 18-inch cylinders, and the sizes given on the drawing are sufficient explanation. It is reported that engines run with a very much larger opening with this nozzle than they do with the plain one, but we are inclined to think that it will cause a very perceptible back pressure on the opposite cylinder.

The Erie employes have not yet answered President King's letter replying to the demands of the grievance committee. He says, with one or two exceptions (that are stated and a remedy promised) the men receive better wages than those on other lines in the same field. His argument that no better wages can be paid on account of the cut in freight and passenger rates is a bad argument—the road's management should do something to restore and maintain rates. His answer to their demands that the road hire no conductors at all, but promote them all, and to hire as many outside engineers as they promote firemen, is right and just. The road is responsible through its officers to the public, and any rule that puts the discipline of the men or the chances of selecting the best and discarding the worst out of the hands of the operating officers means a demoralized and incompetent train service. There are many abuses that the men are subject to that can be corrected, and should be, but the broad one of wages, and the narrow one of deciding who and what the men in service should be, it would not seem policy to go to war over just now.

We are in receipt of the report of the 23d Annual Convention of the Am. Ry. Master Mechanics' Association. The report is gotten up in Secretary Sinclair's usual tasty style, and has a valuable addition in the shape of a brief description and illustration of all the standards so far adopted by the association. This feature is of great value, as it keeps the standards before the members without the necessity of going back in the files to hunt them up; then, again, many new members have not got the complete reports.

The secretary is hard at work upon the complete index for all the reports, covering twenty-three years. This index will be valuable, and save time.

Richard N. Allen, who came up from the scoop and the throttle, the first man to use steel-tired car wheels, and the inventor of the paper wheel that bears his name, died at Cleveland, O., on Oct. 10th. He was in actual service as fireman, engineer, and master mechanic for more than a quarter of a century, and in his day saw hard times and grief, but in his own words, "made a go of it in the end."

A correspondent wishes to know something of the hours, pay and condition of the engine and trainmen on the Reading road. We do not know what their conditions are, but don't suppose their hours or pay are far different from other men in the same service on other roads. The officers of the company reserve the right to tell them what they shall and shall not belong to, when to button up their coats and how to shave—but they don't all obey, thank God.

Some Old-timers at the B. L. E. Convention.

The Brotherhood of Locomotive Engineers was not born until August 17th, 1863; before that there was an organization known as the Knights of the Footboard.

This order was merged into the Brotherhood, or died about the time the present organization was born. In 1855 the old order was at the height of its glory, and at the convention held that year at the city of Baltimore there were present ninety-five delegates.

During the past year John Brunton, of Pueblo, Col., who was at the Baltimore convention, tried to get a few of the survivors of that meeting to be present at the Engineers' Convention in Pittsburgh; it was the design of the grand officers to have the fathers of the order on the stage, but Mr. Brunton was married recently, and, like all bridegrooms, a little late in getting any place but home, and he arrived too late to make the arrangements. There were present, however, four survivors of the convention of 1855.

John Sexton, once engineer of the old Camden & Amboy road. He has been roundhouse foreman at South Amboy, N. J., for the past twenty-seven years, and has been in active service for the Pennsylvania road, or its predecessor, since 1842. He was the last man to run the "John Bull." Mr. Sexton looks able to write orders for coal-picks and emery for many years to come.

H. R. Smith was with the old New Jersey Railway & Transportation Co., and the P. R. R. got him with the road long years ago. For the past twenty-one years he has been supervisor of track for the first division out of Jersey City, and for eleven consecutive years has won the $150 prize for the best section of track on the system, and his road is over marshes and hills, too; this prize money Brother Smith always gives to his workmen. The other supervisors of track on this road are civil engineers, as a rule, and try hard to get their track up to his; he says he knows what track needs to be, from his years of experience on an engine, and they know what it ought to be by squinting through a transit —and who will dispute him? Mr. Smith was one of the seven men who, in a Jersey City roundhouse, organized the present insurance feature of the Brotherhood, and he holds policy No. 2. This insurance plan has since distributed more than three millions of dollars to the widows and orphans of dead engineers, or to engineers totally disabled. Brother Smith has been in service almost fifty years.

William Osborn commenced his railroad career with the old Transportation Company, and after ten years went with the old Morris & Essex road—now the N. Y. end of the D., L. & W. For a great many years he has been engine dispatcher at the Hoboken shops, has as many friends as the company has ties, and looks as if he would be on deck for ten or fifteen years at least. He was one of the younger delegates in 1855.

John Brunton was for many years a plug puller on the old Bellefontaine road in Ohio; he helped to build the first engine he ran, and was, like most engineers of his time, a "machinist runner." He was with the "Bee Line" for many years, and some ten years ago was given charge of the Y. M. C. A. building at the Brightwood shops. Five years ago he went to Colorado for his wife's health, and was given charge of the stationary engine of the Pueblo shops of the D. & R. G. road, where he still is. Mrs. Brunton died shortly after her arrival in Colorado, and, as we stated before, Brother B. is again a bridegroom. Some of the others of the quartette may look younger, but certainly none of them feel younger than he.

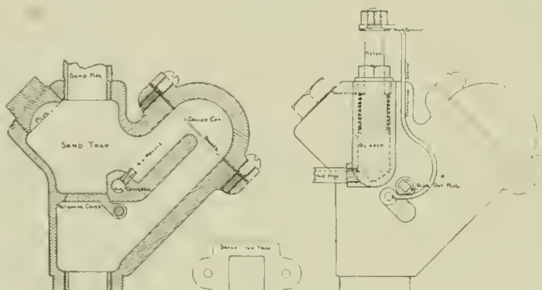
There may be several other ex delegates to the 1855 convention, but they are probably few and far between. Thirty-five years of railroading leaves only the toughest. All of them are grandfathers, or ought to be, and the color variety of hair is limited to white, in small quantities.

These men are of the pioneers of organized labor upon American locomotives, and the forefathers of the present order, just as the old Knights of the Footboard was the forefather of the Brotherhood, and we are only sorry that they were not given a place on the stage, out of respect for age and effort in labor's behalf; they cannot always be with us, and are as entitled to our distinguished consideration now as they will be to eulogy after death. We are too free with the latter and too stingy of the former.

Leach's Improved Sanding Device.

In our September issue we illustrated an air jet device for sanding rails, designed by H. L. Leach, Jr., assistant sup't. M. P. of the Fitchburg road, and in the description suggested that provision be made for using a large quantity of sand for emergency, stops and such purposes. These changes have now been made in an ingenious and substantial manner, and the new device is here illustrated.

The jet device is located in the sand pipe above the running board, and in its normal condition leaves the sand pipe free, just as a plain pipe is, and any quantity of sand can be dropped. When it is desired to feed sand automatically and in small quantity, air is admitted under the small piston shown, and this moves up, closing the trap door marked "retaining cover," and admitting air through the small jet, then, when sand is admitted to the trap it is held there, and the jet carries small quantities of it over the bridge and down the pipe to the rails. There is a chilled cap, cheaply replaced, that is subject to the sand blast cutting; the rest of the device does not seem liable to wear.



LEACH'S IMPROVED SANDING DEVICE

It is well known that any body moving rapidly through the air causes a partial vacuum behind itself; a fast moving train is a good example. The lower end of sand pipes collects moisture from the rails from this cause, and some relief has been had by placing a **T** in the pipe a foot or so from the bottom. This device ought to prevent the collection of moisture in the pipes, because air can be admitted to them and keep them blown out. The slightest pressure above the atmosphere should suffice.

This device is being introduced by H. L. Leach, 237 Franklin street, Boston, Mass.

The New Shops of the Boyden Brake.

The Boyden Brake Co., of Baltimore, have moved into their new shops at the corner of Biddle and Chester streets.

The building is a large and substantial one, two stories high, with separate power house, blacksmith shop and foundry buildings. One floor of the building is occupied by an electric motor company, the other by the brake company.

The shop is not different from other manufacturing shops of moderate size—it has a good many standard tools, and quite a number of special ones, together with many jigs and other attachments to facilitate the work. They have fifty complete brakes set up in a row, and in operation, together with driver brakes, and a complete engine equipment, the brakes operate very quickly on the whole line, the fiftieth brake being set in about three and a half seconds from the moment of application.

About the shop are located air pipes for various purposes. One use that it is put to could be well imitated in railroad shops—an inverted brake cylinder is used as a press to force bushings into work; how much quicker and easier to handle than a screw press! One of these rigs is used, with proper dies, to form the leather packing rings for air cylinders.

The Boyden air-pump will run in any position, and one is running here upside down; in this position there is less water carried into the air cylinder from a leaky gland on the steam cylinder than when the air cylinder is located at the bottom.

They have here a cheap and ingenious plan for closing the large core hole in the end of cast auxiliary drums; instead of tapping it out and screwing in a plug, they cast the sides of the hole inclined toward the inside, with a projection at the bottom, that leaves the hole smaller there than at the top; then a small cast iron disk with a beveled edge is dropped into the recess in the drumhead, being held central by a circular projection on the bottom that fits the smaller opening; around this disk they pour lead, and calk. There is no machine work at all, and a boy can make a good job of three times as many in a day as a mechanic can tap out, and put plugs in.

Their brake is in use on thirty-six different roads, in many cases on trial, but in several instances has been adopted as the standard. It interchanges with the Westinghouse, using their hose coupling.

Vote on M. C. B. Standards.

The results of the letter ballots sent out in August on the adoption of recommended standards have been announced by Secretary Cloud.

The journal box for 60,000-pound cars, and the one for 40,000-pound cars, was rejected.

The plan for loading poles on cars, the rack for loading bark, the making of standard height of passenger car draw-bars 35 inches, the safety chain for passenger cars, the fixing of the lateral angle of brake beams at 40°, and the fitting for train pipe for steam heat to be two-inch female, standard pipe thread, were adopted.

Who Told You?

The reports of the Brotherhood of Locomotive Firemen, presented at the recent annual meeting, show that the organization borrowed $20,000 from the Brotherhood of Locomotive Engineers, to help pay strikers during the Burlington strike. The loan has not been paid, and there seems to be some question whether either side desires to have it paid. —*Ry. Gazette.*

Several correspondents ask us to tell how to set eccentrics on an axle before the wheels are placed under an engine. An illustrated article, by H. R. Jones, covered this ground thoroughly and plainly, in our issue of July, 1888. Read that.

The new Wisconsin Central passenger station in Chicago is said to be worth more money than any station building in America. The finest in the world is in India.

The Pittsburgh Locomotive Works are using cast-steel rockers with good success. They are as light and strong as wrought-iron, and very neat in appearance.

The Mason Regulator Company, of Boston, have issued a neat little catalogue and price list of their goods. Their air-pump governors and pressure-reducers have a very large sale in the railroad trade.

Correspondence

"Doc," the Indicator and the Coal Pile.

Editor The Locomotive Engineer:

My friend "Doc," who kicked so vigorously about new fangled ideas in the February number, met me the other day, and in a very mysterious way asked me to tell him what these things meant, at the same time taking out of his time book—what do you suppose?—some indicator cards! He did not wait for me to answer him, but went on telling me that he was pretty old—he is 40—but he was going to school again "You see the traveling engineer rode up and down on my engine pretty often, saw how she worked, and finally told me that as she was about as good an engine as they had, he was going to try some experiments with her. When he held her in to have the holes drilled in her cylinders and a speed recorder put on, I made up my mind that I was going to be bothered to death. Well, he rigged his little chair out on the front end, got all his brass fixings on the steam chest and levers fast to the crosshead and rode out there Another fellow rode on the fireman's seat, watched the steam pressure, where she was hooked up to, what time it was by the speed indicator, and measured the water every time we stopped at a tank, but he never said a word to me the first trip except how-de-do and good-by. I had nine cars and had to pound her for all she was worth to make the time. In the mean time, Ike—that is, the traveling engineer—sat out on the front end making the marks on these papers, and every time he threw up his hand for a signal the fellow in the cab made a lot of entries in his book That lasted for one round trip, when he took all his fixings off the front end and was gone for a couple of days. When he came back he had the eccentrics all set over—she was as square as a die before—and divided up the clearance at the ends of the cylinder so it was even, fixed her up and gave her another trial. This time the other fellow set up in front and he sat in the cab. I had to work her just so, to suit him. I had the local passenger, only five cars, so I made out to hold the time and got in on the tick When we got turned around he had her put on the fast line to go right back, though it was not my turn She had ten cars, most of them delegates to some convention, and they had a guaranteed time to get in on. You can bet the old girl had to do her best, but we made it all right The next night he came over to my house and showed me these cards that I just gave you. He tried to explain the way it worked to me, but Lord Harry, I could not make head nor tail to it. He asked me how much less coal I burnt after the valves were set than before? I told him he ought to know, as he had it all weighed at both ends of the road. Says he, 'How much less water?' Says I, 'About the same; we stopped at the same tanks.' 'Yes,' he says, 'that is a fact, but your tank was not as near empty.' I did not say anything about that, so he said he was going to keep a close record of the coal for the next month and for me to give as good a showing as I could and figure as close on coal as if it was worth a dollar a ton to me. I run her as fine as I could for that month.

To-day I was up in the 'old man's' office to see how she made out. I took on 13 tons less coal this month than last, and used steam heaters more The 'old man' looked solemn enough when I first walked into the office, but he let a little chuckle out of him when he said, 'How was it, Doc, did putting the indicator on your engine save all that coal or did you do it?' Says he, 'That much of a saving on every engine would amount to quite a sum and the company needs it bad enough to buy some more engines' He gave me all the cards to look over and study up and come back when I wanted to ask any questions about them. I won't get around there very soon, you bet. Ike will get a chance to post some one up pretty soon; he has got all the books on the subject he can get hold of I used to think the rule book and daily papers was reading enough for me, but these scientific things have got to be learned." Well, Mr Editor, I looked the cards over, some of them were good, some were not, explained them the best I could, told Doc to subscribe for THE LOCOMOTIVE ENGINEER right off and get all the back numbers. When he reads this and the February number I will have to look out for trouble.

It may be that setting the valves helped Doc's engine, although she did beat square before If she exhausted square that was no sign that she took live steam and cut off at the most economical point. But it is probable that, now he is interested in saving the coal pile, he will beat his old record and make just as good time. Some men get credit for saving coal that never make up any time and always get to the meeting point last, so as to let the other fellow take the siding. But it is a fact that less coal is burned per ton hauled than five years ago on a majority of roads Larger boilers and more heating surface for the same sized cylinder have had much to do with it, but better machinery and more intelligent use of it will make still greater savings. The enginemen are alive to the necessity, and are getting there.

C. B. CONGER.

Lansing, Mich.

Some Nuts to Crack.

Editor The Locomotive Engineer.

In an experience dating back into the other half of this century I have stumbled upon some problems on the road, and will briefly state one or two "circumstances" for the boys to think about and answer

Question 1.—A freight engine on starting her train on a curve broke her back driving axle close to the hub on both sides of the engine, allowing the axle and boxes to drop down on the binders; the wheels both remained in their natural position. By virtue of the writer's position at that end of the road it became his duty to put the engine in a condition to run back to the division shop, 157 miles. She was a 15x22 Roger eight-wheeler, with the forward wheels well ahead She made the run in twelve hours without any trouble, except to warm up a little. The question is, how would the readers of THE LOCOMOTIVE ENGINEER block up so as not to strain the frames or springs?

Question 2—Was out with a work train, had five cars of cinders; shut off for a bridge. The closing of the throttle was followed by the engine taking steam and slipping at a tremendous rate, sending the fire in all directions. As it was dark, I concluded at once that the dry pipe had collapsed. I put on the air and held the train—could not get the lever up—while the fireman knocked out the fire. The racket stopped just as suddenly as it began, and with fifty pounds of steam and some water. I put on injector and filled up boiler as long as steam lasted, sent word to man following to push me into side track close by. If she collapsed dry pipe why did she stop showing steam and water? Or what was the trouble?

Question 3.—Was running a Norris 16x24, had seven cars and was killing time; road level. Heard a strange noise on right side, stopped and examined everything carefully, eccentrics all right, all keys, crossheads and cylinder head all right; told fireman to give her steam, when there was a roar and stream of fire out of the stack, engine would not move. Disconnected right side; put valve at half stroke and tried again, with same result—steam blowing through. Got the train following to tow me in, being under the impression that the right valve was broken, allowing steam to blow through the exhaust What was the trouble?

Corry, Pa. W DE SANNO.

Pay of English Engineers and Firemen.

Editor The Locomotive Engineer:

I have taken your valuable paper for more than a year, and have several times been on the point of writing you on one or more of the various topics discussed in it from time to time.

Have just read that "The engineers and firemen on the Great Western Railway in England earn 4½c. a mile," as high, you say, as the average Eastern roads of this country. This, sir, is a mistake, as, if such were the case, your humble servant would not have left that road, with its double track and block system, for an American single track with no block system.

I worked on that road for more than ten years, four of which were spent in roundhouse, and more than six firing, and having on one occasion conducted the correspondence for the firemen of that road, during an agitation to "lessen the work of firemen before leaving roundhouse," I ought to know a little about the state of things there.

We were paid an hour before leaving time, but as we had to leave the roundhouse thirty minutes before train time, to get water, and at some stations get our engines coaled, as well as help to make up train, we had only thirty minutes in which to get engine ready.

Fireman had first to unlock tool-boxes, sweep up deck, then had to fill sand-boxes (two ahead and two behind), next pack the stuffing-boxes, of which there were six, the valve stems being extended through front of steam chest; and last, but not least, had to clean inside cab and head lamps (two).

Well, sir, we wanted the cleaning taken off the firemen, and pointed out that the work could not be done in the allotted time, but somehow the officials could not take our view of it.

But I am digressing; I started to give you the scale of wages paid on that road, which is as follows:

Switch engine firemen,	3s 0d per day.	
Road eng. firemen, 3d class,	3s 6d per day	1st year
" " " " "	3s 9d " "	2d "
" " " 2d "	4s 0d " "	" "
" " " 1st "	4s 3d " "	1st "
" " " " "	4s 6d " "	2d "
Hostlers,	5s 0d per day.	
Engineers, 3d class,	5s 6d per day	1st year
" " "	6s 0d " "	2d "
" " "	6s 6d " "	3d "
" 2d "	7s 0d " "	" "
" 1st "	7s 6d " "	" "

Hostlers and switch engineers are paid the same rates, 5s 0d. Twelve hours to constitute a day's work on switch engines. The trains were classified as follows

1st class, all passenger trains.

2d class, through main line freight trains.

3d class, local freight trains. Ten hours a day to be paid for all time worked.

Sunday work to be paid for at the rate of eight hours a day, to apply to trains worked in and out on Sunday.

Promotions to be made as vacancies occur.

Firemen or switch engineers employed temporarily as road engineers to receive 6d (12 cents) a day extra.

A premium of £10 ($48) to be given each engineer at the end of the first year at 7s 0d per day and annually afterwards.

The premium was supposed to be given for economy in oil, fuel, etc., and general good conduct, but the man who stood highest on the consumption list seldom got his premium.

The schedule time of freight trains varied from eight to fourteen hours. I have fired main line coal trains 107 miles, and made the bare 4s 0d (96 cents) a day, and also a through coal train running 163 miles for a day's work for the sum of 6s 0d ($1 44), schedule time from 5.40 P. M. to 8.05 A. M.

On the English roads the fireman has to make all the stops with the hand brake, and the help of caboose brake, as on through freight trains they have no brakemen and only one on local runs.

A great many freight engines are now equipped with steam brakes, which makes it easier on the fireman in making stops

With the system of classification in vogue on this road, and also promotion according to seniority, men have to move their families two or three hundred miles for the handsome advance in wages of 6d (12 cents) a day, the names of the engineers and firemen of the whole system being on the books at Swindon, and whenever a vacancy occurs they take the man whose name comes first, and send him to wherever the vacancy is.

I have known engineers who have been running as third class for six and seven years before being promoted to second, and in the case of firemen I was, after firing five years, the youngest of about a dozen second class firemen.

I left that road in the spring of '88, but from letters received up to a few months ago I know that the same state of things exists yet.

Thanking you in advance for inserting this in your next issue, I remain, sir, CURNRO.

Louisville, Ky.

[Some of our New England roads pay no better wages than those mentioned by our correspondent. The item was written after reading an address in an English paper from the chairman of the road to the employes, in which he cited the new rate of wages paid to drivers and stokers as being double the amount paid in 1867. Our correspondent will find a great deal of difference in the wages paid for the same work in New England and Kentucky.]

Pull of the Reverse Lever—Dry Pipe Lubricators and the Back Action Slip.

Editor The Locomotive Engineer:

In regard to connecting lubricator to dry pipe, engines are arranged that way and give good results. Still one cylinder would get all the oil if the ball joint ring on one side was set up too high, or if the T bend was tipped a little to one side, or if, from some bad adjustment of the core when it was cast, the oil would naturally run to one side, one cylinder would not get any oil when the engine was shut off. Engineers using this device tell me that the cylinder with the tightest packing gets all the oil when shut off, as it draws from the other side. As to the difficulty of keeping oil out of the boiler when the engine is reversed, that is the case when oil pipes connect with the steam chest. When the old gridiron slide valve throttles were used, it was usual to oil them frequently b reversing the engine immediately after giving a dose of oil to the cylinders.

W D S., on page 187, thinks the reverse lever jerks because "the link wants to slip *up* the link block." The angle at which the link stands, in relation to the line of motion of the bottom end of rock shaft arm which carries the link block, tends to slide the link down and the block up. On both the forward and back strokes of the valve—in forward gear—the link is at its greatest angle about the middle of the stroke of the piston. When the link leans towards the eccentric, the eccentric rod is pushing, which forces the link down; as it nears the perpendicular position the motion from the back up eccentric tends to keep it at an angle till nearly the end of the travel, when the back up eccentric pulls over the bottom of the link and places it in an angle in the other direction or towards the cylinder, and the pull of the go-ahead rod forces it down again.

Once in the revolution the links are both perpendicular, at that point there is very little pull on the lever, the difference in the pull at that point and where both sides are pulling makes a jerk. Both links are at an angle when the lever hunts for the bottom notch. The eccentrics give a *steady* pull, as can be seen when the engine is towed with valve rods disconnected or when they get a little dry.

It is a fact that a balanced valve *does* make a difference in the pull on the lever when shut off with the valve at full travel. An engineer soon sees it when he has a balanced valve put in in place of a plain valve. The compression and outside pressure may have something to do with it. Give her a little steam, just enough to shut the relief valves, and see if it won't stop part of the jarring our North Carolina friend complains of on page 167.

Master Mechanic John Shields can give some pointers about copper fire-boxes; he is still using them, from choice I understand.

Do not some of the engineers whose engines "slip the wrong way" when running down hill shut off, get the matter mixed up with the jarring caused by valve motion? C. B. CONGER.

Lansing, Mich.

Electricity on a Locomotive.

Editor The Locomotive Engineer:

In reply to Mr Wallace's inquiry in your October edition as to cause of electricity generated at safety valve during the blowing-off process, I would say that the storage of the fluid in the metal of the dome and contents was doubtless effected in one or both of two ways

First. It is a well-established fact in electrical science that when certain metals are subjected to highly-varying temperatures, an electrical current will be generated when such metals are connected, and will continue to flow between them so long as the differential temperature is maintained. Copper and iron compose one pair of metals which produce the effect described. In the case under consideration it is, therefore, reasonable to conclude that the brass work of the dome, or of those parts immediately within its upper portion, may have been heated to a high degree by the escaping steam, while the iron work at a little distance from the dome, and in contact with such brass work, would remain at a much lower temperature than the brass attained, the result being that, according to the above-mentioned process, a current would be established between the overheated brass and the cool iron. A wrench applied to any portion of the "pop," under such conditions, would divert the current, and Mr. Wallace's feet or body, resting on the cab roof, would furnish a sufficient ground connection to effect a discharge of the accumulated fluid, although that it should be present in sufficient quantity to produce such a severe and startling result as that he mentions, is to be wondered at. Many attempts have been made by prominent electricians to utilize this property of certain airs of metals, and such men as Siemens and Jablochkoff have taken out patents on certain methods of producing a current in this way, but the results have so far been unsatisfactory, for several reasons. It is said that Mr. Edison is at present giving much attention to this idea, and hopes to ultimately reduce it to a practical basis.

A second cause of the phenomenon noticed by Mr. Wallace may be looked for in the friction due to the passage of escaping steam over the edge of escape port, or other similar projecting metal edges. This friction might produce a storage of electricity in the surrounding metal by a process similar to that which takes place in charging a Leyden jar, although, as in the previous instance, the quantity thus generated could scarcely be expected to be sufficient to produce the marked effect described. C. H W

New York City.

An Old-timer Satisfied with the Present.

Editor The Locomotive Engineer:

Enclosed find one dollar for another year's subscription to your very valuable paper. I, like Brother Alexander, had a boy promoted. He has passed a satisfactory examination before that august Board of License Commissioners of Alabama, and, like Brother John A., I feel proud of him; for be it known that a parent who raises and puts a son on an engine has accomplished something for the good of his fellow man

A word or two about the opportunities the youngsters have in these days compared to what us old-timers had.

In 1852, when I first commenced crossing hard beech blocks in an old Harkness ten-wheeler between Columbus and Cincinnati it was grief, sure enough; seventeen cords of hard wood in 120 miles, you will no doubt agree, was a good day's work, but that was not all—at the end of the trip, with a long pair of tongs we drew what fire remained in the box, then, to give us an appetite for our meals, we sparked a balloon stack. How would some of the lads like to try it now? The stack was balloon-shaped, with a straight inside pipe; this pipe was surmounted by a cone somewhat larger than the pipe. The cone caught the sparks and deposited them in the bottom of the stack, on which was a small pipe with a cap over it. To remove the sparks at end of trip we had a pipe that fitted over the capped pipe on stack, a hook and a club—made by putting a turned stick through a piece of tank hose. With the hook we raked out the sparks, and when they stuck fast we pounded them down with the stuffed club. Let old-timers prate about the good times they used to have, but I will take mine as they are at present.

The Grasshopper C W Crawford speaks of was switching on the piers previous to the time spoken of. Some time in the early '50s she was wrecked on the Cleveland & Pittsburgh road by cross ties being placed in a cattle-guard; her engineer was killed; I think his name was Watson.

The slipping of drivers when engine is shut off is no new thing. I run a five-foot wheel Baldwin, the "Alentanga," cylinders 13x26, that had it bad (This was in '56 or '57.) If the rail was a bit damp, and her nose the least bit down grade, unless I gave her a little grit she would make the fire fly out of the ash-pan; shortening the stroke cured her.

East Rome, Ga. WHEEL OF FORTUNE.

About Pinkerton Men.

Editor The Locomotive Engineer:

It seems to me that the squib on the "Curse" business is a little out of place in a paper of this character.

Pinkerton men may be, and probably many of them are, toughs from Toughtown, but are they not amenable to law, the same as any police, or the constables of England, against whom John Burns says not a word?

England has a standing army that can be called on at a moment's notice to protect property. we have none, and so, when train-wrecking strikers ply their trade, men are hired to prevent their hellish work.

But that is not the point. When a man strikes he leaves his job because he is not satisfied with the conditions, and when he leaves he has no right whatever on the firm's or company's ground. He has left them, and they can insist that he stay "left," and not trespass. Now, if these strikers, wherever they may be, do not intend to trespass on the railroad, either to block trains or to intimidate workers, what need they care if there is a Pinkerton man on every tie? They have no right there, and he has. The moment he breaks any law he is liable to arrest, the same as one of the strikers. That arrest and conviction does not follow is a fault of the town in which the trouble occurs.

"The people have a right to resist the sword by the sword." Very true; and have not the Pinkerton "toughs" a right to do likewise? The first attack, in nine cases out of ten, is made by strikers or their sympathizers, and if the "toughs" do kill a man once in a while, is it any worse than derailing trains and imperiling the lives of hundreds? The strikers use the sword first, and then cry "coward" because the "toughs'" swords are the sharpest.

I have no love for strikes nor any of their attending evils—Pinkerton toughs included—nor do I believe the fault is always one-sided; but as long as strikers will persist in destroying property, in trespassing where they have no right, in order to block trains or intimidate men at work, so long must the railroads or firms in question take steps for the protection of their property. If the government will afford it, so much the better. In the meantime, Pinkerton toughs are in demand, and their lawlessness, even if as bad as painted, is better than the derailment of trains and the burning of bridges

The suggestions made in the article referred to are hardly in keeping with the law-abiding LOCOMOTIVE ENGINEER. C. B. RICH

Philadelphia, Pa.

[Our correspondent mistakes the case entirely. The police of this country and the constables of England are authorized officers of the governments. Pinkertons are a mob. No one objects to the protection of property by the police. We object because they do not protect it from one mob, and do turn it over to another mob.

If the civil authorities are too weak, our militia can be put afoot just as quick as England's standing army.

In nine cases out of ten crowds collect where Pinkerton's men are stationed—to see what they will do. Every one knows that they are usurping the authority of the police, and they are disliked. Some boy jeers at them, another throws a stone—and the Pinks shoot into the crowd, generally hitting a woman or an old man—they seldom hit a striker.

Our correspondent says if Pinkertons do wrong they are amenable to the law and can be punished. That is just what we are kicking about—they should be arrested and fined for appearing in any community armed. They are a menace to the safety and peace of the people. There is little doubt that they do as much train-wrecking as the strikers—they want to stay in a soft job as long as possible. Train-wrecking is murder, and guilty parties should be punished—no matter who they are.

We do not object to Pinkerton's men because they are opposed to the strikers—let the strikers take care of themselves—but because they are a menace to the public, and have killed more people in strike times than all the train-wrecking ever did—innocent people, too.]

Getting Patents.

Editor The Locomotive Engineer :

You say in the September paper that the patent office should not issue such patents as the V-shaped slide valve. I agree with you, but would call your attention to the fact that fully three-fourths of the patents issued are no better.

The trouble is in the system, and in the existence of patent lawyers; these are the fellows who swell every young inventor's (?) head, and wheedle his money out of him.

When a man gets a patent, his trouble is only commencing—he has to defend it in the courts, and if he is poor he has no chance at all.

Montgomery got bounced from the patent office because he proposed to give every applicant a patent for a fee of one dollar, and then let them fight out their priority of claims, etc., in the courts—as they have to do anyway. The patent lawyers got his scalp in no time—the plan he proposed would kill their trade.

The beneficiaries of any form of misgovernment or mismanagement can always be depended upon to fight reforms or changes, and a reformer's lot is always an unhappy one, if he is the pioneer.

After the battle of Chattanooga, General Rosencrans made an estimate of the amount of ammunition used, and the killed and wounded on the enemy's side, and reported that it took sixteen pounds of lead to kill one Confederate; he said it was not the lack of numbers or of bravery that prolonged the war, but *bad shooting*—the very thing that received the least attention—but this was a criticism on the "powers that were," and the reforming general was soon after removed.

It seems to me that if witnesses were required to swear that they had seen the invention in actual use and report, independent of the lawyers and the inventor, that there would not be so many patents by half—after seeing his invention in practical form many an inventor has wished that he had never patented it. HUGH CRUMLISH

Buffalo, N. Y.

Experience with Broken Side Rods.

Editor The Locomotive Engineer :

It is claimed by some mechanical engineers that there is no such thing as gradual crystallization of iron, when properly used, although constantly in vibration.

I would like to ask if broken side rods are ever examined minutely at the point of fracture, and comparison made with that part of the rod that receives the cold bend, by end thrust on a tie or frog?

Have seen so many broken side rods that showed a clean, sharp, square break, that it proves to me that constant vibration does crystallize iron. Enclosed find sketch of broken side rod. The writer was taking an engine to the shop, running light (about twenty miles an hour), when the left side rod snapped square off about the middle of the rod; the forward part struck a tie and doubled up in the form shown, flew around and jammed against the main rod, the rear section took the usual course—through the bottom of the cab. The fracture was clean, bright and sparkling.

I would like to say a word right here to young runners, to wit: Never reverse your engine when she breaks a side rod, but stop as quick as you can with the brake, allowing your engine to roll ahead. There is a possible chance of saving the other rod and pins, when in reversing you are likely to throw the engine out of tram and wreck both sides; it was by adopting this course that I saved the right side of this engine.

I make the assertion that bad quartering will not break side rods, it may pull off a pin or break a strap, but with a solid-end rod the pin is most likely to go.

Mr Camel advises the filing out of the brasses to allow for variation in length. If rods are bored out the distance of the driving axles between centers, and $\frac{1}{16}$ larger than the pin, they will run ninety-nine times out of a hundred, and it is a waste of time to adjust a rod with the tram, and then tram the pins; if it is a strap rod, couple up one end and turn the other pin around until it comes up against the brass in other end of the rod. Mr. Camel's advice is all right, but impracticable.

Ross Winans was about the first to use solid-end rods; have heard it said that his wife suggested the idea, railroad companies could have followed the idea up with advantage to themselves. Long live the solid-end rod

Corry, Pa W DE SANNO

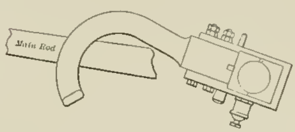
[Our correspondent seems to think it possible to crystallize a piece of iron, through constant vibration, all in one spot, the cold bending the rods endure after the break seems to show pretty good material. We are inclined to think the rods are broken by a tensile strain caused by being too short. Any strain between the pins is transmitted through the rod, and bad quartering will pull off a pin or break a strap only when the pin or strap is weaker than the rod]

How to Twist an Axle.

Editor The Locomotive Engineer.

In reply to Mr Frank Phelps, Ft. Hancock, Texas, I will say that I don't know how both back and forward axles could get twisted alike, nor did I say that both axles on 121 were twisted, I will say, however, that the forward axle was twisted badly, and both were worn badly enough to throw away

I think you can twist an axle very easy by giving your engine sand when she is slipping, especially



when one sand pipe is stopped up; for instance, suppose your right-hand sand pipe is stopped up, your engine gets to slipping, and you give her sand on left side just as she gets on her center. She would be on her quarter on the right side, where she would get, not only the momentum of the wheel, but force of steam also (providing you are using steam when you give her sand, which I think is a very unwise thing to do), don't you think that would twist an axle?

Syracuse, N. Y. W F RELYEA.

In Place of "Hog."

Editor The Locomotive Engineer:

I have noticed in your paper the name "Hog" given to some engines on the P R. R. I can't see any resemblance to the hog, and I thought that as locomotives are generally called "The Iron Horse," why not call them the "Perchon." I believe that is the name given to the largest horse in this country. I will admit that under the wheel covers of these engines there is a place that looks very much like a hog-pen, and perhaps they deserve the name. EDWARD GIBSON

Wilmington, N C.

Last Word on Squaring Valves

Editor The Locomotive Engineer:

When a poor devil gets into a dispute on any mechanical point it is devilish hard to quit, especially while you have personal charge of a lot of old scrap heaps during cotton season in Texas. Our friend De Sanno seems to differ with me on setting a valve and squaring one. I call squaring one getting your valve yoke to fit your valve so that it will be square at both ends of steam port, getting your links plumb and hangers the same, and proper length, also arms on tumbling shaft proper length, and reach rod the proper length. Now I do not claim to do all this in ten minutes, but I do claim that a man should take his trams, get his centers and run his valves over both motions, forward and back, in ten minutes, and tell his machinists what to do if eccentric blades are to be shortened or lengthened and eccentrics moved.

He should be able to tell all this in ten minutes. Let his machinist move eccentric blades to their proper length, and if eccentrics are to be moved, let your man get his set-screws loose. Always let your man take off lead before he puts it on, and see that he does not get his eccentrics too close together or too far apart. Whatever lead you want your engine to have he gauges with the thickness of sheet-iron; then let your valve gauge drop in all four center punch marks from all four quarters of driving wheels, and then you can bet on her exhausting square and doing all the work she is capable of doing.

Now, dear Editor, I hope you will excuse me, as this will be my last letter until next spring. I am satisfied that some readers of your valuable paper will be glad to see me out of the ring. Do not forget to keep sending me the paper, because I like to hear from the boys. E. A. CAMPBELL.

Houston, Tex. Supt. M P. & Machinery.

[Bro Campbell's ten-minute rule for squaring valves works something on the plan adopted at Altoona, Pa., for building a complete locomotive in ten hours—had the parts all made and half assembled before they commenced.

If the valve stems are marked with the port marks, and a standard tram used, it might be possible for a mechanic to see if the valves were out in ten minutes, and perhaps tell where the trouble was; but as for squaring them up, as should be done, most master mechanics would consider that ten times ten minutes would be fast work, and forty times ten pretty good if there was much to do, or it was necessary to take all the measurements.]

An Indian Brake Trial.

On the Eastern Bengal State Railways of India there has been a brake trial in progress for nearly a year, and Mr. A W Rendell, the locomotive superintendent, has just issued his report on the same.

Among other data sought, Mr Rendell compared the fuel used by the two brakes with rather surprising results. Finding that the engine equipped with the Westinghouse brake burned considerably less fuel than the one fitted with automatic vacuum, he ran them some time without brakes and found that the Westinghouse engine was in better condition and using 4.8 per cent. less fuel than the other engine, so in his report he deducts this amount from the air-brake engine's showing and still shows the following results

	Westinghouse lb.	Vacuum. lb.
Coal per train-mile . . .	31.87	36 08
" 1,000 ton-miles. . . .	237 98	259.42
Water per pound of coal. . .	6.45	6.31
" train-mile	205.47	227.73
" 1,000 ton-miles. .	1533.83	1637.38

A saving of about 10 per cent. in favor of the Westinghouse brake

It is very well known that a jet of steam is a considerable drain on a boiler when hard pressed, and trouble has been had in England and India from the engineers shutting off the vacuum-producing jet to save steam, on some roads they have introduced an air pump—coupled to the crosshead—to maintain the vacuum. This, however, is no fault of the brake, as engineers often shut off the Westinghouse pump for the same reason; still where it uses so little steam there is not the temptation to economize in this way.

There is great agitation in England on the brake question, over the alleged fault of the automatic vacuum in freezing up; this brake has been very popular, but in the present discussion and trial Westinghouse seems to be taking first money.

The prosecution of the alleged N Y Central train wreckers has flattened out; there was but one man indicted by the grand jury, and no case was shown against him, and he was discharged by Justice Gragan, Oct. 11. The railroad should learn from the experience of its men, grievance committees are dismissed if no grievance is found by them, and the Central will probably find that the men (God save the mark!) employed to find train wreckers knew where they were to be had.

Making Bricks Without Straw.

You do not have to go very far or hunt very long now-a days to find a master mechanic or machine shop foreman kicking about the quality of mechanics, and bewailing the fact that "machinists ain't what they used to be"

Motive power officials are themselves wholly at fault for the lack of good railroad mechanics and for the hordes of useless ones. This is a broad statement, but it is true, nevertheless. A look around a railroad shop is enough to convince any one.

Good mechanics are in constant demand now, first-class machinists are worth $3.50 and blacksmiths $4 per day—yet there is no supply for the demand. Botch workmen are plenty, and dear at any price.

In order to make first-class mechanics it is necessary to have, as seed, apprentices of intelligence, with common school educations, a taste for mechanics and an ambition to become proficient in the business. With this kind of material to begin with, time, opportunity and experience will produce a first-class mechanic—just as a little attention in the right line produces a chick from a good egg; time, attention, opportunity nor anything else ever made anything of a bad egg—except a worse egg.

Show us a railroad shop where they try to select good material for apprentices; it is not done in one case in a hundred. Let the average youth, say 18 years of age, go to an M. M. or shop foreman, seeking an opening for a chance to learn the machinist or blacksmith trade, or to get a job firing, and what encouragement does he get?

In the first place he is too old, says his judge, don't want no schoolboys anyway, and, if the applicant has pride enough about his personal appearance to wear a clean collar he is put down as a "dude."

The very youths who would make bright and useful mechanics are shut out from a field of usefulness that they would honor and adorn—for what?

To give room for boys who go into the shops for the bare wages in sight or because they are forced there by their fathers, who are in the service some place or have some influence with "the powers that be."

Mickey Doyle is the oldest wiper on the road, hasn't missed a day for nine years, he wants to get his boy Dennis doing something to help support him, as he won't go to school, so he makes application early and the boy is worked in as helper, serves three years as an apprentice—just as he would serve three years as a prisoner—and turns out as a machinist; he don't go to work as a jour. in the shop. No, the foreman can't put on any full pay men, just then, so he goes off, a finished mechanic, and the master mechanic or foreman is glad to be rid of him

If possible, Dennis is got on the road firing—pays more on the start—he is given a job cleaning ashpans or wiping, the foreman mentally declaring that he knows enough for that, and that's about all; but a rush occurs, and the first available man is pressed into the service, so Dennis gets to be smoke shoveler, and, as the agreement with the men says seniority is the proper qualification for promotion, Dennis gets an engine in his turn. One more plug engineer added to the list of bad ones, and another young man, who would have made a good one, forced to drive horse car, tend bar, or go into politics.

The railroad officers are complaining about the quality of engineers and mechanics, and are themselves making poor ones all the time It would take some work, a little thought, and a departure from precedent, to choose apprentices for all positions upon the merits of each case, to give intelligence, natural aptitude and decency preference over cousinship, friendship, politics, religion or boodle.

Anything will do for a wiper or a helper, and after the wiper or helper has been pushed up to promotion, his own maker will complain of the bricks without straw on hand, and blame the brick—instead of blaming the maker.

If a boy wants to drive a canal boat, and his father wants him to be a machinist, and forces him into a shop, the parent stands just as much show of making a good mechanic of his boy as he would of making his daughter happy by marrying her to the man of *his* choice, and murdering the man of *her* choice.

When those who have the making of mechanics will seek to improve the quality by selecting good timber, and keeping up a constant inspection for "culls," instead of employing in subordinate positions those who are forced upon him, or who are the least trouble to get, we will have a better crop of machinists and engineers—and not till then.

We have no patience with that class of pessimists who are constantly declaring that good, bright boys don't want to learn trades. Once announce that you will put to work only intelligent young men who have gone through the public schools, and who themselves desire to learn the trade, and who will, after six months' trial, satisfy you of their adaptability, and desire to become mechanics, and that they will be promoted on merit, and you will be overrun with applications, and can pick out the future mechanics of your road from the cream of the land.

There is a crying need for good mechanics, the brightest boys in the land are anxious to become such, and there is room for them. Why don't they get the chance? Is it because of the inability of American shop foremen to tell good material from bad? Is it because they want poor mechanics, so that they can be whales among toads? Is it because they are apathetic, and do things the easiest way? Or, is it because they are themselves the wrong men in the wrong places, promoted on account of the date they hired to the road, instead of what they know about their business or the selection and management of men?

The New York Railroad Club.

The New York Railroad Club has been brought to life again and has started in to hold meetings for the winter. There has been a surprising lack of interest taken in this club for the past year or two. New York city ought to have the best railroad club in the country—it has been about the poorest. In looking around for the cause it does not seem very hard to locate—the practical railroad men have lost interest. Why? Because the benefits derived have not been enough to pay for time and trouble to get to meetings. The club is composed of railroad men and supply dealers in the railroad trade, the latter class contributing most of the expense money. Perhaps the efforts to have things too nice have used up the surplus energies of the club. They have recently rented a room and hired a janitor, this room is in the Gilsey House, is accessible, and all that, is to be open to club members and their guests from 9 A. M till 12 P. M. every day. This costs money, and few railroad men will congregate there except on meeting night Without presuming to criticise, we should say that the amount expended in keeping open house would hire able speakers, or set up a good supper every meeting night, and a good speaker on a live subject or a good supper for live subjects will call in the railroaders every time A meeting of supply men and newspaper fiends, calling themselves a railroad club, is like an oyster supper without oysters.

If the N. Y Railroad Club will hire a good meeting hall one night in the month, pay a secretary enough so that an able man can afford to devote some time to its business, and set up a fair supper and a short paper on a current topic, providing a seat for each member and one friend, we guarantee the regular display of the "Standing room only" card. And they won't be all supply and newspaper men, either.

Books Received.

THE WESTINGHOUSE AUTOMATIC BRAKE CATALOGUE OF 1890 Issued by the company, Pittsburgh, Pa

For free distribution to those having in charge the repairs and maintenance of brakes. It is not a descriptive catalogue, and therefore the cuts are made to specially show parts in a way best suited to the purpose. Every part of the complete automatic brake of all kinds used are illustrated, numbered and named, and the prices given. The illustrations are new, and the information all that can be desired by master mechanics and car builders having the maintenance of brakes in charge, the size is 9x12, the same as former catalogues

SOUVENIR OF THE TWENTY-SEVENTH INTERNATIONAL CONVENTION OF THE BROTHERHOOD OF LOCOMOTIVE ENGINEERS

This is the usual bound volume gotten out every year for advertising purposes to meet the expenses of the convention. It contains an historical sketch of the city of Pittsburgh (where the convention was held), and biographical sketches with portraits of the grand officers and the committee of arrangements. We believe the book is not sold.

TRIPLE-EXPANSION ENGINES AND ENGINE TRIALS. By Prof. O. Reynolds, LL.D., F. R. S. M. Inst., C. E., &c. Edited by P. E. Idel. D. Van Nostrand Co., publishers, New York. Price, 50 cents.

This little work describes a series of tests made with triple-expansion engines under many different conditions, with and without steam jackets, condensers, etc. The work is chiefly valuable in showing how such experiments should be carried on, describing every detail of the apparatus, and giving the results with triple-expansion engines with various pressures and piston speeds. The book is gotten up in neat shape, bound in green boards in Van Nostrand's uniform size known as the "Science Series," about 4x6 inches in size.

HANDY LISTS OF TECHNICAL LITERATURE, PART III. Heise & Haferkorn, publishers, Milwaukee, Wis. Price, paper, $2.50; cloth, $2.75. Key, 25 cents extra.

This work is a 200-page catalogue of all standard work on civil and mechanical engineering. The price seems at first to be very high for such a list, but for a busy student the list is invaluable. It gives a brief summary of the contents of the work, the year in which it was issued, the author, the price, and a list of those who sell it, and the address of the publisher. It tells at a glance all that is extant on a subject, and saves hunting absently over libraries.

HAND-BOOK OF CALCULATIONS FOR ENGINEERS, FIREMEN AND MACHINISTS. By N. Hawkins, M. E. Theo. Audel & Co., publishers, 91 Liberty St., New York City.

This book is intended for both reference and instruction in the first principles of the mathematics of steam engineering. The opening parts teach first, how to write and read figures, and from this primer like commencement, the work proceeds to give the elements of arithmetic, mensuration, geometry, algebra, etc., all illustrated with examples of calculations relating to the every-day problems of the engineer.

Beginning with natural or mechanical philosophy, in which the primary powers are mentioned and briefly described, the lever, wheel and axle, the pulley and inclined plane are illustrated with examples and description. Next follows as general subjects thermo-dynamics, or heat-power; *i. e.*, the power which is produced by burning of fuel; horse-power, with copious rules for its calculating, both of engines and boilers and of every variety, pumps, with many practical "points" to their management and calculations; steam, description and figures relating to this main subject; injectors; gravity; strength of materials, with useful tables; the steam boiler; the safety valve, with many rules for ascertaining the safety limit of pressures, the steam engine, with illustrations and calculations and description of varieties; engine counters; illuminating gas, and how to read the gas meter; table of melting points of solids; electricity, how to measure and figure it, with many useful "points" in its management; table of conductors and insulators of electricity; chimneys; transmission of power by belting and pulleys; the indicator, with illustrations and rules for figuring the diagrams; business points for engineers, and index combined with useful definitions.

The work is published in ten parts, neatly bound in green paper covers, and also the whole ten parts in cloth with stiff covers. The price in parts is 25c. each; in book form, $2.50.

THE WESTINGHOUSE AIR-BRAKE INSTRUCTION BOOK. Issued by the company at Pittsburgh, Pa. Price not stated.

This work of 70 pages is in pocket form, bound in leather, with a pocket containing cuts of the principal Westinghouse apparatus. The body of the work is a brief instruction lecture on how to handle the quick-action automatic, although it has chapters on the signal, the driver-brake, levers, etc. The cuts used are all new and neat, and the work is complete in the fewest possible words, making it invaluable to locomotive engineers and firemen. The best chapter in the work is called "Don't," and is reproduced in another place in this issue. No locomotive engineman who has to do with air-brakes can afford to do without it.

ASKED & ANSWERED.

(64) J. G. S., Long Island City, writes:

What is the longest tunnel in the world? *A.* The Croton aqueduct, New York, 32 miles long.

(65) W., Chicago, asks:

When a steam gauge registers less pressure than the boiler carries, is it called light or heavy? *A.* Light.

(66) J. W. P., Senney, O., writes:

I see in the October issue of THE LOCOMOTIVE ENGINEER, where John Alexander states in his letter entitled, "That Hoodoo Model," that valves cannot be divided square at all points of cut-off. Please tell me the reason why. *A.*—He stated that it was impossible to get them *exactly* square *for all points of cut-off forward and back*. This is impossible with the link motion on account of the angularity of the main rod. Practically, the cut-off can be set all right, but not *exact*.

(67) C. W. S., Janesville, Wis., asks:

What is meant by total wheel base, and driving wheel base, and do we not sometimes see the terms rigid wheel base used? If so, please explain. *A.* Total wheel base is the distance from the center of the front to the center of the back wheel, regardless of what they are, trucks or drivers. Driving wheel base is the distance from centers of extreme drivers. Rigid wheel base is the distance apart of the extreme drivers having flanges; thus an eight-wheeler with the front driver tires bald has no rigid wheel base, properly speaking.

(68) S. W., Milwaukee, Wis., asks:

Is lead a benefit to an engine in starting a heavy train or a dead pull? *A.*—There are two sides to the question. All pressure put upon the pin at the dead center only increases the friction and does no work until the pin has got away from the center; in a dead pull, perhaps negative lead, or a lack of lead would be a benefit. The other side is in the economy. We want heat in the cylinder, and the walls heated as soon as possible. Lead would materially help that. Generally speaking, under the conditions named, lead would not be a benefit.

Locomotive Running Repairs.

BY L. C. HITCHCOCK.

The subject of running repairs is so broad, that in writing upon it there can be no assurance given that many new ideas will be advanced, owing to the fact that there are scarcely any repairs to be made on an engine which may not be made in several different ways, any one of which may produce good results.

It is not the intention of the writer to have his articles convey the idea that the ways he describes of doing work are the only correct ways, for it may be proven that in some instances the ways described are not the ways which will produce the best results.

"All men are prone to error," and I do not believe in the "My way is the best and only way" theory, for if there lives any one man who knows it all I have never had the pleasure of meeting him.

There is always a *best* way, and the object of the writer of the articles on running repairs will be to get this best way before the readers of THE LOCOMOTIVE ENGINEER, and whether they get this from reading his articles, or from the criticisms and suggestions from some of his readers, is immaterial if the desired object is gained.

The intention of the writer is to tell the boys in the plainest manner possible of the way different classes of work has been done which has produced the best results, as far as my observation has enabled me to judge. And where there exists a probability that, by doing work in a certain manner, poor results would follow, the desire is to explain to them what these results would be, and why they would be produced, that all may avoid doing work in an improper manner; and should any of the readers of THE LOCOMOTIVE ENGINEER "pick me up," and explain better methods of doing running repairs than those which will be described, I shall thank them, and cheerfully "stand corrected." The writer is selfish enough to hope and expect that he will derive as much, if not more benefit from the corrections and suggestions from his readers than they will receive from reading his articles, though an effort will be made to make them as interesting and instructive as possible.

GRINDING IN BRASS VALVES, COCKS, ETC.

It is a good plan, I think, for roundhouse foremen every morning and noon to personally look over the book in which the engineers report the work to be done on their engines, and to assign to each man under his charge the particular work he is to do. While doing this recently I noticed where an engineer had reported, "Grind in right injector line check," and told a machinist (a new man who had only begun work that morning, and who was awaiting to have his work assigned to him) to take off the cap of line check, and examine the condition of the valve, and also to have the boiler washer lower the water in the boiler to enable him to examine the condition of the boiler check valve, and to note the lift of each. Then I wandered around through the house, apparently not seeing anything in particular, but in reality keeping a close watch of Mr. Machinist. The first thing he did after examining the condition of the check valves, as instructed, was to go to his tool cupboard and take out two cans of emery, a little cotton waste, and a squirt can, and start for the engine. On his way there I met him and asked him what he intended to do with those things. Said he, "Grind in the checks, they need it." Right then was when the lecture began, and he was told that the checks did not require to be ground with the emery and oil he had, he was shown where to get a piece of an old grindstone which had been broken, and was told to powder it up, and sift it through an old red flag which we had for the purpose. Then he was sent to the storeroom for a bar of soap—not cashmere bouquet, but yellow soap. The boys call it "washerwoman's delight," and in an old box lid we mixed the grindstone powder and soap with water into a thick paste.

This for grinding brass surfaces together, when water is used instead of oil, gives the best results of anything we have ever seen used, owing to the fact that the particles of grindstone will not embed themselves into the brass surfaces, as will the particles of emery, causing the surfaces to cut.

Never grind brass cocks, etc., with emery. The proper way to grind a brass cock (if you have the cock off so you can catch it in the vise) is to catch the large end of the plug in the vise, and grind the shell to it, giving it each time about one-half turn, pulling the shell a little away from the plug after each half turn, continue this for six or eight seconds; then remove the shell from the plug, and clean each thoroughly and rub them together dry, rub hard; do not be afraid that they will cut, for they will not, if there has been no substance other than the grindstone powder and soap between them.

When rubbed together dry, the heaviest bearing will be indicated by dark yellow lines. Should these not be universal the entire length of plug and shell, rub clear soap on the dark yellow lines on the plug, and put the paste and water on the other parts and grind again, but only a few turns before cleaning off and examining again. When the bearing is perfect on shell and plug, put a little beeswax and tallow melted together on the plug, and put it into the shell, and you will have a nice, tight, free-working cock.

Before commencing to grind brass surfaces, pains should be taken to get as nice a bearing as possible by the use of a fine file or scraper, using lampblack and oil, or something of that nature, for a marker. Then, while grinding, care should be taken not to bear on too heavily, or grind too long, before separating the surfaces, as this allows the particles of grindstone on each surface to change their positions, and this prevents cutting. Those who will follow these simple directions while grinding brass cocks, etc., will have no cause, I think, to regret having done so. I know of one man at least who believes it to be the correct way, and that is the man who ground the checks; for, said he, "It used to take me longer to get the emery and cuts out than it does now to do the entire job."

While speaking of checks it may not be out of place to suggest here that every time a boiler is washed out the check caps be removed, and pains taken to see that the check valves, and the passages in the check shell are perfectly clean, and that the joints are perfect on the valve and seat, for while boiler is being washed, scale, etc., is liable to be washed over on top of the check valve, and this oftentimes prevents the free working of the injector, and in this case, as in most others, "An ounce of preventive is worth a pound of cure."

The Old Colony disaster has called out orders from many roadmasters and superintendents to invariably place track jacks on the outside of the rail. This order is well enough where a "step" or "hook" jack is used, but don't count where those abominable straddle jacks are found. The safe plan is to use jacks that are entirely below the line of the rails.

The standard fire-door on the B. & O. is the double-sliding door operated by a lever, in common use in Europe; they have no liner, and get hot enough to crack, but are cheaply replaced.

Simple Lessons in Drawing for the Shop.

By Orville H. Reynolds.

THIRTEENTH PAPER.

A drawing of a slide valve and its seat can be made productive of much good, not alone as a work showing skill acquired, but more for the practical ideas which are sure to be developed by a careful study of it, as will be shown later.

Let us take for an example a valve and seat such as is found on a modern 17x24 passenger engine, and draw it to a scale of 3 inches to one foot, as shown in accompanying engravings.

Draw horizontal line *A B*, Fig. 87, to represent the valve seat face. Erect a perpendicular at *C D*, which shall be the center line from which to lay off all horizontal dimensions.

To draw the lines representing ports on the valve seat, lay the scale on line *A B* and mark off equally each side of center line *C D*, one-half the width of exhaust port *E*, either with the pencil or a needle point; the latter is preferable for close work, for the reason that it leaves a fine dot on the paper that cannot be erased or misunderstood.

Drawing pens are often equipped with such a needle point in the end of handle, and is visible only when the pen is unscrewed from the handle; but in the absence of one of this kind the point of divider leg will be of use.

Leaving the scale in the position first taken, prick off distance *F F* on each side exhaust port for bridges, and in like manner *G G* for steam ports; next lay off distance *H H* each side of center line for total width of valve seat.

Through points laid down, erect perpendiculars to line *A B*, making them about two inches long; this forming an outline of valve seat, and a true one, because of the way in which the points were laid off.

It will be seen that there is not the same probability of error when leaving the scale in one position while laying off points each side of a center line, as there is in shifting continuously from one dimension to another; this is a fact that should always be borne in mind.

Taking same center line *C D*, use the scale as before, and lay off the valve in its middle position, or central over the ports, the valve face joining that of the seat on line *A B*.

Laying off first the lines of exhaust edges *I I*, then width of valve yoke fit *K K*, and lastly the width over all, *J J*.

All dimensions in a vertical plane are next laid off, beginning with thickness of valve face; after which lay off height of yoke fit on line *K K*.

The total height of valve having been marked on line *C D* we have three points through which an arc should be drawn by the compasses, the center to be found as in Fig. 40, seventh paper.

From this center describe another arc at a distance below the first, equal to the thickness of metal, or about ⅞ inch.

Lay off a like distance inside of lines *K K*, and draw to intersection of lower arc, then connecting lower end of lines to exhaust edges *I I* by a small arc.

The outline of valve and seat being completed, they should be section lined in the usual way, and dimensions placed as shown.

Fig. 88 is another sectional view of valve and seat taken on line *C D*, Fig. 87. Using the T square, project from Fig. 87 all lines lying in a horizontal plane, beginning at the top of valve. No special instructions are needed in this view other than to lay off from center line *L M* all dimensions without moving the scale as in preceding case; this view represents a section crosswise of cylinder.

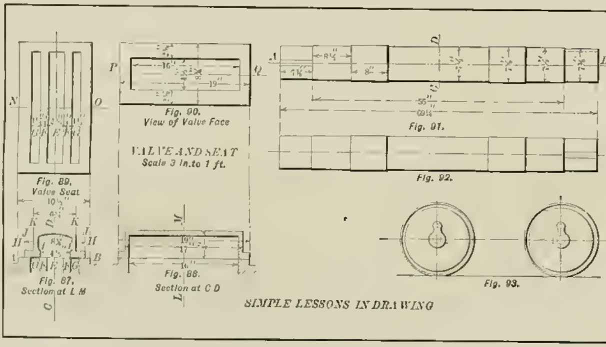
Plan view of seat is shown in Fig. 89; the vertical lines are projected from Fig. 87, and horizontal lines laid off from center line *N O*.

The dimensions are taken from both Figs. 87 and 88. A bottom view of valve is next shown in Fig. 90, the vertical lines being projected from Fig. 88, and horizontal lines laid off from center line *P Q*.

The operation of laying off the valve and seat in the shop, as a preliminary to the machine work, is plainly identical with the drawing of them, hence it can have no terrors for one who has been through the subject on the drawing board.

By drawing Fig. 87 full size, and cutting the valve and seat apart on line *A B*, all the functions of the valve are nicely shown when moving it back and forth over the seat. When the steam edge *J* of valve reaches outer edge of steam port *G*, admission begins; the valve continuing to the end of its travel and returning, steam is cut off when edge *J* again reaches outer edge of steam port *G*, expansion then begins and continues until edge *I* of exhaust cavity reaches inner edge of steam port *G*, when exhaust occurs; when edge *I* of exhaust cavity and inner edge of steam port *G* coincide on return stroke exhaust closes and compression begins.

The extreme travel of valve will show how much line *I* over-travels on the exhaust port *E*, and will also show how far steam edge *J* travels on bridge *F*.



To determine when valve is at end of its travel, measure the horizontal distance between center lines *C D*; thus, if travel is 5 inches, the center line of valve should be moved 2½ inches beyond center line of seat. Another method is to describe a circle whose diameter equals valve travel, taking for a center the intersection of line *J* with valve seat when valve is in its middle position.

When the valve is central over the ports, as represented, the laps are plainly shown; the outside lap is ⅞ inch, and equals the amount that steam edge *J* stands over outer edge of steam port *G*.

The inside lap would be represented by the amount that exhaust edge *I* of valve stood over outer edge of bridge *F*, but in this instance there is no inside lap, the valve being what is known as "line and line," that is, the edges *I* coincide with outer edges of bridges *F*.

It is thus seen how edges *J* control the admission and expansion, and edges *I* govern the opening and closing of exhaust.

Placing the dimensions on the drawing as in examples, see that they scale what they are marked, and in addition to this measure of safety add together all dimensions, and see if they foot up to total distance; if the footing is correct, the figures are right; if not, be sure to find the error; without accuracy in this work the time is worse than wasted.

It will be interesting as well as profitable to the student to sketch as many different designs of valves and seats as possible, obtaining the travel of valve in each instance, so that the subject may be handled same as the one just considered; a diversity of practice will be found which may lead to a desire to know why.

Fig. 91 represents a driving axle which should be drawn by first laying off two center lines *A B* and *C D*. From *C D* lay off all vertical lines, representing shoulders; from *A B* lay off all diameters and draw them to intersection of vertical lines.

The distance between wheel hubs is the important dimension in this example, although all others should be correct as well.

The key seats are next shown at right angles to each other. All dimensions having been marked in their proper places as shown, we have a driving axle as drawn for shop use.

The ever present opportunity for making mistakes is lurking right here in this innocent little axle drawing, as will be made clear.

With the key seats as represented we have what is known as a right-hand crank—that is, the crank on right side leads or is ahead of crank on left side, when engine is running forward.

Fig. 92 shows a left-hand crank when key seats are put in as shown, the usual practice being to cut those in the wheel, so that they are on the center line of pin and axle, in which case each key will represent a crank-pin.

Now, let us suppose that the man who has charge of the "wheel job," or whose duty it is to lay off the key seats, puts the lines for same at right angles to each other, but fails to notice that they are laid off like Fig. 92; then there is trouble after axles are pressed into their wheels if old axle is a right-hand crank and new one left-hand.

The result is shown in Fig. 93, where crank pins on one side are in tram, and opposite side is not. It is apparent that careless work in laying out key seats will lead to disaster, even if they are quartered right.

The Topeka shops of the Santa Fe are turning out twenty-six engines per month, although previous to Mr. Player's administration the output was ten. To G. W. Smith, the division M. M. who has immediate charge of these shops, much credit for the increased output is due, and his ability as a pusher is so well recognized and appreciated that he has had other offers, which the Santa Fe has "seen," and gone one better to retain his services. Mr. Smith's forte is rushing out work, and, it is timely to add, good work which stays out.

"Abe" Cherry and "Bill" Harrison, after nearly fifty years of service as engineers on the N. Y. Central road, have gone over to the great majority. These two men did nearly a hundred years of work upon a locomotive. Just think of the experience, the grief endured, and the wealth produced by this pair of workers—and they saw some improvements in railroading, too.

The Peerless Rubber Manf'g Co. some time ago placed on the market a brand of rubber packing known as the Rainbow brand; it has been found to give good service in air-brake cylinders in place of the usual leather packing. It is in use on some of the largest eastern lines, and seems to wear well, and stand the action of the oil.

L. C. Noble, after twenty years of service, has resigned as superintendent of motive power of the Houston & Texas Central, and accepted an important position with the A. French Spring Company, of Pittsburgh. C. H. Burns, who has long been a division M. M. under Mr. Noble, succeeds him on the H. & T. C.

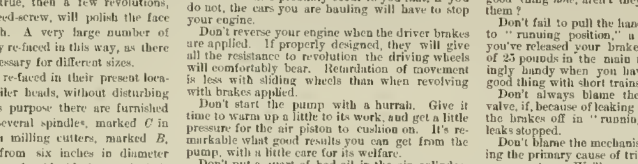
A Valve and Seat Grinder.

The machine shown herewith is a device for refacing valves and seats, instead of grinding them. It prevents bad fitting, insures a full bearing, and accurate work. For grinding valves, the stem and valve-stem box are put between the centers of the machine, as shown in the cut, and the valve revolved by the dog on the cranked spindle. The center of the other end recedes against a spring in the head as the valve is forced against it by the feed-wheel next to the crank. This keeps the valve spindle central, and forces the seat of the valve against the three steel jaws of the stationary chuck, one of which is a cutter. A turn or two cuts the face of the valve true, then a few revolutions, without using the feed-screw, will polish the face of the valve smooth. A very large number of valves can be quickly re-faced in this way, as there is no adjustment necessary for different sizes.

Valve seats can be re-faced in their present locations, on pipes or boiler heads, without disturbing the joints. For this purpose there are furnished with the machine several spindles, marked *C* in the cut, and enough milling cutters, marked *B*, to face all valves from six inches in diameter down. There are several guide blocks, marked *A*. These have threads on the outside to fit all the standard gas-pipe threads up to six inches. With the spindle through one of these guides, and a cutter screwed upon it, the guide is screwed into the body of the valve, in place of the valve-stem box, and the cutter is revolved by a common brace, a ratchet, or a drill press of some kind. When the seat has been cut down enough, the collar, *D*, is screwed fast to the stem on top of the box, and a few revolutions of the cutter polishes the seat up neatly.

Where loose valves are used, they are secured from turning by putting a leather washer between the valve and the stuffing-box, and using the latter to pinch it.

These tools have been made for some years, and are popular where known. They are admirably adapted to railroad work, and should be better known there. They are made by C. F. Hall & Son, Skaneateles, N. Y.



A VALVE AND SEAT GRINDER.

Don't.

The Westinghouse Air Brake Co. have sent out a "Chapter on Dont's," with their instruction book, that is worth preserving and learning by heart. In republishing this we give the Air Brake Co. a pretty good ad. and the ink we are using on this notice is probably worth about $20 per drop to them, still we would not be doing our duty by our readers without giving the Don't chapter in full, so here it is :

Don't think that the present improvement in the Westinghouse Automatic Brake Apparatus isn't necessary, and that the old automatic was good enough. It wasn't, and we'll vouch for it. Some day you'll agree with us, just as you did after a season when the old automatic took the place of the straight air brake.

Don't get impatient when you think the brakes are not operating to your liking, and blame them with containing defects which may exist only in your imagination. It may be that you are not so skillful in handling the brakes as your neighbor. Think a little when such a trouble is upon you. You may find the remedy and learn something more than you already know

Don't blame the fault on the brakes "failing to act," in an accident which may happen your train. It's wonderful how well they acted, and as usual just *before* and *after* such disasters, when anything was left of the train to make a subsequent trial. Somebody might discover this. Maintain your air pressure properly, apply brakes in a reasonable season, and you'll stop promptly as usual. *The Westinghouse Automatic Brake don't fail to act if you have done your duty.*

Don't cut out your driver brakes, imagining they are causing your driving boxes injury. This reasoning was exploded long ago. Keep up your wedges, and you'll have no trouble, we assure you, and you'll have a valuable stopping device which you may some time need. Don't use your driver brake as an emergency device only. You may some time in an emergency not have time to get it to work, or may forget it's on your engine. *Instances of this kind have been known to occur.* Cut it in and use it in conjunction with train brakes *always.* Your train will stop ever so much quicker. It will also probably occur to you that, if you do not, the cars you are hauling will have to stop your engine.

Don't reverse your engine when the driver brakes are applied. If properly designed, they will give all the resistance to revolution the driving wheels will comfortably bear. Retardation of movement is less with sliding wheels than when revolving with brakes applied.

Don't start the pump with a hurrah. Give it time to warm up a little to its work, and get a little pressure for the air piston to cushion on. It's remarkable what good results you can get from the pump, with a little care for its welfare.

Don't put a quart of bad oil in the air cylinder, when a small spoonful of good oil, that won't gum, will do just as well, and put it in at the proper place, *not* the suction openings. Air passages stop up with poor oil, and some time, when you don't want it to, your pump may get hot for you.

Don't fail to have the roundhouse people look after the repairs of your pump when required ; it's not very frequent, but will save money to the company you work for

Don't crowd the pump and attempt to make it do in a minute what can just as well be done in five. It may resent this treatment some time.

Don't fail to keep the piston stuffing-boxes of your pump packed nicely. It prevents the condensation entering the air cylinders and main reservoir. Drain the latter occasionally. Water takes up room better occupied by air

Don't imagine you must have 100 pounds of air, or more, when 70 will produce the greatest braking force the wheels will bear without sliding, if the proportions of the brake gear are properly calculated. This you can readily ascertain to your satisfaction, by making use of the simple rules contained in the instruction book. If they are not, call the attention of the proper official to the matter.

Don't imagine you can stop a long train of cars by operating the brakes on a few of the head ones next the engine, in as short a distance as if the entire number of cars in the train were fitted with brakes, and because you can't, increase your air pressure in an attempt to do so. Half a dozen to ten cars braked will handle a train of 25 to 40 cars quite nicely on ordinary grades, if properly used, but they can be made to do so much and no more.

Don't attempt to stop a train in a few feet, when you have several hundred in which to do it, and no danger impending

Don't set up the rear of a train by applying the brakes suddenly at the head end in an ordinary stop. It's so easily done the right way, and pleasanter to the crew in the caboose. Apply the brakes gently until you have the slack of the train against your engine.

Don't have leaky air pipes around your engines or cars. It isn't economical any more than if so much steam were blowing away, and then it's hard on the pump.

Don't use small main reservoirs on your engines. Big ones don't cost much, if any more, and they hold a lot more air and the brakes operate better with plenty of it. If you can't find room for the big one, you can for the two smaller ones. Don't put the main reservoir on top of the tank. It isn't good practice and you'll regret it some time in winter weather

Don't think that your old friend, the three-way cock, is going to survive always, just because you're used to its ways, and you are just a little loath to try something better in the new brake valve. You'll get used to the new one shortly, and it is really needed, as the injector was when it took the place of your pump. Don't you remember what you said about the change ? Injectors are a good thing *now*, aren't they, since you're used to them ?

Don't fail to pull the handle of your brake valve to "running position," a reasonable time after you've released your brakes. An excess pressure of 25 pounds in the main reservoir comes exceedingly handy when you have a long train. It's a good thing with short trains as well.

Don't always blame the trouble on the brake valve, if, because of leaking air pipes, you can't keep the brakes off in "running position." Have the leaks stopped.

Don't blame the mechanism of the brakes as being the primary cause of triples "sticking" in ordinary practice. We'll assume for the sake of argument, they do sometimes fail to release, but did it ever occur to you that it might possibly be caused by your peculiar method of operating the brakes, or that your main reservoir was too small ? With a fair show, triples don't "stick." Don't argue to the contrary. The facts asserted *can be* demonstrated.

Don't "cut out" the brakes on any cars in the train unless there is something wrong with the brake gear. Even then a little thought and judgment may enable you to apply the remedy. Operate them all. There's just a little trick in doing it on a long train, but you can learn it easily if you'll only try. Here is where the excess pressure comes particularly handy, and helps you out. Besides, you can stop quicker

Don't fail to call the attention of your crew and the inspector to any defect that may exist in the brake gear or apparatus, sufficient to render it inoperative, and that you can't remedy. Prompt repairs may be possible and save you some future anxiety.

Don't get excited because the grades are a little steep. Keep cool and your wits about you, a good supply of air in reserve, *use it judiciously*, and don't fritter it away by unnecessary applications and release of the brakes, and you are perfectly safe on the steepest grades of the ordinary railway

Don't apply the emergency brake except when it is absolutely necessary. The effect of so doing is especially disagreeable to passengers, when you are creeping up to a water crane or a coal chute, and they talk about you, while your passenger department promised them a smoother ride, than *via* the other route. You can make smoother stops if you try.

Don't make more than one application of the brakes in stopping at a station, or two at the v ry outside. Your passengers also notice this and make observations on your skill The traveling public are very knowing and critical these days.

Don't exhaust train pipe pressure to zero in applying brakes. It don't do any good. They are on as hard as they can be applied long before this, and you waste the difference in air. If you've been addicted to this practice in the past, now is a good time to reform. Somebody who knows better will find out your practice and tell it as a joke on you at the roundhouse or lodge room.

Don't leave a terminal station until your brakes have been thoroughly tested, and you are sure they are operating throughout the entire train. Instances *have* occurred when somebody neglected his duty, and didn't open a stop cock, which you found out only when you attempted to make your first stop. It's better to stop a minute in testing brakes before departure, than to muss up things and block the road for several hours ; longer, perhaps, as the wreck crew may be engaged elsewhere.

Don't fail to take up the slack in the brake gear when necessary. If you don't, you can't stop so quickly, and it takes more air when the pistons bottom on the front heads. If your brake gear is weak and contributes to this defect, stiffen it up. It pays to do so, and wooden brake beams are out of date. Metallic beams are cheaper in the long run, and better.

Don't think because a six-wheel truck car has an air brake on it, and shoes acting only upon four pairs of wheels, it can be stopped as quickly as a four wheel truck car. It won't, but it can be made to if shoes are applied to all of the truck wheels, as they ought to be, and it's safer.

Don't fail to clean triple valves and cylinders occasionally. How often, depends upon what goes into the train pipe. Keep out foreign matter, which *should not* get there, and will not if some of these dont's are observed, and you needn't clean them for quite a long season. A half gill of good oil will answer the brake cylinder better than a quart. Economize.

Don't fail to hang up the brake hose in the "dummy" when you uncouple it. Your road may be sandy, and sparks are sometimes thrown by the engine. We've found lots of this stuff in triple valves. It don't do them any good, and annoys the fellows who have to clean them. It's a good idea to blow out the pipes with steam and ease out the fins at their ends before putting them up. It will save you lots of trouble later on.

Don't use the conductor's valve except when absolutely necessary, and then close it immediately after stopping the train, *and before you do anything else*. We suppose you have the cord attached to its handle, traversing the entire length of the car. If you haven't, better make it that way. Cord don't cost a great deal, and it's sometimes handier to pull it from the other end of the car.

Don't for a moment think we are unaware of the fact that the brakes release just a little slower than *you* think they ought. Did it ever occur to you that there was a purpose in having a retarded exhaust of the air in releasing brakes? There is, and a good one. If there wasn't, the exhaust ports would be made larger. Handle the brake properly, and it will release in good season for you.

Don't think, in reading this chapter of "Dont's," we are finding fault with *you*. It's the other fellow, who don't know as much about brakes as you do, and then there's some good advice for him, which, if heeded, may save him a lot of worriment sometimes.

Don't fail to let us know when anything you think serious is the matter with your brakes, that you can't quite size up to your own satisfaction, we'll try and do it for you. It's a pleasure to us, and won't cost you anything. Besides, we want something for our corps of inspectors to do.

Don't alter our standards. We sort of lose the sense of responsibility when you do this, and it is believed these are about right now.

Don't use so-called safety valves in any of the brake appliances to blow off any surplus pressure. Such a practice is wasteful and *dangerous*. Give the governor a little attention occasionally, and it will restrain the pressure to the right figure.

Don't fail to apply a most rigid and searching investigation, if inclined to do so at all, of other alleged *cheaper* and *superior* (?) brakes, which may be brought to your attention, and although you may be told they operate in harmony with your own, demand proof. The claims haven't been substantiated as yet. We've investigated for ourselves, and think we know something on the subject, which may also be interesting to you. Pressure gauges and practical demonstrations in actual service tell tales. It's quite a simple thing to make a brake to operate on a *few* cars. The rub comes in attempting to operate fifty of them coupled together as the Master Car Builders' Association specify. Try it.

The Black Railroader.

On the Houston & Texas Central there are many colored men employed as switchmen and brakemen, and the white men employed with them were, as a rule, disinclined to work with them harmoniously. Recently the white men in the Houston yard struck, but afterward went back to work; the federated board of railway men were down there and patched up the trouble in some way.

The color question in the Southern States is a mighty hard thing to handle. Colored men can be had for small money, they are not organized, and have no means of resisting any wrong, no matter how grievous—and, therefore, wrongs are heaped upon them.

They are not promoted to better positions, and, were the condition of their race equal to that of the whites, they would not seek a hard job at small pay to "learn the business," when there was no hopes of promotion. The question that now confronts the railroad orders is, "What shall we do with the negro train hands?" To demand their dismissal is manifestly unjust, and would meet with little sympathy. To admit them to the associations means future negro engineers and conductors—if they are fit for associates, on a level, they are as worthy of promotion as white members of the same experience.

The colored men seem content in the lowly stations, and will work for smaller pay, and live more miserably in that section of country than white men of the same degree of intelligence. No railroad can do its duty to the public and close its schools of experience, in the shape of employment as brakemen and firemen, and the public, especially the Southern public, would not patronize a road employing colored men in positions of great trust—like running a passenger locomotive. Either way you fix it, it looks rather gloomy for the colored railroader.

Many roads in the South have dismissed all their colored firemen, and others have weeded them out of the train service, but all employ them in yards.

If the railroad orders can fix up a just plan for the adjustment of this question, it might set an example to the legislative sages of the country—they have wrestled with the negro question for years, and have made it worse every time they touched it.

The Reading R. R car shops at Reading, Pa., are very busy, and the company have put up a notice that the 900 employes will be allowed to work fifteen hours per day three days per week, thus increasing their wages. There are plenty of men hard up and out of employment in and around Reading; what is the matter with letting a few of them work ten hours once in a while? Fifteen hours' continuous work is too much for any man—ten hours is long enough.

There has been a company formed in Chicago to manufacture a draw-bar stop, invented by Geo. W Cushing.

Automatic Pressure-retaining Valve.

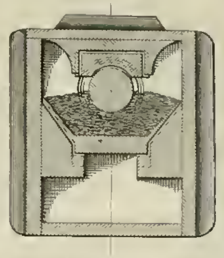
A patent has recently been granted to George Westinghouse, Jr., for a device intended to supplant the "pressure-retaining" valve of the present freight equipment, and thus eliminate the objectionable feature of the necessity of turning a cock on each car at summits. It is also designed to regulate the release of air from triple valve, and to afford a short interval for re-charging auxiliaries between the time of restoring maximum pressure in train pipe, and the actual release of air from brake cylinders.

A bell crank is attached to one of the drawbars of each car, and operates a release valve similar to present pressure-retaining valve in the pipe leading from the release port of the triple. This valve is opened whenever its draw-bar is drawn by the admission of steam to the locomotive cylinders, with the resulting pull on all draw-bars of the train. This elongating motion does not, of course, take place on grades, where the cars "pile up" on the locomotive on release of brakes, and as the draw-bars remain compressed in such cases the air is released under a pressure of twenty pounds, as with the present pressure-retaining valve. On level track, however, draw-bars are drawn on each release of brakes and forward movement of locomotive when given steam, and the new valves being thus opened by the pull on draw-bars, pressure is released without passing under the twenty-pound valve. The interval between the movement of triple valve slides to release, and the release by motion of draw-bars as described, affords an opportunity for re-charging the auxiliaries, so that the entire or partial release of brakes depends on the amount of draft exerted by the locomotive after releasing brakes in the usual way, as the port to outside air is not opened except by a sufficient pull on draw-bars.

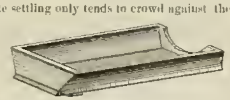
The Pittsburgh Locomotive Works have been obliged to go back to coal for some of their boilers; natural gas got too thin to burn.

An Improved Car Axle Box.

The common car axle box does well enough, so long as the waste packed into it remains saturated with oil, and in contact with the journal, but just as soon as the waste gets rid of part of the oil, and gathers some dirt, it settles and leaves the journal.



Some years ago Stephen B Stinard, of Pompton, N. J., patented a box with inclined sides and a false bottom; this prevented the waste from leaving the journal, but the oil got below the plate, and away from the waste, and it called for a new box He has recently patented an improved oil tray on the same principle, the sides inclined so that the waste settling only tends to crowd against the bottom of the journal,



this tray can be used in a common box, is itself a good dust guard, and is easy to get out to do work on the journal, such as putting in a new brass.

The side lugs that hold up the tray can be bolted into old boxes, or cast in new ones.

The Pittsburgh Locomotive Works are turning out fourteen heavy ten-wheelers for the K. C., Ft. S. & M They are being equipped with the New York air brake. Four of them have Dean guides, and the rest the standard guide and crosshead of the Pittsburgh works. This is an improved Laird guide, being extra strong, and having very large bearing surfaces. The crosshead has a cast-steel fork keyed to the piston, and carrying the pin for the front end of the main rod This pin goes through heavy bosses on each side of the fork, giving a long bearing Around the bosses the side plates fit, and are bolted at the top to the bearing block, between the guides. There are no bolts between the wings and the fork, the fit being entirely around the boss. It is therefore impossible to cramp the crosshead on the guides, and being in four pieces, it is easy to repair. One fork does for all crossheads, the only change needed for an engine having two inches more between the piston and the guide is deeper wings. These works have been building this guide for several years, with no reports of failures. These engines have Mr. McCrum's pot-bellied exhaust-pipe, from which he reports good results. We have no doubt that he gets a steadier blast on his fire, but believe that the use of the indicator will show a back pressure to pay for it

---

The town of Maine, Ill., is trying to induce one of the locomotive works, now in an Eastern trance, to move West and locate there What has any of the played-out locomotive works got to move West, except the name? and most of them had better leave that and start new. Most of the works that have dropped out of sight have been forced out because they were behind the times. The West don't want any chain-feed lathes that are good because they built locomotives before the war, or any slippery elm drill presses that are used to locomotive work.

The recent brake trials in Australia were not very complete or satisfactory

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 240,000 cars. This includes 140,000 freight cars, which is about 15 PER CENT. of the entire freight car equipment of th s country. Orders have been received for 80,000 of the improved quick-action freight brakes since Dpcember, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

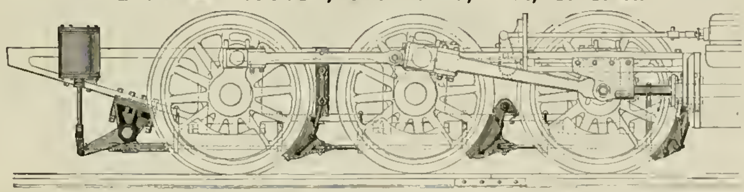
LOCOMOTIVE BRAKES.

GENERAL OFFICE, ST. LOUIS, MO., U. S. A.

BRAKES Made to Order for any Special Form or Class of Engine.



All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear & Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM, AIR or VACUUM.

DIXON'S

GRAPHITE

PIPE JOINT

GREASE,

FOR STEAM OR GAS PIPES, BOLTS, SCREWS, ETC.

Far Better and Cheaper than Red Lead.

Makes a tighter joint than red lead, that can be opened with perfect ease many years after.

No longer any necessity for

BROKEN PIPES, STRAINED TONGS or LEAKY JOINTS.

Put up in 1 lb., 5 lb., 10 lb., 25 lb. & 50 lb. packages.

☞ Send for Illustrated Catalogue containing more information concerning Graphite and its uses than is in print elsewhere in any language.

JOSEPH DIXON CRUCIBLE CO.,

JERSEY CITY, N. J.

OUR NEW REVERSIBLE LANTERN

AVOID ACCIDENTS.

GREATLY reduces the chances of accident, takes the place of two ordinary lanterns, and saves one-half the oil. Trainmen need not be burdened with so many lanterns. Gatemen need not keep two burning, one inside their box and one outside. For Station Agents it is a necessity, and for other employes a reliable safeguard.

THE "LACKAWANNA" LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank-pins in hard daily service.

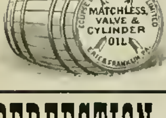
In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound is specially recommended for these cups, being first-class in quality and low priced.

LACKAWANNA LUBRICATING CO.,

SCRANTON, PA.

MATCHLESS VALVE AND CYLINDER OIL.



Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

Main Office: FRANKLIN, PA. Refineries: FRANKLIN, PA. OLEAN, N. Y. ERIE, PA. OIL CITY, PA.

VOL. III, NO. 12 | NEW YORK, DECEMBER, 1890. | $1.00 per Year or 10c. a copy.

A Typical English Eight-wheeler.

On this page will be found an engraving of a first-class, inside connected, eight-wheeler, of modern English design. Inside connected engines have not been built in the United States for a quarter of a century, and our enginemen are inclined to consider them as out of date as the hook motion.

Mr. Aspinall, the locomotive superintendent of the Lancashire & Yorkshire road, who built this engine, is one of the younger English engineers in charge of motive power, and is considered a very progressive man, his engine is therefore interesting.

As will be seen, the design of the running gear is the American eight-wheeler, but the engine otherwise is a fine example of the English locomotive

She has plate frames, inside cylinders, Joy valve motion, copper fire-box, stays and tubes, inside opening fire-door, the typical English cab, screw reverse gear, and the engineer located on the left side—all English.

Both cylinders are cast in one piece; the exhaust nozzle is single, and as high as the top row of flues, there being nothing in the front end to deflect or guide the gases except a perforated pipe above the nozzle reaching to the stack base, and of the same diameter as the stack. Cast steel wheels are used, braked as shown; the engine is equipped with automatic vacuum brakes.

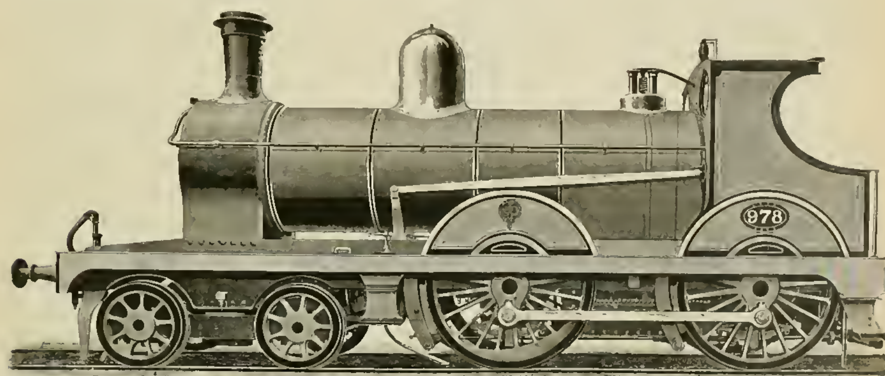
Over each driving box and inside the wheel covers there is a square oil-box, with a cock under it to regulate the flow of oil, then from below the cock three copper pipes extend to the box proper, one to the center, one to the wedge, and one to the shoe. There are other boxes of a similar kind for the trucks and other parts hard to reach, and it is possible to oil all the important parts of this locomotive when in motion.

There are no equalizers, but a pair of heavy springs under each driving box. Coiled springs are used on some of these engines. The form of rod cup, one formed in the rod, with a cover and feed device screwed in, is popular in Europe, and is coming into use here. It never looses off.

This engine has a balanced throttle, of the American type, but the lever is of the grindstone crank pattern.

The principal dimensions are as follows:

	Ft.	In.
Cylinders—		
Diameter		18
Stroke of piston		26
Length of ports		12½
Width of steam port		1⅝
" exhaust port		3¼
Distance from center line of cylinder to valve face		12¼
Lap of slide valve		1
Maximum travel of slide valve.. full		4½
Lead of slide valve ... bare		1/16
Distance between center to center of cylinders		23
Joy's motion—		
Diameter of piston rod		3
Length of slide blocks		13½
" connecting rods between centers		74
Wheels (cast steel)—		
Diameter on tread—driving		72
" " bogie		30½
Crank axle (steel)—		
Diameter at wheel seat		8¼
" of bearings		7¼
" at center		7
Crank axle (steel)—Continued.		
Distance between center to center of bearings		15¼
Length of wheel seats		7
" bearings		9
Diameter of crank bearings		7¼
Length " "		4½
Bogie axle—		
Diameter of wheel seats		6¼
" bearings		5¼
" center		5¼
Distance between center to center of bearing		43
Length of wheel seats		6 1/16
" bearing		9¼
"Main" frames (steel)—		
From center of bogie to back of buffer plate	4	10¼
From center of bogie to center of driving axle	10	2¼
From center of driving axle to center of trailing axle	8	11
From center of trailing axle to end of frame	4	8
Total length of frame plate	28	3
Distance between frames	4	2
Thickness of frames		1
"Bogie" frames (steel)—		
From leading wheel to front of frame	1	5¼
Center to center of bogie wheels	5	6
From hind wheel to end of frame	1	5¼
Total length of frame plate	8	5
Between bogie frames	4	0¼
Thickness of "		0⅞
Boiler (steel)—		
Height from rail to center line of boiler	7	8½



A MODERN ENGLISH EIGHT WHEELER.

	Ft	In
Boiler (steel)—Continued.		
Length of boiler barrel	10	8¾

Diameter of tubes		1⅞
Thickness 10 and 12 I.W G.		

Heating surface—Tubes 1121.32 square feet.
Fire box 107.68 "

1229.00 square feet.

Grate area—18¾ square feet

Working pressure, 160 pounds per square inch.

Weight, ready for road

Bogie	30 760	pounds.
Main driver	33 600	"
Trailing	32,360	"
Total	96 720	"

The engine has a six-wheeled tender, carrying 2,000 gallons of water and three tons of coal, and weighing, ready for the road, 60 480 pounds.

We are indebted to the *Railway Engineer*, London, for the engraving and data.

A Sensible Feed Pipe Support.

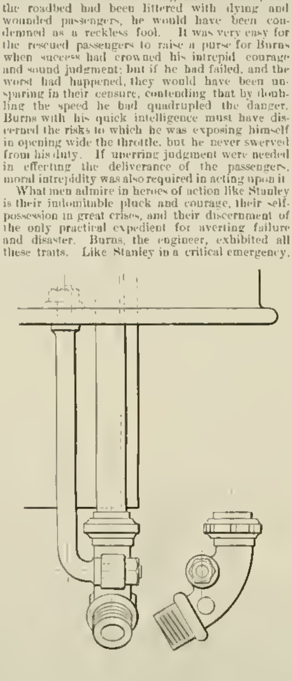
The cuts on this page show, better than we can tell, a sensible scheme for supporting feed pipes, the elbow has a lug that is cored out to receive the supporting rod from the tail casting; it can not cramp, and does not rattle loose and wear holes in the pipe, as the usual clamp device does. This same clamp scheme is a constant source of trouble and expense, forever loose and forever springing enough in service to loosen the joint of the injector pipe This pipe hanger is in use on the B & A , they use ball joints in the injector pipe work, and when they put a union nut on one end of the elbow it goes without bending the hanger with a coal pick.

Heroism and Judgment (?)

The conduct of Engineer Burns in driving an express train through a railway wreck at lightning speed cannot be too highly extolled. It was a most remarkable exhibition of fidelity, self-possession, heroism, and sound judgment. Coming suddenly in sight of the wreck across the track, his mind operated with extraordinary quickness. Th horrors of the situation were appreciated at a glance. The first and natural impulse with ninety-nine engineers out of a hundred would have been to reverse the engine and set the air-brakes in motion. If Burns had done this, and a terrible accident had followed, his conduct would not have been subject to criticism, even if he had jumped from the engine before the wreck was struck He would have had the credit of doing everything in his power to stop the train, and would have escaped censure. Burns did not follow the ordinary impulse of the moment His mind, working with the force of intuition, disclosed the futility of attempting to stop the train at so short a distance from the wreck. There was only one chance of saving the train, and that lay in going ahead at tremendous speed. He took the chance He pulled the throttle wide open, and by the force and momentum of the onset the engine and train cut through a wrecked car loaded with horses, and all was well.

Such incidents as this do not occur frequently, and deserve to be critically studied It was a display of heroism and something more Heroism alone would not have saved the lives of the passengers by the Chicago Limited Burns would have been a hero if he had taken the usual precautions, reversed his engine, and perished with other victims of an inevitable disaster. It was to the combination of unerring judgment and heroism that the passengers owed their lives. There was only one chance of preventing an accident and carrying the train through the wreck in safety That chance was taken; but Burns in that terrible moment must have known that if his train were to be wrecked appearances would be against him Instead of attempting to stop the train he was doubling the speed, and possibly more. If the accident which he succeeded in averting had occurred, and the roadbed had been littered with dying and wounded passengers, he would have been condemned as a reckless fool. It was very easy for the rescued passengers to raise a purse for Burns when success had crowned his intrepid courage and sound judgment; but if he had failed, and the worst had happened, they would have been unsparing in their censure, contending that by doubling the speed he had quadrupled the danger. Burns with his quick intelligence must have discerned the risks to which he was exposing himself in opening wide the throttle, but he never swerved from his duty. If unerring judgment were needed in effecting the deliverance of the passengers, moral intrepidity was also required in acting upon it

What men admire in heroes of action like Stanley is their indomitable pluck and courage, their self-possession in great crises, and their discernment of the only practical expedient for averting failure and disaster. Burns, the engineer, exhibited all these traits. Like Stanley in a critical emergency,



he was a law unto himself. He perceived the only possible way of escape, and he whipped up his racing engine as calmly and resolutely as a jockey on the home stretch drives the spurs into his horse's flanks. His judgment was not paralyzed with apprehension of criticism if he were to fail. He thought only of success and had the moral courage to achieve it.—*New York Tribune.*

This is the worst kind of rot, and shows what outrageously dumphools newspaper men can be when they try. Think of the statement—the wreck was too close to make any attempt to stop, still, Engineer Burns, by "calmly holding the lever and applying his heroic judgment," doubled ("and possibly more") the speed. Burns probably didn't have time to collect his thoughts before the crash came; he ran desperate chances by not doing all in his power to stop at sight of the wreck We do not believe he tried to go faster when he saw the wreck ahead of him—he did nothing until the smash brought him to his senses to find himself a hero (?) Even if he did the best thing under the circumstances, it is a bad precedent to follow

The traveling public can thank their lucky stars that "ninety-nine out of a hundred engineers would have applied the air-brakes and reversed their engines under similar circumstances " It is altogether likely that the next hero of this kind will kill himself and about half his passengers.

The Canadian Pacific advertise that all their engines and passenger cars are equipped with the best and safest Krupp steel wheels

The Way Engineer Skeevers Illustrates a Point.

Jim Skeevers runs a freight engine on a road where the men do pretty much as they please—so long as they pull the trains. To be sure, there is a monthly bulletin of coal and oil used and repairs made, but no one is censured for using too much or complimented or paid for using little. The firemen are not required to clean much and—it's a pretty easy place to get along.

But Skeevers prides himself on economy of fuel and oil, in doing his work well, and getting along with a reason for everything. Among other things, Skeevers likes to see his engine wiped off and the front end and stack neatly blackened, and Skeevers' fireman generally has the neatest looking engine on the road.

Other firemen quit cleaning cab brasses, wiped the jackets about once a week instead of daily, and quit painting the front end altogether long ago. Then they guyed Skeevers' fireman, and called him a fool and a sucker and a chump, till Skeevers' fireman got sick of it and struck for liberty. He didn't wipe the dust off her, and she went out with her front end looking pretty scabby—for Skeevers.

When Skeevers got to the engine in the yard the other day he put his siege-can in the box, got out his overclothes, put them on, and started around with the long can. Billy sat on his seat and smoked a cob pipe

Skeevers got up on the deck, wiped off his can, and remarked rather hintfully

"Forgot to dust her off this time, didn't ye, Bill?"

"No," said Bill, "I got sick of being guyed by the rest of the gang, and called names, and in bein' accused of trying to make firemen do more work, and cleaning for my ride after firing for my day's pay and all that

"Billy," said Skeevers, "it's all right; don't blame you at all. It takes a long time to find out that you know your own business best. Now, haven't you often heard it from all quarters that we had the best-looking engine on the road? Yes, 'corse you have. Don't she run lightest on coal and on oil? Never was beat. Do you have to wipe a dose off her once a year because she was too full of water? No, because we are careful and take pains in our work. We may be suckers, but it's a good deal of satisfaction for me to know we're doin' our work about right—near as we can, anyhow But it's wrong, I guess, Billy, dead wrong, after all. So let's do as the rest do, you fire and clean just as the other boys do, and I'll run just as the other runners do, there's no use in bein' odd."

Billy had expected a row with Skeevers, and felt quite relieved that he took to the change so good-naturedly, and in a few minutes both were busy, as they pulled out with a big train.

Skeevers jammed the injector on full just as they started, and Billy had a hard half-hour's work bringing his green fire up, with the pressure down twenty pounds; he was tired and sweaty when the engine commenced to churn water through her stack, plastering the front windows with dope. Skeevers jerked his head inside the window, smiled, said he forgot it, shut off the injector, and eased off the throttle, then she commenced to howl, and Billy opened the door.

Skeevers was working her down a notch further than usual, and it told on the coal pile, and Billy remarked that it was an awful hard pulling train, by way of calling Skeevers' attention to it, but Skeevers agreed that the train did pull hard.

Skeevers forgot to put the injector on again till the water was down to one gauge, then he acted startled, and put it on full. The fire was low, and Bill had another fight. This was repeated all day, and each time the coal got further and further away

Half-way over the division they took 150 bushels of coal, where they never took more than 100

Skeevers kept good-natured. Bill was mad

"I think you are doin' this a purpose," said Bill, at last.

"Doin' what?" asked Skeevers, as innocent as a child.

"Why, pounding this engine so hard, and workin' water, startin' out in the corner, wide open, and pulling my fire all to pieces"

"Is there any other engine on this road that don't burn more than six tons of coal over this division?" asked Skeevers.

"No; but she never burnt but four and a half and five before," said Billy.

"Yes, but that was when we was both careful and worked together," said Skeevers, as he prepared to get off at the end of the run; "but none of the rest of the engineers are careful about coal, what's the use of me being? And when a man works as hard as you have to-day he would be a fool to put in an extra hour cleaning and fussing around; we get just as much money when we *don't* as when we *do*. Good night, Billy."

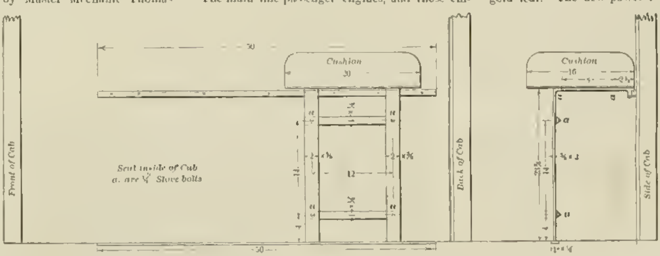
The next morning, when Skeevers came down to go out, the Mary Ann was wiped up, her front end black, and Billy was whistling "Annie Rooney" and spitting on the side windows to make the whiting take hold.

"Skeevers," said he, "I'd a good deal rather put in half an hour a trip cleaning up than to shovel coal against that extra notch and an injector that 'forgits.' Just run her like you used to, Skeevers, and I'll keep her tidy."

Sliding Seat for Switch Engines.

On most switch engines, especially those with short boilers and open cabs, the engineer can only sit down comfortably when going one way, and, in order to be comfortable and see, he stands up about half the time, getting in the way of the fireman, and making himself unhappy.

On the B. & A. switch engines they use a very neat seat designed by Master Mechanic Thomas Purvis, of East Albany. There is no box under the seat, but it cannot be lowered; it can, however, be moved along the entire length of cab, thus allowing the engineer to get his feet either side of the seat, or move it out of his way altogether. The seat frame is made entirely of angle irons, very little machine work being required. The cuts are so plain that an explanation is unnecessary. We have seen the seat in use, and found it very easy to handle, and it is not trappy or "wobbly"—the men kick it where they want it. Try one on some of your scrap heaps where the engineer has to lay on his back to see one way; it will pay.



SLIDING SEAT.

About fourteen readers have written to ask why the release of Westinghouse air-brake is slow, as stated in the chapter of "Dont's," and, replying to all at once, we would say that brake is made to release slowly so that the runner can release gradually as the train comes to a stop, and thus prevent the backward surge of cars caused by stopping with the brake on. Watch a car truck when being stopped with brake on and you will find the truck frame forced down in front and up behind, when the brake is released the truck frame rights with a disagreeable jerk. Try to handle the brake so that it will be just released as the train comes to a stop. You can do it if you try.

We are in receipt of Vol. 1, No. 1, of the *American Federationist*, published at Mattoon, Ill., by W. H. Johnson & Co., and devoted to the interests of the federated railway employes. The first number gives indications of its being a lively and aggressive champion of the cause it represents.

The Westinghouse Air-brake Co. have entered suit against the New York Air-brake Co., to restrain them from using the triple valve. The valves used by the two companies are almost identical, the difference being in detail of construction rather than in principle.

Shops of the Central Vermont.

The Central Vermont road is the lessee of what is known as the consolidated railroads of Vermont, consisting of seven different roads.

The main line of the road runs nearly north and south through the State of Vermont, having a southern connection with all the New England roads, and a northern connection with the Grand Trunk of Canada, by whose lines the C. V. trains reach Montreal.

Compared with western roads it is small, but its 687 10 miles is spread out in the State of Vermont like the spokes of a wheel, making connections with all the other roads around the rock bound rim.

MOTIVE POWER.

They operate some 185 locomotives, some modern, some old-fashioned ones. Quite a number of the old 15 and 16-inch engines are wood burners, and are practically just as they were when new, except that much of the brass has been painted over and air brakes applied.

On a road doing a through business, and using these old engines in freight service, it would be money in their pockets to give them away, but here there is use for them, and at an advantage.

The road has so many branches where light passenger trains of two or three cars are run, that a light engine does it as well, or better than a heavy one, and is easier on track. So it is probable that for many years to come these little old wood burners will pull jerk-water trains on the plug runs of the Green Mountain State.

The main line passenger engines, and those employed on through freight service, are as heavy as can be found in New England, and as modern.

Some of them were built at the shops of the road, but most of them are from well-known builders.

The variety of makes is great, and the variety of sizes still greater, running from cylinders as small as 14, and as large as 20 inches in diameter, and any kind of stroke you want, from 20 to 28 inches.

THE SHOPS.

The main shops of the company are located at St. Albans, in the northern part of the State.

The buildings are good and substantial ones of brick, but most of the tools are old, and there is a dearth of them.

The motive power and rolling stock is under the superintendence of Mr. J. W. Robertson, who has been in the service twenty years, and in his present position about six years.

P. R. R. PLAN.

The enginemen are under the charge of the transportation officers, and not the motive power officers.

THE MAIN SHOP

has pits running lengthwise of and through one side of it, with the tools arranged on the other side.

Some tire turning is done on common or single-head lathes of large swing. There is nothing uncommon in the shop, and few modern facilities for getting out work.

Repairs were being made on some half-dozen engines while we were there, and the work was being done in a very thorough and painstaking manner, the best of materials used, and all modern improvements put upon the engines.

A KINK.

On an old common lathe they have fitted a very efficient device for cleaning flues. It consists of three toothed and corrugated rolls about a foot long, two at the bottom and one at the top, the top roll being hung in a frame that can be swung up by a lever.

This little train of rolls is fast to the tool carriage, and when the lever is swung back, the top roll is out of the way, and a flue can be put into the lathe, there being driven by a chuck; the lever is brought down clamping the tube between the three rolls, pressure being applied by the lever in the hands of the man in charge. The revolving of the tube itself operates the rolls, and the feed of the carriage moves it from end to end.

BRAKES.

The engines for passenger service are all equipped with air brakes and steam heat apparatus, while the freight engines have driver brakes operated by vacuum, steam or air.

INJECTORS.

This is one of the few roads that originally had all the engines equipped with the Hancock inspirator. These instruments are large, as compared with other injectors, set high in the cab, and look odd. They work well, however. The new engines are not coming with inspirators, injectors having been found to require less repairs. Sight feed lubricators are to be seen on many engines.

NAMED ENGINES.

About half the locomotives are named, and the old ones show here and there a bright spot through the black paint, that tells of the days of brass and gold leaf. The new power is black, with a slight stripe, shaded letter, and are nameless.

Rebuilt engines, especially some of the light ones, have red wheels and red stacks.

NUMBER PLATE KINK.

Baldwin engines, with the solid figures cast on the plate, discolor easily by the heat; here they cut out the numbers from brass plate about an eighth thick, and attach them to the plate by half inch long studs. These do not discolor, and look neat and tasty.

OLD PLANS.

Many of the old-timers have underhung links, and eccentric blades of round section with right and left hand sleeve and jam nuts to lengthen and shorten them.

Some have wedges ahead of the box, with each pair of jaws separate, and bolted to the main frame.

BALANCED VALVES

are used in all engines, and great care exercised in fitting up valves and pistons.

ROUNDHOUSES

There are two roundhouses of good size, and during our visit they were busy taking down the doors and swinging them from the outside; they formerly swung in, and could not be closed with one of the new "hogs" in the stall.

KRUPP WHEELS.

For all the passenger car service, and for engine trucks and tenders, they use the best Krupp steel tired wheels, with wrought iron or steel centers of Krupp's make; all tires, both for drivers and other wheels, are fitted with the Mansel retaining ring.

IRON PILOTS

are used, but Mr. Robertson has taken out the crossed heel braces that ran from the pilot heel back to the cylinder saddle, and substituted a heavy, outside heel brace. When an accident bunged up the pilot it was almost impossible to get to these braces to get them down.

EXTENSION FRONTS

are to be seen, and there are a good many balloon stacks for wood, but straight stacks on short fronts is the popular plan for coal burners. These fronts run with the largest nozzle, and throw less fire than the extension or the diamond stacks. The front door has a heavy liner of very rough section, against which the diaphragm throws the cinders, breaking them up; trouble from fires has diminished in proportion to the use of this device.

GOOD PLAN OF BOILER REPAIRS

Mr. Robertson keeps a boiler for each class of engine on hand, either new or in full repair, then when an engine comes in that needs extensive boiler repairs, like a new fire-box, he puts the extra boiler on her frame, and repairs her boiler for the next one.

CAST-IRON

guides are in use on everything, they are of ample proportions, and give no trouble at all, links of cast iron are also used with satisfactory results.

The country through which the road runs is beautiful, the water excellent, engines running for months without washing out; the engines are comfortable, fitted with modern improvements, as a rule, and are light and easy riding.

The men have pleasant jobs. A man who can't run a locomotive successfully and contentedly on the C. V. wouldn't make much of a success at the business anywhere—providing the pay is reasonable there, and we believe it above the average New England pay.

A Tank Cab.

As the cold weather comes on, engineers and firemen begin to kick for back boards and side curtains and other little things to keep out the wind, the snow and the cold.

On consolidated or mogul engines, where the boiler comes through the cab, firemen often suffer from the weather, and better means for their protection needs be employed. The best and cheapest thing for the purpose that we have seen is the tender cab used by M. M. Thos Purves on the B. & A.

On each side of the tank and about a foot back of the extension of the engine cab roof he puts up a tight board or sheet-metal covered side, about three feet wide and just as high as the corners of the cab roof; these sides he joins by a roof, arched to match the engine cab roof.

From the engine cab roof he extends a thin sheet-metal apron, curved to fit the roofs and wide enough to cover the opening between the roofs on any curve.

These sides are considerably back of the tank heads and pretty well enclosing the pit.

The apron between the engine and tank is lengthened to the full width of the tender deck and the side bracket castings are filled with wood, to keep out wind and snow.

The side curtains extend from the engine cab to the tender cab and are carried by a rod fast to the engine cab and sliding in a staple on the tank cab.

With these side curtains up and buttoned the whole pit is well protected, the fireman out of draughts and wet, and if a back curtain is added to the tender cab it is pretty near storm-proof.

The tank cab is also a protection from sun and rain in summer and is so high that it is cool with the side curtains down, there being enough room under it for the fireman to swing his coal pick or handle the longest fire tools.

Old Engines for the South.

Last summer a speculator, who was just a little behind the times, bought some forty locomotives of the B. & A. They were mostly of the class known as "Eddy clocks," and were good engines in their day—but that was ever so long ago.

These engines were taken from the service and sold by the company for $12 per ton, tank and all. They cost the contractor less than $500 each, and he expected to fix them up a little and sell them as second hand engines.

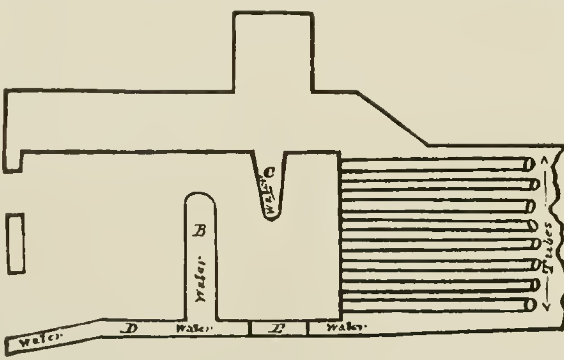
He wrote to all the roads in the South offering them locomotives in running order for $1,000 each, but never sold one, and was obliged to cut them all up—which he could do without loss.

The day when the Southern roads were glad to get anything that would run is gone. They are buying and running as fine motive power as there is on the continent. There is far worse looking and more ancient power in the North now than in the South.

Some Early Fire-box Devices Now Being Re-Invented.

On page 225 will be found cut of a 10-wheeled locomotive with a peculiar boiler, the invention of Wm. G. Norris, a draftsman at the Norris Locomotive Works, he received a patent for this boiler in 1857.

His idea was to place the fire-box above the frames and axles, and thus get the weight better distributed, and admit of placing the forward driver, in 10-wheeled engines, far enough back to admit of the main rod being coupled to it, instead of to the center pair of wheels; but his main object was to get better combustion, and to increase the heating surface. In order to get room under the grates, he raised them up in the fire-box as shown at *G*, and then used a shallow pan from the front to back of the rear axle, where it dropped into a box with slides marked *P*.



SOME OLD FIRE-BOX PATENTS.

Well ahead in the fire-box there was a water wall built entirely across the box as at *A*; this was full of short tubes, through which the flames passed to the combustion chamber marked *C*. The barrel of the boiler *W* was full of tubes to the top. Steam was conveyed from the dome on the wagon top to the cylinders by outside pipes as shown.

This boiler was approved by some roads, and orders given for them, but none were built just this way. The mechanical engineer of the works, Mr. S. Norris, changed the fire-box and built it like the outline shown in Fig. 2, page 224. He employed a water bridge such as have since been patented three or four times, and a deflecting wing or "feather," as it was sometimes called, the barrel of the boiler was full of tubes, but the dry pipe was inside, coming out in a T on top of the boiler, just back of the stack, where the outside steam pipes connected the T with the steam chests.

Engines with this form of boiler were built for many roads; four roads in Cuba were equipped with them, and there were several on the Brooklyn Central & Jamaica, the Long Island, Little Schuylkill, and the East Pennsylvania. One on the latter road we have a record of. She was received by the road in June, 1859, and put into passenger service; she had cylinders 14x24, four 60" wheels connected, and weighed in running order 51,550 pounds, and on July 4, 1859, drew twelve long coaches, excursion laden, up a 52-foot grade without throwing fire. Her regular service being four cars, thirty-seven miles, in ninety minutes, including eleven stops.

The next "improvement" was the omission of the water arch *O*, leaving the wall *B*; many engines were built in this way. In this plan there was an opening at *E* for cleaning out such cinders as were drawn over the wall *B*. These boilers cost more than those with plain boxes, and did not give back enough to cover the extra cost, so they died; but many devices that look surprisingly like their ghosts still bob up and haunt inventors occasionally.

Locomotive Running Repairs.

BY L. C. HITCHCOCK

RODS

Too much care cannot be taken to keep rods the proper length. Some of the troubles which arise when main rods are not kept in this condition are, first (and probably the most dangerous difficulty), there is great liability of breaking the front or back head of the cylinders when the rod is too long, or too short, as the case may be. Then the brasses are not in their proper position in the strap, and if they are too far out of the proper position the supply of oil from the rod cup is in a measure cut off, and the pin will possibly lack proper lubrication. And again, when main rods are not of the proper length it is a more difficult matter to set the valves so that the engine will exhaust regularly, or "beat square," as the boys say. This may not be considered by some to be a very serious difficulty, but it sounds bad, to say the least, and I believe that if an engine does not *sound* square it is not using the steam properly, and an indicator card taken from such an engine would, I think, clearly show that something was wrong. These are some of the effects. Now, why are they produced? I think that the reason the first two effects are produced is very plain. If the rod was too long there would not be sufficient room between the front cylinder head and piston head when the engine was on the forward center, and in case a follower bolt worked loose the cylinder head would be broken sooner, and if the engine was over pumped and water was worked into the cylinder the cylinder head would be more liable to break. If the rod was too short the back cylinder head would suffer in like manner from these causes when the engine was on back center.

When the brasses are not in their proper position in the strap the oil hole through them is thrown out of line with the hole through the strap into which the oil cup is screwed, and where this difficulty exists to a great extent the oil supply is cut off by the hole through the brasses passing beyond the hole through the strap.

The reason an engine will not sound square when the main rods are not of the proper length is, that if the steam is made to cut off at an equal distance from each striking point (as it should be made to do) there will be more space between the piston and cylinder head in one end of the cylinder than in the other when the exhaust takes place, which causes a difference in the sound of the exhaust.

A full explanation of this will more properly come under the head of "Valve Setting," with which we intend to bore the boys at some future time.

When a main rod is put up, the engine should always be pinched on the center, and the distance from the nearest striking point to the end of crosshead be measured. Then, if the engine has 24-inch stroke, lay an opened 24-inch rule on the bottom guide with one end against the crosshead, then measure the distance from the other end of rule to the other striking point. If these two measurements are the same the rod is the proper length. In case there is a difference, one-half of this difference is what the rods need to be altered. Some one may say, why write these things, which any apprentice boy should know? I answer, simply because I have seen machinists who considered themselves pretty good workmen put up main rods without taking these measurements, and the piston head struck the cylinder head the first time an attempt was made to move the engine.

If the rod is down at both ends, a good way to get the proper length is to place the crosshead centrally between the striking points, then the distance from the center of the crosshead pin to the center of the forward main shaft is the length the rod should be from center to center of brasses.

When rod brasses are reduced much care should always be taken to reduce each half square with its edges and sides, as this causes the parting edge of each brass to come squarely together when they are keyed in the strap. The brasses in the forward end of a main rod should be reduced enough, I think, to allow the parting edge of each half to stand a full thirty-second of an inch apart when they are keyed sufficiently tight to the pin, as this will allow the engineer to key them up two or three times before it again becomes necessary to reduce them, and, as these brasses never revolve entirely around the pin, there is less liability of their "hugging" the pin and heating.

I would not advise a person to leave the brasses in the back end of a main rod open, as at each revolution of the driving wheel the pin makes a complete revolution in these brasses, thus increasing the liability of heating if they are keyed too tightly to the pin. They should be reduced so that when the key is driven down solid the brasses will revolve freely on the pin, at the same time having no "pound" or lost motion between them and the pin. This can better be determined by placing them in the strap and keying them to the pin, for when the brasses are put together out of the strap, and only the calipers relied on for the fit, it is only guess-work, as one has to *allow* so much for keying them together, but when a person keys them together on the pin he can revolve them before the end of rod is put into the strap, and he does not need to allow anything, for then he *knows* how they fit.

When making the fit to the pin I would not advise draw-filing the brasses, as this brings the file marks parallel with whatever lines or marks are in the pin, if it is cut in the least, and this makes them more liable to heat and cut. I think the best way is to cross-file, using a rather fine file for the finish. I do not think it necessary to use a scraper for the scraper has had its day for such work. It is better, I think, to give all parts of an engine what space they require with a file than to be compelled to run it around the shops and yard for a week or two that it may free itself before we dare put it into freight service, as was the custom fifteen or twenty years ago.

For brasses in the back end of main rods, I think that those which have babbitt metal inlaid in the bearing surfaces give the best results, as babbitt, being an anti-friction metal, wears the pin smooth.

If any foreign substance gets between the brasses and pin it cuts out the babbitt metal. This causes the brasses and pin to heat, and often melts the babbitt. In case a person has a pair of brasses out of which the babbitt has been melted as described, and the time to make the repair is limited, after the brasses have been nicely fitted to the pin, a good substitute for the babbitt is a piece of sole leather fitted into the slot in brass from which the babbitt was thrown.

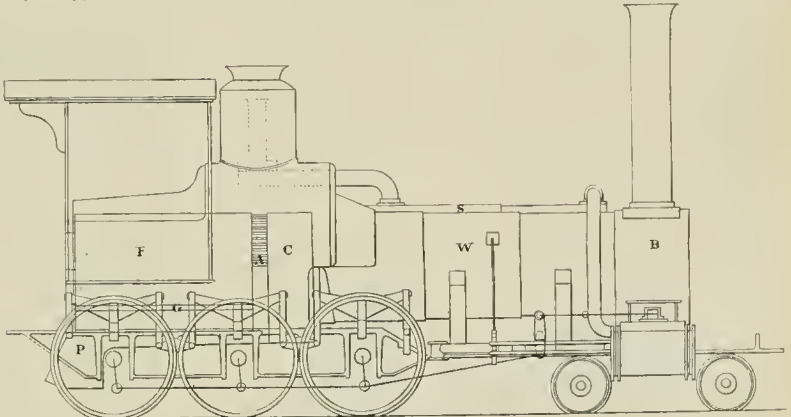
In case the pin is very rough this will be found better than the babbitt, for if any piece of scale from the pin, or piece of foreign matter of any kind (which is hard), gets between the pin and brass it will imbed itself in the leather instead of cutting out a piece, as it would from babbitt. These foreign particles will remain in the leather below the surface and have more of a tendency to wear the pin smooth than otherwise.

A little plumbago and sulphur mixed with tallow put on such a pin before the rod is put up will be found very beneficial.

There are some engineers who imagine that every time they set up a wedge the length of the side rods should be altered. This, I think is a sad mistake. It causes the engineer sadness on account of the way his engine will ride, and the roundhouse foreman, who is expected to keep the engine in good repair, does not feel very jubilant over having to take down the rods and readjust them every trip or two. I believe that a pair of side rods put up in the proper manner should run twelve or fifteen months without being adjusted or having the brasses reduced, provided, of course, that all other parts of the engine are kept in good repair.

SETTING UP WEDGES.

The first thing to do when side rods are to be put up is to see that the wedges are set up properly. This can be done very satisfactorily in the following manner. First have the engine on a piece of straight, level track, then get under and pull down each wedge until it is quite loose, now have the driver pinched as far ahead as possible and held in that position with the bar. Set the wedge up quite snug and try if the driving-box will stick between the wedge and shoe by having another man put a pinch bar ahead of the wheel and both men jump the wheel together. Set the wedge up until the box *does* stick, then draw the wedge down until the box just works freely between wedge and shoe. Treat each wedge in like manner and the wedges will be in a proper position. Now pinch the engine a full revolution on each side and try the trams on the main centers and pins at different points to see if the main centers and pin centers tram correctly. If they do, see that each brass is fitted so it can be keyed solid in the strap and still be perfectly free on the pin; then put the engine on the center on the side you wish to put the rod up, and put the forward end of the rod up first. Now, if the engine is perfectly cold put the rod up as tight as possible between the pins. I have never known of a case where a side rod was put up too tight between the pins when the engine was perfectly cold. On the other hand, I have seen too many rods put up too loosely between the pins, and when this is the case, the strain (when the engine is warm) will come on the rod bolts and they will be sheared. A side rod can be sprung between the pins if too long, but it cannot be stretched a particle if too short, and, consequently, the rod bolts suffer, though this assertion is not intended to convey the idea that a side rod will run good if too long; for if too long the strain is on the pins, though there is less trouble from a side rod which is a little too long than from one left a little too short.



Wheel Base 20 Feet 9 Inches

SOME OLD FIRE BOX PATENTS.

TRAMMING.

In case the pins do not tram correctly with the main centers, care should be taken to note the greatest difference shown between the pins, then put up the rods as described, being careful to file out of the back half of the back connection the full amount of this difference. This will insure the rod passing over the longest point between the pins without binding. Rods put up in this manner will run nicely when the pins are considerably out of tram, and if the engineer who runs the engine can by any hook or crook be made to believe that he *must* let them alone, I feel confident that no trouble will arise for a long time. But it is a difficult matter to make some engineers believe that their side rods should not be tampered with, and this fact is what makes me pin my faith to solid ended side rods, that is, those whose brasses are pressed into the rod in the form of a bushing, and that have no straps, bolts or keys, for an engineer cannot change the length of these, and in our experience they have always given very good service.

The New Haven road are putting on a straight stack, with considerable taper, and without top ornament. Their old straight stack was loaded down at the top with an immense flare. We knew they would do something about it after we called it an inverted dish-pan, which it resembled. By the way, why is it that everybody calls an open stack a *straight* stack, whether straight or tapered?

New Train Order Holder for Cabs

The accompanying cut shows a new train order holder, the invention of C. E. Biddison, an engineer on the Rock Island road.

It consists of a small box, deep enough to contain a small lamp, and large enough on its side to hold three train orders

The orders are held between two plates of glass, the outer one being hinged at the top so as to admit of inserting and holding the orders in such a way as to be readily seen and kept clean.

The front of the case is inclined, so that the light, when the case is not full, is thrown up in the cab and away from the engineer's eyes.

There is a small slide or damper in the case, which shows a red light when open; this is used as a reminder that orders are necessary or that the red board was out when the engine passed the station.

The device is cheap, and seems to answer all the requirements; the inventor's address is Goodland, Kan.

Some Early Valve Motions.

FOUR ECCENTRICS WITH V HOOKS.

One of the earliest forms of hook motions using four fixed eccentrics—the same as is used with the link—was that designed at the Haigh Foundry in England, although Stevenson and Jackson had already adopted four fixed eccentrics. The reason four eccentrics were first used was to secure lead for both forward and backward motions.

The cut shows the forward motion V hooks engaged with the lower pins of the rockers, the back-up motion being out of gear; the moving of the lever operated a crank in the slot of the arm holding the back-up hangers, and pulled them in and out of gear. Stevenson made his tumbler in the shape of an inverted T, suspending the hooks from the opposite ends of the cross piece, but in this plan the hangers had to be long and inclined toward a central point under the tumbling shaft.

The spring and rounded notches, shown at G, were rather a weak means of holding the motion in the desired place, and soon gave way to a latch and quadrant.

Drop-hook gears differed from V hooks only in the V shaped extension of the hook, which insured the hooks engaging with the pin under all circumstances. The plan of four fixed eccentrics and four separate hooks became the standard and most popular valve motion for freight service, but was wasteful on passenger trains at high speed, which called for the invention of the cut off valve

A Compact Small Forge.

One of the neatest designs for a small forge that we have seen is the one shown on this page, and manufactured by Hugh Crumlish, 80 Virginia street, Buffalo, N. Y. The forge is solid and substantial, and occupies but nineteen inches of floor space, has no exposed parts, no flimsy legs, no fan, and no gears. The blast is furnished by a 16½-inch round bellows, entirely concealed in the base of the forge, the operating handle, as shown, taking up the least possible amount of room. This forge only weighs ninety pounds, and as it occupies so little room is very convenient for construction trains and other places where there is little room

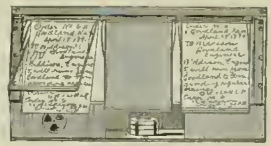
As a rivet forge for bridge and ship work its small size, quiet and steady blast make it popular.

It is the most forge in the least space for the least money we have seen.

The articles on drawing by Orville H. Reynolds are brought to a close in this issue. Mr. Reynolds has given plain instructions in the art of mechanical drawing, avoiding all puzzles and using the plainest of language and scarcely any figures. He has confined his lessons and examples to those that can be followed by a student having but a limited number of tools With these lessons, and a ten-dollar set of drawing tools, any young mechanic can become a good enough draughtsman to make drawings of almost any work he will meet with in the shop.

Automatic Shut-off Cock for Steam Heat.

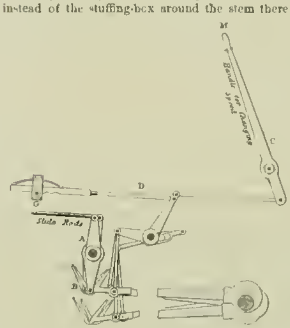
The fear that steam from the locomotive would be as fatal to life, in a railroad wreck, as fire, has called for numerous inventions to prevent its flow, the simplest and most promising of which is shown on page 227. This is a steam valve operated by the pressure in the air brake pipe, and is the invention of J. R. Drozeski, superintendent of the Erie Car Heating Co.'s Works, at Erie, Pa. The valve is ingeniously designed, having no stuffing-boxes



ORDER HOLDER.

whatever, thus doing away with endless trouble in keeping up packing and making the valves move with far less friction; this has been possible because the valve is always either wide open or closed.

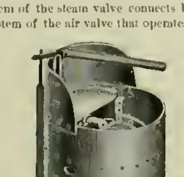
As will be seen by the engraving on page 227, the steam pipe has a plain, straight-way valve in it, but instead of the stuffing-box around the stem there



HOOK MOTION.

is a case with a plain surface at the top, and a projection above the valve head carries a disk of Jenkins packing that is held against the top of the box, forming a steam-tight joint when the valve is open; when it is closed no packing is needed on the stem.

The stem of the steam valve connects by a yoke I to the stem of the air valve that operates it.



CRUMLISH FORGE.

The air valve consists of a cylinder, a piston and rod and a heavy coiled spring, which, in the absence of air pressure, forces the piston down and closes the steam valves.

When air is admitted under the piston it is forced up until it strikes the projection E, which forms an air-tight joint against its packing disk D, on top of piston, and compresses the spring H. So long as there is pressure in the main brake pipe the valve will remain open, but as soon as the brake pipe pressure is removed the heavy coiled spring forces the piston down, closing the valve. On the piston rod, outside of the air cylinder and between it and the steam valve, there is a ring formed on the nut connecting the two stems, that carries a rubber ring which is forced into the coned stuffing-box at the bottom of the air cylinder, thus forming a tight joint when the air is on and the heater cock open. In case there is no air, because the pump fails, or any other cause, the handle G is drawn up by hand, and a slight pressure put upon the button C throws out the catch B and holds the valve open—the catch is shown out in this engraving. The two valves are held in their proper positions by the side pieces P, and connected to the two lines of pipe under the tender, where most convenient.

This is not one of those automatic devices that only operates, or is supposed to operate, in case of accident. It operates every time the air in the train pipe is reduced below the pressure required to compress the spring. Ordinary service stops do not affect it, but the emergency stop will. There is seldom an accident but what the air is applied full, either by the engineer, the trainmen, or by the rupture of the main brake pipe, and it will be considerable satisfaction to know that steam is shut off from the train on these interesting occasions.

Correspondence

Chain-ganging Locomotives and Crews.

Editor The Locomotive Engineer:

The topic for discussion you suggest in the October number—viz., "Chain-ganging engines, or to run them in charge of regular crews," is also to be reported on in the Master Mechanics' Convention in 1891.

It might be dismissed by the dogmatic assertion that there is no way superior to the "one crew on one engine" system. The only reason for chain-ganging would be to get greater mileage, and consequently more service, or to afford the engineers and firemen more rest than can be had by following their engines.

It cannot be gainsaid that on most of our great railway lines the men are run too hard, and do not have sufficient rest, though there are as many extra men kept in reserve as would be needed to relieve any of them that required rest. But it is an every-day occurrence that men do come in who are unfit to make another trip, and there is no one to relieve them, and, not wishing to delay traffic, or disoblige the roundhouse foremen, they go out again. It is an acknowledged fact that a very large share of wrecks that occur are due to men in charge of engines and trains being asleep, or for the want of necessary rest their faculties are blunted, and proper care is not taken to avoid trouble. This fact is concealed by officers and men, for obvious reasons.

The rest afforded to the enginemen by laying off when too tired for further service, and being two or three days in idleness, is not what is required, but a fair amount of rest at each end of the division. This can only be had by having a sufficient number of engines to take care of the traffic, or to chain-gang them. I like the word "pooled" better than chain-ganging.

As regular crews are handled the same every where, we will consider how engines can be pooled to the best advantage. Every good engineer in charge of a regular engine looks upon it as being personal property, and treats it as such, and nothing is too good for it. To pool engines is to treat them as machines, or livery horses, the driver having no care in maintaining them, but simply accomplish the business in hand, and turn them over to the owners to be cared for.

The engineer and fireman on coming on duty should find the engine to which they are assigned in complete order for the trip. No hustling around to get supplies, tools, or to find this or that, but ready in all particulars. This to be done by competent inspectors at each roundhouse. The engines on each division to be as nearly of a class as possible.

On arrival at end of division, engineer to make a careful inspection of engine and report all necessary repairs. In every roundhouse there should be one or more inspectors to examine all parts of the engines thoroughly, such as rod cups, brasses, wheels, and bearings, keep headlights clean, pack all cocks, valve stems, and pistons—in short, do all those duties that ordinarily fall on the engineer when in charge of a regular engine. In all roundhouses there should be a good locker for the engineers and firemen to put their extra clothing, and such conveniences as all men like to have about when on the road. The cleaning of the engines to be done by regularly employed cleaners in each roundhouse. In this it might be well to reserve some part to be taken care of by the road firemen.

In short, the engine is to be treated the same as a sensible man would a good livery horse. It may be said that engineers would lose their knowledge of how to care for an engine. Better this than to injure some wearing part by an ill advised attempt to adjust that which they will have but a short time to observe the effects of, as the same engine may not fall to them in a month again. The care of engines should be taken by traveling engineer and roundhouse inspectors. The record of fuel used and other supplies is a difficult matter to get at, but can be done by measurement of coal at each end of trip, and furnishing the men individual oil cans to be cared for by themselves. But it is my belief that, on the whole, a greater mileage can be made by engines with a regular crew than by pooled engines. But when the power is insufficient to do the work, pooled engines will give the men more and better rest than any other plan, and delay traffic less. GEO. H. BROWN.

Chicago, Ill.

Theory and Practice in Railroading.

Editor The Locomotive Engineer:

In our experience as railroaders how often we see theories upset by practice. Engineers will report hot boxes; the M. M. will storm around, and abuse the machinist for not making a good fit when he put the brasses in; advancing the theory that, had they been a good fit, they would have run all right. The whole secret of the trouble was that the brass fit the journal too well.

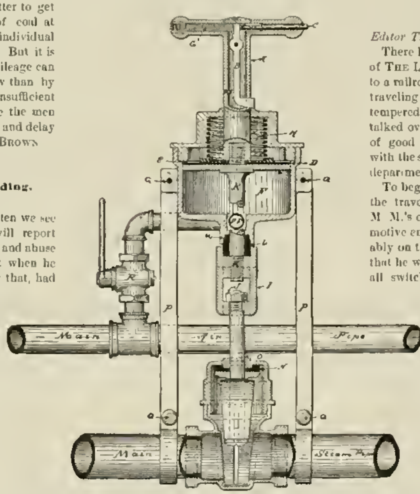
The writer has scraped and filed on a tender brass to get a perfect fit, and when all was said and done, it would warm up before the engine got out of the yard. So much for theory. Practice says don't scrape them at all; use a bastard file, and file them not less than $\frac{1}{16}$ larger than the journal, and they will run all right. I used to work on a road where it was the practice to draw-file (with a bastard file) the journals of tenders and car axles, using a solid brass (no lining metal), and they would run all right, entirely upsetting the theory that a journal had to be perfectly smooth to run well. Some who read this will remember how they put in a brass on the road that did not fit the journal, and that it run all right.

Theory says valves and their seats must be scraped, to be tight, and give good satisfaction. Practice says that planed surfaces, if they are right, are the best for valves and seats; and why? The scraped surfaces are too close for two raw metals of the same kind to come in contact, with good results, as it is nearly impossible to keep any oil between them long enough for them to glaze over; but with planed seats there are a multitude of minute cells that will hold oil, and keep the two surfaces lubricated until a good wearing surface is produced.

I know an M. M. who would take it as an insult for any one to suggest a valve seat planer as superior to the file and scraper, yet the writer's experience is that no railroad shop is complete without one of these little useful machines.

Cab oilers were introduced (not sight feed) to avoid the necessity of the fireman (it always fell to him) crawling out on the running board to oil valves; when the wind was blowing a large percentage of the oil scattered over the jacket. Have seen smart engineers take a hammer and chisel and cut off the oil pipes inside the cab, remarking at the time, "they are no good, *I* want to know where the oil goes;" *they* had a theory born of ignorance, that unless *they* could see the oil in its passage through the pipe that it did not go into the chest, although the reverse lever said very plainly that it struck the right place. The mere fact that in the act of oiling, with their engine shut off, that the oil would disappear about as fast as they could pour it in, they could not get the idea through their thick skulls that the piston was sucking it in; but they had a theory, and the fireman had to go out and oil the valves. This same class of men, when they dropped off at a switch, or got stuck in the snow, found out by practice that injectors were just the thing, after all.

An M. M. had a theory that engine trucks, to run good, must have wrought iron jaws planed, case-hardened, and the face of the jaw ground to make it perfect, it no doubt made a good truck frame, but he put on ordinary chilled wheels, with no certainty that any two of them were the same size. Another man puts on cast-iron jaws as they come from the foundry, the same of the journal boxes, and they run and do good service, and at half the cost, and practice comes out ahead. What about driving tires? Some M. Ms. would be dumfounded to think of sending an engine out without turning off a new tire, and at the same time get one or two years more wear out of the tire by so doing; but they lose sight of the fact that, by examination, over fifty per cent of their engines that are doing good service have a greater variation in the size of their drivers than the new tires would show as they came from the rolling mill, but they have a theory, and the tires must be turned to make it hold good.



DROZESKI'S AUTOMATIC STEAM SHUT-OFF

Theory says side rods must have keys, so their length can be preserved (this length only holds good while the engine is standing in the roundhouse); on the road the key rod and solid end rod are identical.

Theory says soft valve seats wear out faster than hard ones, and practice says they do not. There are engines in service to-day that have been doing work on mountain grades for over twenty years, that have valve seats that chip and file easily, nice close grained soft iron, and they are good for twenty years more—McQueen, Rogers, and Cooke. Yet I have seen engines that destroyed their seats in six months, but the iron was more like rotten wrought-iron than soft cast-iron. A soft seat will wear out a hard valve, and a soft valve will wear out a hard seat. In speaking of hard seats, we do not mean chilled; have run engines with chilled seats and valves; they did good work.

Theory says bad quartering will break side rods, if so, why do they not break in the neck, or close to the stub, where they are weakest? I quoted a case in November LOCOMOTIVE ENGINEER, where an engine broke side rod. Here was an engine in use nearly twenty years, and at the time of the accident she was a poor, old "loose-jointed" affair, did not have a tight place about her, but she broke a rod just the same. Again, if bad quartering has a tendency to break rods, why don't they break when everything is tight and snug, or just after coming out of the shop?

Now, don't let the readers of the best railroad paper in the country understand that I favor shiftless work, for I do not, neither do I favor spending a dollar on a job when twenty-five cents will produce as good results; I believe in having things as near right as possible, and save trouble on the road. No man can tell better than I know, what it is to get over the road under difficulties. Who knows anything about the Baldwin compound? You spoke some time ago about a magnificent Baldwin ten-wheeler on the B. & O. in passenger service; how did she do? You speak of a locomotive works using cast steel rockers; the late A. J. Stevens, of the C. P., used them over fifteen years ago.

Corry, Pa. W. DE SANNO.

The Traveling Engineer.

Editor The Locomotive Engineer:

There has been some discussion in the columns of THE LOCOMOTIVE ENGINEER as to the real value to a railroad company and the enginemen, of the traveling engineer. Some of it was a little hot-tempered, but this subject can be looked at and talked over with just as much reason and exercise of good judgment as any other matter connected with the successful administration of the locomotive department.

To begin with, it will be taken for granted that the traveling engineer is *not* a clerk out of the M. M.'s office, or one of the draftsmen, but a locomotive engineer of considerable experience, preferably on the road where he holds his position, so that he will be acquainted with grades, location of all switches, water tanks and railroad crossings; have a correct idea of the mechanical construction of the different classes of engines in the service, and their weak points as well as their strong ones, so he can judge as to whether the engine is doing her best when her full strength is required. While it is possible for a bright, well-informed man to take this position on a road where he has not seen service before, yet a traveling engineer who knows the road, the engines, and the men, will be better able to take hold and make a good record for efficiency. Of course he must be a progressive man, and not content to follow the old rut *always*, because others were successful that way in past years, for this is a progressive age; the great struggle to haul more tonnage for less money keeps the locomotive department hard pushed all the time.

The small 16 x 24 standard engines of a few years ago could not keep up with the procession, and are being replaced with larger ones, some of them such monsters that their own weight has as much to do with their wearing out and breaking down as the weight of the trains they haul, or the speed they make. Some of them are so complicated that an ordinary man has his hands full to get along with them.

The coal consumption is a question of so much interest now that it pays to have some one to look after that alone. Inexperience or incompetence in the men in charge of the engine can only be remedied by the efforts of some one who has had the experience, can locate the trouble and suggest remedies, which his own experience, or, what is better, his observation of how some successful engineer or fireman handles his engine, or attends to the firing, may call for.

Some engineers make a special effort to keep the coal consumption at the lowest point, with the effect of making a fine art of it. Another one is noted for the small amount of oil and stores that he uses, and the fact that he rarely has a hot box or broken machinery. Another one can draw a heavier train with ease, and actually use a smaller supply of water day by day to do the same work.

than the majority of the others Still another can get a few more miles an hour out of an engine with the same amount of fuel and pressure of steam used by the rest of his fellow engineers. All of these special good points are rarely combined in one man. The observant traveling engineer can, as the saying goes, "get on to" these special advantages, helping out those who do not know how, by his advice and instruction, on the points needed, thus making all of them better. We do not for a moment expect that the T. E. will have all these good points; his best point will be in learning how these records are made, and by what special efforts; then if he has the faculty of telling how it is done, so the others can understand and do likewise, he is a valuable man. A lack of discretion or control of temper will render him unfit for a successful T. E. more than lack of mechanical knowledge. A man right off another road can sometimes do this as well or better than any of the force employed, especially if old fogy notions have to be done away with.

This work the M M cannot do; he cannot give three or four days a week, or a month even, to looking up any of these specialties. If he has a big road, his legitimate duties in the office will not allow of his spending much time on the road, while the M M of a little road of 10 to 30 engines has so many different lines of work to look after that he never finds time to go anywhere. He has to be foreman of the repair shop, keep his eye on the car department, look out for the orders for supplies, give all necessary attention to the maintenance of discipline; in short, he has to give his personal attention to shop and headquarters. If anything goes wrong on the road, trains stall, get out of water, or break down, the train dispatcher has more to do with fixing the blame, while the engineman who was right there at the time is not supposed to be a competent witness, because he is interested in getting out without any blame Therefore, I believe it will pay all large roads to have a competent traveling engineer. The saving of a few tons of coal a day will pay his salary, for when he is successful enough to save that his influence will be felt all along the other lines of expense.

Though *all* master mechanics do not believe it, many of them think that locomotives can be tested with an indicator and then altered to show better steam distribution. Some of the poor steamers waste the steam through the cylinders, while the boiler is doing its best, forcing the fire in this case of course wastes the fuel. Some engineers cure one defect by introducing a worse one, as, for instance, if the exhaust will not cut a fire a foot thick, instead of firing lighter and more even, make the nozzle smaller and pile in more coal. This properly should come under the charge of the T E.; there is no better way to learn about it than to go over the road, see how she does her work and where the defects are located. A more important point in favor of the travelling engineer is, that most of them are the future master mechanics, and it is for the mutual advantage of both companies and enginemen that the business is learned from the bottom up in the school of experience, and—but I'll tell you the rest next month.

Lansing, Mich. C. B. CONGER

Santa Fe Items—Tests With Annular Exhaust Nozzle—New Stack Design—The Strong Front End Experiment New Power.

Editor The Locomotive Engineer :

I notice in your last number your opinion that our annular nozzle, which you illustrate, will cause back pressure in the opposite cylinder. The nozzle was designed to obviate this very trouble, and enclosed cards show with what success. Card No 1 was taken from ordinary nozzle, and has a shoot-over of about 20 lbs Card No. 2 was taken from nozzle you illustrate, and, as you will observe, has no shoot-over. (Both were taken from the same engine, with 140 pounds steam and at starting, they are reduced for this use just one-half.)

This is accomplished by making the area at top of bridge equal to a 4⅛" common nozzle, or the same practically as the final exit at top of nozzle

We find our 18x24 engine required a 4¼" common nozzle to steam, but the nozzle you illustrate steams much better with a 4¼ and 4⅜" opening.

We use an ejector stack all in one piece with the saddle This stack is 23" at the flare of the base, tapered to 15" inside diameter about 20" from the bottom, and then increasing in size to 16¼" at the top

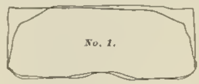
We find engines formerly burning, with old nozzle, 4 tons on certain trips, with new nozzle are down to 2, 2½, and 2¾ tons

We have a Schenectady compound here which promises well. She has the nozzle you illustrated, and steams simply perfect We are now getting out a dynamometer to test the pull of the compound and standard engines.

The Strong engine has not been a success here. Grates that do all right in ordinary fire-boxes last but three weeks in the Strong; her poor circulation caused leaks, which have been measurably stopped by the circulating pipes put in by Mr. Player. In three months' service she has been idle, from enforced causes by failure, two months.

Brick arches are going into everything. Like most other locations where the brick arch "cannot be used," it succeeds when put to the test

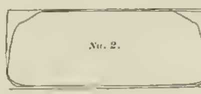
We find a two-inch hole in the front door, or the ring just under the door, very effectual in prevent-



No. 1.

ing ignition of sparks and burning of extension—apparently a large leak having the opposite effect from a small one. Much less black smoke is thrown with the hole open, and either no effect in the steaming is noticed, or better steaming qualities result With a leaky front door, which shows a gradually increasing white spot from burning cinders, the spot stays the same when the two inch plug in door is taken out. In fact, it cures a leaky front end from burning. This is one of the cases in which pure reasoning—like your opinion of the nozzle—is not carried out by facts.

We are getting 150 new engines from Schenectady and Brooks. They are ten-wheel, 19"x24,



No. 2.

with 62" wheel, and are suitable for freight or passenger. The Santa Fe is recovering rapidly in the motive power department from the policy of Mr Player's predecessor, who reduced the output of overhauled engines to ten a month. It is now 28 a month here; and there was plenty of material to work on in the shape of dead engines, too

Topeka, Kan. APPRENTICE.

Burning Cold Air.

Editor The Locomotive Engineer :

In the November issue of the *Master Mechanic* one can see another new-fangled idea for burning cold air in locomotive fire-boxes in place of coal for steam-generating purposes. Such things are in the habit of coming up like the flowers in spring, but the frost in the fall cuts them down to rise no more without planting fresh seed, which is done by some other person; for it appears that one crop always satisfies the most fastidious.

One consulting D. K Clark's work on the locomotive, which was published many years ago (1854) can find a good sample which has all the merit of its successors.

Whenever I see a new crop of these cold air burners I am reminded of an instance that happened in the early 50s, when a railroad company came to the conclusion that to burn coal on their locomotives was a necessity, and the M. M had changed some of the wood burning engines into coal burners, the men all kicking on account of the change, which is always expected when any innovation is to take place, for humanity as a class are orthodox, and engineers are no exception to the rule

The M. M had taken great pains to get posted fully on all the necessities of perfect combustion, how it was necessary to burn all the gas from the coal, and how much cold air it required to do so, besides a hundred others pertaining to this matter. One thing was a fixed fact, and that thing was this: Whenever any fresh coal was put on the fire there *must* be *cold air* admitted to the fire-box above the fuel to burn *that gas and smoke* which, if not burned, there could be no heat had from said coal The above facts being well understood by the M. M, he devised a very ingenious arrangement connected with the fire-door in such a manner that when it was opened to place coal on the fire, it would open a register in the fire-door, and after a sufficient amount of air had passed in to burn the gas and smoke, the engineer was to close the register with his foot, which often times was quite annoying, but the engine did so well it proved a great invention, which was to be applied to all engines that burned coal.

After a few months it was discovered by some one that the opening device for the above register was out of order, and the engineer had failed to report it so repairs might be made, and when the "powers that be" learned of the above facts Mr. Engineer was ordered to appear before the M M, who was a man that sometimes used emphatic language when it appeared to him needed. He could also, when circumstances called for it, talk as smooth as an insurance agent.

Now in this case he was very angry to think that an engineer should slight so great an invention as his register apparatus enough to not have it put in order when needed. There are times when even engineers have luck with them, and this was one of them; for when Mr. Engineer arrived before the awful presence of the said M. M he found a great friend of the M. M's there, who had just called in at that time unexpectedly, and this changed the tone of the M. M. so much that he addressed the engineer as Mr.—a thing unusual—and the following interview took place:

The M M—Mr. Engineer, how came that apparatus broken off your fire-door?

Engineer—I broke it off with a hammer.

"Why did you?"

"It was too much trouble to shut it every time it opened."

At this point the M. M straightened up, took in a long breath and swelled out to his full size, which was of no mean order, and then commenced after this fashion: Mr Engineer, *we have got to burn coal* on our *engines* We know that engineers will have more work to do, but it is the same with all connected with this coal burning, it is more work for the fireman, more work in the shop, we must all take hold and do our share. Now, Mr. Engineer, it is impossible to make steam with coal without the *cold* air; and he went into full details of how much there was needed for each pound of coal, etc His lecture was one that would have done credit to a professor of chemistry, and while this was going on the engineer stood there like a school boy before his teacher—all attention—*i. e.*, taking it all in. At this stage of the game the engineer, who was profane, took a hand and said

Mr. M. M., *when you can make steam out of cold air* I will eat h——l. The curtain dropped, and then came investigation about the engine, which showed that it had been running some time with the apparatus broken, and was doing better without it, and it has been the experience of many that cold air above the fire regulated the amount of steam made, *i. e.*, the *more cold air* the *less steam*.

If all who attempt to do this cold air act had some of the experience of our Mr Engineer it would save lots of trouble and probably some money

Baltimore, Md R. W. CAMEL

A Kicker from Kickersville.

Editor The Locomotive Engineer.

There! I've done it. Gone and written THE LOCOMOTIVE ENGINEER a letter for publication. It's my first offense, and maybe you'll kindly consign it to the waste-basket

I'm one of those "kickers" you read and hear so much about nowadays.

Kick when the (long) time freight I pull is held in yard at end of division two or more hours Kick when I'm forced to double back 150 miles away from home on Saturday night because the extra men are all sick or can't be found. Kick when engines are put in chain gang, and I am called at 2

A. M. to go out in a Minnesota blizzard, with the thermometer registering 40° below zero, and find no packing in the old mill's pistons.

However, I didn't start in to write all the way to New York just to tell you this—put it down, though, that I'm a kicker. I've a kick coming against those fellows who are forever writing in the L. E. and other railway mechanical papers about the density of the average old engineer's ignorance. The young, progressive ones are "all right." The old fellows like myself, though, know next to nothing after spending twenty or more years banging around the country over five or six different roads. I'll admit that I don't know much in one way. I ought to have saved money enough to be independent by this time. I have a progressive cub firing the engine I run at present. The other day cub says to me: "Dad" (this with the air of a man who knows whereof he speaks), "what does water boil at?" I like the cub, but answer with some severity that water boils at 270. Cub laughs immoderately and tells me I'm off. I tell cub that water boils at 270 when the air is all expelled therefrom. I score one on cub and he subsides for balance of trip. Because I'm an old-timer, and don't wear a stand-up collar, cub thinks I never learned to read, and that I spell cow with a "k." I know a good engineer, though, who does. He can draw his check for $25,000, and have it honored too—made it all in Duluth dirt. He can pull as many loads with as little coal as the best of 'em, locate a "blow" or set an eccentric in as little time as if he wrote M. E. after his name.

I've got a kick against the smart man that runs an engine on a light passenger run that never wears rod brasses enough to need filing until engine gets an overhauling; who never has to touch a key after once getting rods in shape, who has five or six hours per day leisure to write about how little we fellows know about hogs, moguls, decapods, etc., and how careless we are in the use of oil and coal, and the way our rod brasses gape open. We work eighteen hours out of the twenty-four, and have found by experience that when an engine has been out of shop twelve to eighteen months and gets hard usage at the hands of different men—some of them "grinders," too—that the brasses can seldom be kept keyed solid. So we do what the most expert machinist would have to do—leave them where they will run and not pull keys out, run hot or break rods. This class of men have been in Co's. service long before the advent of the hog. They have always run light engines on light work. Run 600 miles to the pint of valve oil. Have time to take off cylinder heads every day or two and note condition of cylinders. They are car-pullers, too—in the roundhouse—twenty years ago they pulled twenty-four loads with the old 9-spot—the 9-spot might pull fifteen 60,000 lb. cars now. The hogs now pull about twenty-six. This fellow seldom lets his engine pop. He has no use for a high steam pressure, as there is no danger of his stalling. The engines we run on freight now are no Keeley motors. You can't get something for nothing out of them.

I've a kick against the master mechanic who fails to assist a freight engineer who has barely time to eat or sleep half the time, to locate trouble with his engine. Say, for instance, one that is not able to do the same work as well as others of its class. The engineer often can't tell why. Why is not an indicator put on to learn the cause? M. M. graduated from an engineering school, too. This M. M. promotes all his engineers. If a man comes looking for a job he assumes conclusively that something is wrong with him (M. M. has had five or six jobs himself, too). My progressive stoker thinks the M. M. is right on that one point. Stoker has fired on three roads, but doesn't favor the plan of giving wipers and brakemen the preference for positions as firemen. Well, neither do I. What is the incentive for men to study up their business, beyond enough to keep the job, when so many roads won't hire a man, but promote every one in his turn, regardless of whether he is competent or not?

Men get discharged for causes that ought not to bar them from re-entering the business they have spent years in learning. Some are let out for fast running—burning too much coal—and some in this part of the country quit occasionally. I think if men were hired and kept more on their personal merit, and less on account of their being "old men" (I'm a twenty-year-old myself in railway experience), it might be better for all of us.

I've a final kick against the builders of engines from which you can't see a signal in switching without being a contortionist. I'll make this felt too, some day, when I buy some engines. Why don't they put cabs up where you can see over trains?

This is all I have to kick about this time. I just read over my production to "Mary Ellen," my wife, and she says that while she likes John Alexander's stories much better than this, that she thinks you'll be real mean if you don't print it.

Duluth, Minn. "ZENITH CITEE."

Air Pump Puzzle.

Editor The Locomotive Engineer:

Like De Sanno I have a nut for some air-brake man to crack.

Engine 434 left here Friday P. M. via Auburn road, and when near Rochester the air pump stopped.

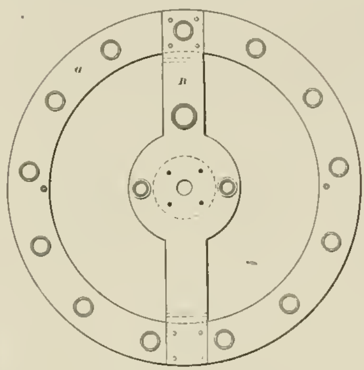
When she got to the engine-house at East Rochester a machinist examined the air pump as thoroughly as he knew how, but could find nothing wrong. After he got the pump together it seemed to work all right, and continued to work until near East Rochester on the return trip, when it stopped again. As soon as he arrived at East Rochester, where the engine-house is, the engineer went in and reported the trouble, and another engine was sent out to take the train. 434 was sent down to Syracuse light. When she arrived I examined the pump and found the defect in the steam cylinder. Some might say that one end of the main steam valve was off, but it was not. The reversing piston was all right, as was also the reversing valve and all its attachments. The main piston and rings were right. Now will some of the readers of THE LOCOMOTIVE ENGINEER tell what the trouble was with this pump? It took me about twenty minutes to fix it.

Syracuse, N. Y. W. F. RELYEA.

Template for Drilling Cylinder Heads.

Editor The Locomotive Engineer:

Herewith find sketch of a template used in the East Albany shops of the Boston & Albany road for drilling the holes in both forward and back cylinder heads without laying off any of them. *A* is cylindrical ring made of ⅜" flange iron. *B* is made of $\frac{5}{16}$" flange iron, cut and flanged as shown, and fastened to ring *A* at each end with four ¼ machine screws. *C* is a brass washer riveted to *B*, and serves as guide to keep template in central position by entering stuffing-box. Bushings are of hardened steel pressed into plates, and admit the required size drill. When used for back head it is held in position by placing bolt through center hole. When used for forward head, small clamps are placed on opposite sides.



CYLINDER HEAD TEMPLATE.

This class of work is done by our cheapest labor.

THOMAS B. PURVES, JR.

East Albany, N. Y.

This issue of THE LOCOMOTIVE ENGINEER will be 24,000. Great demand for specimens among the club raisers.

On another page will be found a "kick" from a "Kicker," but there is method in his kicking, and some good common sense, too. Fancy records of any kind are seldom made on heavy freight engines in hard service, and Kicker makes a point about the comparisons made to his detriment by the fellow with the soft run.

To run long, open, bogie carriages of the American and Colonial pattern would not only prevent the assaults and robberies at present so frequently occurring on our railways, but would put a stop to the numerous false charges of assault made by abandoned females when left with but one fellow passenger in a compartment. We fail to understand why this obsolete type of car riage, which is merely a survival of the old coaching days, should continue to be so tenderly cherished by our railway managers. It is true that it closely resembles the type adopted by George Stephenson, but a good many things have changed since his days, even in this country, and it is about time we had an improved form of railway carriage.—*Railway Herald* (Lon.).

There is a greater amount of freight being moved this fall than there has been for years, yet it is said by railroad officials that very little of it is being carried at a profit, and considerable at an actual loss. This is not because it costs more to move a ton of freight a mile than it used to—it costs less. It is not because the roads are paying their employes too highly—they get less per ton per mile than ever. It is simply because irresponsible agents have been put in authority, and have been allowed to fight and cut down the rates below actual cost of transportation. If the property was theirs, and they alone suffered the consequences of their folly, we could well leave them to their own devices, and let them settle their own fate. But their action stops the payment of dividends, pinching the money market and helping to make hard times; the stockholders insist on retrenchment, and the first cut is invariably in the motive power department, shops are closed or many of the men laid off, trains are abandoned, the power is allowed to run down, accidents multiply, and the value of the property shrinks. Perhaps if the managers would retrench in the traffic departments awhile it might be beneficial.

The Boston & Albany management have ordered all the pilots taken off their freight engines. Pilots are some expense, and the road is thoroughly fenced. They were not quite prepared to adopt the English hooks, or life guards, but they came pretty near it, and are putting on a plain step, such as switch engines carry. The pilot or cow-catcher is an American affair, and answers its purpose of throwing things off the track very well, but where there is little or nothing to throw, and crossings are guarded, there is no reason why the engines won't run as well without it. What the step-ladder front will do in snow remains to be seen.

CONTENTS

Have But One Object in Sight When on Duty.

Every engineer should train himself to think only of his work while on duty, to lay aside all his troubles, and joys, and hopes, and fears, and aspirations, and think only of that particular engine and train, and how best to bring them to their destination safely, on time, and in the best possible manner known to the art of locomotive engine running.

Just think for a moment, and see if you don't remember of a wreck, and a bad wreck, when in your own mind you are satisfied that it was caused by an engineer thinking of something else—family troubles, religion, love, or real estate.

When you step upon your engine, try to lay aside every other care, and every other thought but the exacting duty in hand.

If you were out riding with a friend, and telling him or her a story, and your horse suddenly took fright and ran away, you would bend every energy to subdue the horse, and then resume your story. Learn to do that on your engine.

Lay aside all engrossing thoughts on religion, love or money, as of secondary importance, until you are at the end of the run, then, if you so desire, take them up where you left off.

The writer once fired for a man who, in this particular, had mastered himself completely; he left all his cares at home—and he had some sad ones—and thought only of his work.

He would sit as rigid as stone for an hour, his hand on the brake valve; his eyes on the track, you would think his thoughts far away, but ask him where any train was, what orders he had, or what that extra click was, and he would tell you in an instant—he was thinking of his work.

He put all his life and soul into his present duty, ask him a question outside of the work in hand, and he invariably replied, "I wasn't thinking about that." This man was afterward killed by a fireman who, after letting their light engine into a siding at night, locked the switch for the side track, and let an express train crash into the engine from behind: the fireman confessed at the hearing that he was thinking about what the Rev. So-and-So said the day before, and forgot what he was doing.

If you are running, remember that your success and reputation does not depend on how good an all round, average man you are, or how much you know about running the master mechanic's office; it depends upon how well you perform your duties each hour and each minute.

The safety of your train does not depend upon your remembering what place you will meet a train that has just left the other end of the line, but upon your knowing where and where not to meet the *next* train.

If you are a fireman, remember that your first duty is to do your particular work the very best you know how, to think of your fire, and all that pertains to its evaporating the most water on the expenditure of the least coal, to think of your signals, your lamps, and of everything under your care; you will rise in the estimation of your engineer and the officers of the road, only on your reputation as a fireman.

You cannot afford to think of anything else than your duty while on an engine, train yourself to this now, it will be of the greatest value when you are promoted.

No man does his whole duty to his employers or to himself when he "thinks about something else" while on a locomotive—do you do it?

Three Years Old—Going On Four.

With this issue THE LOCOMOTIVE ENGINEER completes its third year.

There were a good many people, especially some in the publishing business, who were real sorry for us when the first L. E. came out; one of them wrote:

"THE LOCOMOTIVE ENGINEER came to hand to-day; it is as sparkling as champagne and *ought* to win, but I fear it can't. In the first place, engineers and firemen don't read; they are a class of close-communion hardheads—that will keep you from getting a big subscription list. The master mechanics, etc., are from the ranks, as a class, and are a little more dense and bigoted than the men under them; they pretend to be 'high science' men and take class papers with a high price and a department of puzzles in geometry. The advertisers want to cater to the motive power officers and advertise in the class papers—this will prevent you from getting advertising. I sent out over a thousand specimen copies to locomotive engineers three months ago and have never got one subscriber in return—they won't read."

But we were mean enough to think he didn't know how to strike practical railroad men, bigoted enough to think that we did; and wicked enough to think that he was a sorehead on master mechanics anyway.

We are happy to say that none of his dire calamities have befallen us. All took an interest in the paper from the start, we got some nice advertising—and want more—and the subscription list is now more than double that of any other *two* mechanical papers in the railroad line. Almost every club is increased as it is renewed, and all renew.

The increased size has widened the paper's field and its usefulness and has been duly appreciated. We have no further worry about what support the paper will receive—that is insured—we will now devote our energies to making a better paper.

Watch for This Man.

This is about the season of the year when the Christmas present fiend commences to pass his little list for the names and the dollars of such suckers as will put up. If there is an official on your road who needs a Christmas present, don't stand in the way of his buying himself one. You buy your own. If some official is going away who has been a man among men, and you want to encourage him for it, it might do to give him a present. But a well-written memorial or set of resolutions will show him your appreciation just as well as a gold watch—and is cheaper. If there is an unfortunate fellow worker of your acquaintance, or the needy family of one, put your hand in your pocket and fish up all you can spare. When the man who has the list for the "old man's present" comes around, don't plead poverty, don't sneak away, but say *no* in as clear English as you can command.

If the different orders of railway men would collect and publish a brief account of each of the hundreds of fatal accidents where the victim is not only mangled, but cooked to death, the list would drive nervous people insane. A large part of this torture can be prevented by the use of modern appliances. The practice of perforating boiler heads full of small holes for this cock and that is a bad practice. Checks on the side of the boiler cause sad havoc when a side collision takes place, and cars have a habit of getting out over the switch. Gauge cocks that close from the inside, and that can close automatically when broken off, will work a fair percentage of the time, and save life. Fountain-heads, where one automatic valve closes all communication with the boiler, are good, but the valve should be located inside the boiler and worked every day to keep it in order. This is easier said than done. Anything that will in the least tend to lessen the number of victims of this awful torture is worth trying and using.

There is a very feverish feeling among the road men of two or three Eastern lines, and considerable strike talk. If the officers of these roads would go among the men, and remove three or four little grievances that are annoying, it would stop half the trouble. Men who are constantly harassed by small things are less liable to look reasonably upon larger ones. It will be a cold winter and hard times for a strike. Both sides should avoid it.

The Southern Pacific bought the Northern California road last summer and got some old engines with it, among them two little Norris engines, built in 1851; these engines had cylinders 12 x18", four 54" wheels, and weighed about 16 tons. Both of them had copper tubes that originally came with the engines, one of them had the original copper fire-box and the other had got a new box but a year before.

Books Received.

THE RAILWAY COMPANIES AND RAILWAY BRAKES By N D. Macdonald, Advocate Reprinted from *The Scotsman* by Turnbull & Spears, Edinburgh, Scotland.

This work is a linen-bound pamphlet comprising a series of letters to the press, in which the writer denounces the railroads for using the automatic vacuum brake, and replies from the friends and users of the vacuum device. The author says that in a space of two and one-third years 106 cases of the freezing up of the vacuum brake have been reported—a statement he partially substantiates with day and date. On the other hand, D. Jones, locomotive superintendent of the Highlands Railway, which traverses the coldest part of Great Britain, says that in three years' service of the vacuum on his road not a single case of freezing has been reported No price is stated for this interesting little work, but the Air-Brake Co. should furnish it free—it is a good advertisement

ASKED & ANSWERED.

(69) W. H. J., Conneaut, Ohio, asks:

Can all steam ports be covered at the same time, and in what position will the engine stand if done? *A* —No, One port will always be open the amount of the lead.

(70) W. C. S., Frankfort, N. Y , asks:

Why is the saddle pin placed out of the center of the link? *A* —To equalize the cut-off, and overcome the distortion caused by the angularity of the main rod.

(71) H. M. S , Philadelphia, asks.

How much of the Midland American Railway is completed? It now goes under the name of the Findlay, Ft Wayne & Western *A* —There are no such roads reported as you mention. The Midland (Ind) Railway is 74 miles long

(72) Constant Reader, Birmingham Ala., asks:

Why are offset keys necessary in resetting eccentrics? *A* —They are not necessary unless it is desired to shift the position of the eccentric in order to increase or diminish the lead; then they are used because it is impossible to get a square key into the mismatched key seats in eccentric and axle

(73) Young Runner, Savanna, Ill., writes:

Our ten-wheel engines have the blind driving-wheel in the middle. If tire on back driving-wheel should break and come off, while out on the road how could engine be fixed to run it home? I have asked some old engineers, and it was a puzzle to them They said they could not see how it could be done. *A* —The only way to do would be to block the wheel up so as not to touch the rail, and proceed slowly. Even this would be a doubtful plan. The bald tire should always be ahead in a ten wheeler.

(74) H C. S., Columbus, Ohio, asks;

1. What is foaming, and what is the cause of it? 2. What is the difference between foaming and priming? 3. What will prevent foaming? *A* —1. Foaming is the condition of suds or froth in the boiler, foam. It is caused by foreign substances in the water, such as oil, alkali, soda, etc. 2 Priming is when the whole body of water raises through lack of room to free its steam, or from forcing a boiler too hard It may occur with pure water. Foaming can generally be temporarily remedied by blowing out. Anything that will remove the disturbing foreign matter will stop foaming.

(75) M R. B., Washington, D. C., asks:

1 How many gallons of water will an "old style" Monitor injector, No. 8, throw per minute under 150 pounds pressure of steam? 2 How much will a No. 10 Monitor, of '88, under 180 pounds steam pressure? *A* —The amount of water that any injector will throw depends upon three things—*a*, the pressure of steam; *b*, the size of delivery tube, *c*, the temperature of the feed water. The "old style," "new style," name of maker or any other cause does not change this law The makers of the instrument named say that the No. 8, at 110 pounds pressure, throws 2,430 gallons per hour, and the No. 10, 3,450 gallons per hour at the same pressure—which does not answer your question Experiments made some years ago with a No. 6 Sellers showed that an increase of 10 pounds in the pressure—from 140 to 150—increased the delivery about 2¼ gallons per hour for each pound of pressure added The colder the feed-water, the more steam it will condense, and thus more work can be done and more water is delivered The hotter the feed-water, the less will be thrown. The capacity of a No 10 injector, of any make, with 180 pounds of steam, and the feed-water at 62°, would be very close to 4 000 gallons per hour

On an Eastern road a test was recently made of the wearing qualities of iron and steel axles in actual service. The iron was a high grade fagot-bar from an English maker—the steel was Krupp's standard axle. The axles were the same size, 3⅞x7, and in the same service The iron axle ran 10,608.6 miles to $\frac{1}{32}$ of an inch wear, the steel axle ran 22,366.41 miles for the same amount of wear.

George Stephenson invented and patented in 1833 the steam driver brake.

The Westinghouse air-brake seems to be the winner at all the tournaments of tests lately made in Germany, India and Australia.

At some of the small stations of the Central Vermont road they still use the old-fashioned telegraph machines with paper ribbon attachment

Horace Eddy, M M. of the B. & A., at Springfield, Mass , is putting plain sheet-iron on for jackets and painting it—making a very neat job.

The largest locomotive driving wheels in use are under the London & Northwestern Co.'s engine "Cornwall." They are 8 feet 6 inches in diameter.

Geo. H. Brown, traveling engineer of the C., M. & St. Paul, at Chicago, gives some sensible views in this issue on the chain-ganging of engines and crews.

Keep the index that accompanies this number, and see if the subject on which you seek light has not been touched during the year. If it has, don't ask us to repeat.

The Brotherhood of Locomotive Engineers will meet in convention hereafter but once in two years The next convention will convene at Atlanta, Ga., in 1892. Often enough.

The compound locomotive on the Brooklyn elevated road is reported to be running on much less coal than her neighbors with two cylinders alike. No tests have as yet been made.

The N. Y. C. & H. R R. have given Wm Buchanan, Supt. of M. P., a three months' leave of absence for a trip to Europe. Mr. Buchanan has served as the head of his department for forty years.

The New York Central road has four main tracks, two for passenger and two for freight, and yet it is one of the worst roads in the country for lay-outs—the great trouble being the delay in unloading and loading cars, thus filling up the yards. The traffic is something enormous.

Some Shop Points on the Del. & Hudson Canal.

At the shops of the Delaware & Hudson Canal Co. at Green Island, N Y., Master Mechanic J L. Cory has some little kinks of his own that are ingenious and useful.

Instead of a drop pit, or table, they take wheels out by lifting the engine off of them bodily ; this is done by four hydraulic cylinders. These cylinders are 18x72 inches, and four 2 inch wire cables come down over the stripping pit so that they are a little farther apart than the widest part of the engine, and somewhat nearer together than the extreme length of engine. These tables have a heavy fork end, with pin holes through both sides, and heavy bars about 1½x6 inches are placed under the engine frame at each end and pinned to the fork end of the cables.

The hydraulic pressure is controlled by a three-way cock for each cylinder, all four located together and under the hand of the operator. By this arrangement any corner can be lowered or lifted as desired, one end raised without raising the other, or all four corners lifted at once.

After the wheels are rolled out from under a boiler it is dropped down on dummy trucks and rolled to any point desired.

About eighty pounds pressure is carried in the water-works about the shops. On a car wheel boring mill, originally fitted with a hand or power crane, the chain has been extended and passed around a sheave and up to an hydraulic cylinder overhead, doing the work quicker and easier than by the old method

Hydraulic cylinders also lift pairs of wheels and drivers to the wheel presses.

They have taken an old lathe, big enough to swing drivers, and fitted it up with special gears so that it is driven from a gear on the face plate, same as a wheel lathe, then on the tail-stock they have fitted a quartering attachment of their own design that seems to do the work all right. This lathe develops all the faults and flaws in driver axles as they are shown by the twisting strain put upon the axle, when the tire next the tail-stock is being turned, the wheel at the head's end doing all the driving. This tool has been fitted with two tool posts much like those in use on regular wheel lathes.

Automatic brake rigs on tenders are put up differently here than anywhere else. The triple valve is located under the outside sill on the right side, and in about the center of the tender—this is where it can be seen and got at for inspection and repairs without getting under tender, the drum and brake cylinder being located out of the way under the tank frame. The engineer's valve is on side of cab ahead of the engineer and where it is easily reached, and where it does not get hot.

The engines are all hard coal burners with boilers coming through the cab, but most of the cabs are high on the boiler, and many of them have seats on the side of the boiler for engineer and firemen.

They use short fronts and diamond stacks.

They now make their fire-boxes with a seam in the side sheet about six inches below the crown; below this seam the side sheets are corrugated They have had a great deal of trouble with side sheets, and always below the fire line—a common occurrence with hard coal.

Since the introduction of the corrugated sheet less trouble is had, and they can be renewed from the extra seam down without disturbing the crown, and at comparatively slight expense. They have no trouble with the extra seam leaking. They use stay bolts but three inches apart for side sheets.

Passenger cars are heated by the McElroy system, and in the yard for the storage of cars a complete set of pipes and couplings are provided for each track, and all the cars are coupled up and kept warm, so that when extra cars or trains are called for in cold weather they are ready for the road.

They seem to let freight car axles run as long as they will, as we saw many pairs of wheels in which the bearings were worn to three-fourths the original size.

Old tanks and other sheet metal, instead of going into the scrap, is cut up into washers, a couple of punches being employed on this class of work

The grounds around these shops are nicely kept, and there is altogether about an acre of flower beds. This flower bed addition was put in a little at a time to make the place look cheerful, and from it has grown quite a landscape department, and flowers and foliage plants are to be seen at all important stations on the road.

On one side of the shops there are several large greenhouses, heated by hot water and neatly fitted up as the winter quarters for the plants, of which there are thousands. This department is under the care of Master Mechanic Cory, who seems to be a personal acquaintance to each plant, knows its name, clan, class, habits and previous condition. Ladies who want to see interesting shops should take in those at Green Island.

The D. & H. Canal Co. was the first road to use a locomotive in America—they imported the "Stourbridge Lion" in 1828.

The B. & A. road have an automatic traction increaser that, it is claimed, works very well in its original shape, when not burdened with steam cylinders, etc It is simply a link between the engine and tank, that is fast to the tender draft iron, about a foot below the engine connection. The harder the engine pulls, the more of the weight of the tank is thrown on the drivers. It looks as if all this would make a hard riding tank

Geo. W Wollaston, until recently on the advertising solicitor force of the *Railroad Gazette*, has reformed and gone to work. He is now on the road as sales agent for Pedrick & Ayer, special railway tools, Philadelphia. Representing a first-class house and handling goods in constant demand must be a pleasant change from the bulldog and bouncer interviews of old.

Simple Lessons in Drawing for the Shop.

By ORVILLE H. REYNOLDS.

LAST PAPER.

Having endeavored in these papers to furnish some light for the beginner on a subject which is practically inexhaustible, and having only touched on those portions of it that are absolutely requisite to a successful beginning, we will close the series with this paper, in which we have an example each of intersection of solids and conic sections.

Fig. 94 shows the intersection of two cylindrical surfaces, say a dome and boiler, for illustration.

The problem is to find the shape of curve at junction of the two bodies. First draw end view *B*, Fig. 95, laying off the diameter and height of small cylinder, from which project side view *A*, Fig. 94, and lay off diameter of small cylinder. We now have three points, *D*, *E*, *F*, which were formed by projection from end view. *D* and *F* correspond to shortest length of small cylinder and *E* to its greatest length.

The top view or plan, Fig. 96, is next drawn by laying off from intersection of center lines the diameters of circle *G* and large cylinder *C*.

One-half of circle *G* should be divided into any number of equal parts, say eight, as shown by radial lines *a*, *b*, *c*, etc., after which draw lines *i*, *j*, *k*, etc., through these points, perpendicular to horizontal center line of plan.

Setting the compasses to left of line *m c* on plan, Fig. 96, transfer the dimension to end view, Fig. 95, by taking point *R* for a center, and we have *m'* on end view. Taking on the compasses each point *n o* in turn and transferring to end view as before we have *m' n' o'*, from which vertical lines are drawn to intersect circle *B*, Fig. 95.

These points of intersection are next projected to side view, Fig. 94, and vertical lines *m*, *n*, *o*, let fall to intersect them. Such intersection giving points in the curve sought.

One-half of the curve is shown completed, the other half showing the points only which are to be connected by means of compasses or template as in other cases of irregular curves.

The usual practice in these problems is to lay off one-fourth only of circle *G* and find points in one-half of curve, from which points in other half are transferred with the compasses.

The construction of a conic section is next shown, in which the cone is cut obliquely to the horizontal plane. In this example we have an elevation of that portion of the cone lying below the cutting plane; the upper portion shown by dotted lines, Fig. 98—a horizontal projection of the section, Fig. 97, a projection of the ellipse formed by cutting the cone in the place shown, Fig. 99, and a front elevation showing the cutting plane foreshortened, Fig. 100.

First draw outline of Fig. 97 by taking point *E* for a center on line *A B*, and describe required circle; divide this circle into any number of equal parts, *a*, *b*, *c*, etc., and draw dotted lines from points found to center *E*.

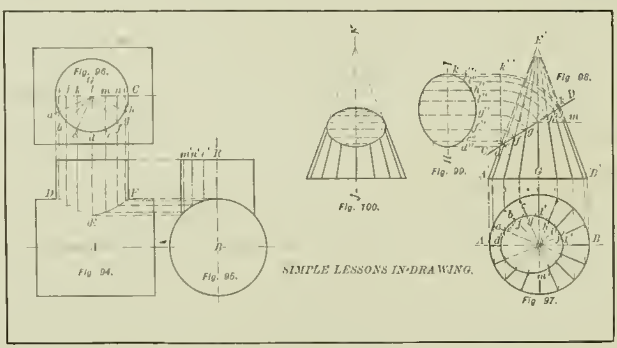
On line *A' B'* project diameter of Fig. 97 and all points on circumference of same figure. Set off on center line the height, *G E'*, and drawing *A' E' B' E'*, also projecting the points on base line *A' B'* to vertex of cone, we have what are called the exterior elements of the cone.

Line *C D* represents the cutting plane, the section of which we are to show on the horizontal projection *A B*. Letting fall perpendiculars from points d and *k* on cutting plane to *d' k'* on line *A B*, Fig. 97, we have the major axis or long diameter of the section, which is an ellipse. Perpendiculars let fall from points *e*, *f*, *g*, etc., on cutting plane to intersect radial lines at *e*, *f*, *g*, respectively, will give points in curve, except on center line *G E*. To find the projection of the points lying on this line, take distance *l m*, Fig. 98, on the dividers and transfer it to both sides of center line *A B* at *l' m'*. The reason for this lies in the fact that all points in the circumference of the cone are equi-distant from the center, in a horizontal plane.

If we suppose the cone to turn on center *G* until *G* assumes the position occupied by *A'*, then *m* will have reached the position occupied by *l* before movement occurred. It is plain that the distance from the center to *m* equals the distance from the center to *l*; we can therefore take *l m* and set it off from *E* on line *A B*, as explained above.

The actual dimensions of the ellipse not showing on the horizontal projection, owing to the obliquity of cutting plane on Fig. 98, they can be obtained by projecting all points on cutting plane to a line passing through *d* perpendicular to base line *A B*. Conceive the cutting plane *C D* to revolve in a vertical plane, on *d* as a center, then *d k''* will equal *d k*. Produce these projected points so as to pass through center line *H I* of proposed ellipse at any convenient distance from Fig. 98.

We have now to find the points in the curve. With the dividers placed on line *A B*, Fig. 97, take the distance *e'* and transfer it to each side of line *H I*, Fig. 99, making the points on projected element *e* at *e*.



SIMPLE LESSONS IN DRAWING.

Taking all the other points in the same manner from the horizontal projection and transferring to Fig. 99, the true dimensions of ellipse are delineated by points which are to be connected as before.

One more view of this conic section is shown in Fig. 100, where we have a front elevation showing the section foreshortened.

Draw outline of cone, using Fig. 97 from which to take the dimensions, and from circumference of same figure take the exterior elements, and transferring them to base line of front elevation produce them to vertex of cone. These elements should be taken from line *A B* and set off from line *J K*. It should be remembered that *A* and *J* represent the same side of cone.

Project to front elevation from Fig. 98 all points in which the elements intersect the cutting plane, as *d*, *e*, *f*, *g*, etc. The intersection of these projected points with the exterior elements of cone will be points in the curve on Fig. 100.

With the belief that any one with a desire to learn the rudiments of drawing can, with proper application, be able to place on paper a drawing of any simple object, we will say once more to the beginner, let no obstacle, however great it may appear, swerve you from your purpose. To persevere means success. As hinted in a former paper, there are so many sources of information to draw from which are practically free to all, that failure is possible only to the apathetic student.

For the benefit of those who would like to pursue the subject further, it is recommended that they procure "Practical Drawing," by J. G. A. Meyer, who has in that work treated the subject not only in a masterly manner, but exhaustively as well.

The work on "Locomotive Construction," by the same author, would also be of material assistance to those interested in locomotive work.

Data Card for Ten-wheeled and Consolidation Engines.

Continuing the subject of keeping data, we show on page 233 Mr. Pomeroy's outline for 10-wheelers and consolidations. like the others it is flexible, and sizes and the position of pieces can be changed with the least amount of work.

The Locomotive Works of Dubs & Co., Glasgow, Scotland.

By C. CRAIGIE YOUNG, GLASGOW.

The city of Glasgow, with its half million of inhabitants, has been appropriately termed the "commercial capital of Scotland." It may be said to be the chief seat of the great Scotch iron and coal trades, and it is likewise the principal center of that great shipbuilding industry in connection with which the river Clyde has long ago become famed. It is here, too, that some of the largest and most flourishing locomotive engineering works in Scotland are situated. One of the best known of these concerns is the firm of Dubs & Co., whose premises I recently had the pleasure of inspecting. These works, which were erected in 1864, are situated on the south side of the river, in the busy district of Polmadie, about one mile and a quarter from the center of city, and cover an area of fully 13 acres. The average number of hands employed is over 2,000 (there are sometimes as many as 2,300), including a considerable proportion of highly skilled artificers. The staff of draftsmen engaged (including apprentices), varies from 40 to 50, according to the amount of work on hand, while there are in addition thereto some score or so of girls employed in making the working tracings. The mechanical operations are carried on in a number of separate blocks, each measuring 300 feet by 280 feet, in parallel spans of 40 feet each, and the required steam power is supplied by sixteen engines of various types, having a combined horse-power of about 900 (indicated). The productive power of the firm is great, the average output amounting to 4 complete locomotives per week, or an aggregate of 200 per annum. Each locomotive weighs on an average about 30 tons, so that the average annual output of the firm amounts in rough figures, to 6,000 tons of new work. The drawing office is one of the largest and best equipped offices of the kind it has ever been my lot to inspect. This room is lighted from the front and back and has separate desks or tables for each draftsman; right down the center of the room runs a broad counter, underneath which are numerous receptacles containing the original drawings of engines and tenders in course of construction.

At one end of this hall is placed a wooden contrivance by which the proper arrangement of the steam valves connected with the cylinders of locomotives is ascertained with mathematical accuracy, thus releasing the draftsmen from a good deal of responsibility and at the same time obviating the risk of error on a point of vital importance to the subsequent smooth working of the engine being designed. It is here worthy of note that the term "designed" has much greater significance in the eyes of the Messrs. Dubs & Co. than it has in some other establishments, as not only must the machine be represented in its complete form as well as in separate parts, as regards its principal sections, but, *every separate bolt and nut must be sim-*

ilarly represented on paper, each with a little sheet to itself, before the engine is made.

After the drawings have been finished and approved they are taken up-stairs to the tracing room, where the girls speedily duplicate or triplicate the originals as may be required, and these are then distributed amongst the artisans outside, the originals being carefully retained inside the drawing office until the work they represent has been finished.

The store-room is located in the same part of the premises. The interior of this place is quite a study in itself, containing as it does a vast collection of tools and other articles in daily use, including a goodly pile of accurate steel gauges, kept for the use of the workmen when preparing a piece of mechanism, thus leaving as little as possible to chance error, and enabling the men to dispense with the ordinary foot-rule. The store contents likewise comprise a number of Whitworth's measuring instruments, with which sizes to .1000 of

shed is one of the busiest "hives" in the whole establishment. This department is supplied with a large number of powerful steam hammers, the blows struck varying from 3 to 60 hundred-weight. The forgings comprise all the malleable parts of locomotives, with the exception of crank axles, which, with steel tires and springs, are the only items not manufactured on the premises.

The boiler makers' shed is closely adjacent to the smiths' shop. Here the visitor is struck with the comparative silence which prevails, which forms a curious contrast to the dismal clang of hammers which is usually associated with the ordinary boiler shed and shipyard where riveting is carried on on an extensive scale. By means of hydraulic apparatus the red-hot rivets are noiselessly squeezed into position in previously drilled holes, and the suspended heavy plates, which but a few minutes before seemed perforated and useless, rapidly assume the form of a well-made boiler, and this under the manipulation of one man and a boy.

rows of pits, engines and tenders are being built, it is not so bewildering; the wheels and axles having passed their appointed routine, are here united in a cold state by the aid of powerful hydraulic presses, which virtually weld them together and render keying unnecessary, although, to satisfy a prejudice which still lingers, wedging is still to some extent used. The locomotive being now mechanically complete is "towed" by the little crane engine above mentioned into the painters' workshop, where it receives its decorations and devices, an operation which is generally begun and finished inside a space of six days.

In concluding this brief description of my visit to this celebrated Scotch locomotive establishment I should like to add that I was particularly impressed with the "congenial spot" on which these premises are reared. The natural situation is entirely favorable to the successful development of a concern of this kind. There is in the immediate neighborhood a plenteous supply of coal and iron,

an inch can be tested, and with which scales can be prepared for the drawing office. Just outside the store-room there is a large open space intersected with various lines of railway, which connect with the different portions of the works. Almost the first thing which attracts attention is a curious little locomotive, surmounted by a steam crane. This locomotive, which was built so far back as 1868, has been appropriately termed an "automatic porter," and has been found extremely useful for picking up large boxes and masses of metal weighing several tons, and depositing them where required. Its peculiar adaptability for such purposes is found in the fact that duplicates have been ordered from the Messrs. Dubs & Co. by other engineering firms and railway companies for their ordinary yard and shunting work. The one I refer to has been constantly at work during these 22 years, and bids fair to stand the strain of several additional years of "toil."

In the pattern shop, I found a number of efficient craftsmen rapidly putting into substantial form the pictured ideas of the draftsmen. The forging

The foundry is close by. They were, at the time of my visit, engaged in casting the cylinders required for immediate use. These are composed of a peculiarly hard and tough material—a mixture of various brands of iron—which the firm have acquired a wide celebrity for producing, and which, we were informed, is greatly sought after by marine engineers for parts of their engines subjected to severe friction. The most central feature in the whole establishment is the mechanical workshop. This department—quite a model workroom of its kind—is open from end to end and covers an area of some 200 feet by 100 feet. It is chiefly occupied by Whitworth's machinery, arranged in parallel rows, for planing, paring, slotting, drilling, milling and polishing purposes. The grinding machines for sharpening the numerous tools in use are also kept here. These machines—we ought to state—are attended to by men who do nothing else, the result being that the chisels, drills, etc., used throughout the factory are always kept in the highest condition of efficiency. In the quieter atmosphere of the erecting shop, where, over double

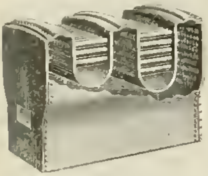
ready communication can be had per rail with all the busy centers of the kingdom, while the shipping accommodation of Glasgow harbor is, with the possible exception of Liverpool, second to none in Great Britain. And this latter remark reminds me of the fact that the Messrs. Dubs & Co. have not failed to take advantage of the facilities for the development of foreign custom thus placed at their doors. In the quarter of a century which has elapsed since they started business on a comparatively humble scale they have supplied locomotives of various types and sizes to railway companies in many distant parts of the world, including Canada, South America, Australia, New Zealand, West Indies, Japan, Cuba and China, and the manner in which the Dubs products are appreciated is seen in the regularity with which repeat orders arrive from the different parts of the globe where these have already undergone the most severe practical tests.

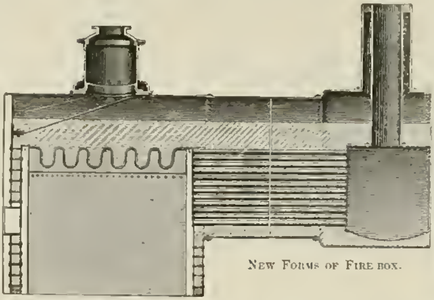
New Form of Fire-box.

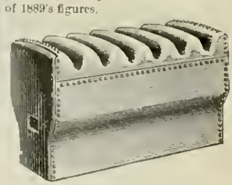
The boiler and two forms of fire-box shown herewith are the invention of Mr. Wm. Malam, lately manager of the boiler department for the Edgemoor Iron Co , at Wilmington, Del. Mr. Malam has had a great many years of experience in boiler making both in England and America.

The surrounded smoke-box was designed more for a torpedo boat boiler than a locomotive. It would put too much weight on the front trucks to be successful and would present practical difficulties in attaching to the cylinder saddles. This, however, is not the important point in his boiler.

The arched and corrugated crown sheet, as shown, would be a grand improvement in locomotive boilers, if it can be made to stand, as it does away with all crown stays, admits of the carrying of a large body of water over the crown, and presents more surface to the action of the fire. The inventor has made a great many practical experiments and is satisfied that he can construct a perfectly safe crown for locomotive use upon this plan.







NEW FORMS OF FIRE BOX.

A few years ago there was neither material nor machines for forming such a sheet as this, but both are plenty now. That such a sheet can be made there is no question. That it will stand in service Mr. Malam is confident, and anxious to build one for trial. The other form of fire-box, with drop legs and short flues, is also his design, but it costs more than the corrugated sheet. His address is 142 Oak street, Paterson, N. J.

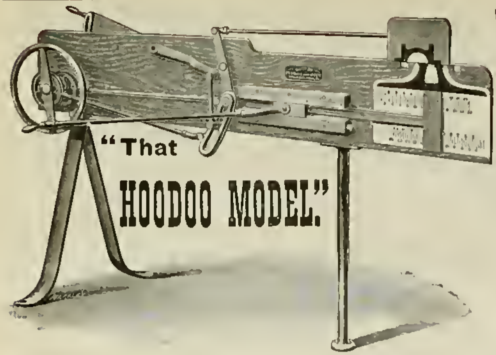
A Heroic Engineer.

The newspapers have been gushing lately over the act of an engineer who performed an act of questionable bravery , and almost nothing has been said about an act which we consider one of the most heroic of the many noble deeds performed by locomotive engineers. The boiler of an engine which was running wild at night on the Chicago & Erie exploded, and Edward Murphy, the engineer, escaped with severe scalding and a broken leg. An express passenger train was following the engine. Although he was suffering excrutiating pains from the scalding he had received, and the pain of his broken leg was almost beyond endurance, Murphy found a lamp, and crawled back with it to flag the expected train. The act was a sublime instance of devotion of duty.—*National Car and Locomotive Builder.*

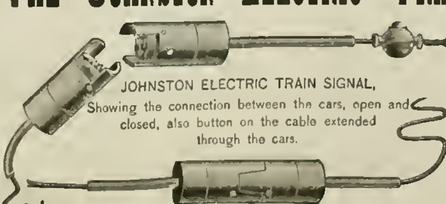
The Edgar Thompson Steel Works of Carnegie Phipps & Co , Pittsburgh, made the most tons of steel rails in October that they have yet produced. The output was 32,500 tons, an increase of about 2,500 tons over the previous best month's record. Outside of the Edgar Thomson plant, the best month's work on rails was about 28,000 tons. The total production of steel rails at all the mills in the country for the current year will probably run 400,000 tons ahead of 1889's figures.

James F. Hobart, lately editor of the *Northwestern Mechanic*, has assumed editorial charge of the *Journal of Railway Appliances*. It's funny how men will desert the free and bounteous West to work free lunch routes and wear second-hand clothes in Sodom. Can't hardly account for our own fall.

It is said that the Grant Locomotive Works are actually at work on their new plant near Chicago.



"That
HOODOO MODEL."



GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 240,000 cars. This includes 140,000 freight cars, which is about 15 PER CENT. of the entire freight car equipment of this country. Orders have been received for 80,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, MANAGER. JOHN B. GRAY, AGENT. C. C. HIGHAM, GENERAL SUPT.

THE "LACKAWANNA"

LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank-pins in hard daily service.

In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound is specially recommended for these cups, being first-class in quality and low priced.

LACKAWANNA LUBRICATING CO.,

SCRANTON, PA.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

Main Office: FRANKLIN, PA. Refineries: FRANKLIN, PA. OLEAN, N. Y. ERIE, PA. OIL CITY, PA.

PERFECTION BRONZE

Is the best Journal Bearing Metal in the world. Genuine Babbitt and Anti-Friction Metals

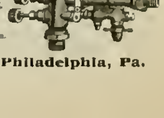
EASTWOOD WIRE M'F'G CO.,

BELLEVILLE, ESSEX COUNTY, NEW JERSEY.

"LITTLE GIANT" INJECTORS

WITH ADJUSTABLE TUBE.

SUITED TO EVERY SERVICE. POSITIVE, CONVENIENT AND DURABLE.



BOILER WASHER AND TESTING DEVICE.

Uses warm water, avoiding injury, and facilitates raising of steam.

Improved Swing Truck.

Apropos to the discussion now being carried on by the different railroad clubs on the relative merits of rigid and swing trucks, the new engine truck being put under Canadian Pacific locomotives, and illustrated on this and page 3, is of interest, containing, as it does, some of the better features of each style of truck.

To begin with, the top frame is forged in one piece, both sides and both cross braces, this insures a square truck. The truck is of the well-known floating box style, strongly built, and with the details carefully worked out.

The novel part of the truck is in the swing bolster arrangement. On each side of the swing bolster, or cradle, there is cast a downward projecting lug that bears against a double-coiled spring, held by a central bolt to a heavy brace on the truck frame. It is plain that the bolster of the truck cannot swing either way from the center without compressing one of these heavy springs. Thus the truck is a rigid one until the side thrust upon the flanges exceeds one and a half tons, when the bolster will swing.

A very perceptible improvement in flange wear can be seen since this truck has been put into service. On very crooked track it swings and guides the engine without shock or jerk.

It looks as if it had all the best points of both styles, and was better than either.

Commissioner Rich, of Michigan, one of the best railroad commissioners in the country, has sent out a circular to the railroads of his State, notifying them of his intention to recommend an extension of the time allowed for equipping all the freight cars in the State with M. C. B. self-couplers, but wisely draws the line on cars that have deadwoods or buffers above or on each side of the draw-heads. He says: "The railroad managers are usually of the opinion that considerable hardship would result to railroad companies and shippers by excluding this class of cars from the State, and are disposed to think the danger resulting from their use is overestimated. The trainmen, regardless of the branch of train service in which they are employed, or the company employing them, are universally of the opinion that the cars are unusually dangerous, and that their use, unless equipped with automatic couplers, should be prohibited." If automatic couplers will reduce the number of fatal accidents, by all means let the most dangerous class of rolling stock be equipped first.

The N. Y., N. H. & H. have issued an order against the giving or receiving of presents between men employed on the road. That's business.

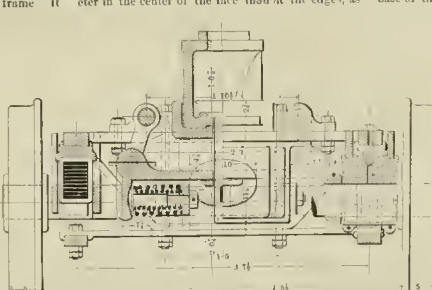
Locomotive Running Repairs.

By L. C. Hitchcock.

SPRINGS.

If a driving spring or engine truck spring is allowed to remain in an engine after the set is nearly gone, it is liable to cause serious damage to the wheel flange.

The theory has often been advanced that if one side of an engine is allowed to remain lower than the other side, the engine will crowd to the higher side, and for proof a belt running over a crowning pulley has been cited. This is an erroneous idea. It is true that a belt will run to the highest point on a pulley face, and this is the reason why some pulleys are made crowning, or left larger in diameter in the center of the face than at the edges, as this will insure the belt running in the center of the face. The principle involved in this case is altogether different from that in an engine with one side lower than the other. The belt principle I think can readily be understood by reference to Fig. 1 (page 2), which represents a belt passing over two pulleys, the face of one having been turned straight, and that of the other crowning; the representation is exaggerated, to better illustrate the principle. Now, the belt when placed at the edge of the crowning pulley will take the position shown by the heavy lines, and will not be in a straight line from one pulley to the other. The edge *A C* will be drawn tighter than the edge *B D*; the bearing *C D* is uniform, but the bearing at *A* is harder than at *B*. When the pulleys are turned on their axis it has a tendency to straighten the belt, and to make the bearing from *A* to *B* uniform; the consequence is that the belt is moved on the crowning pulley to the position indicated by the dotted lines.



A Semi-Rigid Truck.

The cause of an engine sometimes having one side lower than the other is that the weaker spring allows the engine to settle, and the spring on the opposite side, having more "life," raises the engine, consequently more weight is thrown on the weaker spring, and the engine has a tendency to move in that direction, which crowds the wheel flange against the rail. This principle is demonstrated by Fig. 2, which represents a weight, one side of which is raised by means of a lever; this throws a large proportion of the weight on the point *A*, and the weight has a tendency to move in the direction indicated by the arrow; in this case the lever represents the action of the "live" spring, and I think proves that an engine will crowd the wheel flange to the side which carries the weak spring. When a wheel flange begins to cut, it should have immediate attention, for when it is allowed to run in this manner until it is quite sharp, much more has to be turned from the face of the tire to entirely remove the groove worn by the rail at the base of the flange.

The most serious difficulty attending sharp wheel flanges is the liability of derailment, caused by the sharp flange "climbing" the rail at low joints, and at curves.

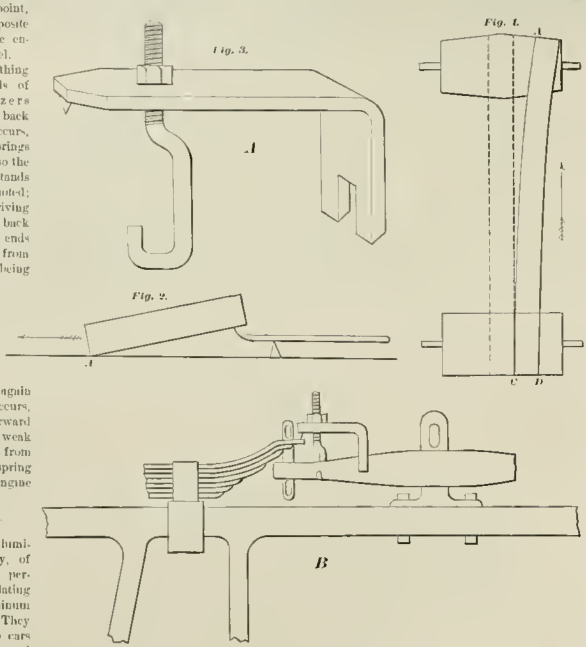
When springs show weakness by allowing the engine to settle, the best way to proceed is to remove the weak spring, and substitute either a new one or one which has been re-set, for when a spring begins to lose its set, clipping it up gives but temporary relief from the trouble, as it will generally straighten out again after the engine has made a trip or two. But it is not always possible to replace an old spring with a new one, as a sufficient number of new springs are not always kept in stock, and where it is necessary to clip driving springs, the old time U piece of iron may be placed between the upper surface of the spring and the hanger gib, and where this is to be done at the back end of the forward driving springs, or at the forward end of the back springs, it can quickly and easily be done by the use of the little arrangement shown in Fig. 3.

Take a piece of 1¼ x8" iron and cut a slot in the end wide enough to take the top edge of the equalizer, bend it as shown at *A*, then as close to the straight end as possible drill a 5/16" hole about ⅜" deep; into this insert a tempered steel pin having a sharp point; the end which contains this pin should be ⅝" wide by 1⅛" high. Then make a hook as shown at *A*, of 1¼ round iron, with straight part threaded; hook this under the equalizer, then slip the bent piece of flat iron over the top end and adjust it to the equalizer and spring as shown at *B*. By screwing down the nut the end of the spring will be lowered when the U piece can be inserted from the opposite side of the hanger from which the pin rests.

When weak engine truck springs allow the engine to settle too much in front, a flat iron ring made in halves is often put in the female center casting to raise the engine; this is not a good practice, as by this means the engine is only raised away from the truck, and the truck frame is as near the top of the truck boxes as it was before. In case it is really necessary to clip an engine truck spring, it should be done by placing the clip between the upper surface of the spring pocket and the lower surface of the truck frame; for in this way the distance between the truck frame and engine remains the same, and the truck frame is raised away from the top of the truck boxes.

When one side of the pilot of an eight-wheeled engine is very high from the rail, and the opposite side is very low, those in charge often order the truck spring on the lower side out, and a new one substituted. Now this may often be the case when neither spring is weak, the fault being the weakness of the back driving spring on the low side, and by replacing this with a good spring the engine is raised at that point, and lowered at the opposite forward point, and the engine is thus brought level.

It is quite a common thing to see the forward ends of driving spring equalizers much lower than the back ends. When this occurs, the forward driving springs should be examined; also the distance that the pilot stands from the rail should be noted; for, if the forward driving springs are weak, the back springs pull the back ends of the equalizers up, and from the fact of the fulcrum being in the center, the forward ends are lowered. Now, if the front end of the engine is too high, too much weight is thrown on the back driving springs, and the results described are again produced. When this occurs, substituting good forward driving springs for the weak ones, or removing clips from above the engine truck spring pockets, will bring the engine and equalizers level.



LOCOMOTIVE RUNNING REPAIRS.

The Harvey Filley Aluminum Plating Company, of Brooklyn, E. D., have perfected a process for plating any metal with aluminum or aluminum bronze. They are now fitting up two cars for the Manhattan elevated with all fittings plated with aluminum bronze, and one car for the Suburban Rapid Transit road in pure aluminum. This plating is white, like silver; will not peel off, and will not tarnish; requires no lacquer and no attention. If it will stand on cab fittings the firemen of the country will bless the inventors of the new process.

The gross receipts of the twenty-three principal railways in the United Kingdom for the week ending November 16, amounted, on 16,235¼ miles, to £1,329,895, and for the corresponding period of 1889, on 16,130¾ miles, to £1,305,473, an increase of 104½ miles, or 0.6 per cent., and an increase of £24,422, or 1 8 per cent.—London *Engineering*.

In round numbers the average length of line of railway in India worked last year was 15,382 miles, upon which the traffic was equivalent to 4,677 millions of passengers, and 3,644 millions of tons of goods carried one mile.

On the railways of India, during 1889, the highest average number of passengers carried in a passenger train was 315.63, on the Madras Railroad, and the smallest, 145.8, on the Indian Midland.

Air-brake Failures.

At the last meeting of the New York Railway Club, Robert A. Parke, Eastern representative of the Westinghouse Air-brake Company, read a paper on air-brake rigging, which pretty effectively covered the alleged causes of air-brake failure. He complimented the engineer some and censured him a good deal, and yet we believe it was deserved.

Engineers are not familiar enough with the details of braking and with the apparatus they handle. The elements of perfect braking are to be found in the automatic air-brake apparatus. Failure can be traced to bad equipment, lack of attention or faulty handling.

The management is responsible for not having driver brakes in constant service, for not using shoes on twelve wheels instead of eight on twelve-wheeled cars, and for lack of attention, inspection and repairs. But the engineer is to blame every time he makes out an accident report saying "the air-brake failed," without stating how it failed, and why. If it failed to hold because he kept applying and releasing it so often near the final stop that the pressure was reduced below a safe pressure for effective work, it was his fault, not the brake, and he should say so. By so doing he commands the respect of his officers, and proves that he has learned a lesson. If the trouble is caused by the brake's failing to hold, and on investigation he finds some of the pistons at full stroke, the fault is lack of attention; let the fault be placed where it belongs.

Every road that attends to its brakes, clean and oil the triple valves once a year at least, and oil the air cylinder every four or six months, when they don't, they invite disaster.

The most trouble comes from slack, and the neglect to take it up. There are travel indicators that tell how many inches the piston moves. These are handy for the car repairer, but if he won't look at the piston he won't pay much more attention to indicators. There are some forms of brake rig that automatically take up the slack when it exceeds a certain amount. Westinghouse should not rest till this feature is added to his brake.

Engineers and firemen had better study the brake from the ground up. Simply saying the "brake failed," will not do. Say *why* it failed. If the cause was the fault of the road's inspection and management, the brake company will sustain you, and if you are discharged for knowing something, or for telling the truth, it will be a recommend for you. Never say it "failed" and you don't know why.

Manager J. E. Chollinger, of the Philadelphia Car Service Association, has issued a report of the operations of the bureau in November. The number of freight cars arriving in the city during the month was 52,617, and the average detention was 1.46 days. Only 3,244 cars were delayed over forty-eight hours, and the detention in these cases was only 2.56 days. The association has been in operation only three months, since September 1st, and in this time 157,320 cars have been handled. Shippers are becoming used to the new arrangement and the efficiency of the organization is increasing. In September the average detention was 1.68 days, and in October it was 1.55 days, and in November it had been reduced to 1.46 days. The number of cars detained over 48 hours has constantly decreased. Of the 157,510 cars handled in the three months, 87,899 belonged to the Pennsylvania and affiliated roads, 59,688 to the Reading, 5,579 to the Wilmington & Northern, and 4,354 to the Baltimore & Ohio.—*Ex.*

The new broad gauge equipment of the Denver & Rio Grande will be cheap power to keep up. There will be the fewest possible patterns and pieces to be kept in stock for repairs. The freight engines are all consolidations of one size, and alike, except the numbers. The passenger engines are ten-wheelers, while the switchers have the passenger engines boiler and cylinders, and the freight engines wheels. All are of the Baldwin build. Mr. Sample has been at the head of the mechanical department of this road from its early childhood, and while the old narrow gauge system climbed the Rocky Mountains time and again, furnishing the very hardest service for motive power, he has kept it up at a remarkably low rate, mostly due to a standard sized engine in the main, and avoiding the building of odd or the buying of strange engines. All the narrow gauges were Baldwins except twenty eight Grants. The broad gauge equipment from pilot to tail lights is as fine and as modern as the best on the continent.

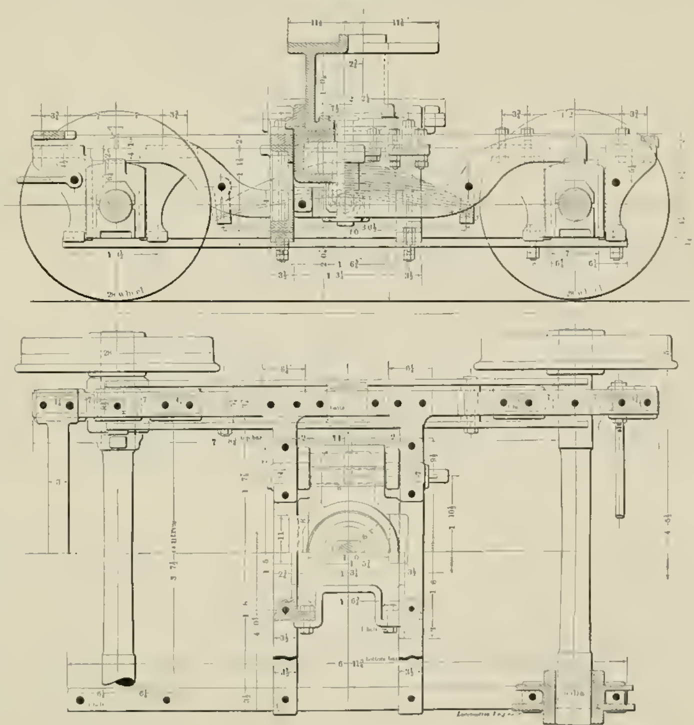
We have a letter from a young man with the firing fever. He modestly describes himself thus: "I am 20 years old, good-looking, of fine address, good parentage, sober, honest, truthful, no bad habits; I may say without a fault or the thought of a fault; do you think there is a place for me on the great iron horse?" We answered him by letter thus: No, honestly, we don't; we don't think there is a place for you on earth—heaven is your home.

The Chicago & West Michigan have a traveling yard master. Few men wear that title in this country.

In locomotive shops it is considered a very fair average of drawing-room force where there is one draftsman for every hundred men employed.

Cause and Effect.

All railroad officers kick about the men trying to manage the road when they resist their right to discharge a man without good and sufficient reasons, which must be stated. Perhaps things are not just as they ought to be, but all of them can have the satisfaction, if it is a satisfaction, of remembering that it has been the injustice and inhumanity of themselves or other railroad officials that have brought the arbitrary demands about. For years it has been customary to discharge somebody for every accident of note on the road; the official in charge must clear his own skirts of the charge of faults of operating, the road of mismanagement; it satisfies the public and prevents comment and perhaps lawsuits, stating, "that upon investigation it is found that Conductor A. and Engineer B. caused the wreck at C." Engineer B. was killed in the wreck, and as it was his fault his widow does not sue; Conductor A. goes away branded, and the official speaks out. Had railroad officials always been decently fair the men would never have organized to defend themselves, as there would have been no cause. But men always go farther than is right in a case of this kind; they feel that interest is due them, and try to make a right out of two wrongs. The unreasonable demands they then make only tend to harden the higher officials against them, until the employes of a road resemble two armies facing each other, a battle being avoided only because each is afraid the other is the stronger. One army is composed of the rank and file demanding better rations, and often offering poor allegiance to the flag for it, the other is composed entirely of officers, who, however able, have the common fault that if a fellow officer becomes a martinet they defend and imitate him instead of courtmartialing him out of the army entirely. Both sides need to use more justice in dealing with the other, they need to "get together" They should be allies, not enemies.



SEMI-RIGID TRUCK

Federation of all men in train service seems to be an established fact. Enough are now enrolled to leave the strictly neutral and "we only" orders in a minority. When strikes cannot be hatched in every hotbed, but must go through the supreme council cooler, there will be fewer of 'em come out alive.

On September 20, 1850, the national legislature made the first land grant to aid a railroad, this was the Mobile & Ohio railroad that had been chartered in 1848.

Get In.

General foremen of railroad shops are entitled to membership in the M. M. Association, and should see to it that their names are enrolled now. Your M. M will recommend you if he is large enough for his place, if not, he may refuse for fear some one will find out that he don't know more than anybody and everybody else on the road. If you are worthy of being general foreman or division master mechanic you are worthy of his endorsement for membership in an association that is for the benefit of your road, your superior officer, and, incidentally, yourself. You don't have to attend a meeting to become a member. You can be enrolled by corresponding with the secretary.

There is a marked tendency toward huge consolidations of business and manufacturing enterprises, of which recent railroad stock purchases are only a small indication. Within a month upward of thirty mower and reaper establishments have been consolidated on a basis of $35,000,000 capital and upward of twenty threshing machine factories on a basis of $20,000,000. Now we hear of a proposition to unite all the lead and silver smelting concerns, for which not less than $35,000,000 capitalization would be required. If the craze for consolidation continues there will presently be nothing left to consolidate. —*New York Press*

Railroads are consolidating in the same way and for the same purpose, *i. e.*, to better their condition. If it is good for them it is good for the men.

At a recent discussion on power plants before the National Electric Light Association, a motto was proposed that would come in first-class for those in charge of locomotives and locomotive firemen. It was "Feed the flames little, feed the fireman well."

Why Piston Rods Break.

In nine cases out of ten where piston rods are broken it is in the taper fit at crosshead, generally through the keyway. An examination at the fracture will generally show that the fit was only at the end of the taper and at the shoulder, caused by driving the key hard enough to stretch the material in the rod at the weakest point, which is where the keyway is located. The crosshead key has so slight a taper that the rod can be broken by driving it too hard. In driving a crosshead key put a block of wood on the piston head end and strike it with a sledge at the moment the key is struck with a soft hammer, and don't strike the key too hard or too often.

The Melbourne *Leader* states that the conference of railway managers, invited to meet at the instance of the South Australian government, may be regarded as the opening incident of a battle of the gauges At the present time there are three different gauges very widely spread on the Australian continent. Of the 3 foot 6 inch gauge there are 3,221 miles, of the 5 foot 3 inch gauge 2,854 miles, and there are upwards of 2,000 miles of the 4 foot 8½ inch gauge in New South Wales During the recent strike the break of gauge between New South Wales and Victoria has been a great disadvantage. —*Engineering* (Eng)

William D. Robinson, founder of the Brotherhood of Locomotive Engineers, and its first grand chief, died on November 8th, of cancer of the stomach. Father Robinson was not always treated as a parent should be by those who enjoyed the privileges he suffered to establish for them.

Compound Locomotive Extraordinary.

The Laredo (Tex.) *Times* says The Mexican National road is expecting every day from the Baldwin Locomotive Works one of the latest pattern compound engines, with three steam cylinders. The third cylinder is to be used for setting brakes, and it is claimed that the heaviest locomotive running at full speed can be "choked" down to a full stop at a distance of 40 feet

The Baldwin works built over 900 locomotives last year.

A modern vestibuled train of six cars is worth in the neighborhood of $100,000—handle 'em easy.

The New-old and the Old-new.

BY W. DE SANNO.

Some months ago mention was made in THE LOCOMOTIVE ENGINEER that iron flags were being used on locomotives. Away back in the early days, iron flags, as signals, were carried on the engines of the old State road (Philadelphia & Columbia), now Philadelphia division of the P. R. R. At that time freight trains were not run at night, or by time card.

Now some of the modern railroaders will say the road could not be worked without some regulation in the running of freight trains, but please remember it was a *double* track road. At the same time we do not claim that the boys did not get together sometimes. The writer has seen the little four-wheeled freight cars of that day piled up like so many packing-boxes, in cases where the following train had found them on a curve. But about those iron flags. They were painted in imitation of the American flag, with the words, "last train" across the end next the staff.

It was useless for any one to try for a ride on a freight train, or for individuals to try to get cars off that day, if the flag had passed. When a flag was not at hand, a stick of wood, with a lot of rags tied around the top, or an old broom stuck in the bumber beam was used; either one was an infallible sign that no more trains would pass that day. We are now speaking of freight trains only. Passenger trains ran on time, unless they were blocked, not by a flag, but by virtue of overhauling one or more freight trains going in the same direction, and on the time of the passenger train.

It was not an unusual thing for two or three freight trains to come into a station, the one pushing the other, with a passenger train bringing up the rear, each little engine doing her best and their valves all on a different key, good, bad and indifferent. How interesting it would be, knowing what we do of modern railroading, if we could go back and see the old-time way of doing things. Passenger trains would run around freight trains at the first crossing or switch they came to.

What interest the writer, as a boy, used to take watching mechanics setting valves in the old times. The engineers would often do the work themselves, but in either case it was done with the steam chest cover off, and a wooden wedge stuck down in the opening to divide the lead. While watching these proceedings the thought did not occur that some day I would take a train and do the same work, with nothing but two little marks on the valve stem as a guide, engine hot, and covers on—one was the old, the other the new way of doing the same thing.

Mention is also made that some roads are putting on plain sheet iron jackets, and painting them. In the early days, boilers were often lagged with beaded lagging, the strips painted alternately black and green, and then varnished, and, with a clean brass band around, the effect was pleasing. Afterwards sheet-iron was put over the lagging, and the iron painted. Some engines had the jacket painted a bright red; have seen the old-fashioned diamond stack painted red. Other roads talk of taking off the pilots, or cow-catcher. The old timers had none. Verily history is repeating itself. In the old time engines, lifting pipes (petticoats) were not used, the exhaust pipes running up into the base of the stack. It is useless to say that the engines would not clean themselves, and it was the fireman's duty to clean out the front end at all water stations. The petticoat was introduced, and the exhaust pipes shortened, with good results. Now comes extension fronts, no petticoats, and the exhaust pipes are creeping up again.

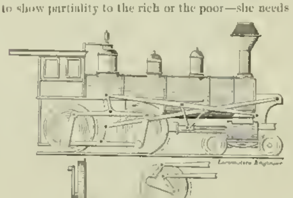
Telegraph for the Fool-killer.

A man signing himself Howard in the New York *Press* gets off the following in regard to the sentence of the semi-religio-society forger Smith:

Judge Fitzgerald thinks that it is worse for an intelligent man of education, high social and business standing to commit a crime than for one who is poor and without the advantages possessed by the other, whereupon he sentences such a one to seventeen years at hard labor in the State prison. The judge would have us infer that he would have sentenced a poorer man less severely.

That's nonsense. The man of refinement, of education, of previous high social and business standing, will suffer more in seventeen days than the other kind of man would suffer in seventeen years. The one falls from wealth and station into disgrace; the other not only doesn't fall from anything, but is pulled up from hunger, from want, and given all that he cares for in life, released from worry with enough to eat and drink, comfortable clothing, a roof over his head, and not one-half the work he would have to perform if he were fighting the world for his bread and butter. Any other kind of talk is clap-trap demagoguery, pure and undefiled, and of the Tammany stripe at that.

That kind of teaching suits some people, and is a good kind to widen the breach and cause trouble; it is what we may well imagine might have been taught by the *rich* and *good* (?) people before the fall of the Roman republic, and what we know was taught by the refined and sensitive (?) demagogues of France that maddened the poorer classes to insist so cruelly upon extermination when they sat in judgment as the commune. The writer of this item assumes that "the poor" are ex convicts anyhow, without hope, ambition, hardly without life—better off in prison. A poor man has no fine feelings; he will not suffer mentally because his family are deprived of his support and company; he is an animal that only knows that he is, and will lay down to sleep when his stomach is filled—unless goaded up to work by those that know what is good for him. Smith was a rich man, a pillar of the church and Sunday-school, a society man, but a robber, a forger, and a thief who carried on his operations for years, hiding them under his cloak of heavenly groans and saintly smiles. America needs no judges to show partiality to the rich or the poor—she needs justice—but it will take a long time for the poor man's judge to get even with the verdicts given for the rich, because they were rich.



AN AWFUL EXAMPLE.

An Awful Example.

William E. Lockwood, the hammer-blow man, has, we fear, great things to answer for in the eternal subsequently. He has said so much about the awful destruction caused by the counterbalance of ordinary locomotives, that half the real made a purpose inventors are at work devising schemes to do away with counterbalances.

Look at this awful example, recently patented by J. M. McMaster, of Rochester, N. Y. This is only one of many.

Lockwood is not a young man, and we sincerely hope that he will see the error of his ways, and repent before it is everlastingly too late. Just think how his children would feel to stand beside a railroad track, and see one of these button-hole attachments go by, and have to think that their father was in any way the instigator of such a criminal abortion of mechanics.

It was announced last month that the master mechanics and the master car builders would hold their next meeting in New York City instead of Cape May. But the executive committees of both associations now announce that the next meeting will be at Cape May, commencing on June 9. Headquarters will be at the Stockton Hotel.

Baldwins are building twenty-seven locomotives for the government of New South Wales, Australia.

The gross earnings of the Union Pacific are about $4,000,000 per month.

Average Pay of Railroad Men.

Carroll D. Wright, Commissioner of Labor, has recently issued his report for 1889, which deals exclusively with railroads. He has taken considerable pains to get the average daily wages of the principal railroad workers in the operative field, compiled from the actual pay rolls, which, reduced to the simplest shape, stands about as follows.

AVERAGE DAILY RATE OF WAGES.

Occupation.	New England.	New York	Georgia	Ohio.
Brakemen	$1.80	$1.73	$1.26	$1.86½
Conductors	2.82	2.54	2.58½	2.61½
Engineers	3.32½	3.15	2.91	3.07½
Firemen	1.69	1.72	1.29½	1.79½
Laborers	1.51	1.23½	.98	1.21½
Tel operators....	1.42½	1.31½	1.50½	1.47
Switchmen	1.78	1.27	1.11	1.63½

RATE OF WAGES—CONTINUED.

Occupation.	Texas	Northwest States	Pacific States.	Average of all.
Brakemen ...	$1.95	$1.75½	$1.96	$1.78
Conductors	2.92½	2.85½	3.00	2.63
Engineers	3.53	2.79½		3.22½
Firemen.	2.04	1.90½		1.79½
Laborers	1.21	1.30	1.87½	1.36
Tel. operators	1.67½	1.38½	2.00½	1.43½
Switchmen .	2.30½	2.15½	2.20	1.60½

It's terrible how roads can stand to pay such wages to men who do nothing but risk their necks, rack their nerves and benumb their brains to get the trains over the roads. It's about time that the fellows that know everything about running railroads got together and fixed the pay of all the hired hands at ninety cents a day—a man can live on ninety cents a day if frugal, look at the Chinese—or else abolish trainmen altogether. Just think of it, presidents of railroads in the good State of New York only getting from $25,000 to $50,000 per year, freight agents only getting $10,000 to $15,000, and engineers sapping the life out of the revenue of the roads at the scandalous rate of $3.15 a day. Horrible, simply horrible.

A Play on Initials.

In the early days of the road, the trainmen changed, for their own use, the reading of the Delaware, Lackawanna and Western to Dam Long & Windy. After the road took in the Morris & Essex the passengers dubbed it the Delay, Linger & Wait. It is more than likely that both had good cause for their christening.

There is a great strike of railroad men in Scotland. The roads are completely tied up. Many factories, gas works, etc., are shut down for the want of coal. The great shipyards of the Clyde are at a standstill and several lines of ocean steamers have ceased to run. There is great privation among the men, but they propose to win and will not compromise.

W. J. Rice, who has been chief clerk of the motive power department of the R. & D. at Marion, N. C., for the past five years, has been appointed chief clerk of the motive power department of the G., F. & S. at Macon, Ga.

Work on the Pike's Peak ladder road has been given up for the season, and the two little dromedary engines put under cover until spring.

Over forty million passengers went over the Brooklyn bridge last year. The fare is one cent to walk, and three cents to ride.

At the G. T. shops at Montreal they saw off flues with a circular saw, but they heat the tube red-hot first.

A Cheap Dynamometer Car.

The engravings shown herewith illustrate a very efficient and cheaply made dynamometer car, recently constructed on the A., T. & S. F., under Mr Player's instructions.

As will be seen, it is in the shape of an attachment to a flat car, and can be taken off when so desired. No particular description is necessary; the dynamometer is simply a huge spring balance, the spring used being a driving spring tested for depression. The spring is held in a harness as shown, and a lever multiplies the movement, and registers the amount of pull on the dial. This instrument works nicely in service, and its register agrees with the amount of work shown by the engine indicator, but as the indicator accounts for *all* the work done in moving a train — which includes overcoming the friction of the locomotive and tender —it gives the *gross* power required, while the dynamometer registers the *net* or effective power of the engine.

Engineers and other railroad men who have not studied very deeply into the science of their business are always surprised to find how little actual pull a locomotive can give at its draw-bar. An eight-wheeler 18x24 does exceptionally well when she exerts a pull of 12,000 pounds on her train.

The dynamometer is the true way to test a locomotive's work, but offers no advice about remedying defects such as the indicator does—unless it be to point out the need of more adhesion.

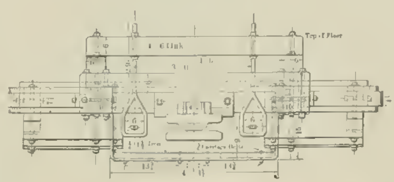
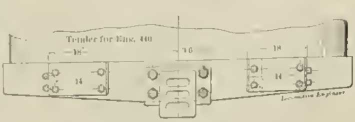
PLAN



END VIEW



END VIEW OF TENDER
SHOWING LOCATION OF BUFFER BLOCKS.

We have received from Pedrick & Ayer, Philadelphia, a very handsome and elaborate catalogue of their milling machine, open side planer and cylinder boring bars; also a framed picture of their new shop. The catalogue is the best one we have seen this year, and the picture of the shop is as natural as life, but we do wish P. & A. would take that little P. & R. switch engine, shown in the foreground, into the shop and make a few changes. The axles are bent, whistle is on the sand-box, and the bell on dome, where pop ought to be, and there is no valve gear at all—it ought to be fixed soon, or the street car horses, waiting for it to pull a train off the crossing, will starve to death.

Talking to a manufacturer lately about the piece-work system, we asked him where he thought he saved by it. "Everywhere," he replied. "I was opposed to piece-work myself until this general foreman came to me. He wanted to introduce it, but I objected. He finally offered to take as his salary the time spent in water closets by the men or the machinists' time that was spent going to and from and waiting upon the tool dresser. This set me to thinking, and I put a boy to check up time spent in the closet by the men in the shop. They averaged about twenty minutes each per day—went there to loaf and smoke. I had 300 men then, and paid some of them four dollars; but at twenty-five cents per hour this time, which is 100 hours per day, amounts to $25 per day, or $650 per month of 26 days. That is all saved in the piece work plan."

In the Grand Trunk yard at Montreal we recently noticed a locomotive that had come in on one side on account of a broken piston. She had solid side rods, and when the main rod was taken down there was nothing to keep the side rod from slopping around over the whole length of the pin, and the engineer had sawed short blocks of wood and tied them around the pin on the main rod bearing. An old side rod bushing, carried in the tool-box, would be handy to slip on to the pin in a case of that kind, and would save time.

The Reading road have placed an order for 5,050 freight cars with the Pullman Co. They will cost $2,500,000, and be paid for on the installment plan. A big order.

The Interstate Commission has sent circulars to railroad officers and organizations of employes asking information on the treatment of employes. Among the points covered are: Insurance and guarantee funds, accommodations furnished the men when away from home, technical education in the shops, possibilities of promotion, and special rules as to the competency of trainmen.—*Ex.*

What the Interstate Commission want to be doing is to investigate, show up and demand a change in the hours that men are obliged to work on locomotives. Forty-eight hours of continuous duty is not uncommon, and twenty-four is a regular thing on many roads. This alone is the cause of many accidents, is a constant menace to life, and must be stopped.

The proprietor of the *National Car and Locomotive Builder* recently presented Editor Angus Sinclair with a gold watch. When Sinclair had that old penitentiary-escapement in a nickel case that he used to run engine with, he never wanted to compare time with us, and if a man asked him the time on the street he looked at the sun and guessed, but now it's different. A man with a new yellow watch always feels constrained to haul it out and look at it every four minutes, to be sure it's going and is there.

The Gt. Northern, formerly the St. P., M. & M., are building track from Fairhaven, Washington, toward Westminster, B. C., which, when done, will be known as the coast extension of the Gt. Northern. Engineer P. E. Adams was sent from the main line over the C. P. to Westminster, where the engine and one car were placed on a barge and towed to Fairhaven, on Puget Sound. Now she is slowly working her way out of the wilderness toward the British possessions.

It is getting to be a pretty regular thing to see accounts of locomotive boiler explosions. During the past month nearly a dozen have gone up. The Reading lost one of their Wooton's—blew up in the roundhouse in Philadelphia. The Lehigh Valley have recently lost two. D., L. & W. are "in it," as is also the Fitchburg, though not within the month. Boilers that have been in use on locomotives twenty years and more are not fit to carry high pressures. In a recent meeting of the M. M. Association, a well known superintendent of M. P. said that he had boilers that were covered with asbestos mortar that had not been removed in sixteen years. Some grand juries would make a road squirm on that, in case of an explosion. Better and more frequent examinations are needed on most roads.

Fireman Martin Conniff, of Louisville, Ky., recently fell from the headlight when cleaning, and was impaled upon a flag-staff on the pilot. He died in great agony. Look out for these traps, and don't tolerate any flag-staff with spears and battle axes on top to make them pretty.

The First Successful Screw Propeller.

The screw propeller was first proposed by Hooke, 1680, and between that time and 1835 many propositions to use, and several patents were issued, in different countries.

Col John Stevens, of Hoboken, N J, experimented with a screw in the North River as early as 1804

In 1836 Capt. John Ericsson and Francis P. Smith, of Hendon, England, brought out their screw propeller, and by their energy and ability forced it upon the attention of the world and proved its merits.

When Ericsson exhibited his little screw-propelled boat in the River Thames, in 1838 one of the interested spectators was Commodore Robert Stockton, of the United States Navy. At that time Commodore Stockton was at the head of the New Jersey canals, and thought he saw in the screw the future tow horse of America.

Before coming home Stockton ordered a boat that was to be seventy feet long and draw five feet of water This boat was built under Ericsson's direction, and came to America sloop rigged, in 1839, being the first iron hull to cross the Atlantic.

This boat had a double screw, one running on a hollow shaft, the second on a shaft extending through the tubular one, the wheels running in opposite directions. This plan called for complication in the engine, and endless trouble in many ways.

It was found that, instead of drawing five feet of water, the boat drew seven, and she would not go up the canals. This so disgusted Commodore Stockton that he had her name changed to "New Jersey"—she originally bore his name—and sent her to Philadelphia to tow canal boats from the Schuylkill around to the city front

The rudder was of iron, in two pieces, one above, the other below the double shaft, and was fastened to the stern post, the shafts passing through the connecting bars of the upper and lower pieces of the rudder, and the boat was, in consequence, very hard to steer, doing damage by running into other boats and the piers—for most of which the screw was blamed. She was so unmanageable that it was customary to tie her up to a wharf and let the tide turn her around.

After a year's service the boat was turned over to Mr Isaac Dripps, the superintendent of motive power of the Camden & Amboy (now Pennsylvania) road, with instructions to fix her so that something could be done with her

As she was designed expressly for towing, the engine was a powerful one, for a boat of her dimensions, having two cylinders, sixteen inches in diameter, and of eighteen-inch stroke Mr. Dripps therefore designed and built the single screw propeller, as shown in our engraving, which was made direct from a photograph of a small model made from the original drawings. There was no former practice to guide the designer of this screw, he discarded the double screw of Ericsson's design, and made a single one on his own ideas As will be seen, it had six blades, which were very wide at the circumference and narrow at the hub. Having sufficient engine power at his command, Mr. Dripps, for this reason, gave the blades as large a surface to act on the water as the form of screw would allow.

Believing that the action of the propeller would tend to crowd the water away or throw it out circumferentially, he cast a projecting rib on the front edge of each blade, as shown, to enable the screw to get a firmer hold upon the water.

The blades were cast separate from the hub, for the purpose of cheap renewal in case of breakage, and the ends were let into a recess in the hub and held against a flange by bolts. The pull of the blade in the water was against this rib without putting strain upon the bolts. There is no doubt that this screw was the first perfect single screw propeller (true screw) ever built in this or any other country.

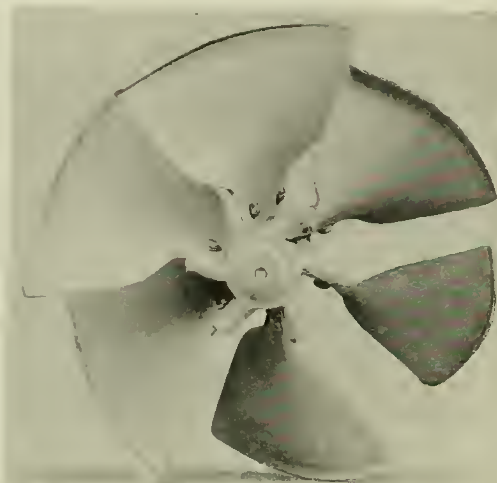
The rudder was placed behind the screw When these alterations were completed, and the boat tested, the new arrangements worked very satisfactorily The boat towed much stronger, ran faster, and the steering was perfect.

This boat and the screw were in use for many years in the harbors of New York and Philadelphia, and the wheel was only broken up at South Amboy, N J., a few years ago.

It is too bad that this specimen was not preserved in the National Museum, and it is equally fortunate that Mr. Dripps has kept his sketches and drawings all these years.

The editor of this paper is under obligations to Mr. Dripps for the use of the patterns, from which a very handsome model in brass was made for our museum by Fred H. Colvio, tool maker of the Rue Manufacturing Company, Philadelphia.

Isaac Dripps was the first man to handle the locomotive "John Bull" on her arrival in America He was the first American railway master mechanic, superintendent of one of the first locomotive works on the continent, and for many years at the head of the motive power department of the P., Ft. W & C., and the P. R. R. He was with the American locomotive from its birth up to its present efficient design, and had much to do with its ultimate individuality



THE FIRST SINGLE SCREW PROPELLER.

Though somewhat remarkable, yet to this same man should be conceded, and justly so, as shown above, the honor of designing and constructing the first successful single screw propeller—a device that has revolutionized the ocean carrying trade of the world—practically that now in use. He was not the first, it is true, to conceive the idea of such an instrument as a marine propeller, but in applying it in a simpler and more efficient form, and adapting it to operate *in front* of the rudder, he stripped the ideas previously conceived of it of some illusions, among them the belief that a single screw would list the boat, and, in view of what he accomplished, was the first to practically solve the problem of successful marine screw propulsion. His screw (designed for a tow-boat) had more blades, with more pitch, than modern practice, keeping step with modern improvements in engines and hulls, has occasion to use, but it was certainly a most splendid success as a first attempt, in practically solving the problem of screw propulsion, and one among many of the substantial improvements that should forever stand to the credit of the first American railroad master mechanic and that modest gentleman, Isaac Dripps.

Santa Fe Notes.

There used to be a tradition on the Santa Fe that course netting could not be used without setting fires, and that brick arches would not work—because they had been tried The new management of the motive power put in coarse netting at once, and opened the nozzles so as not to throw so much fire, before, the nozzles had to be pinched in order to force the gases and cinders through the fine netting. Brick arches seem to work all right now, too. By substituting inside clearance for inside lap the indicator shows a very large increase of power on the 19-inch cylinders

They have been getting up a new smoke-preventing device that has some novel features and will be covered with a patent. It is the well-known Clark jet, which is set in operation by the closing of the throttle; this action also applies the blower; when the engine is at work the admission of air is maintained by the suction of the exhaust; when shut off the jet starts automatically. It makes the engine smokeless at stations.

The Topeka shop has a large capacity, but the method of handling work is bad and the cost of repairs altogether too high—it has been pretty close to five cents per mile for repairs alone.

Mr Player is systematizing matters and getting more work done. Twenty to twenty-three engines rebuilt per month calls for lots of work, the men being pretty thick. Mr. Player is investigating the plan of piece-work, with a view to starting it in the shop, believing that he will do more work, can employ better men and pay them more wages. The piece-work plan pays each man for what he does, not what he is supposed to do. Engineers have to make their miles for their pay and can work little or much, as they feel; it is probable that machinists will have to do the same.

Mr. Player is also bettering the oil consumption. But ten miles per pint of lubricating oil was the average. This was not due to the engineers, who were anxious to do better, but to the want of any system whatever in the use of oil. The oil was not charged to the engineer, but to the engine, thus creating no individual sense of responsibility. Oil was as free as water, never locked up on an engine, which meant wiping and firing up with it. Two gallons per engine trip for tender-boxes alone was allowable. Mr. Player has indeed a big job on his hands, but he is the man for the emergency. The success he is having in his work is in no small measure due to the respect and friendship he inspires in his men He is honest and just and always has time to hear any one, be he a sup't, apprentice or a drummer.

Mr Player has done something very few new officials ever accomplished—got the good will of the men from the start. He sits down sudden and hard on unfair acts of officious underlings that makes the men respect him. The engineers already swear by him, and to a man seem anxious to help him further his plans in the development of better and more economical service.

The Strong is laid up and will be rebuilt into a compound. Constant leaks in the fire-box, caused by poor circulation, was her worst disease, but her valve motion developed enough lost motion, in a week's work, that an eighth of an inch lead was changed to one-sixteenth inch of blindness. When she goes out again she will be a 10 wheeled compound with plain fire-box and valve gear.

Greased Track.

"Speaking of grease," said the old-timer, as he dug a chunk of sausage out of his beard at our suggestion—"speaking of grease reminds me of a little gob of experience quite some time back in my wild career.

"I allus owned a crack ingine, crack for speed, steam, or something—have had 'em with cracked fire-box when I couldn't do better. Well, on the 'casion whereof I'm speaking I was sole owner of the 'Sebenteen,' and she was noted for shackling onto a row of freight cars and going to the other end of the division a little faster and slicker than anything else on the road, though there was plenty jest like her. When the 'Sebenteen' was new she had a cracked spider, which caused her to cut her left cylinder bad, and they bored a half inch out of 'em both before she were a week old, but, bless you, young man, that happened at the far end of the system, and nary a water biler but me knowed of it on our end, and I jist heard about it accidental like.

"The 'Sebenteen,' 'Eighteen,' and 'Nineteen' all came new together, was broke in and sent to us, and Bill Karr, John Dixson and me were in for 'em. Karr an' Dixson was older'n me, and had their pick, leaving me the 'Sebenteen.'

"Then to have her noted far and near for 'git' made 'em mad. I had a bragging conductor and a fireman that allus added 40 per cent. to every story he told of her speed or startin' power, but I naturally cling to the truth, bein' particular, however, to mention her virtues around where Karr and Dixson was.

"They declared I had monkeyed with the pops and falsified the gauge, and had the old man investigate—but I was honest. Then they settled down to saying the con. and dispatcher was in cahoots to down 'em by queering the register and train sheet, and believing it was all lie anyway.

"But one day all them three ingins was ordered out on three sections of 26—our regular merchandise train.

"The 'Sebenteen' was ahead, each scrap had 14 loads, and I knowed right away that it was to be a case of 'git thar,' every man doin' his darndest. To make matters worse, it was Sunday, and few trains on the line to bother us.

"I lit out first with red rags up for Karr, and his caboose was about thirty feet ahead of Dixson's mill.

"I got the 'Sebenteen' to making every turn in her before I dast to look back, but when I did Karr was there, and so was Dix. I dropped her down a notch, but she seemed to lose on it, and the fireboy was not keeping up with the stack. Then I hooked her back and tried to take the throttle lever out in the tank, but Karr whistled me ahead, and finally I got her in her regular notch with about half throttle—just where she could do her prettiest.

"The 'Sebenteen's' big cylinders would tell on the up-hill pulls, but she couldn't get to the foot any sooner than the other fellows—a stone will fall down a well.

"When I stopped for water they tooted their whistles to imitate a rooster. When I stopped half over the division for coal, Karr had to pull his ingine over to keep from hittin' my caboose, and both on 'em whistled fit to bust their bilers. The last half of the road was mostly up hill, and I counted on gettin' away from these fellers, but 25 miles were made with them within sight.

"After this we got ahead, gained steady, and Mike, the 'Sebenteen' and me were shakin' hands and yelling like konkerin' heroes.

"Ten miles from the terminal they were out of sight, and in five miles more we lost sight of their smoke.

"After gittin' in we got the engine turned, and Mike and me washed up and set down on the eatin'-house steps with a toothpick in our mugs, each tryin' to appear like he had been there a week or ten days.

"It was two hours before their trains got in, and when me and Mike saw Karr and Dixon coming we laffed fit to bust.

"Two madder men you never see. They dared me to come off the stoop while they licked me, said I was a 'nordinary low-down whelp to resort to such tricks to keep up the reputation of the worst old scrap on the road, &c., &c.

"I couldn't git a word in edgewais, and I don't know how much longer it would have been before I would have got licked—for either of 'em was bigger nor me—but just here we heard the darndest noise up in the yard—the pony was slippin' 80 mile an hour, krashed into some cars, come back, still a slippin', and run off a switch. We all run up there.

"Well, then it was soon explained—the track was greased!

"The last car on my train was loaded with oil in barrels. They was piled up three deep at each end, and one of 'em fell down, busted, and let the grease run through the doorin' onto the track, and so to the rails.

"Those follerin engines like to slipped their innards out when they struck it, and run out of sand in less than no time, had to stop and hunt ant-heaps and all that. Both Karr and Dixson thought I greased the track back of my ingine to do 'em up, and come near doin' me up for it.

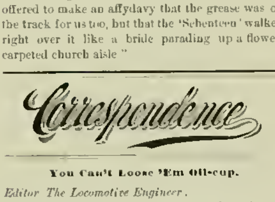
"But I got even with 'em. Mike and me both offered to make an affydavy that the grease was on the track for us too, but that the 'Sebenteen' walked right over it like a bride parading up a flower carpeted church aisle."

Correspondence

You Can't Loose 'Em Oil-cup.

Editor The Locomotive Engineer :

I send you a sketch relative to the fastening of rod-cups, as this is an item of importance in engine supplies—and a large one, if the immense pile of



crippled oil cups that are lying around any shop be any indication.

The great difficulty, as I see it, is that constant screwing up by the engineer, gradually pulls the stud down in the strap, and by slowly yielding to the immense strain separates the metal at the junction of the cup.

The plan I suggest would certainly obviate this, the idea may be old, but there is no possible reason why it would not effect the desired point; the tap screws should be of iron, and the whole may be fitted to either old or new straps. Of course, it is obvious that special shape may be given to the base, to conform to circular ends.

Denver, Col. L. C. SHARP.

Cabs.

Editor The Locomotive Engineer :

There are cabs and cabs. Just now I have got one that would make a good hen-coop or a grape arbor. Last summer, when it was ninety in the shade, I had a new engine with an air-tight sweat box on the back end of the boiler that ought to have been used in the blacksmith shop for an annealing-box. Our company are in season—hot cabs for hot weather, cold cabs for cold—why not? It beats thunder that I can't get locomotive builders, or at least our master mechanic, to see what is wanted in the cab line, and build cabs—not hen-coops or coffins. Cabs are supposed to be put on locomotives for the protection and comfort of the engineer and fireman, nothing else, and a little intelligent study will show that there is no need to attempt to imitate a house, a church or a corn-crib.

In the first place, every cab should be high enough, so that a man can stand up on the running board without ducking his head. The front ought to be air tight when closed, and means provided for ventilation and light, the latter to be admitted in the right place, and excluded at the wrong.

No front door or window ought to open *in*, or slide—you can't keep 'em tight if they do.

The front door should be hinged on front of cab nearest boiler, and swing from the corner *out*; this will admit air, and throw most of the cinders on the running board, and a rubber batten on the outside will keep it air-tight when a head wind strikes it—the inside opening door can never be kept tight. When it is partly open it throws all the cinders over on the man on the opposite side of the cab, and it is hard to get out of in an emergency. The front windows ought to be as large as possible, hinged at the top and swing out and up—less cinders and more air. The pressure of head wind will tend to tighten them, and they will not rattle.

There never ought to be glass in the front pane of the side of cab, a board panel is better; you can see ahead better at night with your head out side, as the dark panel does not allow light from the gauge lamp or fire door to shine in your face; if you have glass already, paint it over. The back side sash ought to be held open or shut by a stiff spring, to prevent wear and rattle.

Below the front door there should be a slide or small door to admit air, and the joint between the boiler and cab should be tight and the inaccessible corners filled with wooden blocks to facilitate cleaning out. In winter the reverse lever slot in deck should be covered with a slide—a wood or iron one may freeze fast, and a strong wind will lift a leather or rubber one, but one of the latter materials, with strips of iron on it crosswise, is tight, and will double up before it will be stopped by an obstruction at either end.

All these little things will make a cab comfortable and endurable, in cold weather and in warm. Some of the snow clearing devices shown by you are good things for the front cab door—and that reminds me. Once upon a time I was sent out on the west end to run snow plow—the superintendent was mad at me, and thought he would get me killed off.

It was one of those great, big, wedge plows built onto the front of the engine, and the habit it had of covering up the cab, inside and out, was partly its fault and partly the fault of the cab. I never go out snow plowing without having boards cut just the right size to board up any window, should one be broken.

With a wedge plow you want your front windows clear, as you dare not look out the side, but it is hard to get just what you want—especially on a snow plow.

A young Swede, named Dennis Murphy, was shoveling smoke for me, and Dennis, in his way, was a genius—he had more schemes of his own, that wouldn't work, on that engine than I had.

Dennis was happy on the plow—little firing and lots of excitement—but he had bored the front of the cab full of holes for all kinds of snow cleaners, and all were failures. Dennis got hold of one of those railroad papers that have so many nice kinks, devised by druggists and plumbers, for locomotives, and among other fool things read that item about putting in a double glass to the front door and filling the space with alcohol to prevent frost from forming—it's floating around yet (the item, I mean).

Well, Dennis worked four evenings and all one Sunday to get a joint between those double panes of glass, and Monday morning we started for Drift dom with the clear morning sun shining across the snow and through Dennis' half inch of alcohol.

An hour later Dennis was telling me how he'd make me a "whiskey door," as he called it, and, lighting his pipe with the torch, when a big chunk of crust knocked out both glasses and deluged Dennis' head with alcohol, which took fire from the torch with a loud "whiff."

Before I really got it through my head what had happened, the "Snow Bird" was up to her ears in a drift, and off the track, and Dennis crawled out from under a wagon load of snow that had him down on the deck, and commenced to fumble around for his coal pick, still holding the stem of his clay pipe between his teeth. When he found the pick he coolly proceeded to paralyze what was left of that front door.

Dennis looked like a singed cat, and was real mad at the paper for advising him to do such a fool thing, but it wasn't two weeks until he rigged up a pole-and-monkey movement that was to open the fire door, and slightly start the blower when the throttle was shut off—this was going to save coal, smoke and work, mostly work—but the pesky thing took off his thumb, somehow or other, and Dennis traded the "Snow Bird" for a dinky in the yard.

I wish that one of the fellows who are responsible for the kind of cabs we have was placed in his own room, the windows fixed just like cab windows, and the doors just like cab doors, and that room or that house was hurled through the air one good, stormy night, at the rate of forty-five miles per hour, with a wind going the other at the rate of fifty, and that fellow's whole skin depended on his paying particular attention to what was in front, regardless of frozen feet—I'll bet he wouldn't haggle a hole in the front of it for a reach rod that was big enough for the boiler. That's what I'll bet.

JOHN ALEXANDER.

The Air-pump Puzzle

Editor The Locomotive Engineer:

Relyea's question about crippled air-pump reminds me of the story of the marine engineer who, when asked what he would do if he had a pump that would not work after he had taken it down and found all the parts in good condition, replied that he would look over the side of the boat to see if the lake had dried up. Relyea's pump is all right, yet it won't work. After I had satisfied myself that there was really air for it to pump, I think I should see if it got any steam. But to the question: In the first place, we are to understand that the trouble was in the steam end; the main piston and rings were right, so were the reversing piston, main steam valve, reversing valve and all of its attachments. What was the trouble with the pump?

Mr. R. says that some might say that one piston or end was off of main steam valve, but I don't imagine that any one that understands the principle of the air-pump would have any such a thought. For if that happens you will never get another stroke out of the pump until it is replaced. Below will be found some of the causes for a pump acting as Mr. R. says this one did, that have come under my personal observation. First and most common is an ill-fitting reversing piston which will stick when in certain position, or a crooked reversing valve stem working all right until it happens to turn just right to come out of reversing valve plate, causing pump to stop until it was replaced, or an irregular shaped piece of iron like a reversing valve plate bolt head is in main cylinder, which will prevent the main piston from making a complete stroke with same effect as a bent valve stem, or a loose reversing valve bushing, that may turn sufficient to cut off the supply of steam from reversing valve, thus stopping the pump until replaced, which in that case might have been done when the cap was removed by machinist number one, or the little dowel pin that holds reversing cylinder in position might be out or broken off, permitting the cylinder to turn with the same effect as the reversing valve bushing. The machinist unwittingly turning it in proper position when he removed cap, or the little pin or stop that supports main steam valve when steam is shut off, being too short or broken off, allowing the valve to drop low enough for one of the packing rings to catch below the bushing, stopping its operation untill it was raised, which might have been done by machinist number one, but this latter case is not apt to be the trouble, for it sometimes happens that you cannot remove it without breaking it.

Mandan, N. D. C. E. N.

Editor The Locomotive Engineer:

In the December issue W. F. Relyea has a nut to crack on air-pumps. I am not an air-brake expert, but I want to take a whack at the nut—even if I do miss. I should say that the packing rings on main steam valve were too loose or broken, or that the post that stops main steam valve on its downward stroke at bottom of cylinder had become worn off, and let steam valve travel too far, thereby causing rings to catch on bottom of bushings wherein they work, consequently could not make its upward stroke. If I am right or wrong let us know the trouble. READY.

Clinton, Iowa.

Editor The Locomotive Engineer:

I think it possible that in Relyea's pump something got into one of the ports, or his reversing valve rod was bent and worked around and got out of place. What surprises me most is that he was able to get the top head off and piston out to examine rings and put them back and got the pump in shape to run in twenty minutes. EDWARD GIBSON.

Wilmington, Del.

Editor The Locomotive Engineer:

In the December issue I saw the air-pump puzzle by W. F Relyea. I should say that he probably found the third piston broken (the one that works in cavity above main steam valve). The engine that I am firing had a pump that acted the same as this one. On examination we found the third piston broken where rod screwed into the head; we replaced the broken parts, and pump worked all right balance of the trip, when a new valve was put in. SANTA FE FIREMAN.

Mulvane, Kan.

[The third piston spoken of by our correspondent is known as the "reversing piston," which Mr. Relyea stated was all right.]

The Answer.

Editor The Locomotive Engineer:

I presume, or at least I hope some one will answer my problem in last month's paper about the air pump on engine 434, and while somebody is preparing an answer for the next issue, I will tell them all about the difficulty, in the same paper

It was this: The main steam valve stop broke off, and let the valve drop through the bushes; now I think I hear some one say, if the main steam valve got through the bushes, the bottom ring of each end of the valve must have expanded enough to catch the lower edge of the bushes and hold the valve so it could not move; if that was so, how could the pump stop for a while and then go to work again? Well, I will tell you. When I put new main steam valve bushes in, I always round out the bottom of the bushes, so that if the stop should break off, I can pull out the valve easy; now this pump I speak of worked while the rings kept control, but after a while one end of the bottom ring, which was worn very thin, got out and caught between the bush and lower end of valve, and held it there, and then she stopped My way of putting in stops is this: With a long punch I drive out the piece left in the center piece, then taper the point of the new stop so it will enter the hole easy, then with a long pair of tongs put it down through the bushes and into the hole, then with a long punch, with one end turned to fit lower bush, I drive the stop down, all of which can be done in less than twenty minutes, if everything goes right.

Syracuse, N. Y. W. F. RELYEA.

Do You Miss Your Paper in this Way?

Editor The Locomotive Engineer:

I have a question, relative not so much to the running and management of the locomotive as to the regular distribution of THE LOCOMOTIVE ENGINEER. It is this:

Is the U. S. Post Office Department supposed to deliver periodicals to subscribers who do not have boxes, unless the subscriber calls specially for a paper or magazine, as the case may be? From observation I am led to believe that a great many people understand that when they ask for their mail it will be delivered to them, if there is any to their address in the office, whether it be letters or periodicals. That it is the practice in the offices to examine the letter files only when patrons apply for their mail, accounts for the non-delivery of a good many publications. A. H. TUCKER.

Chillicothe, Mo.

Data Wanted.

Editor The Locomotive Engineer:

Having been a link in a chain-gang for a year, I am somewhat interested in learning all there is to be said for—I know enough against—the system of pooling engines. Will George H. Brown, or some one else in position to do so, give average mileage, and cost of keeping up and running pooled engines?

Galesburg, Ill. CURIOSITY.

[We want "Curiosity" to tell us the disadvantages of the chain-gang system—this is no one-sided affair.]

Two New Air-pump Problems

Editor The Locomotive Engineer:

I want to give the boys a couple of air-pump puzzles

First case: Pump would run all right for five minutes, then stop, starting again of its own accord in ten to fifteen minutes, and stop again in five. On examination, all valves and the reversing valve rod, and all the ports were in first-class order. Machinist fixed it in twenty minutes. What did he do?

Second case. Pump would not raise more than thirty pounds of air, it was taken off the engine and to the shop. Nothing was done to it in the way of repairs, it was set up and tested, and would pump more air than it had steam to drive it. With sixty pounds of steam it would pump seventy five of air. All the pipes on the engine and the pump governor were all right. What was the matter? EDWARD GIBSON.

Wilmington, Del.

Stroke of Driver Brake Pistons.

Editor The Locomotive Engineer:

In the September number of your paper, in the column "Asked and Answered," Question Number 55, C. B. N., Galena, Ill., asks: Why does an engine's driver brakes hold better when the piston has less travel? *A*.—Other things being equal, the length of stroke will make no difference with the retarding power of the brakes.

Now this answer will do in some cases, where straight air (or non automatic) is used, but it will not do where the automatic brake is meant. To be sure, the same area or piston surface is exposed to pressure, which forces the piston either way, whichever it travels, no matter how far the travel may be, or how little. And were the air pressure the same, of course the answer would be right.

The cams have curved faces and are so arranged that a constant pressure is brought to bear against the brake blocks at all parts of the stroke. But when we use the automatic brake, the farther the brakes travel the more the air expands, which, of course, reduces the pressure, retarding the power of the brake in proportion to the distance traveled by the piston.

For example, we will say, as all versed in air-brake practice know, that the air is stored in an auxiliary reservoir, and when the brakes are applied the air is decreased in pressure by being brought in communication with the two driver brake cylinders, and no more air being allowed to get in the reservoir while the brake is on, the body or volume of air is expanded into space equal to the space in reservoir, plus the two spaces in the cylinders and pipe connecting cylinders, so you will readily see that the further the pistons travel the more the air is expanded, thereby reducing the pressure on the brakes, preventing them from holding as tight as they would were the travel less.

I contend that this subject should be well studied by all having the management or handling of air-brakes, and I think your paper is doing splendid work among those who take interest enough to read these different questions and answers in its columns from time to time. FRED. B. ARMSTRONG.

Camden, N. J.

[Our correspondent is right about the expansion of air in automatic brakes, but our questioner wanted to know if the length of stroke made a difference, other things being equal, and we answered no. With steam brakes the stroke makes no difference.]

Those Breakdown Nuts.

Editor The Locomotive Engineer:

I have seen an 8-wheeler come in without back drivers, as De Sanno describes, by simply chaining back end of frame to the tank and running slow.

To his third question I should say that there was a hole in the wall between steam pipe and exhaust cavity in cylinder casting JOHN ORTON.

E. St. Louis, Ill.

Making Tools of Air-pump Valve Stems.

Editor The Locomotive Engineer:

I take a reversing valve stem and cut off the button at the lower end and cut it in two between the shoulders in valve fit, draw out the top for a handle shank and the bottom into a screw-driver bit and make a round handle of apple wood and ferrule of brass pipe. If you take a valve stem that has been in use for a year you can hammer out the point and shank cold. The longer these valve stems run in steam the more pliable they become. Small taps and reamers can be made of them also.

Syracuse, N. Y. W. F. RELYEA.

[Bro. Relyea's screw-driver would be a good one, but it would cost somebody about twice what a good one could be bought for.]

The Traveling Engineer.

Editor The Locomotive Engineer:

It is nothing unusual to see notices each month in the railway publications that some traveling engineer has been promoted to division master mechanic. There is no reason why a M. M. who has passed through the various grades of machinist, fireman, engineer and road foreman of engines will not make a better M. M., for both the company and employes, than one who has not had that line of experience. It is, therefore, in the interest of the enginemen to give the T. E. a cordial reception and all the assistance possible. Some of the enginemen are apt to look on him as a petty official who is going up and down the road trying to catch them doing something wrong and getting them punished for it promptly. If he appears at a station unexpectedly, they seem to think he has a grudge against them in particular. If a man is appointed T. E. who thinks it necessary to do much detective work, except for the protection of the good industrious men against the carelessness or incompetence of the bad ones, he is out of his place. Such a man will soon hang himself, if given rope enough. No honorable, upright man will stoop to dishonorable practices because he holds a subordinate official position; the sense of his responsibility will tend to make him just. But the man who is able to attend to his business, and does it at all times, is not afraid of meeting any of the officials at any time. The careful and conscientious engineman finds that the services of an intelligent T. E. are of value to him at all times. He finds that his co-operation is assured in any move to better the condition of the men and the machinery. It is a selfish view, perhaps, but enginemen should favor the T. E. for another reason: it is to his direct interest to have one who has had an engineer's trials to contend with, as master mechanic, rather than a man who has come up to his position through the grades of the repair shop. A shop man does not always see the necessity of material and devices absolutely indispensable on the road to the engineer, if he has authority to say they can't have it, they don't get it.

There is one branch of railroad practice in which the T. E. is absolutely necessary—instruction in the operation and care of the automatic brake. There is a big army of men who handle it and look after its maintenance in the best order, as far as they are able. Among them are thousands of bright, progressive men who are always ready to learn, and from anybody that knows about it. No one can post them up so well as the T. E., if he knows about it himself and has the proper appliances for doing it, thus settling all the vexatious questions that come up, by an object lesson with the brakes themselves. Many a man has wrong ideas about the matter, some have none at all, as is found out when there is an accident. The value of a first-class instructor in air-brake practice is acknowledged by all.

Where engines are double crewed, or, what is worse, "chain ganged," there is lots of work for the T. E., who can put in all his time with the engines while in service. Double crews on engines are getting to be quite the fashion nowadays, for it is possible for an engine to make more miles a month than a man can stand. Every man cannot be his own T. E. then, for it is every man for himself and get all you can. Engines have hard enough service where each man has a regular one, but with everybody wearing them out and no time to repair them properly, engines don't always get a fair show out on the road.

This article is the result of observation on roads with traveling engineers in service, on roads without any and on roads which have adopted the plan recently. Some of the M. M.'s say it is a good plan and makes their duties much less arduous, others are non-committal. Most of the employes believe it to be a good thing for the companies and engines, but there is a difference of opinion as to the advantages for the men. As for myself, I must confess that it is a matter of observation only, not of actual experience. CLINTON B. CONGER.

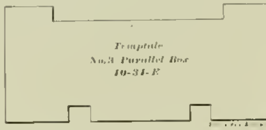
Lansing, Mich.

Rod Brass Template.

Editor The Locomotive Engineer:

Herewith find drawing of template used for rod brasses in the Boston & Albany shops. It is a cheap and handy thing for the planer man to hang on his cupboard door. It is made of ⅛-inch steel, and has all dimensions of the brass.

The length and width is the size of section of stub end or back of box. The upper or large notch is the length of half the box, the two lower notches fit over the flanges, giving the distance apart, and thickness of same. When a brass box



is planed from this template it goes into the strap without any filing.

The template for each sized brass is marked as per cut, in this case it is for the No. 3 side rod brass of our Baldwin consolidation engines with 20-inch cylinders as shown by the Baldwin symbol 10-34-E.

E. Albany, N. Y. MECHANIC.

That Pot-bellied Exhaust Pipe.

Editor The Locomotive Engineer:

In a recent number of your paper I saw a reference to Mr. McCrum's "pot bellied" exhaust, in which the writer expressed a belief that an indicator would show back pressure to pay for what advantage the pipe might have.

In mechanics, facts are what tell, and here are the facts about this "pot-bellied" exhaust pipe. It has about two and one-half times the internal capacity that an ordinary pipe has; it gives a soft, steady blast on the fire, throws little fire, burns less fuel than the common pipe, and runs with larger opening than any common pipe can. Our 16x24 inch cylinders use a 4 inch nozzle; 17x24 use a 4¼; 18x24 use a 4½ to 4¾, pretty large sizes.

Our 16x24 engines have steam ports 1¼"x14", equal to 15¾ square inches, a 4" nozzle gives about 12 square inches—not much back pressure there. The area of the "pot-bellied" pipe is, at the center, about three and a half times the area of the exhaust opening in the saddle, and patterns are now in the shop that will give us a "pot belly" five to one. Come and see us, look in the fronts, ride on the engines, test, if you want to, and you will see the advantages of the expansion, or "pot-bellied" pipe. H. KINGSLAND.

Kansas City, Mo.

About the Compound on B. & O.

Editor The Locomotive Engineer:

While reading the December LOCOMOTIVE ENGINEER, I saw an inquiry from W. de Sanno about the Baltimore & Ohio compound locomotive, and feeling that all curiosity should be satisfied when it is convenient, will try to assist you in the matter of enlightening his mind a little on that subject, by stating what I found out concerning that engine.

After looking around Philadelphia, and attending to some business matters the other day, I still had some time on my hands, and "thinks I to myself" I'll go to the B. & O. shop out at 58th street, and see the "compound engine."

She was in for repairs, had bent a piston rod in one of the large cylinders, and broken cylinder head; the pistons were all out and the large cylinders were cut so badly that they were going to rebore them, the valve covers were off, and one valve out, which showed a very little wear had taken place on them.

I learned that this engine was now using same size nozzles as the other engines. Also that it did not do as well as the regular engines. Was informed that the B. & O. was having some new engines built at Baldwins' locomotive works, but they were not to be of the compound type.

One was apt to form the impression, from what could be learned around there amongst the engineers and shop men, that one compound engine was enough for any road. None wished to say much about it in any way, but were very willing to entertain one on any subject, except when the compound was referred to, which appeared to throw a chill on the conversation at once. I was not able to learn why they used larger nozzles on the compound during the test than they do now—in fact, there were a good many things that were hard to find out about that engine; why the piston bent was a mystery only to one not skilled in the arts. R. W. CAMEL.

Baltimore, Md.

De Sanno's Puzzles.

Editor The Locomotive Engineer:

There have been a great many questions asked and answered in regard to what to do in case of a breakdown on the road, but I think that Bro. W. De Sanno has got his graft in on some of the boys this time. For my part, in the first case, I would take down both side rods, load them on the back end of tank, then jack up back end of engine high enough to slip a pair of old pony truck wheels under the back pedestal braces, block up on top of the pony axle-boxes high enough so that the engine will set level when she is let down on the blocks. With a pinch bar pry up the back ends of both spring equalizers as high as they will stand and block them, fasten all blocks securely and let engine down; she will now run to the shop by careful handling. If this happened on the road where a man could not get a pair of old pony truck wheels I would take down both side rods, jack up engine until she was about three inches higher than I wanted her to run, block her, take out my jacks, place them under the tank back of the front truck, take down my feed pipe hangers on both sides, uncouple both hose from feed pipes, take out center pin of front truck under tank, jack up tank till the truck is clear, run truck up in under footboard of engine as far as she will go, put a block on center casting of truck, thick enough to hold back end of engine up level, take two rails, long enough to reach from the bolster of the truck under the footboard through under the tank onto the bolster of the back truck, fasten one on each side near the wheels securely, if it needs it, put a piece of plank across the rails under the front of the tank to hold it up level with the footboard, let tank down on the rails, block back ends of equalizers and let engine down on the truck, put up feed pipe hangers, couple hose, and run carefully to shop.

Second. The dry pipe was not collapsed, the throttle was disconnected, and when you shoved in the throttle lever it cocked the throttle valve so she got a full head of steam, as soon as the valve worked loose and dropped into place it shut off steam. This happened with me once.

Third. In answer to this one, I think one of the bridges between the steam ports and the exhaust port was broken, or the valve was jammed in the yoke so it held it cocked up off the seat and allowed the steam to blow through.

El Paso, Texas. FRANK PHELPS.

In Pedrick & Ayer's shop, at Philadelphia, they have rigged up some very ingenious devices for moving heavy face plates, or tables, on their long Richards planers. In scraping the traveling carriage to a fit it is a job to move it along the bed by main force. They hitch it to an iron link belt running over sprocket wheels, between two posts in the shop, there is a simple reversing motion, so that it can be moved backward and forward. When not in use the chain is thrown off the wheels, the device thus occupying no room when out of use. It is driven by a rope belt.

The Priest snow flanger, one of the best extant, is meeting with approval in the Northwest, where the trials are severe. A partnership has recently been formed between Mr. Priest and W. E. Haskell, of Minneapolis, and the introduction of the device will be pushed.

CONTENTS.

The Pool System of Running Locomotives.

Within the past twenty years there has been considerable improvement in locomotive engines; no radical changes of moment, but a gradual perfecting of the machine in detail, until its efficiency has been nearly doubled.

Now, if anywhere in this broad land an engineer or a master mechanic believed and said that the old engines were the best, he would be at once set down as a back number, a man without judgment, and not a good one to have his say about a railroad or its power. Improvement is the order of the day; better service must be got out of our engines and rolling stock to please the public, and more interest must be earned on money invested to please the stockholder.

There is just as much chance to improve conditions, to earn more money or give better service by changing the mode of running engines or trains as in changing the engines or trains themselves. Why not? There are hundreds of master mechanics and thousands of engineers crying down and fighting against changes in running locomotives longer or harder than one man can stand to follow them. And every one of them stand in the way of improvement, and must either let loose and get into the current and go with it, or be swept into an eddy of dead water. They might just as well stand out for a return to wood as fuel or wrought-iron for tires. There are still many who believe that an engine gets tired, just as a man does, and needs as much rest. We have always noticed that a clean fire and fresh men seem to revive a tired engine wonderfully.

Especially in freight service is there room to increase, if not to double, the earning power of the locomotives by the plan of pooling.

Chain-ganging locomotives has its disadvantages, and as at present managed is fraught with tribulations and discomforts to the enginemen; but would it not be as well to use the energy now exerted to condemn the system, to improve the details and lubricate its rough bearings? Can't it be made endurable and far pleasanter for the men?

There is no use trying to kill the plan; it will live—because it pays the owners.

Let us suppose a case. We will say that a railroad—the P. R. R., for instance—has two thousand locomotives, two thousand engineers and two thousand firemen. Each engineer, fireman and locomotive work ten hours per day. Now, what difference would it make to the enginemen or to the company to double-crew all engines used?

There would have to be as many miles made as ever, therefore the number of men employed would be the same, they would have more regular hours of rest, but would not have their own regular pet engine. Financially it would make no difference. Let's see how the company would come out.

If they double-crewed the engines, each engine could give twenty hours of service and have the other four for running repairs. This would call for but half the locomotives. Two thousand engines are worth, at eight thousand dollars each, the sum of sixteen million dollars. The interest alone on this investment would be, at five per cent., eight thousand dollars per year. On one thousand engines it would be but four thousand, and this would release eight million invested in other engines, and this eight million dollars would earn four thousand dollars per year interest. The taxes on power would be cut in two in the middle again. The roundhouse facilities need not be as large, hundreds of tons of fuel now used to keep housed engines alive or to fire them up would be saved every year.

Engines would require more repairs, but not double the amount, as boiler and tank repairs are less per mile when engines are used continuously. Engines would earn double the money per year, but would last but half as long; this would be a good thing, for roads would not be stocked with power over ten years old, and would be able to own the best.

Of course there are details of expense against and some in favor of the plan—extra engines must be kept in steam at terminals to take place of cripples, etc.—but it is plain to any one who thinks for a moment that there are great advantages to a road in the plan. We cannot expect railroad managers to run roads to suit the notions of the master mechanic or the convenience of the enginemen. Every one ought to take hold in the right spirit to accomplish the most work with the least investment and at the least expense.

Master mechanics who oppose every improvement in the handling of their department are fast finding the handling of their men and engines on the road taken away from them. Engineers who oppose changes in running stand in the way. It must come. Don't get in the road and say "you can't do it"—they will go over you.

Let's study the problem, and fight now for every detail that will add to the safety, comfort and usefulness of locomotive engineers.

The system of blank reports of condition of engine when turned over by one man to the next needs elaborating and simplifying. The duties of inspectors need be clearly defined. Oil and fuel will have to be charged to men, not engines. Some scheme needs devising whereby you can have your clothes-box, oil cans, etc., put on the engine and taken off at end of your run. You will do no running repair work, the fireman will do no cleaning, and there will be other things to let alone that you are used to doing, and some to do that do not now belong to you. Try and get these details settled on a good, fair basis when the chain-gang system strikes your road—for it won't miss many.

It is rather curious that almost to a man railroad managers or presidents are for a consolidation of interests, for rate agreements, and combinations of roads to better the conditions of the road they represent, suppress strife and maintain rates, and yet are so eloquent against a consolidation of the organized employes of the roads. They tell the engineers that to federate means the loss of prestige of their order and makes them no better than trainmen or firemen, and they tell the other boys that with federation the engineers would dominate and control them. What is sauce for the goose is sauce for the gander. Federation goes just as far toward insuring peace and prosperity for men as for roads—in union there is strength.

When you think you are being unfairly treated by your officers or associates, before you kick very hard just think the matter over and see if you are entirely in the right yourself. Put yourself in the other fellow's place and take a fair, honest look at the case. Remember that this world would be pretty nearly free from wrong if each individual did right. Be fair. Sometimes justice cannot fly because she is weighed down by the leaden wing of selfishness.

Books Received.

VALVE GEARS. By H. W. Spangler, P. A. Engr., U. S. N. Whitney Professor of Mechanical Engineering, University of Pennsylvania. John Wiley & Sons, publishers, New York. Price, $2.50.

This work is an analysis of the Zeuner Diagram, and a general treatise on laying out valve motion of all descriptions. It was written with a special view to teaching the principles of valve motion, and is as complete yet concise a work of the kind as has come to our notice. The work contains nearly 200 pages, and over 100 engravings. It is especially valuable to those designing valve gear, and as a text-book in engineering schools.

MECHANICS OF ENGINEERING AND OF MACHINERY. Being Vol. III., Part I., Section 2. Treating the Mechanics of the Machinery of Transmission. By Gustav Herrmann, Professor at the Royal Polytechnic School, Aachen, Germany. Translated by J. F. Klein, D. E., Professor of Mechanical Engineering, Lehigh University, Bethlehem, Pa. Published by John Wiley & Sons, New York. Price, $5.

This work is one of a series of the highest grades of technical works published in America. This volume alone contains above four hundred illustrations on this particular subject. The works of this series are very exhaustive and complete, and necessarily employ the higher mathematics, and are considered the ablest efforts of a great German mathematician and engineer, whose works are an authority in many of the greatest technical schools in the world.

CATECHISM OF THE LOCOMOTIVE. By Matthias N. Forney, M. E. Published by the *Railroad Gazette*, and sold by Frederick Keppy, scientific book publisher, Bridgeport, Conn. Price, $3.50.

This is the second, and enlarged and revised edition of Forney's well-known book, the original edition having had a larger sale than any other work on the locomotive.

The author has culled out the least desirable parts of the old work, and added complete new chapters on Force and Motion; Resolution of Motion and Forces; The Principles of the Lever; The Action of the Piston, Connecting Rod and Crank; Action of the Pistons, Cranks and Driving Wheels; The Westinghouse Air-brake; The Care and Use of Air-brakes, and The Eames Vacuum Driving-wheel Brake.

The cuts are almost entirely new, and the plates are smaller and better arranged than in the original work.

Forney is one of the ablest mechanical engineers in the railroad line, and his writings are especially plain and clear. This work treats, in an elementary way, of the construction of the locomotive, tells how each part is made, and why it is made as it is, and gives rules for figuring out all practical questions concerning the "why and the wherefore" of locomotive service. No railroad mechanic, locomotive engineer or fireman should be without this work; it is almost all about the engine, and not so much about running or firing. The book is worth double its price to any man who has to do with locomotives in any way. It contains over 700 pages, considerably larger than the original work.

THE MECHANIC'S COMPLETE LIBRARY OF MODERN RULES, FACTS, PROCESSES, Etc. Compiled by Thos F Edison, A. M , and Chas J Westinghouse. Laird & Lee, Chicago, publishers Price, $1.

This work is a collection of a little of everything that a man who was not a mechanic might imagine would interest mechanics. It contains a great variety of reading matter, good, bad and indifferent, mostly the latter.

To begin with, a mechanic's complete library, or "five books in one," as this is called, is just like a patent medicine, warranted to cure everything from cancer to homesickness—it's a big job. While the names of the compilers may be all right, it looks like an attempt to use the reputation of two of America's greatest engineers, Edison and Westinghouse. Be that as it may, the book is bad, it contains so much misinformation. It would be a misfortune to any young man to read and place confidence in this work, because it teaches so much that is not true of mechanics that must be discarded and learned again, or forever hang like a millstone about his neck.

Of course in so large a collection of matter there is some good to be found; it would be almost impossible to get a book full of bad things The compilers seem to have clipped everything without being able to judge of its merits, or to even take time to eliminate references to illustrations that were in the original descriptions and are not in the book. The simple rule for figuring the safety valve is wrong. The description of the air-brake is horribly garbled. Repetitions are numerous They have collected some of those queer statements, such as a way to prove that the earth revolves, by the use of a dish of water—long ago proven untrue There is a list of things that "will never be settled," including, which side of a belt to run next the pulley, the right way to lace belts, whether water wheels run faster at night than in the day, the principle of the injector, etc., all of which are no more mysterious to a mechanic than the reason that fire burns They use a daily paper item about the Shaw locomotive burning gas (when used as a stationary engine) and state that with large machines for mixing gas and air, mounted on a car, gas can be used on locomotives. This is as useful information as it would be to say that it is believed that, with large reflectors mounted on cars, the rays of the sun can be so concentrated upon the locomotive boiler as to do away with the use of coal Here is a specimen item of information (?)

"A pound of tenpenny cut nails will do as much work as two pounds of wire nails. Taking the average of all cut nails, they are worth nearly double as much as wire nails, from tests make at the Watertown Government Arsenal."

There are already too many cure-all mechanical books on the market and not enough good ones, and we believe that we do ourselves credit, our readers a favor, and save them money when we tell them the truth about this latest collection of everything, apparently made only to sell.

ASKED & ANSWERED

(1) E. D. C., ———, asks.

At what temperature (Fah.) does water boil, at Leadville, Col.? *A.*—About 194° F. Leadville is 10.025 feet above the sea At sea level water boils at 212°, and will boil at one degree less for each 550 feet of elevation.

(2) New Subscriber, Paterson, N. J., asks:

What is the cheapest and quickest method of removing oil from nuts and bolts as they come from the threading machine? *A.*—The best known practice is to remove the grease in a bath of hot lye or caustic soda, drying them, while hot, in sawdust.

(3) Inquirer, Tulare, Cal., asks:

Will you please inform me through your paper what causes the short blow of air from valve when brakes are released with Westinghouse equalizing discharge valve? *A.*—We do not understand your question. Do you mean a blow of air from the engineer's valve? If so, from which port?

(4) J. A. N., Ayer, Mass , asks

Why will a lantern in the cab go out when the whistle is blown? *A.*—This only happens under favorable conditions, and is caused by a lack of air to supply the flame. If the cab is closed up so that the air coming to it is removed by the blast of the whistle, the effect will be more apparent. Anything that causes a partial vacuum in the cab will tend to choke the lights

(5) L F. W , Indianapolis, Ind., asks.

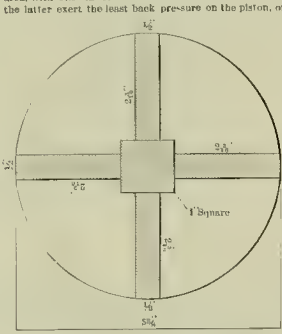
Why, in the Westinghouse quick action triple-valve, is the quick-action piston not made rigid, or solid, with the rod it operates? 2. Also, in the New York air-brake, after the release from emergency stop, where does the pressure reduce to which has forced down the quick-action piston? A.—1. To admit the emergency valve stem to the guide on the seat. 2 Into the brake cylinder.

(6) B. C. R., ———, asks:

Please give a brief description of the so-called bicycle railroad which was built and is in operation in New York? What power is used to propel it? How fast does it run? *A.*—The Boynton bicycle locomotive was designed to run on a single rail below and a guide rail overhead It is a steam locomotive, with an 8-foot wheel directly under the boiler, the top running into a slot formed in the bottom of cylinder part of boiler. The cab and cars are two stories high There is only a short line at Coney Island, but the engine shows that it is capable of high speed—the inventor claims 120 miles per hour—but that remains to be seen. It is a novelty, that is all.

(7) Frisco Line, Monett, Mo., asks:

The area of a 4½" single nozzle is 15.901 square inches, circumference in contact with exhaust steam is 13 13" Now, if I bridge a 5¾" nozzle to 18½ square inches in area, with 34.8" in contact with the exhaust steam, will the latter exert the least back pressure on the piston, or



will the additional surface counteract the increased opening? *A* —The increased area on your bridges will be so short that the friction of the steam in passing through will be very little. If the two nozzles had the same area of opening, the bridged one would produce a slightly greater back pressure, but with nearly three inches of area in favor of the bridged nozzle, there is no doubt that it would show the least back pressure of the two.

(8) H. S. R., Yonkers, N. Y , asks:

1 What do four whistles mean? What do two whistles, followed by two short whistles, mean? 2. What are the two green flags carried on the rear end of a passenger train for, which I see very often? 3. What does the sign (") mean? 4. If a young man wished to become an engineer on a locomotive, would he not have to serve his time in a machine shop first? If not, what is the very first thing he would have to do after having received a common education? *A.*—1. Whistle signals differ on different roads The standard code is used on most roads, however. Four whistles is a call for switchman, or a call for trainman out flagging. Four whistles, two short and two long, is often used as a highway crossing signal. 2 Green flags on rear of trains are markers that tell the engineer that his whole train is following 3. The sign " means inches, the sign ' feet—thus, 3'3"=three feet and three inches. 4. Get to firing; take any subordinate position to put you on the firemen's list.

(9) J. H. R , Huntington, Ind., asks:

Please tell me how to determine when the cylinder packing is blowing, and also tell when the valves are blowing and how to determine which side, without opening the front door of smoke arch. I have often heard my engineer say the valves were blowing. I could not see any difference between the valves blowing than when he said the packing was blowing. *A.*—When the valves blow, the sound of escaping steam to the exhaust nozzle is more nearly continuous than it is when packing blows, especially when links are hooked up. By moving engine slowly you can tell on which side packing blows, as when one side is using steam the other is not To be sure a valve blows, place the suspected side on or about the center, put reverse lever in corner notch, open cylinder cocks, and give engine a little steam If steam shows at cylinder cocks, the joint between valve and seat is not tight. If you place and block the engine so that the piston of the suspected side is in the center of the cylinder, put the reverse lever in the corner and open cylinder cocks, and give her steam. A strong blow will take place from the cock in the end taking steam If any steam appears at the other cock, the piston packing is not tight There are half a dozen ways to hunt for blows, think about them and reason them out Once you get the difference in sound between these blows in your head, you will be able to tell them by the sound alone.

Canadian Pacific Shops, Montreal.

[Editorial Correspondence.]

The Canadian Pacific Railroad is one of the wonders of this decade, and is a magnificent monument to engineering skill and human perseverance, showing what men can do in a short time when backed by money and with brains.

This company was not chartered until 1881, yet it has in operation 5,186 miles of road, only 1,257 of which are leased, and less than 1,500 were acquired by purchase. The line reaches from Quebec on the Atlantic tide-waters to Vancouver on the Pacific, over 3,000 miles Two thousand miles and over of this road was built across the barren wastes and the northern ranges of the Rocky Mountains in less than five years.

The road enjoys great privileges and has authority to operate telegraph and express lines as well as lake and ocean steamers.

It is the great rival of all the Pacific roads for through trade between the east and west.

There are in service 413 locomotives and over 12,000 cars. They have large shops at several cities on the line of the road, but the main shops at Montreal are the most extensive.

This shop was established here in 1882 and is a complete English shop, the original plant having all been imported Last year new car shops were built in another part of the city and the old car shop given up to the use of the mechanical department

THE ERECTING SHOP

is a long brick building, well lighted , it is high, having a gallery on one side where all the light tools are located. The shop has long tracks down one half of its width ; the other half is occupied by the heavier tools.

Over the pit shop heavy traveling cranes are located, capable of lifting a locomotive bodily. These cranes are rope-driven, almost noiseless, and very fast. They were built by the Cravens, Manchester, England.

A HANDY TRAVELER.

Right through the half of the shop occupied by machine tools there is an aisle some six or eight feet wide ; down this aisle there is laid a single rail; over this rail, on the iron framing above, there are two girders running the length of the shop. A crane is built on two wheels, one ahead of the other, the mast of the crane extending up between the girders, on which the crane load comes by rollers bearing against them. This crane is driven by a rope overhead, and has a seat for the operator, who, by handling one wheel, like a brake wheel, can cause the crane to travel in either direction or stop, and by using another wheel he can hoist or lower a load on the arm of the crane or swing it where wanted This crane can serve any tool within some fifteen feet of the track on either side, occupies but two feet of space itself, and will thus go in between work where an ordinary locomotive crane could not get. This little crane is neat, simple and cheap, does away with the desirability for individual cranes over such tools as heavy planers, etc. It is capable of lifting a pair of cylinders or frames and can handle a large amount of work.

There are several new American tools to be seen, but most of them are English ; some looked to me, awkward and complicated, while others looked exceedingly simple.

CYLINDER BORER.

One of the latter was a cylinder borer reduced to the smallest number of pieces ; the bed plate carried two uprights that supported the boring bar, which was very heavy ; this bar could be drawn out of one head to admit of the placing of the cylinder casting on the machine ; the cutter head was large and carried three cutters of steel let into slots not radial from the center of the bar, but so that the strain is thrown upon the cutter in the direction of its length. The bar is driven by a large worm meshing into a worm wheel on the bar itself.

CHUCKING LATHES

capable of swinging large pieces, but of short lengths, are not common in American shops. They have several here. They have no bed except enough of the base to support the tool carriage, which is automatically fed across the machine, but not to and from the work. These lathes are capable of doing a great deal of work that can be held in a chuck or fastened to a face plate, cylinder heads, casings, etc.

Small shapers, having a movement of but a few inches, and very small millers, are used for many purposes.

Planing and slotting machines are very heavy and massive, but all of Cravens' tools have a neat outline, though severely plain.

There are a great many multiple drills and other tools for hurrying work.

In the department of the smith shop, devoted to bolt and flue work, they use a very efficient

FORGING MACHINE.

This is a heavy frame carrying at the top a shaft on which are five eccentrics of, perhaps, an inch throw. These eccentrics move up and down plungers carrying dies, some rounded, some square at the bottom; most of the dies are double, that is, two sizes on a head; these are about an inch by two and a half inches square, of steel, and come down to anvils just like themselves; one ram carries a knife that meets its mate; at the bottom it is tapered from an inch opening at one side to nothing at the other. The smith takes an iron from the fire, and commencing at a large die can draw the piece down round, square or flat, and cut it off by simply moving it along from one die to another. The hammers or dies run very fast. While I watched this machine the smith was making heavy gate hinges, and doing it lively.

THE ENGINES

are American built, most of them, yet they build some themselves, but all bear marks of the individuality of the mechanics in charge. All the frames are solid, the lower rail being welded in.

Some of the passenger engines have steel cabs, round corners, and not a screw or bolt head in sight. They are sealed with wood inside, and are the handsomest cabs I ever saw anywhere.

FOR SAFETY,

all checks are on the boiler head, making the branch pipe very short and direct; inside the boiler an open-ended pipe carries the feed as far ahead as the side check usually puts it.

INJECTORS.

They use on some old engines a class of injectors made in England and classed here as "self-contained." They are located on the boiler head above and each side of the door, where checks are located for non-lifters. These injectors contain the steam or starting valve, the check, primer and water valve. They were efficient, but rather complicated and prone to kick about starting when hot—but most of them do that.

After this style the road adopted the non-lifter, such as used by the Grand Trunk, and made it themselves at a cost of $10—without any valves or fittings—but are now applying Gresham's re-starting non-lifter. This is located back of the rear driver, and looks much like a horizontal non-lifter with the mumps. The men say it is an excellent boiler feeder.

ENGINE TRUCKS

are made with great pains and at considerable expense to guard against their getting out of square. The top frames on both sides are made in one piece by welding in the cross-ties. The form of truck is illustrated on another page.

CROWN SHEETS

on wagon top boilers are supported under the dome by crown bars, but back of the dome radial stays are used. They report good results from this plan.

THE REVERSE LEVERS

have their fulcrum on a half-inch plate to which the quadrant is fastened, the latter going through a slot in the lever, like a Baldwin. With this plan there is no chance to bind.

CYLINDERS

and steam chests are very carefully lagged with wood to prevent radiation, as most of their engines run in a very cold country. By sawing a board of the right width full of notches to miss the studs, it is not at all hard to lag a steam chest, the cylinder lagging runs to the center casting under the saddle, and the front and back of the saddles are carefully covered; the space between the steam chest and saddle is generally filled up entirely. This costs but little and cannot help but result in a saving of heat—which means fuel.

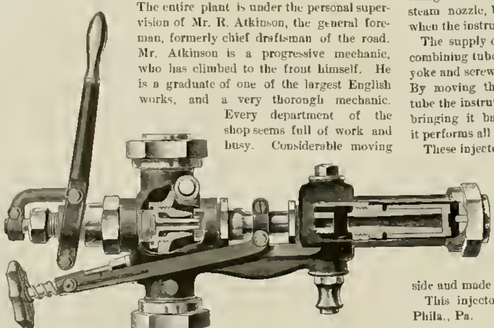
TESTING NEW CYLINDERS.

When new cylinders are built they test them up to 200 pounds before putting them on the frames. Blocking up the exhaust port by screwing down a wooden block upon it and screwing a cap on the exhaust cavity opening to the arch, the pressure tests the walls between the steam and exhaust passages. Steam passages are tested in the same way, then the cylinder heads are put on and the steam ports blocked, then pressure tests the heads, the cylinder and the walls of the steam ports both to the air and to the steam induction ports.

THE DRAWING-ROOM

is light and well arranged, and contains a full-sized valve motion model and other testing machines.

The entire plant is under the personal supervision of Mr. R. Atkinson, the general foreman, formerly chief draftsman of the road. Mr. Atkinson is a progressive mechanic, who has climbed to the front himself. He is a graduate of one of the largest English works, and a very thorough mechanic. Every department of the shop seems full of work and busy. Considerable moving of men and tools is going on in order to use the recently vacated shops of the car department.



LITTLE GIANT OF '89.

DOME COVERS AND SAND-BOXES

are made of sheet steel flanged out by hand. They are light and of neat shape, but expensive.

PIECE WORK

is done on most of the regular work; all forging is done by the pound or by the hour, most of it at one and a quarter cents per pound. Apprentices work by the hour.

A SIDE ROD KINK.

With some of their 8 wheelers having long, slab, side rods, there was trouble from broken rods, and it was decided that it was caused by the constant vibration of the rod. This was cured by clamping oak strips on the rod—top and bottom. These strips are thicker in the center than at the ends, and, being painted black, look like iron rods weighing about a ton. They are homely, but do the business.

KRUPP TIRES

and Krupp steel wheels are used under everything except freight cars. Mansel retaining rings are used.

TO HELP THE DRAUGHT

on locomotives being fired up in the roundhouse, a steam jet is used in the jack over the stack.

CHEAP ENGINES.

Labor and material are cheaper in Canada than in the States, and these shops have turned out a 17x24 engine, weighing 108,000 pounds, for $5,800.

THE CAR SHOPS

are under the charge of Mr J. Higginson, M. C. B. They build many of their own passenger cars and some freight cars. For freight service they make their own wheels in Whitney contracting chills.

FINE CARS.

This road run their own sleepers, and neater designs of finer finished cars cannot be found. Their sleepers are far above the average Pullman in convenience and beauty. Some of these cars cost $15,000.

First-class cars are not painted on the outside, but are oil finished in cherry or mahogany, and it is found that the natural cherry requires less work and looks well longer than paint.

The road has two classes of fare, even for local tickets, and emigrant sleepers of a very neat and tasty kind are run on all night trains, free of charge—there being some 250 of these cars in service.

J. A. H.

The Little Giant Injector.

The cut on this page shows the standard sized Little Giant injector pattern of '89. The cut was made to answer the many inquiries of how the new instrument differed from the old internally. There is little if any difference. As will be seen, the instrument is self-contained without other joints than the regular three connections for water, steam and delivery. The check seats on the end of the discharge tube and the starting jet is located in the steam nozzle, but is entirely withdrawn from it when the instrument is at work.

The supply of water is regulated by moving the combining tube forward and back by means of the yoke and screw shown under the operating lever. By moving the tube ahead against the discharge tube the instrument can be used as a heater, and by bringing it back toward or against the steam tube it performs all the functions of a lazy cock.

These injectors are especially good in bad water, as the combining tube can be taken out by hand, not being screwed in; once out there is ample room to clean out the instrument from four openings to the outside, and, there being no case around the combining tube, it cannot be limed up on the outside and made fast to the body.

This injector is made by the Rue Manuf'g Co., Phila., Pa.

The Railway News Reporter, under the head of "New Use for a Locomotive," tells how the manager of a shop rented a locomotive and used its boiler to run the engines of the works while new boilers were being put in, and ends up with.

"This is a novel but thoroughly practical plan. The locomotive is of 100 horse-power. Old mechanics say that this is the first time, to their knowledge, that a railroad locomotive has been thus utilized."

There is scarcely a railroad shop in the country where this is not done every year or so. We could forgive a daily newspaper reporter for a break like this, but a railroad paper (?) that dishes up such stuff, new or second-hand, must impress a railroader with the value of its information. There, now, take that.

Joseph Billingham has been traveling engineer of the Kansas City division of the C., M. & St. P. for the past three years, and has given such good satisfaction that he was offered a similar position, at much larger salary, on the G., C. & S. F. On leaving the St. Paul, the engineers gave him a handsome ring and all the good wishes he could carry away.

The Canadian Pacific furnish a pair of traversing screw jacks for every engine. These jacks can be used without the base or with it, the load can be transferred a foot or two sideways. They are very useful in case of wreck.

Every engine that comes into the Grand Trunk main shop at Montreal has stenciled in white letters over each check, "Boiler Empty." If this legend is not there, they don't come in.

The McDowell Safety Check Valve.

Our engraving shows the latest form of inside check valve, as used on the Pennsylvania road.

This check cannot be knocked off in a wreck, cannot be pounded out of shape in an attempt to make it seat, and has no pockets or obstructed passages to catch scale or other foreign matter—anything that will go through the pipe will go through the check.

The pipe connection can be at any angle to the check, as the joint next to check is made by a right and left-hand nut.

The valve can be ground in, by using the tool shown, without taking the case off the boiler.

Some years ago this check was made without a stop, to prevent the hinged valve from opening too far, and it sometimes stuck open, or the large opening caused it to hammer—this lost it friends—but it now works perfectly, some 3,000 being now in use on the P. R. R.

This device should be better known and appreciated by engineers. It is sold by the Foster Engineering Company, 81 Fulton street, New York.

New Rail Chair.

The engraving on this page shows a new pattern of rail fastening designed by Geo. W. Rittersbach, 24 North 36th street, Philadelphia. The chair is very cheaply made, the lower plate being formed at one operation, hot or cold. It prevents spreading of rails and is an insurance that the rail will not turn over. It is at once a tie plate and rail brace, such as used for curves. With this tie there is no pulling strain put upon the spikes. It can be put in without taking out rail.

The Grand Trunk Shops at Montreal.

(Editorial Correspondence.)

The Grand Trunk road of Canada was for a great many years the largest road in the British provinces of North America and still does the greatest business per mile of road. It is built, equipped and manned more on the English plan than any other American road, and is therefore interesting to Americans.

It is owned in England and most of the general offices are in London, but they seem to have had good judgment in the selection of operating officers, who have left their prejudices at home and have held fast to such English devices and systems as seemed better than those to be found here and have adopted everything American that is better suited to their needs.

A great deal of the road has a complete English block system and the yards are well protected by signals. We noticed that all main line switches and signals had lights much better than those usually seen here, larger and clearer.

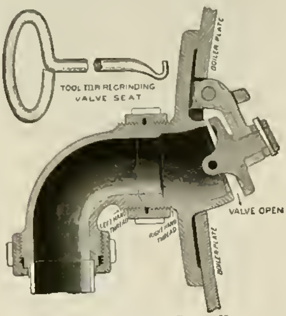
Seventy-pound rails are used on much of the road, and the track work seems to be especially well done, split switches used and modern rail splices and chairs are to be seen.

The Grand Trunk operates 3,419.5 miles of road, using over 1,000 locomotives.

I went into Canada over the world-renowned Victoria tubular bridge. This bridge is the only one of its class in America; it was built in 1859 by that eminent English engineer, Robert Stephenson, and consists of twenty-five spans of square iron tubes supported on masonry piers. These spans of iron tube are 27 feet deep and 14 wide; the bridge rises from each shore to the center; on the American side the tube is tight and as dark as a tunnel, but on the Canadian side the plates at the top have been cut out in the center, which allows the smoke to escape and gives light and air. The bridge has one span of 330 feet and 24 spans of 240 feet, and is one mile and three quarters long, including approaches. It is strong beyond all needs, but the first cost and maintenance is something enormous, as compared with modern bridges. The top and bottom plates of the bridge are double and cellular, while the sides are single plate, on each span there is a light iron framework that can be moved along over the span to accommodate the painters. Enormous quantities of rust are taken from the tube every year, and you can judge of the job of painting when I tell you that the tube has an area of over thirty acres. When Stephenson finished this bridge be went with John A. Roebling, the builder of the Niagara suspension bridge, to see that grand pioneer of great suspension bridges. Looking at its graceful lines long and silently he turned at last to Roebling, and, shaking his head, said, "If your bridge is a success mine is a magnificent blunder."

THE SHOPS

are located at Point St. Charles, close to the bridge, and are very large and well arranged for shops of their age and kind. All the buildings are of brick, well lighted both with side and sky lights. There seems to be a good-sized shop for every process of car or locomotive work; almost all the principal parts of a locomotive have a room or a building for its repair.

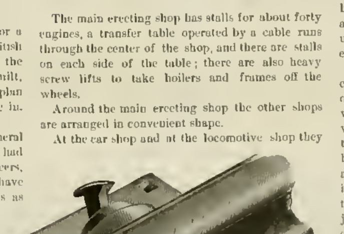


THE McDOWELL SAFETY CHECK VALVE

The main erecting shop has stalls for about forty engines, a transfer table operated by a cable runs through the center of the shop, and there are stalls on each side of the table; there are also heavy screw lifts to take boilers and frames off the wheels.

Around the main erecting shop the other shops are arranged in convenient shape.

At the car shop and at the locomotive shop they have recently built a round shop, about forty feet in diameter, especially rigged up to take off and put on tires. Each is arranged with convenient cranes, presses, gauges, etc., and Pedrick & Ayer tire heaters, the locomotive shop tire house being prepared to handle tire up to six feet in diameter, while that for car shop is fitted more for small sizes and quick work. These little shops are away from the others and in charge of men who do nothing else, and can therefore be depended upon to do their work fast and well.



NEW RAIL CHAIR.

These tire rooms seem to be a fair sample of the plan the management have in mind for the whole works, for each job is being done in a shop especially fitted for it; even the blacksmith shop is divided into departments.

SUBSTANTIAL IMPROVEMENTS.

I noted particularly the substantial work done on the plant. No expense seems to have been spared where a place has been refitted, and no make-shift or "good enough for the present" arrangement seems to have been invested in—this is not the usual plan followed on American roads. Some pretty good looking tools that were out of date were standing near the scrap heap, having been replaced by new ones.

AMERICAN TOOLS.

These shops were originally equipped with English tools, and a great many of them are still in use, and some of the new tools are of English make, especially heavy tools, such as flanging machines, etc., but most of the new machines are of American make. The managers of these works seem to have selected from the markets of the world what they considered the best for their work.

FILE CUTTERS.

In one shop they were putting up two file-cutting machines to re-cut old files and make new ones; these machines are of English make, of a new design, simple and very efficient. In this room they were also erecting two wire nail machines.

NEW ENGINES.

They were just finishing up an order of 20 heavy passenger locomotives at the time of my visit, these engines are especially heavy in the frame and in all the valve motion and running gear. Krupp tire with Mansel retaining ring are almost exclusively used both for truck and driving wheels.

THE LOCOMOTIVES

are unlike anything in America in appearance, although many of them are of American build, many of the older ones were built by Dubbs & Co., at Glasgow, Scotland, but the standard engine they build themselves. They have, as a rule, straight boilers that look small for them, the jacket is of thick iron or steel and is painted like the rest of the machine. All their new engines are painted a dark red all over—boiler and all—the jacket bands have a slight stripe of black and white along their edges and the tanks and cabs are neatly lettered, the engines look nice and are as easily kept clean as anything can be.

The boilers are strong and well made, and great care is exercised in covering them to prevent loss of heat. Angle irons are bent around the boiler, over which a stiff wire screen of ¾ mesh, 18 gauge galvanized wire is formed, leaving an air space next to the boiler; over this wire jacket they put a blanket of mineral wool, this is about an inch and a half thick, then over this a jacket of planished iron or steel is formed, and painted as they finish them in England; this makes a very substantial job. They cover the fire box as well as the barrel of the boiler, and fit pieces of lagging and jacket between the frames on each side of the box.

THE CABS

are comfortable, and arranged on the American plan, the throttle levers are fastened with a screw in the lever operated by twisting the handle; the injectors are all non-lifters, of their own make, they are placed horizontally on side of fire-box and between the drivers on 8-wheelers. These instruments are cheap and effective, easy to operate, and not liable to fill up with scale. Sight-feed lubricators are used some, but not on freight engines.

Cast-iron guides are very much used; they are very heavy, and on some suburban engines are completely covered with sheet-iron to protect them from snow and ice.

Straight stacks are the rule and extension are common.

All passenger locomotives are equipped with Westinghouse brakes.

The Scotch engines and a few of their own build have plate frames, but most of them are of the American style, but heavier. Solid-ended rods are very much used. Six-wheel connected engines are used in the heavier frieght service, but 8-wheelers are the rule.

THE GRAVEYARD.

In the yard there were some thirty locomotives of all kinds and sizes, mostly from the small roads in the West that have recently come into the hands of the G. T.

ROUNDHOUSES.

Two square stone houses with a turn table in the center of each are used for roundhouses, or, as they are called here, "running sheds"; the tracks radiating from the table turn in the direction of the length of the house and each track holds several engines.

The shops are well painted outside and white-washed inside, and the grounds are clean and orderly, and very large, the yard being very extensive.

The enginemen on the G. T., and in fact on all the Canadian roads, are as a rule progressive men, well posted and up with the times. The shop men are of many nationalities, but most of the laborers are French. Near the manager's office there is a large building containing a library, bath-rooms, a theatre, lecture-room and eating-room. The library is large, well supplied with books and periodicals, and contains many instruments and other educational apparatus. One of the largest and finest terrestrial globes I ever saw is here suspended from the ceiling by a wire rope; it was presented to the library by Sir Joseph Hickson. The eating-room is provided with seats and benches where the workmen go to eat their lunch; at 12.30 a gong sounds, after which they are allowed to smoke—looking in here at 12.45 you see a cloud of smoke, smell everything that will burn, and hear a babel of voices.

LIBRARY TELL-TALE.

In the library they have a large board in a case, some 5 by 20 feet, this board is filled with regular rows of small holes, each hole being numbered, each number represents a book, the name of which, and the number, can be found in the catalogue, when a book is out a red peg is placed in the hole representing its number. If you want to read Ben Hur and find it is numbered 1,200, and see a red peg in that numbered hole, you need not ask for it—it is out—while if the hole is clear the book is to be had for the asking. There are two opposition societies who give alternate exhibitions in the theatre every two weeks.

FIRE DEPARTMENT.

They have a fine fire engine or hose-house, in charge of a veteran, who keeps things in apple-pie order; there are several fire companies and considerable rivalry, the company grant them time at stated intervals to exercise and train for fire duty; the rooms are filled with cups and other trophies the teams have won. J. A. H.

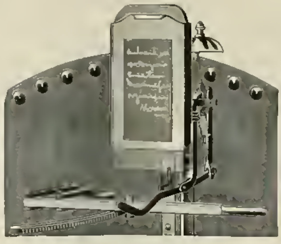
The great Scotch locomotive builders, Dubs & Co., Glasgow, have a yearly capacity of 200 engines and employ from forty to fifty draftsmen and apprentices, besides some twenty girls who make tracings for shop use. In America, with improved systems and blue prints, seven to ten draftsmen and half a dozen apprentices do the work for shops of the same capacity.

Bishop Walker's church on wheels, lately turned out by the Pullman shops, has been succeeded by a steamboat church, built in St. Louis for the Rev. M. A. Shepherd.

Kemp's Order Holder.

There seems to be quite an epidemic of order holders for locomotives, and if they show no other improvement or advantage, are worth their weight in gold to any railroad in making all orders accessible to the fireman and the head brakesman.

The holder shown herewith consists of a front glass, hinged at the bottom, a tin slide and a back piece, also an alarm bell, all set on boiler-head, as shown.



The orders are placed under the glass, the closing of the frame sets the lever of the alarm, so that, in opening or closing the throttle, attention is called to orders.

When the alarm is not wanted, the lever can be thrown up out of the way; but, if an order is put in, it will reset the lever for alarm. When an order expires, it is filed in the back of the holder for reference. A lamp, not shown in the engraving, accompanies the holder.

The inventor, C. W. Kemp, is an engineer on the Ft. S. & K. C., and his address is Charlestown, Ill.

Cy Warman's paper, the *Western Railway*, of Denver, came to hand this month with a touch of Colorado sunset on the cover and two dollars' worth of stuff inside. If Cy. would quit railroad writing and devote himself exclusively to the manufacture of poetry he would starve to death sooner, and then he might have a "statoo" in Central Park, like Burns.

The Massachusetts railroad commissioners have rendered their report in regard to the accident on the Old Colony road near Quincy, Mass., August 19 last, in which twenty-three persons lost their lives. The report lays the immediate responsibility of the accident upon Joseph F. Welch, the section master, who was in charge of the workmen who were using the track jack which caused the accident. The commissioners call for more definite and stringent regulations from railroad companies regarding the use of jacks. The report claims that the brake power on the train was not sufficient.

A Possible Chance to Keep Accurate Fuel Accounts.

The Wanamaker Car Scale Co., of Indianapolis, Ind., are introducing a device to weigh car bodies independent of the truck and no matter where the car may be located.

Their scale is located under each car, and in weighing the load the body of the car is lifted bodily from the trucks.

Our illustrations show the complete apparatus independent of the car, as well as the mode of attaching it. The four levers marked B are fulcrumed to the sills of the cars at G, and their short ends bear knife-edges on steel plates on the truck bolsters at A when car is raised to weigh. The scale beam is located in a small box under the center of the car, this box also contains a small pump.

When it is desired to weigh a car, a few movements of the pump lever pumps oil into the four hydraulic jacks, marked P, that lift the body of the car up on the lever system, where it is weighed. The closing of the door of the scale box releases the oil in the pump cylinders and lifts the knife-edges from the bolsters.

Whatever advantages this scale may have for cars, there is no doubt it would furnish a splendid plan of keeping correct fuel accounts if applied to tenders. With it the tender could be weighed just before and just after loading coal, and a true record of each engine's fuel kept; it would do away with guesswork, prevent the charging of shrinkage to the motive power, and help establish some reliable facts concerning the consumption of fuel that are badly needed.

Laboratory tests of oil do not always prove what real value the oil is in actual service. The road is the best place to test oil.

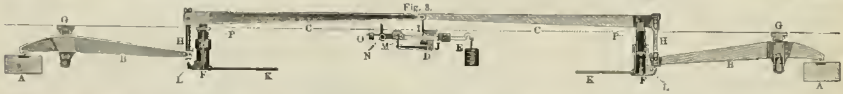
Fig. 3.



Invention of the Block System.

An Englishman named Little is claiming to be the inventor of the block system of signals, dating his invention as 1865, and asking remuneration for his services from the government. Mr. Clement E. Stretton, the able counsel for the Associated Societies of Locomotive Engineers and Firemen, of Great Britain, has proven that Mr. Little has no claim to the invention whatever. He says:

* * * "As early as December, 1839, the Great Western Company telegraphed the arrival and departure of trains from station to station between Paddington, West Drayton and Hanwell, and if a second train approached any telegraph station before the previous one was telegraphed as 'arrived,' it was stopped by signals. To all intents and purposes, this was the object and spirit of what we now call the block system. In 1841 Mr. Cooke introduced separate instruments, to be used only for train signals, and in which the needle was held over to the words 'stop' or 'go on.' He also had an electric bell, to call attention. He further introduced the 'obstruction' signal, which was to ring the bell violently in the same manner as the driver

uses his whistle in case of danger. This use of the bell implied 'danger,' stop all trains in any direction."

Mr. Little says " The word block was not used in connection with railway signaling until after his publication in 1865." How any person can make such an absurd statement I am perfectly at a loss to understand.

I have now before me the instructions for block working upon the Eastern Counties Railway in 1844, they are headed: " Regulations for train signaling by block telegraph system." I can also myself well remember the block system fully thirty years ago, or five years before Mr. Little even claims to have invented the system.

The brakeman who failed to go back the required distance at Roger's Ford, on the Reading road, the night of Nov. 1, from which a fatal wreck happened, has been arrested for culpable negligence. He ought to be in jail if he did not get back far enough when he had time

The Pope Manf'g Co., of Boston, Mass., are sending out their calendar for 1891. It is in the shape of a desk pad, with pencil and pen rack, and has a place for memoranda for each day in the year. If you tell them where you saw this notice they will send you one.

In proportion to its length, the Manhattan elevated railroad is the most prosperous and the largest money-maker of any railroad system in the world. There are many roads having a mileage 100 times greater than this whose figures do not begin to compare with those contained in the annual report of the elevated system. This report has just been made public for the last year, and the figures are simply colossal. Its total receipts were nearly $10,000,000, almost every cent of which came from passenger fares. Its net earnings were nearly $5,000,000, and it was able to pay all of its enormous interest charges, a dividend of 6 per cent on its capital, and to charge a handsome amount to its surplus fund. It carried 188,000,000 passengers last year.—*Exchange.*

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 240,000 cars. This includes 140,000 freight cars, which is about 15 PER CENT. of the entire freight car equipment of this country. Orders have been received for 80,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

VOL. IV, NO 2 — NEW YORK, FEBRUARY, 1891. — $1.00 per Year or 10c. a copy.

The Locomotive that Climbs Pike's Peak.

It is more than a decade of years since a western poet wrote a wild and fantastic article on how disgusted a Rocky Mountain "burro" was at finding a Rio Grande locomotive at the summit of Pike's Peak—western people would not have thought the poet more ridiculous if he had made the meeting in the moon. Yet the locomotive is there.

Five years ago the project took form enough to build a part of the grade for an adhesion road, but in 1889 the Manitou & Pike's Peak Railway feet per mile. The grades vary some, the maximum being 25 per cent. The heaviest climb is 1,320 feet to the mile. The line is crooked, having numerous curves, many of them of but 16 degrees, 39 per cent. of the whole road is on curves.

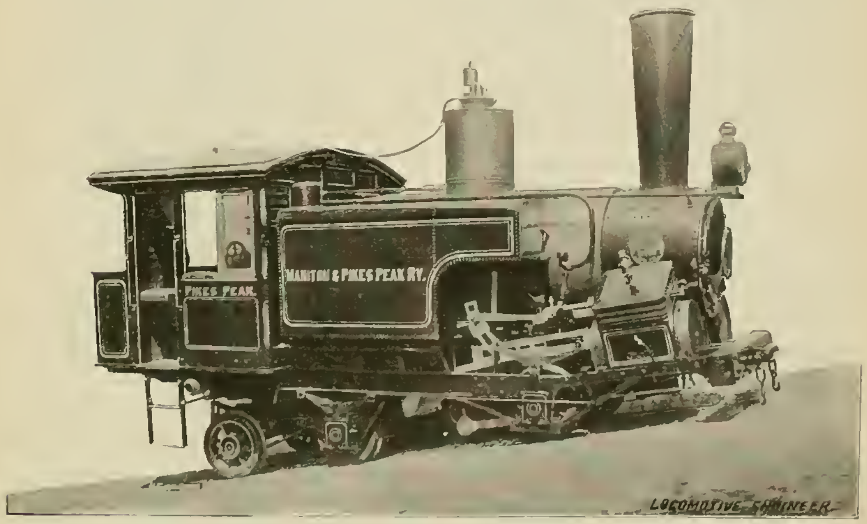
The road bed has been made wide and substantial, 15 feet on embankments, and 22 in excavations. At regular intervals the track is anchored to the rocks, to prevent its creeping down hill.

The gauge is 4' 8½", laid with 40 pound steel, these are for the carrying wheels only.

In the center of the track there is a double line of

The general dimensions of these engines are a follows.

Gauge	4' 8½"
Cylinders	17x20
Drivers	22 468
Total wheel base	11' 8½"
Driving-wheel base	4' 1½
Weight, total	53,600
Weight on drivers	50,700
Boiler, diameter	44'
Number of tubes	176
Diameter of tubes	1½'



THE PIKE'S PEAK CLIMBER.

Company was formed, with money enough to build anything, and a rack rail decided upon. The principal incorporators were the officials of the western roads most likely to be benefited by tourist travel to Manitou and Pike's Peak. Major John Hulbert of Manitou, was made president, and the engineering work placed under the charge of R E. Briggs, C E., of the D & R G Ry

Last fall the line was completed, it is just 46,158 feet long—nearly 8¾ miles. It starts from the Manitou station, at an altitude of 6 600, and ends on the pinnacle of the peak, 14,200 above the tides, the total rise being 7,600 feet, an average of 846

rack rails laid close together; these racks vary in thickness, and are in lengths 6' 8" long, having 17 teeth each; on the lighter grades, these bars of steel weigh 72 pound each, and are ⅞" thick, and on the heavier grades 104 pounds each, and are 1¼" thick, they are fast to common chairs in the center of the track, but the cogs "break joints," so that the pull of the engine is steady, and the trouble from break-downs is diminished.

Three locomotives like the one shown herewith have been built for the line by the Baldwin Locomotive Works, they are built for the Abt system, which is the double-rack rail. These engines have side tanks and a small coal bunker

Length of tubes	7' 5¼"
Fire box, length	48'
Fire-box, width	59⅝'
Fire-box, depth	F. 46¼, B 40⅝
Water space	F. 3½, S. & B. 2½"
Staying	Radial
Truck wheels, diameter	25½"
Truck journals	4x8
Driving wheel centers	15¾"
Main axle journals	6x7
Driving axle journals	7¼x4¼
Support axle journals	6x6
Carrying wheels, diameter	25½"
Carrying journals	4¼x6

They are carried on six small wheels, the two forward pair being rigid in the frame, and 80 inches apart; the back pair is a pony truck, with the radius bar pin just back of the axle of the center pair of wheels.

The outside frame is rigid with the cylinders, and extends back under the cab and fire-box on a level. The inside frame is fastened to solid boxes on the carrying axles, and has a flexible connection to the outside frame, just back of the cylinders in front.

This inside frame carries the three double, toothed drivers in the center of the frame and the engine drum and main shaft.

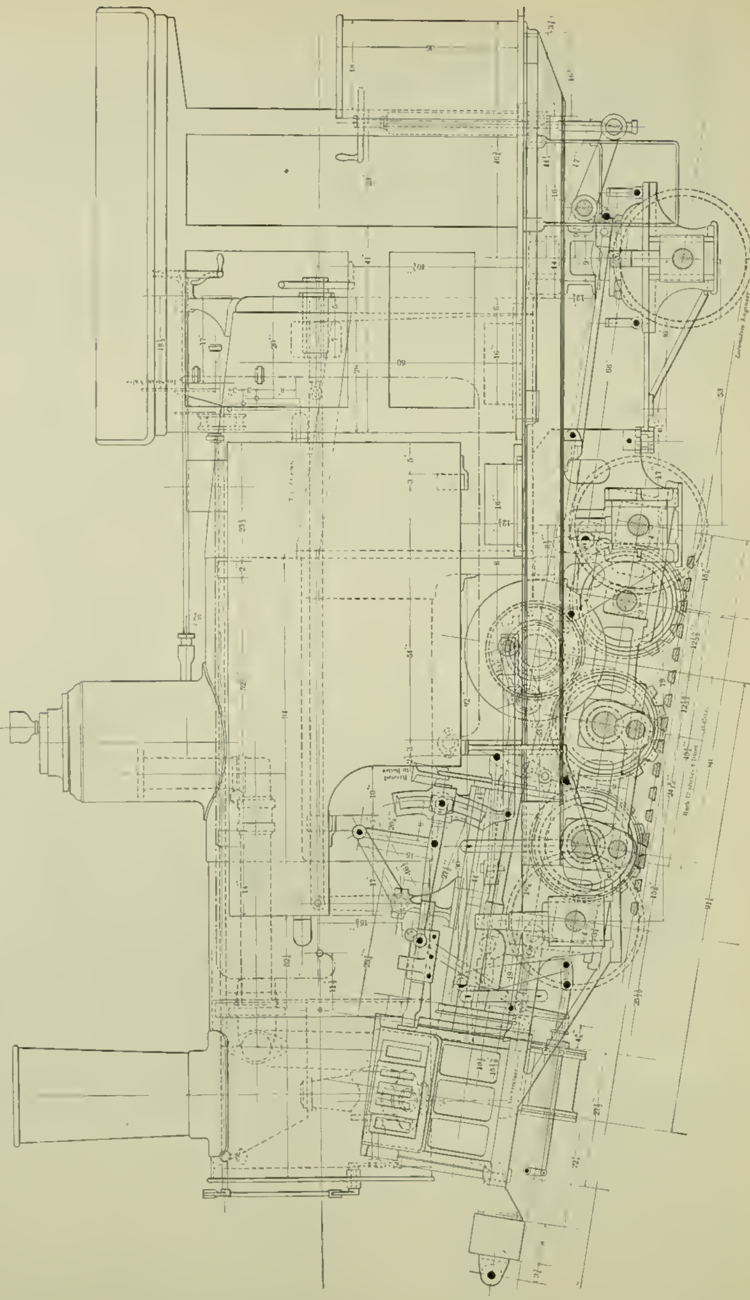
Thus the boiler and frame can move on the springs and equalizers without disturbing the mesh of the gears in the rack. This you can see in the cut on this page.

The main rods from the crossheads turn the master shaft, and gears on the shaft mesh into and drive the two back toothed drivers, the forward one being driven by side rods from the central driver.

On each main pin there is a return crank that performs the functions of an eccentric in moving the stationary link of the Walschaert valve gear, the motion being handled through the system of levers shown, and the screw reverse gear.

On each side of the geared drivers there is a heavy corrugated drum for brakes to operate on, these are of the strap pattern and heavy throughout, and operated by steam. There is also a valve arranged in the exhaust pipe in such a way that the cylinders may be used as air-pumps to operate these brakes. There is also a hand-screw brake in the cab, and the cylinders are fitted with the Le Chatelier or water-brake. The throttle is of the screw type placed on top of the boiler.

The cylinders are 17x20, and placed at an incline of one inch in six and a quarter.



THE PIKE'S PEAK CLIMBER.

The tank holds 700 gallons, and will be filled four times in a trip up.

The passenger cars have a capacity of fifty persons, and will weigh, loaded, 42,000 pounds.

The service which these locomotives were guaranteed to perform is as follows: On a road, 8¾ miles long, ascending, say 7,600 feet, and having maximum grades of 25 per cent., and maximum curves of 359 feet radius occurring in combination with a grade of 22 per cent, each locomotive shall be capable of pushing 42,000 pounds of cars and lading at a speed of five miles per hour on a grade of 16.33 per cent

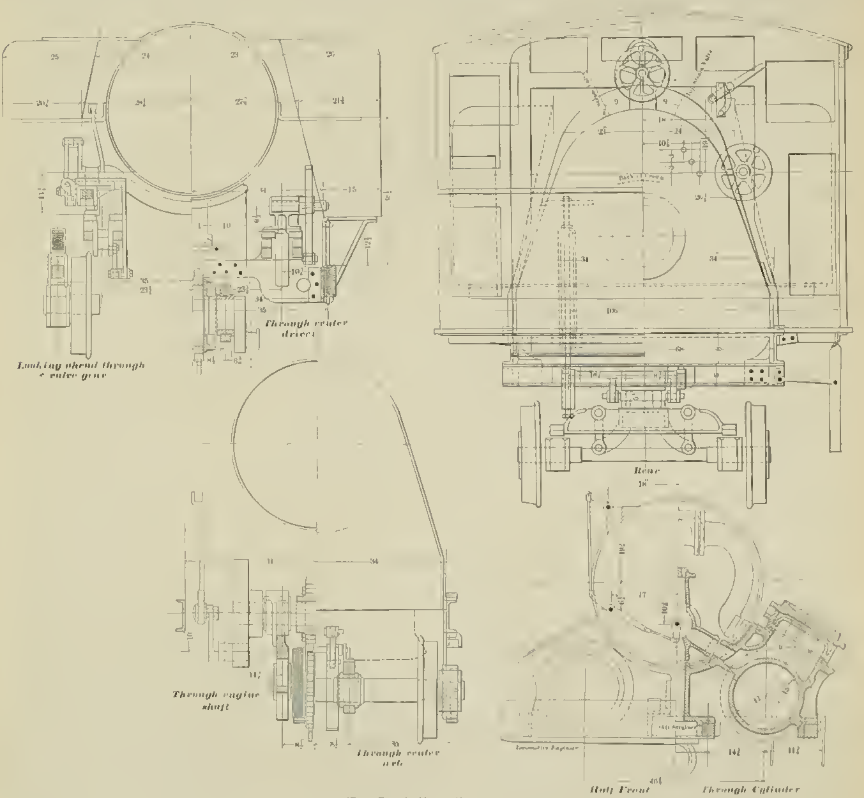
Speed of three miles per hour on a grade of 25 per cent.

Speed of eight miles per hour on a grade of 8 per cent.

In no case will speed exceed eight miles per hour.

They have from the first performed this work satisfactorily, and we are informed through reports to their builders, that, with their continued service, they are developing still better results, and using less fuel and water than was calculated upon.

This is the first publication of the details of these wonderful little engines, and their success will probably establish them as the standard rack rail engine for future mountain roads in this country, of which, no doubt, there will be not a few at no late day.



THE PIKE'S PEAK CLIMBER.

Danger of Roundhouses in Case of Fire.

In a recent article by J. Davis Barnett, superintendent of the locomotive shops of the Grand Trunk, at Stratford, Ont., reference was made, says *The Engineering News*, to the almost universal American plan of designing locomotive roundhouses so that all the tracks converge at a turntable pit outside. Mr Barnett called attention to the serious defect in this plan, in that all the locomotives must pass over the turntable, and in case of accident to this, or in case of derailment on the narrow exit tracks beyond, all egress from the roundhouse may be blocked. Instead of this American type of engine house Mr. Barnett favored the English plan of building engine sheds with longitudinal through tracks, so that in case of accident to one exit another can be used.

A recent occurrence in the yards of the Delaware, Lackawanna & Western Railroad, at Montclair, N. J., illustrates well this defect of the prevalent American system. At about 1.30 A. M., January 20th, fire was discovered in the freight house at Montclair. The local fire companies were slow to arrive, and the fire spread so rapidly as to endanger some of the cars standing on tracks near the freight house. Several engines were in the roundhouse, and one was immediately started out to move the cars to a safe position; but in the hurry and confusion it went off the track at the turntable, which, of course, blocked all the other engines from passing out. Some barrels of kerosene on the freight house platform burst, and their burning contents ran down the tracks, setting fire to six passenger coaches and six box cars, which were totally destroyed The total loss by the fire will approach $100,000.

The radial type of engine house has certainly some advantages, but if it is thought best to use it, an emergency exit should be provided in case of accident at the turntable.

Self-made Men.

Very few of us comprehend how great a part "environment," or rather all that the word implies, plays in our lives. The general idea of men who are too busy, or too careless, to bestow much thought upon the matter, is that from the time they reached man's estate they have molded their own lives; that they have adopted such or such a business, have chosen from all the world the woman who is to be their lifelong companion, have selected their special friends, and in short have ordered their whole career, and this is the reason we so often hear of "self-made men." It is rather remarkable that it is only when a man rises from obscurity to some high position, or from poverty to affluence, that he likes to employ the term, or to hear it coupled with his name. Let his course have been in the contrary direction, and he at once disclaims having had any hand in the matter, then his own will was nothing, heredity, evil influences, bad luck, everything was against him, but, even as he speaks, he is only half convinced of the truth of his excuses; his conscience—if he have one still—whispers to him that he might have done better if he would.

But while courage and energy and perseverance are undoubtedly large factors in a man's success, they do not assure it, many a man possesses all three, and yet his career proves a failure, because his environment has been such as to neutralize them and defeat all his efforts to get on in life.—*Ex.*

In a recent editorial the types made us say that the interest on $16,000,000 at five per cent was $8,000, when they should have said $800,000 When a newspaper man gets to dabbling in money matters he is just like a green farm boy in a switch-yard at night—rattled.

The Reading lost another locomotive by the explosion of the boiler on the 13th. Three men were killed. Explosions are getting too common.

Locomotive Running Repairs.

By L. C. Hitchcock.

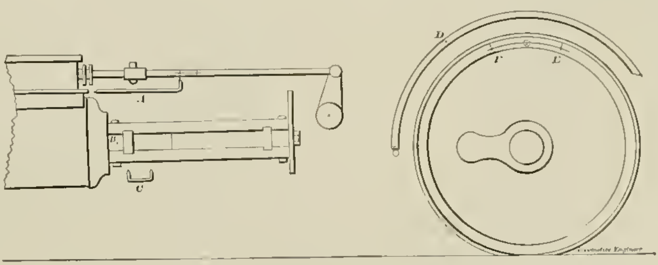
SETTING SLIDE VALVES.

Nearly every work on locomotive maintenance has a rule for setting valves, but not one mechanic in ten would follow to the letter any rule I have ever seen given while doing this work, and should a novice undertake to do this work with nothing but the rule as given to guide him I am confident that he would not meet with success

The work of Angus Sinclair is as clear as any on this subject, and, as he says, "A person can better learn this work by taking part in it." Now, in writing upon this subject I do not wish to be understood as criticising such writers as Sinclair and Forney. Nor do I intend to teach any experienced machinists in this work; but what I wish to do is to tell the younger mechanics some of my own experience in this line, and to tell them in such a manner that, by taking this paper and following the directions given, they will meet with fair success in setting locomotive valves.

We will assume that we have in the roundhouse a standard eight-wheeled engine, with cylinders 17 x24", and that the valves of this engine have been reported as being "out bad," and we are to set them. Now, if there are no rollers upon which to turn the forward drivers, and the engine has to be pinched forward and backward, you should have two helpers to do this work. The first thing to be done is to "gauge off" the engine—that is, to mark on the valve stems the points at which the valves close the steam ports. While you are taking off the nuts which hold down the steam chest covers, have the helpers disconnect the tender, and if the weather is cold they should run all the water from it into the pit, then push it outside.

It is not necessary to lift the chest covers to the floor, but just raise each and let them rest on top of the studs, then by standing on the cylinder, with the feet close to the steam chest, a man can raise the outer edge of the cover and push the inner edge under the heads of the bolts which fasten the cylinder saddle to the smoke arch, and the cover will remain in this tilted position.



Now get two pieces of thin roofing tin, about 1" wide by 10' long, rivet these together at one end, using one rivet. They can then be opened and closed similar to a pair of shears. Then go to the side of the engine where the pins are nearest on the quarter (either up or down), and have the reverse lever moved until one port is opened; then put the loose ends of your tin shears into the open port and open the tins until they will span from end to end of the port. Now have the lever moved *slowly*, and stop when the edge of the valve will have pinched the tin so it can just be moved up and down; then put a prick punch mark on that part of the cylinder upon which the steam chest rests, and with a stiff steel tram, bent as shown at *A*, and with the point on straight end in the punch mark on the cylinder, make a good deep mark on the valve stem with the point on bent end.

When the valve stems are not coupled with a "stretcher" (or right and left nut), this tram is best about 24" long. But when the stretcher is used the tram must be short enough to allow the stem to be scribed forward of the stretcher. Now remove the tin and have the lever moved until the other steam port is opened, then place the tin and repeat the operation just described.

Now have the reverse lever put in the center, or out notch in the quadrant, and disconnect the forward end of the back-motion eccentric rod on the opposite side of the engine. A helper can then take hold of the bottom of the link and move the valve stem forward and back for you while you gauge off this valve. Now see that the wedges are set up sufficiently tight to allow the driving boxes to move up and down freely. Then replace the steam chest covers, and connect the eccentric rod.

The back ends of the main rods should now be disconnected, and the crossheads be moved forward until the pistons strike the forward cylinder heads. Then mark the edge of the guides at the point where the forward ends of the crossheads rest Then move the crossheads back until the pistons strike the back cylinder heads, and mark the guides at the point where the back end of the crosshead rests. These marks are called the striking points. Now connect the main rods.

With a key seat rule now scribe a horizontal line along the valve stem, crossing the heavy lines made with the valve tram and prick punch lightly where these lines cross. Then with a small pair of sharp-pointed dividers get the exact center between these punch marks, and punch this center on the horizontal line. Now move the reverse lever until the valve tram will reach from the punch mark on the cylinder to this central punch mark, and see if the outside rocker-arm is at right angles to the guides. This can generally be done by measuring from the back of the guide yoke first to the center of the rocker-shaft, then to the center of the pin in back end of the valve stem. If these measurements are equal the stem is the proper length. If they are not, the stem must be lengthened or shortened the amount that the center of the valve stem pin is forward or back of the center of the rocker-shaft.

Look the engine over carefully now, and be sure that all bolts and nuts are securely in place, and you are then ready for action with the pinch bars.

Now, as the engine is standing under the smoke-jack, it is handier, I think, to back the engine while taking the dead centers, and, to facilitate matters, it is best to begin with the left pins on the lower forward eighth, for reasons which will be explained farther on.

Now put the reverse lever in the full back motion, and pinch the engine backward until the front end of the crosshead is flush with the back edge of the oil slot in front end of guides Then prick punch the forward guide block as at *B*, and insert one point of a small steel tram, bent as shown at *C* (the points of this tram should be about 6" apart); with the other point scribe a good plain line on the side of the crosshead. Then take a stiff steel tram, bent the same as the crosshead tram, with the points about 24' apart, and hold it in as near a level position as possible against the driver and wheel cover, prick punch the cover at *D*, insert one point, and with the other scribe a line across the tire as at *E*.

Now hold one point of the crosshead tram in punch mark on guide block and pinch the engine back carefully. The mark scribed on the crosshead will then move forward of the other tram point, and for a moment stand stationary at the dead center. It will then start backward. Stop pinching the engine when this line on its backward journey exactly reaches the tram point. Then take your wheel tram and scribe the second line on the driving tire shown at *F*. Now with a pair of maphrodite calipers scribe a line intersecting those made with the wheel tram, about half an inch above the lower edge of the tire, and carefully prick punch the exact point where the lines cross, on the line which you last made get the exact center between the two punch marks, and with a piece of chalk draw a small circle around it. This is called the dead center mark, for when the engine is moved either backward or forward until the wheel tram will reach from the punch mark on the wheel cover to one of the marks obtained in the manner described the engine will be on the dead center. This operation must be performed four times to get the forward and back centers on each side of the engine We now have the left forward center mark, the next one to get is the right forward. This is done by working exactly as you just did to obtain the left forward one. Next comes the left back center; you get this in the same manner as you did the forward ones, except that you must prick punch the guide block in the back ends of the guides, and work with the crosshead at that point instead of at the forward ends. Now for the last center, which is the right back one. After having obtained this in like manner the engine will stand with the pins on the right side, a little below the back center. Now pinch the engine back until these pins are nearly on the lower quarter, then put the reverse lever in full forward gear and pinch the engine forward, holding one point of your wheel tram in the punch mark on the wheel cover. Stop pinching, and remove the pinch bars, when the other point will go *fairly* into the center mark on the tire which has the circle around it.

Now take the tram with the straight end with which you marked the valve stem, and with the point on the straight end in the punch mark on the cylinder, scribe a light line on the valve stem. Now pinch the engine forward again and go to the left side, catch the back center and mark the stem; then go to the right side again and get the forward center, and with the valve tram make the second light mark on the valve stem. Now with the small dividers see if the two last lines scribed on the stem are an equal distance from the center point, between the two punch marks; if they are, the eccentric rod is the proper length. If they are not equally distant from the center mark, put one point of the dividers on the center mark and bring the other divider point to the light line, which is the *nearer* to the center point, then turn the divider point toward the light line, which is the farther from the center point, and note the difference. *One-half* of this difference is what the length of the eccentric rod must be changed, if the line nearest the center point is *forward* of it the rod must be *lengthened* one half of the difference shown; if it is *back* of it the rod must be *shortened* one-half of the difference. Now I consider it good policy to adjust each eccentric rod to the proper length as you go along, for this reason: We are now working on the right side of the engine, and the pins are on the forward dead center; in this position the eccentric rods are not crossed, as they would be if the engine was on the back center, and we can easily get the bolts out of the back ends of the rods and slot the holes in the straps if they require it, this we could not do if the engine was on the back center, for the rods would then be crossed, and if you wait before making the changes until you find what each rod requires, you will have to do much more pinching to get the engine into the proper positions to allow the bolts to be removed should the holes require slotting, and this is the reason why it is best, when you start to take the dead center points, to begin with the left pins on the forward center and pinch the engine backward and get the left forward center first; for then when you are ready to change the forward rods the pins will always be on the forward centers, and if you find that the holes in the straps require slotting you can remove the bolts and slot the holes, and then you can also remove the bolts from the back rods and slot the holes in the straps. After you have adjusted a rod, always pinch the engine nearly a quarter of a turn in the opposite direction from which you caught the dead center point, for by so doing all lost motion in the working parts of the engine will be taken up when you pinch the engine to its original position again; catch the center and see if the adjustment is correct. When the adjustment is correct note the lead shown. The lead is the distance that each light tram mark on the stem is outside of the port closing lines when the eccentric rod is the proper length. Should the light tram marks come inside of the port closing lines after the rod had been adjusted to the proper length, it is called blind, the distance from tram mark to port closing line.

Now to return to our work. When we have the right forward rod properly adjusted, we pinch the engine forward again and go to the left side. Catch the forward center and scribe the second light line on this valve stem. Adjust this forward rod as just described, and note the lead.

Now pinch the engine forward nearly a quarter of a revolution, put the reverse lever in full back motion, and, pinching the engine *backward*, find the proper length of each back rod, and note the lead on each side as soon as each rod has been properly adjusted. The requisite amount of lead can now be given the engine by moving the eccentrics on the shaft. Never move an eccentric on the shaft until the rod is the proper length. If the work has been carefully performed as described, the engine will be square in full forward and back motion. The engine now stands with the right pins on the back center. Put the reverse lever in the second notch in the quadrant forward of the center, or "out" notch, and pinch the engine forward, holding the valve tram in the punch mark on the right cylinder. Stop pinching when the point on bent end of tram will go fairly into the port closing line on the valve stem, and with a pair of dividers measure the distance from the striking point on back end of guides to the back end of crosshead, and write this measurement down. Then go to the left side, pinch engine forward until tram point will go fairly into the back port closing line on stem, and measure the distance from the back striking point on guides to the back end of crosshead.

Care must be taken to mark down each measurement. Now go to the right side again and pinch the engine forward until tram point will go into the forward port closing line, and measure the distance the crosshead will have traveled backward from the forward striking point. Now if this distance is not exactly equal to the distance the crosshead traveled from the back striking point when steam was cut off, then the cylinder is receiving more steam in one end than the other. For instance, if from back point be 6", and from the forward point be 8", the cylinder is receiving 2" more steam in the front end than in the back end, to make it work evenly the distance must be 7" from each point. To do this, pinch the engine backward until the crosshead is near the forward end of stroke. Set your dividers to 7", and with one point in punch mark on forward end of guide, pinch the engine forward until the forward end of crosshead has traveled backward the distance your dividers will span. Now with the valve tram make a light mark on the valve stem. The line in the present instance will come just forward of the front port closing line, and the distance between the two lines will be what the forward eccentric rod needs shortening to make the steam cut off from each end of the cylinder at 7" travel of crosshead, provided the rocker-arms are of equal length. Should the upper arm be longer than the lower arm, as is often the case, the amount to change the rod will be a little less than the distance between the two lines on the valve stem. When the *forward* end of the cylinder receives the greater amount of steam the eccentric rod must be *shortened*. When more steam is admitted to the *back* end of cylinder the rod must be *lengthened*. And when the difference is not too great the rods can thus be changed to bring the engine square, when "hooked up," without materially affecting it while working full stroke. Assuming that we have adjusted the right forward rod to make the crosshead travel equal, we will now go to the left side of the engine, and, pinching the engine forward, ascertain the distance this crosshead will travel from the forward striking point when steam is cut off. If the distances from front and back points are unequal, adjust the rod as just described. Having done this, see if the distances the crosshead travels from the left striking points are equal to those on the right side of the engine. If they are not, one side of the engine is working more steam than the other. This may be remedied by raising the tumbling shaft arm, or shortening the link hanger on the side working the greater amount of steam. Or, what is easier, and most frequently done, is to put shims between the tumbling shaft box and frame on the side using the most steam.

The amount of shim to be used can only be determined on trial, though usually every $\frac{1}{16}$" of shim will reduce the crosshead travel about $\frac{1}{2}$". It is seldom necessary to run an engine over "hooked up" in the back motion. Be sure that the back eccentric rods are the proper length when the engine is working full stroke, and also that the eccentrics are so placed on the shaft that the valves have an equal amount of lead. Then follow closely the directions just given for running the engine over with the reverse lever in the second notch forward of out notch, and I think that you will not be troubled with the engine not sounding square.

Canadian Pacific Fire Door.

Both the C. P. and the Grand Trunk roads use a form of fire door like our engraving.

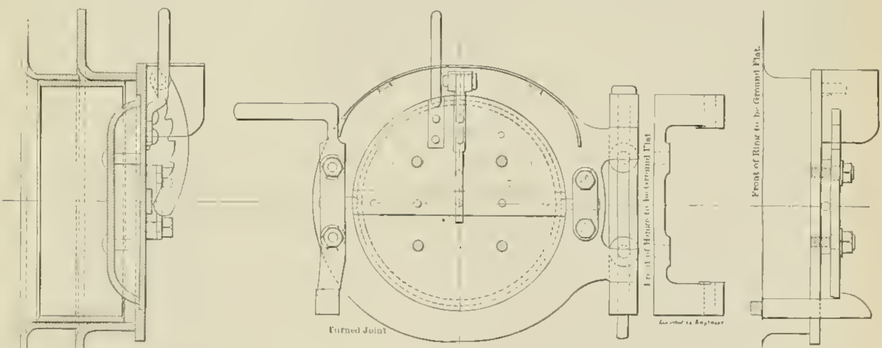
Like the general English practice, the door has a large deflector, but, like general American practice, the door swings on hinges.

The door proper is simply a ring with hinges and a latch on it. In the large opening in the center a damper swings on pivots, as shown in the center cut. This large damper is almost as large as the fire door opening in boiler, and carries on the inside the perforated liner or shield. The damper can be swung on its pivots to almost any degree by means of the upright handle shown at the top of the sectional view at the left, and the damper can be held at any point by the notched sector that drops down and engages the top of the damper casting.

Thus the damper can be set and left indefinitely, and by lifting the catch it will return by gravity to the closed position.

To get the latch out of the way of the pivoted bar carrying the damper, it is arranged as shown, with the catch directly under it.

There is no way to leave this door "on the latch"; it must be closed or open. If the engineman wishes to "cool her off" by means of the door, he opens the large damper, and by its inclination it deflects the cold air down upon the fire, under the arch, and materially assists in preventing black smoke, and the tendency of flues to weep.



John Reed, of Troy, N. Y., was convicted, on Dec. 29th, of *attempted* train wrecking at Greenbush, N. Y., on September 4, was brought into court the next morning and sentenced to Dannemora prison for seven years. His accomplices, Arthur Buett and Thomas L. Cain, entered pleas of guilty to the indictment half an hour later. Buett was given two years in Clinton prison and Cain three years and eight months. The three men broke down and sobbed aloud when sentence was pronounced.

The operators and train dispatchers of the Chicago & Erie road struck on the 20th, and the engineers, fearing to run without proper orders, stopped their trains. The management are trying new tactics, and with evidence of making it hard for the men. They have shut down everything, stopped all trains, shops, etc., suspended the pay roll entirely, and announce that they will not attempt to run trains until the strikers announce that they may. This is cheaper than fighting.

The Chicago & Alton road has notified its passenger conductors that a cash prize will be given to the one who takes up and turns in the largest number of annual passes found in the possession of those to whom they do not belong during the year.

The Consolidated Car Heating Co., of Albany, have issued their first complete catalogue, a very neat and fully illustrated 118 page book. This company control the business of five of the old companies, the most important being the Sewall and the McElroy.

James K. Verner, secretary of the Pittsburgh forge and iron works, and one of the best known iron manufacturers in the country, died in Pittsburgh on the 12th of January.

The engine mileage on the Southern Pacific for the month of November was 703,000 miles. The car mileage, 10,427,273.—*Ex.*

Combination Stand for Cab Fittings.

The accompanying engravings show a very handy form of stand for cab fittings that is cheap and easily made, does away with the necessity of drilling the boiler full of holes, and provides means for grinding in, removing, or renewing any cock in the cab while boiler is under steam.

The body is made very heavy, and of brass, flange jointed to the boiler head as shown. On this road—the Boston & Albany—the injectors are located ahead of the cab, operating rods reaching through to the engineer, and the throttles for both injectors are in the back pipe of the stand as shown. This makes the cabs more comfortable, and gives room, and there is less danger from scalding in case of accident. In this stand both injector throttles, the blower, steam heater cock, steam brake, lubricators (both hand and automatic), and the steam gauge cock are accommodated, and still there are two plugs for possible extra appliances. The stand also supports both gauges and the gauge lamp.

The Chicago Belt

The Belt Railroad of Chicago has about 22 miles of main and 20 miles of side tracks. They control the track of the old Chicago & Western Indiana into the city, and have a belt around the city connecting all the roads. They operate 33 locomotives, enough of them being double-crewed to bring the number of crews up to fifty.

The business of the road is to transfer cars from one line to another, getting them to destination without delay, and delivering loads from any part of the city to any road, whether that company has tracks to where car was loaded or not.

The road has only 125 cars of its own, of all kinds, none of which are passenger cars. The road runs no regular trains, but all hands switch, from Genesis to Revelations, though there are many long transfer runs.

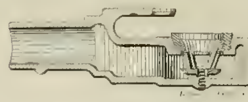
There are quite extensive shops at Auburn, but most of the machinery and tools are not as good as they could be.

The amount of car repairs must be something enormous. Peter H. Peck is M. M. of the road, and he has his hands full in looking after his own engines and everybody's cars.

Westinghouse's New Hose Coupling.

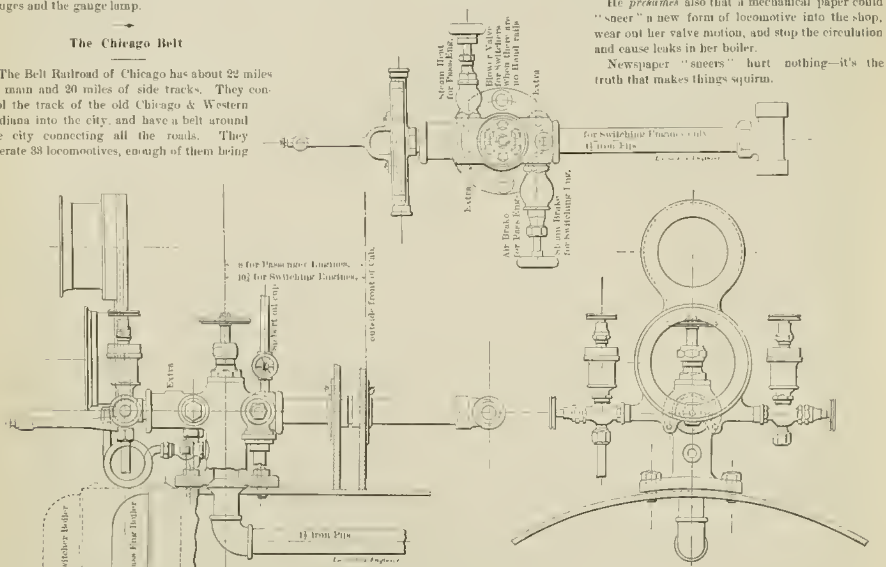
The little engraving accompanying this article shows a new method of holding the rubber gasket in a hose head. The retaining thimble is held down by a small machine screw, and is put in from the face of the coupling instead of requiring a large, air-tight joint on the back of each coupling head, and the expense of threading the hole and the cap for it. The head is just the same shape as the old one, and will, of course, couple with it, but it is lighter, has less joints, and costs far less.

This is one of the kind of inventions that pay—making some good thing better and cheaper. The old patents on the Westinghouse coupler have run



out, and they can be used or made by any one; but no mechanical officer of a road will want the old one, even at the same price as the new, because the new is simpler and lighter, easier to repair, and has less joints.

Thos. J. Hogan, of Pittsburgh, Pa., is the inventor. He has, however, sold his invention to the Westinghouse Air-brake Co.



B. & A. COMBINATION STAND.

Sad, but True.

A contemporary has said that the Boston & Albany has ordered the pilots taken off all its freight engines, and makes the statement a text of a more or less sagacious little editorial. We are informed that the statement "is not true. The company has not changed the policy which has obtained for more than 20 years." Pilots are not used on its switching engines, local freights, and gravel trains.—*Railroad Gazette.*

We are sorry that the *Gazette* man did not ask some one who knew what they were doing on the B. & A. Water boys or car cleaners can't keep posted on the going-ons in the motive power department. We will have to repeat, for the sole benefit of our contemporary, that the B. & A. are actually and honestly taking the pilots off all the freight engines.

The Sharpneck roller bearing is in use on many coaches on the Rock Island road. No lubricant is used and no attention given to it, yet it seems to do well. The cars are reported to pull much easier and require less attention than the old style.

We are in receipt of the Eighteenth Annual Report of the Commissioner of Railroads of the State of Michigan. The report is a large book of over 700 pages, replete with the usual statistics to be found in works of this class.

A Strong Man Who Knows (?)

THE LOCOMOTIVE ENGINEER says the Strong locomotive on the Santa Fe road, by which it is presumed is meant the A. G. Darwin, which was run about this city for a while, is laid up, and will be rebuilt into a compound, with a plain fire box and valve gear. THE LOCOMOTIVE ENGINEER'S opposition to the Strong engine, which has been expressed upon every opportunity, has taken the form of sneers rather than argument, and it is not, therefore, surprising to find it stated in that publication that leaks in the fire-box, caused by poor circulation, was her worst affliction, and that her valve motion developed considerable lost motion. The valve motion has been considered the best part of the engine by competent judges in this part of the country, and if plain valve gear is to be substituted, it means that the present owners of the engine are through with experiments with the Strong devices.—*Providence Journal.*

The above is a fair sample of the verdicts of some self-appointed mechanical judges.

He *presumes* the A. G. Darwin is on the Santa Fe, instead of knowing that that road bought a brand new Strong, the last one built.

He *presumes* also that a mechanical paper could "sneer" a new form of locomotive into the shop, wear out her valve motion, and stop the circulation and cause leaks in her boiler.

Newspaper "sneers" hurt nothing—it's the truth that makes things squirm.

We have never "sneered" at the Strong locomotive; as a mechanic, our editor said at the start that it would not be a practical success on the road, and told why. Since then we have simply and briefly recorded the progress of the device toward the scrap heap—where it must end.

We refer our judge to the motive power department of the Santa Fe road; the officers there may offer no opinions, but they will no doubt state the truth, viz., that there was poor circulation and constant leaks about the fire-boxes; that, to remedy it, circulating pipes were put on; that the valve gear wore badly in a very brief service, and that the engine will be rebuilt into a plain fire-box, link motion machine. These are not sneers, but simple facts. People with stock in the concern will probably still call any adverse criticism "sneers." "Competent judges in this part of the country" may not know what the requirements of a locomotive valve motion (for hauling cars) are.

If the judge is right, and the present owners are through with experiments with the Strong devices, there is hope for the engine—with a common fire-box and link motion the engine will be a very good one.

F. A. Stinard, recently with the Boyden Air-brake Company, is now in charge of the Chicago office of the U. S. Metallic Packing Co. Mr. Stinard is a graduate of the Erie.

New Form of Tire-cutting Brake Shoe.

The ordinary tire dressing shoe has steel pieces cast in it. These pieces are made as hard as possible, but the melted cast-iron when poured on and around them anneals them. This gives but one cutting power, which cannot be made more or less effective. On hilly and crooked roads the tire is not reduced on those portions not bearing on the rail and the flange, as fast as it wears on the rail under heavy engines with small wheels, while on passenger cars the tire is cut too fast. To remedy this defect, the shoe shown in the engraving was put into use. The depressions *E E* and *b* are cast on a chill, leaving chilled cutting edges, *A A*. The hardness of these edges may be varied by different mixtures of iron. On the Santa Fe, where this shoe was designed, three grades of cutting edges are made to cover all the conditions found in passenger car wheels, heavy and light engines on level or hilly divisions, so that the wheels are kept in perfect section, which was not possible before their use.

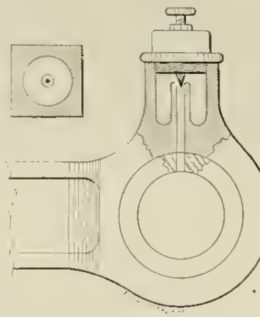
Locomotive Fuel Tests on the Southern Pacific.

A test is now being made of the relative cheapness of wood and coal for use of locomotives on "the hill," in the jurisdiction of Superintendent Wright, between Sacramento and Truckee on the Central Pacific. Fuel is one of the most important items of expense of railroading in California, and the result of the proposed test will be watched with the greatest interest in railway circles. Every factor that can enter into the relative cost of wood and coal as fuel for locomotives will be calculated with the utmost precision. The number of cars, with the exact weight of each, the weight of the locomotive, and of the water in the tanks, and of the wood in the timber will be taken. Few people realize the amount of fuel it requires to operate the section between Sacramento and Truckee. An ordinary light eight-wheeler will use up about twelve cords of wood to Summit from Sacramento—the amount of course varying with the size of the train—while one of the heavy "hog" engines will chew up as much as eighteen cords in the same distance. The quantity of wood annually used on the division is enormous. If it were piled eight feet high by two feet in width, the ordinary length of locomotive wood, it would make a pile fifty miles long. This is only a reasonable calculation of the amount of wood that is used annually on "the hill." Last year the quantity was much greater, and this calculation only applies to years when the winter ranks about average, and when the business is fair.—*Alta California*.

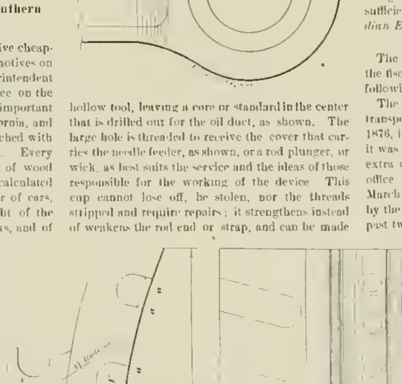
The so-called strike of the agents and operators on the line of the Chicago, Milwaukee & St. Paul Railroad has developed a new feature in railroad operation, which presents an interesting question. It seems that at a small station in Iowa, containing about 500 inhabitants, where the operator resigned, the people refused to have anything to do with the new representative of the railroad sent to that point, even to the extent of refusing him living accommodations. Under these circumstances but one recourse appeared to be open to the company, and they consequently withdrew their agent and closed the station. This move not being appreciated by the residents of the town, they at once made application to the Iowa railroad commission to have the station reopened, and it is stated that an order to that effect will be issued. Just how the controversy will be settled does not yet appear. Perhaps the commission in their order for reopening the station will be kind enough to designate to the railroad company some method by which its agent can be fed and lodged at that point, and also give some reason for ordering station service at a point where the inhabitants refuse to have anything to do with the duly authorized representative of the company.—*Ry Review*.

A Solid Oil Cup.

The accompanying illustration, which was made from a sketch from memory, and not to scale, shows the plan of a cheap and substantial oil cup, formed on a solid rod. The place usually left for the oil cup hole is simply extended up a little, perhaps less than shown, and the cup bored out with a



hollow tool, leaving a core or standard in the center that is drilled out for the oil duct, as shown. The large hole is threaded to receive the cover that carries the needle feeder, as shown, or a rod plunger, or wick, as best suits the service and the ideas of those responsible for the working of the device. This cup cannot lose off, be stolen, nor the threads stripped and require repairs; it strengthens instead of weakens the rod end or strap, and can be made at small expense on any form of rod, but seems peculiarly adapted to the solid-ended rod. Once made it is a fixture. They are in extended use on the Grand Trunk and the Canadian Pacific.



Section A. B.

TIRE-CUTTING SHOE

We have an inquiry for a description of the Hassen air-brake, a California invention. Who knows what it is like?

Improved Boilers.

Three locomotives have just been turned out of the Grand Trunk shops at Point St. Charles, and are intended to run between Niagara Falls and Point Edward. They are built for speed and durability, as well as being of finished design. The driving wheels are 6 feet 6 inches diameter. The cylinders are 18x24 inches in dimensions, with a 24-inch stroke. They have mansells capable of retaining the tires on the boilers, and, in fact, every appliance known to the modern locomotive.—*Port Huron Times*.

Leather Brake Shoes.

Experiments in New South Wales with brake shoes made of compressed leather show that the coefficient of friction is so much greater that 40 pounds of air pressure are as effective as 70 pounds with iron shoes. The leather shoes weigh 4½ pounds, as against 21½ pounds for the iron shoes. The shoes are made of waste leather scraps steeped in a softening solution and subjected to hydraulic pressure sufficient to mold them in the shape desired.—*Indian Engineer*.

The annual report of the Postmaster-General for the fiscal year ending June 30, 1890, contains the following:

The rate of compensation to railroads for mail transportation was established in 1873. In July, 1876, it was reduced 10 per cent., and in June, 1878, it was further reduced 5 per cent. In the matter of extra compensation for the use of railroad post-office cars, no reduction has taken place since March, 1873, though concessions have been made by the companies in the matter of space. In the past twelve years no reduction of rates has taken place, though the freight rates upon all railroads have been steadily lowered. During this period the weight of the mails has largely increased. It is quite reasonable to say that the reduction in freight rates generally between 1878 and 1890 is not less than 20 per cent., and in many instances it is much more. The largest expenditure of the department is for transportation. The estimates just sent to the Treasurer for the next fiscal year cover $22,610,128.31 for railroad transportation alone.

We recently saw three switchers standing in a yard, close together, but not all belonging to one company. All had driver brakes, one the old-style, American, double-piston, spread, steam brake, the second had a vacuum brake, and the third had an American brake operated by air. The first device leaked so you could scarcely see the engine, the second had two shoes out of the six off and braking against the beam-heads, and each arm to the diaphragms was loaded down with broken drawheads, links and short pieces of rail. The air-pump of the third was dancing along about eighty miles an hour, trying to supply air for a half-inch split in a pipe, the wounded pipe having been poulticed with a piece of old overall, and some wire, but the bandage had slipped.

Mr Angus Sinclair, secretary of the American Railway Master Mechanics' Association, has issued the following circular: A general index of the annual reports of this association, from the first to the 23d, inclusive, has been prepared and is ready for sending out. Members desiring to obtain the index will receive it free of charge, on applying to the secretary. The index is of service only to those who have the back reports and use them for reference.

The Jull snow excavator recently purchased by the P. R. R. has done some good work on the road. The company have two new ones nearly complete at the Rogers Locomotive Works.

Who was the first to use a cast-iron brake shoe?

The South Carolina Cup.

On the South Carolina Railway, where J. H. Agnew is master of machinery, they use a novel oil cup that is possessed of numerous advantages, and gives splendid results; they cannot be broken off by rough usage and are cheap.

As will be seen by our engraving, which is full size, they are totally unlike other brass cups.

The stem that screws into the rod strap extends into the cup to carry the feeding device; this stem is made of machinery steel, and is not fast to the cup proper in any way; it simply extends through a plain hole in the bottom of the cup, and holds it in place by the pressure of its flange against the bottom.

The cup is put on and taken off by a socket wrench, also shown in the engraving.

The feeder is a common wood screw acting as a plunger, its throw being regulated by a set screw. With 1-32 of an inch of lift to the plunger this cup has run 10,0 miles, and fed out but ¼ of an inch of oil. The steel shank is a big improvement over its weak sister made of brass.

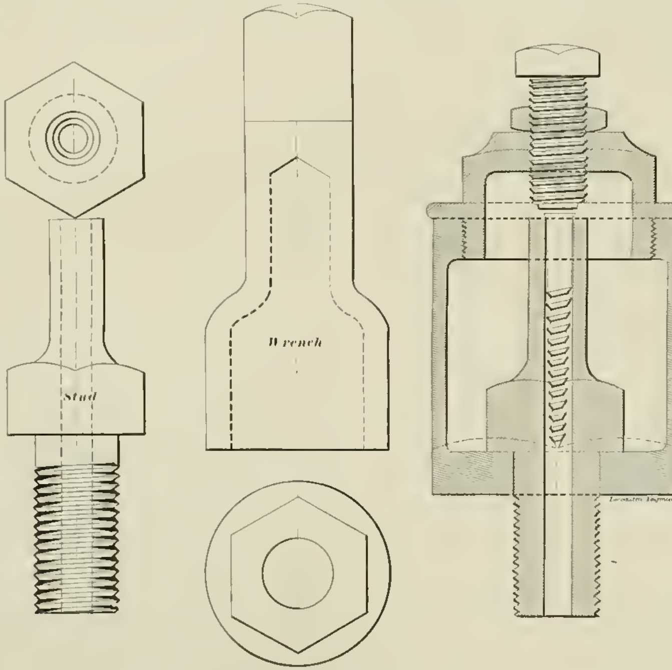
The P. R. R new P's have a weak dome cap; the second one blew off in Pittsburgh recently. They have reduced the pressure on these boilers to 140 until the domes can be repaired.

Soldering.

Under date of Jan. 14th, the associated press dispatches say:

The State Board of Arbitration, in a special report to the legislature on the late Central Hudson Railroad strike, makes several suggestions for legislation. The board urges that entrance into railway service should be by enlistment for a definite period upon satisfactory examination as to mental and physical qualifications, with oath of fidelity to the people and to the corporation. Resignation or dismissal from such service to be permitted for cause, to be stated in writing and filed with some designated authority, and to take effect after the lapse of a reasonable and fixed period, and any combination of two or more persons to embarrass or prevent the operation of a railroad in the service of the people to be regarded as a misdemeanor.

Great changes have taken place this month on the U. P. Harvey Middleton, superintendent of M. P., and John Wilson, assistant, have resigned, and Joseph H. McConnell, for many years in charge of the North Platte shops, has been made superintendent of M. P. Fred. Metzheimer, assistant superintendent, in charge of the new shops at Cheyenne. James H. Manning will be master mechanic of the Eastern Division; John O'Hearne, general foreman of the Omaha shops, and Thomas H. Dailey, chief clerk of the motive power department. All are old U. P. men.



The South Carolina Cup.

Correspondence

Air-pump Valve Stops.

Editor The Locomotive Engineer:

I would like to ask W. F Relyea or some of the other air pump doctors how they get the lengths of valve stops without taking off steam cylinder, as they run in lengths from ⅝ to 1¼ inches, owing to the difference in thickness of center casting. Will he please inform A Reader.

Wilmington, Del.

Why Does a Steam Whistle Extinguish Lamps?

Editor The Locomotive Engineer.

In your reply to Question No. 4, January issue, as to the reason why a lantern in the cab goes out when the whistle is blown, I do not think your explanat on accounts for it in all cases.

In 1866 I sold tickets at Pittsfield, Mass., on the Housatonic Railroad. It being the end of the road, the train after being made up stood for some time at the station, and the locomotive was directly opposite my outside window at a distance across the platform of at least six feet. On the window frame of my office was an ordinary bracket kerosene lamp. One of the rules introduced at that time by Superintendent Hunt was that the engineman should sound a blast of the whistle five minutes before starting. There was one engine (the Litchfield, I believe,) whose whistle was pitched at a lower key than the others, and when blown it always put out my lamp. The distance from the whistle, and the fact that the locomotive stood out-of-doors, seems to prove that there must have been some other reason than the partial exhaustion of the air. I attributed it to the vibration due to that particular whistle, no others having the same effect. Why the vibration should have extinguished the lamp I am not so sure. R. W. Pope.

12 *West 31st Street, New York.*

Forewarned is Forearmed.

Editor The Locomotive Engineer:

Bein' troubled in mind regardin' the futur' (this world, I mean,) and knowin' you was in with some of the men what has shops and stores I tho't you might be able to help me, fur my job ain't goin' ter last long, ef what I heard t'other nite is tru'. I've bin leanin' out the cab winder watchin' signals and keepin' my hand on the throttle, knowin' that any mistake meant axident, and maybe death, to the mothers and babies and little girls and boys what ride on the owl train; but all my leanin' won't be no use now. It's kinder nice to feel that you are responsible for sumthin', even if it's only the old scrap heap that runs extra or owl sometimes, but I must soon bid farewell ter even this pleasur', as the locomotives must go ter scrap; at least that was what I heard at the Franklin Institute (which was called fur that chap that used ter coax lightnin' on a kite string) not long ago, for he said (Prof. Marks, but he ain't no relation) that in a few years the locomotives would be in ther scrap heap, so I want ter get you to look after a job for me—sumthin' easy and kinder decent like. He and another electrical chap named Bell (Dr. of lightnin' or sumthin' of ther kind) went on ter tell us how the moter could just hum and hum and git there, and not have ter lug coal or water, only just scrape up what lightnin' they wanted from a rail or rod and just *fly*.

Wal, I ain't no flyer, and so would be kinder skeery to run one of them things, even if they would let an old plug-puller run one. But sum of the things they told us seemed a leetle queer to us railroaders, for they told about askin' an engineer of some fast train how many j'ints he had ter oil, and after stoppin' fer a s cond or so he told 'em just 64 And they said that if he failed ter oil any one of them 64 holes it meant accident to ther train. Guess they never seed a man makin' up time on a fast run, and not stopping ter oil or anything else for a 60-mile run. But I want ter see ther chap that can count up ther j'ints in ther motion and all ther fixin's under ther machine in a minute, or even two; some can't in a month, and as fur axident or death in case a man forgot to oil, wal, I guess all ther railroading he ever did was on paper in sum office where ther wind all came from ther register Of course, if I am ter git thrown out of my job I s'pose I must hustle 'round and git sum stationary engin' ter play with, as I b'lieve they haven't said we can't do that yet; but it seems kinder queer to me to hear them say it is cheaper ter make ther power at one place and then send it scootin' through a leetle wire way along fer miles, and scrapin' it off as they want. Maybe it's all right, but it seems kinder hard on ther old loco ter send her inter the scrap heap just as they have begun ter git her whare she is doin' sumthin' in the coal-savin' line, and is gittin' so she can hustle trains in purty good shape.

Then, again, it seems as tho' ther' was a big chance fer ther fluid, or whatever it is, ter get loose on ther line, ter kinder radiate, ef ther stuff is built anything on ther steam line, but of course we don't know, fer they tell us about their volts and such like things that we ain't got no time ter read about (and maybe wouldn't if we had), but what I want ter find out is how ther j'urnals can be kept decently cool if they add any heat ter the axles. For I've felt of several armatures (kinder careful like, fer I'm a little skeery,) and they always seem kinder warm, without takin' their runnin' heat inter account (felt of them after they had just stopped), and it seems ter me that addin' heat ter the axles ain't ther way ter keep journals cool. But then it's queer stuff anyhow, and we ain't posted.

Camden, N. J. R. E. MARKS.

P. S. No relation ter the Prof.

In a Criminal Condition.

Editor The Locomotive Engineer:

I see a great deal in your paper about pooling engines. I would like to tell a little about those that I handle. I have been running pooled engines about two years, and it is the meanest kind of work. The other day I broke down and had to take my engine down on one side with a monkey-wrench and a coupling pin for a hammer. As a general thing there are no other tools on an engine that runs in the pool, and the glass broke out of half the windows in the cab; headlights never get cleaned, and don't throw as much light as a common lantern. When you want green or red signals, you must steal them from another engine, and leave that fellow do the same. Oil cans all leak, and have no tops or lids on them. What windows that are not broken are that dirty you cannot see through them. One scraper for the fireman, and no tank boards to hold coal, and if you ask the boss for anything he will tell you that so-and-so got along yesterday without it, and so must you. So much for running pooled engines.

Shamokin, Pa. A SUBSCRIBER.

Gibson's Air-pump Puzzle.

Editor The Locomotive Engineer:

There are two conditions which will make an air-pump run as described by Mr. Gibson:

First, the reversing cylinder being so short that the cap would not hold it in place. In that case the steam would blow past the reversing cylinder, where it ought to make a joint next to the ports. Second, it will act about the same if the reversing valve cap does not make a joint on top of the reversing valve bush, allowing steam to pass over the top of the bush and down its side through the groove to the cylinder, thence through exhaust ports of upper main steam valve bush.

As to Mr. Gibson's second problem, would say that there must have been an obstruction either in the steam or exhaust pipe, notwithstanding he says the pipes were all right. I have seen exhaust pipes in smoke-arch so stopped up with cinders that the pump would not work. Exhaust pipes to air-pumps should reach to the top of smoke-arch, they would be less liable to stop up.

I did not take out main piston to examine rings, nor did I say that I did. When I got the head off, I discovered that the trouble was in the main steam valve, and of course was satisfied that the main piston rings were all right, without taking them out.

I expect to give the boys a "tough" one next month. W. F. RELYEA.

Syracuse, N. Y.

The Answer.

Editor The Locomotive Engineer:

I notice in my last air-pump puzzle a mistake I wish you would rectify. Instead of reading, "all pipes in good order," should read, "all air pipes in good order."

The answer to the first question is: The bottom of reversing valve bushing was broke, allowing it to drop down on reversing valve stem. Machinist wrapped it with tin, drove it in place, and pump worked all right. Second question: We use an exhaust pipe extending into the smoke arch and having a cap screwed over the end, and a number of small holes drilled into the pipe. These holes had become clogged up. EDWARD GIBSON.

Wilmington, Del.

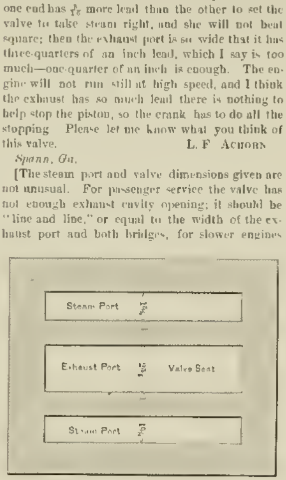
Proportion of Valve Seats and Valves.

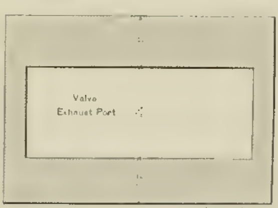
Editor The Locomotive Engineer:

Please find enclosed a sketch of a valve put in an engine by one of the large builders in this country, which they say is all right, but I think is not. I say that both ends of the valve should be the same, as both ports and bridges are alike, and then I say the exhaust port in the valve is too wide, so it gives too much lead on the exhaust. As you will see, one end has 1/16 more lead than the other to set the valve to take steam right, and she will not beat square; then the exhaust port is so wide that it has three-quarters of an inch lead, which I say is too much—one-quarter of an inch is enough. The engine will not run still at high speed, and I think the exhaust has so much lead there is nothing to help stop the piston, so the crank has to do all the stopping. Please let me know what you think of this valve. L. F. ACHORN.

Spann, Ga.

[The steam port and valve dimensions given are not unusual. For passenger service the valve has not enough exhaust cavity opening; it should be "line and line," or equal to the width of the exhaust port and both bridges, for slower engines





an inside lap of not more than a sixteenth is often used with good results. The difference between the two sides of the valve was probably made to get an even exhaust. It used to be the general practice of some builders to pay little attention to the proper proportion of lifting gear and to the point of suspension of the link, the valves were made with inside lap, and set to cut off square, regardless of the exhaust, then the wheel was quartered correctly, and the inside of the valves cut out so that the four exhausts would be even, regardless of the uniform point of release; the valves were then marked F for front, and if you got them in wrong you had a lame engine. This practice has been pretty much abandoned now for more correct methods. An indicator would be the quickest, simplest and cheapest way to find trouble with your engine's valve motion, the compression line would at once tell whether or no the crank was doing all the stopping of reciprocating parts on the centers.]

The Chain Gang from the Fireman's Point of View.

Editor The Locomotive Engineer:

I would like to say a few words about this chain gang business from a fireman's side of the question. In the go-off you are called to go on freight about two in the morning. You get on the engine, and the first thing is, "Where is the torch?" You look about five minutes, and finally locate it in the tool-box, mixed in with tools, coal, pieces of packing, dirty waste, and the Lord knows what else. Then you look at your oil cans, some full, some empty, and just about this time your torch goes out. Cause, no wicking. Put a piece of waste on packing hook (if you can find it), go out to light and fill head-light, find it empty, and about half enough oil to fill it with, and it is the same thing on every one of them. Look around and see what you can find, and if you can't find it, let it go. I have always fired a regular engine until lately, and I could go on that engine the darkest night in the year, and always find what was wanted without wasting an hour looking for tools, torches, oil, etc., and I could put a clean pair of overalls on, and they would last a few days at least; but now they are dirty before I get them unrolled. You can talk about the fireman getting rid of cleaning. Give me the regular engine, and the cleaning, too, every day in the month. I don't know how much the company makes by this deal, but I know it makes me, as a fireman, cuss a good deal. FIREMAN.

Lockport, N. Y.

De Sanno's Breakdowns.

Editor The Locomotive Engineer:

Some time ago I cited a case of broken back-driving axle, and asked the readers of THE LOCOMOTIVE ENGINEER what ideas or plans they would have for blocking up. I took out the broken axle, boxes and wedges; jacked engine up until the forward boxes were down on the binders, then blocked between back spring saddle and top of frame, which of course put a tension on the forward spring which was resting on top of frame over forward driving-box, then put block of hard wood in between top of forward driving-box and frame, then let the engine down. If she crushed the block too much, raised her up and put in a larger block, and increased the size of the block until I got a good squeeze on it, without splitting. My idea was to give the springs about all they would carry without breaking. I put the block of wood on top the forward driving-boxes to catch the engine in case the springs gave out, also to carry part of the load, but not to put the whole weight of the engine into the crown of the forward jaws. I blocked up the back springs to make the load more elastic than it would have been if I had taken out the back springs, and put a block under the back end of equalizer; but I do not claim to have taken any of the weight off the forward drivers. Felt safer to send the engine out that way than to put any of the load on the tender. Had no old wheels to put under the fire-box. Was I right or wrong?

In regard to that bad case of slipping ahead after the engine was shut off, will say, the dry pipe did collapse, and why the engine came to a halt so suddenly was caused by her breaking the right valve stem at half stroke, which shut off the outlet on that side, and when the left valve covered the ports on the left side the game was up.

That other engine that got to bucking, and would not move, her right piston, rings and springs broke into small pieces, leaving the key sticking through the end of the piston rod. A piece of the broken piston blew through and blocked up the valve, and caused the blow. Why that piston and attachments should fall to pieces so suddenly, and while working light steam, is a mystery. The cylinder did not have a scratch on the inside, and the forward head was an old repaired one, and the joint on it was not started. These strange accidents are some of the mysterious things that happen in the life of railroad men, that are not under human control, or brought about by any human agency.

Corry, Pa. W. DE SANNO.

Ambrose Webster, who is and has been for more than thirty years superintendent of the Waltham Watch Works, was once a railroad mechanic. He tells an interesting story of his experience on the Richmond & Danville road away back in '53. He jacked a locomotive up and took out her wheels without shoring up on each side and at the ends of the boiler, and got discharged for it—master mechanic said the boiler might have tipped over. If he jacked up an engine and *did* prop up the boiler now, he would probably have to take a walk just the same.

Grievance Preventive.

Take any of the long lists of grievances presented to the operating officers of American railroads by the employes of any department or departments, and analyze them, and you will, in nine cases out of ten, find the whole formidable array composed of little things, or what at the start were little things

Partly from the disposition of the men to kick only among themselves, and partly from the overbearing manner of many officials, the men do not communicate to their officers the little annoyances of the service, but nurse them and favor them, and believe they are big and dangerous, until a pimple becomes an ulcer or a cancer. The practice of nursing little, petty annoyances until they become unbearable grievances should be discouraged and avoided by both the men and the officers over them. Nothing is better for trouble of this kind than an occasional chat with each other.

It's a pretty poor division master mechanic who don't know what is going on among the men under him, if they are dissatisfied with something he is doing, let him go out into the roundhouse and have a half hour's chat with half a dozen of them —perhaps both sides are laboring under wrong impressions. If there is an annoyance on the road the men ought to feel free to go in, on the start, and tell the master mechanic all about it; a turn of the hand, the scratch of a pen, or a word may rectify the trouble and strangle a grievance at birth.

The old idea that a railroad officer must be out of touch with the men in order to serve the company is dead wrong, and is dying with a lot of other old ideas, the best captain is the man whom the men love, who goes with them and says "come"—not him who gets behind a tree and says "go." Motive power officials who have the good of the service at heart will recognize this, and also that it is a difficult thing for one or two men to do all the talking—he should talk with them all. He should also remember that our enginemen are only beginning to shed their prejudices, and that if any one man went to him regularly, even with the sole idea of righting wrongs, he would be soon marked down as a tale-bearer—a sucker.

The M M. can get a better idea of the exigencies of the service by going over the road, riding on the engines, and putting himself in the places of the men. Where such a policy is pursued you will find more contented men, fewer grievances and less trouble It is not necessary that the master mechanic and his right bower, the traveling engineer, should take in the town, play pool or drink beer with the men—each should preserve his proper dignity and be an example to them—not *above* them, but the best man *among* them.

The officer who does the right thing among the men will soon be picked out and respected according to his acts Not because he *favors* the men, but because he is *just* to them. Not because he puts them on one side and the company on the other and then leans to their side, but because he makes the interests of each identical. Not because he assumes that the rank and file are cattle to be coaxed or driven as the case may be, but because he considers them as, at least, half human, and treats them accordingly

Prof. Marks and Dr. Bell recently delivered a lecture, or read reports, before the Franklin Institute, Philadelphia, in which they made a great many wild statements about the death and decay of the steam engine and boiler, and how electricity was going to haul all our trains, very fast, at little expense, etc. One of them stated that on a locomotive the engineer had sixty-four places to oil, and if he missed one of them disaster was the result; the motor was going to run cool, etc. We have received a number of letters on the subject from practical mechanics, but the one on another page, from R E Marks, about fills the bill.

John D Campbell, who has been general superintendent of the New York elevated roads for the past three years, and was formerly general foreman of the shops, has been appointed assistant to Wm Buchannan, Supt of M P of the N Y Central & Hudson River road. John Campbell's old friends will be glad to see him back in his element —the mechanical department Mr. Campbell's experience as a machinist and locomotive engineer dates back for more than twenty years; he has more than ordinary mechanical ability, is a splendid shop manager, an organizer, a good man to handle men, and above all is clean—he is nobody's "man." The Central road, and Mr. Buchannan in particular, are to be congratulated upon getting so able a mechanic without any "ifs" or "provided howevers" to him

Of about six hundred companies operating railroads in the United States, three hundred and seventy-seven report that they have strict rules forbidding the use of intoxicating liquors.

Book Reviews.

THE CARLISLE ACCIDENT AND THE VACUUM BRAKE. Compiled Opinions of the Press.

This is a book of 100 pages of the opinions of the principal papers of Great Britain on the brake failure that caused the fatal accident at Carlisle on the 4th of March, last year.

The book was issued, no doubt, to refute the claim made by the Vacuum Automatic Brake Co, that the accident was not caused by ice in the pipes. The author cites 214 cases where the brake has failed on account of ice in three years the instances are from the Board of Trade returns. The work does not state the name of the author or the publishers.

REPORT OF THE COMMISSIONER OF LABOR FOR 1889. DEVOTED ENTIRELY TO RAILROAD LABOR Compiled by Carroll D. Wright, Commissioner. Government Printing Office

This work is composed principally of tables of wages on different roads for all classes of employes The pay lists were made up from the actual pay-rolls of sixty different roads There is a great deal of useful information in the work on insurance and relief associations, the number of accidents, and a lot of useful matter concerning the laws in different States on the liability of employers for personal injuries to their employes. There is also a table of wages paid on roads in Great Britain. You can get a copy of this work free by requesting your congressman to procure you one.

ASKED & ANSWERED.

(10) J. D , Durham, N C , asks

Who is the inventor of sight-feed lubricator? *A* —The sight-feed lubricator was invented and patented by J. Gates, Portland, Oregon, April 29th, 1873

(11) M R B , Washington, D C , asks:

What is the size of delivery tube of No. 8 monitor injector? *A*. We suppose you mean the combining tube, which governs the size of an injector; other tubes may be varied for different service A No. 8 injector always has a combining tube eight millimeters in diameter, regardless of the make

(12) J. B Horner, Shamokin, Pa , asks:

1. Does the hooking back of the reverse lever increase the lead on the valves of a locomotive? 2 Does the automatic governor on high speed Armington & Sims engines shorten the stroke of the valve and cause the engine to have increased lead? *A* —1. Yes 2. Lead is constant Shortening the travel does not necessarily change the lead

(13) A L. Swift, Eldon, Iowa, asks:

1. At what point will the exhaust occur when an engine 18x24 is working with the reverse lever hooked up to cut off exactly at 6" of piston travel? The engine's valves are set line and line, no lead, 3/4 outside lap, 5 1/2 eccentric throw. 2. How much should the lead increase by hooking her up two "notches"? *A* —1 It is impossible to tell exactly from this data but the release should take place at about 15" of piston travel for a 6" cut off 2. That depends upon the design of the valve motion, principally the length of the eccentric blade

(14) M. R , Georgetown, D C , asks:

Why is it that the train pipe cock should be turned off on the train before the cock on tender of engine is turned, or the air will apply brakes on train? *A*. —It is only necessary when opening or closing a cock not to reduce the pressure under the train Most noticeable when taking on extra cars or coupling on a new engine; in the latter case if the train cock is turned first, enough air will expand into the hose to reduce the main line pressure enough to set the brake; if you open the tender cock first, the hose is filled from the engine drum, and when the train cock is opened no reduction takes place

(15) C P C., Frisco Line, asks

Do you believe a 15"x1 1/4" steam port will give sufficient port opening to an 18 cylinder, cutting off close at high speed, even though engine may have 5 1/2" valve travel. *A* —There is a great difference of opinion on this subject In average American practice the length of port is short for high-speed engines. It is ample for the steam to get in at, but a large opening is needed for the exhausted steam to get out There are many reasons why a port should be kept as short as possible, and some of the fastest locomotives in the world have ports as small, or smaller in proportion to cylinder, than the size stated

(16) Elevated Fireman, N. Y., asks:

Will you kindly inform me why vacuum is read in inches and steam in pounds? *A.*—Vacuum could be expressed in pounds or steam in inches, but it has been customary, and still is in some countries, to express pressures in "atmospheres"—the pressure of the atmosphere is 14.7 pounds per square inch. Vacuum is always less than one atmosphere, and it was easy to express vacuum in fractions of atmospheric pressure. If you had a U shaped glass partly filled with mercury, one end open to the air and the other connected to some vacuum-producing device, for every pound of pressure that the device took out of its end the mercury would rise two inches in the loop until there was 30 inches more in the connected end of the tube than in the open one, when a practically perfect vacuum would be obtained. An inch of vacuum means, practically, a half pound of pressure.

(17) Frisco., Monett, Mo., writes:

We have a class of engines that ride very hard, working at short cut off and running fast. Some of the boys believe it to be in the counterbalance. Others think it is owing to excessive compression. These engines ride hard only when working under the conditions named. We have another class that do not develop this trait, even with the most inside lap. We have decided to ask your opinion in regard to it. *A.*—The hard riding is probably caused by excessive compression at short cut-off; if these engines ride easy at high speed running down hill shut off, it would help to prove that the counterbalance was not guilty. The engines with the inside lap would have greater compression under ordinary circumstances. There may be a difference of outside lap that is responsible for the extra compression, or other conditions might cause a derangement of the steam admission or release. The hard riding engines may have more or less clearance, different motion, or other chances to cause pounding.

(18) C., Monett, Mo., writes:

Give a concise description of the steam reverse gear, as applied on the P. R. R. *A.*—The reach rod is connected to the piston rod of a pair of small horizontal cylinders placed just ahead of the cab, the rod extending through both cylinders just as it does in an air-pump. One cylinder is for steam, and the admission of pressure to either side moves the piston rod and the reach and tumbling shaft in the direction desired by the runner. The second cylinder contains oil on both sides of the piston, the cylinder being kept entirely full; from one end of the cylinder to the other there is a connecting port that is closed by a plug valve; this valve is so connected to the steam handle that when the latter is moved either way from a central point it opens communication between the two ends of the oil cylinder, and the pressure of the steam forces the oil from one end, through the port, to the other. When the steam valve is brought to a central point steam is shut off and the plug in the oil passage closed; the oil then holds the piston and its attachments in position. The steam cylinder takes the place of the engineer's muscles, the oil cylinder takes the place of the quadrant and the latch. Don't make one of them; the P. R. R. are taking them off, and you can probably get your pick of the pile at Altoona, Pa., for a small consideration.

(19) Young Runner, Durham, N. C., writes:

I have been running an engine with an old style No. 7 Sellers injector, that will not work at a pressure of 130 lbs. of steam, but will readily work at a pressure of 75 lbs. My idea is just this: The tubes in the injector are, from the use of impure water, nearly filled up with incrustation or sediment from this water. Please let me know if my idea is correct. *A.*—What causes the trouble with your injector depends upon what style it is. It may be an old Gifford, an old style (1867) Sellers, or the "76", and "circumstances" govern cases. Assuming that it is an old-style (1867) device the trouble probably arises in this way. This injector was arranged so that the discharge tube moved through a bushing between the overflow chamber and the overflow valve, which was located ahead of the discharge tube; this bushing and discharge tube would become worn by use so the water, after leaving the discharge tube, would pass back into the overflow chamber with sufficient pressure to push the combining tube back against the steam tube and shut off the supply of water, which will, of course, cause the injector to stop working. The reason that it will work at 75 lbs., and not at 130, is that there is less pressure, and the leak at that is taken up and carried through the discharge tube, but when the 130 is there the leak is so much it cannot be all taken in at overflow; the longer it is used the more it will leak and the lower pressure it will work at. If it is any other style of instrument, state what it is.

The very able paper on Air-brake Rigging, by R. A. Parke, M. E., read before the New York Railroad Club, has been issued in pamphlet form. The article is worth a dollar of any railroad man's money, but you can secure a copy free by sending a stamp to Secretary N. Y. Railroad Club, 28 W. Thirtieth street, New York.

The firm name of the Baldwin Locomotive Works has been changed from Burnham, Parry, Williams & Co., to Burnham, Williams & Co. The new shops and new tools added during the past year have increased their annual capacity to above 1,000 finished locomotives. More than double the capacity of any other works on earth.

The Chicago Shops of the Rock Island Road.

[*Editorial Correspondence.*]

The Chicago, Rock Island & Pacific line reaches from Chicago to Colorado Springs, Colorado, a distance of over 1,000 miles, besides many branches, bringing up a total of 3,257 miles owned and leased, which includes the Chicago, Kansas & Nebraska. They are running on all the lines upward of 500 locomotives, and over 10,000 cars.

THE MAIN SHOPS

are located at Chicago, but the new shops of the Western line, located at Horton, Kansas, are said to be the better shops on account of the equipment being new. The Chicago shops are located between 47th and 52d streets, and occupy a large and valuable tract of land in the windy city.

THE BUILDINGS

are of white brick built some twenty years ago, but have been well kept up, and were especially well constructed in the first place. The yards are tidy and neat, but not embellished by landscape gardens—but you don't care much about the shops; you want to know what they contain that is of interest.

THE MACHINE SHOP

adjoins the office, and is of the usual one story design, having the pits on one side and the machine tools on the other, the latter arranged so as to handle material as little as possible. There were twelve or fourteen engines on the pits for general repairs at the time of my visit, and they are also building six new 18x24 8-wheelers—they have just completed six others, and very handsome machines they are.

ROCK ISLAND ENGINES

have for years been remarkable for certain peculiarities, and were unlike anything in the country. The idea of Mr. Twombly, who for years was at the head of this department, was to make a locomotive with as little machine work as possible, thus cheapening the machine. Mr. Wilson has followed out the idea of cheapening parts, but has made his engines look more like standard machines.

CAST-IRON

has been used for many parts, and forgings, nicely made and painted, take the place of much expensive machine finished work.

THE TWOMBLY ENGINES

all had straight boilers, and the first peculiarity you noticed was that the back head was held in by a double row of rivets, while all other seams had but a single row. Then the throttle was located in the smoke-arch, using a large, open dry pipe, the bell crank arrangement was located back of the stack on a rather cumbersome cast-iron frame, from which a rod ran along the left side of the boiler, above the running board, to the cab, the throttle lever reaching entirely across the boiler head to connect with it. When one of these engines stands for any length of time, water collects in the dry pipe, making them disagreeable to handle.

Long years ago the men named the throttle frame back of the stack the "turkey-roost," and this style of throttle was known among them by that name.

CAST-IRON ROCKERS

have been used here for many years, and with perfect success. With cast iron there is no chance to bend or spring, and a new one can be made for less than it costs to straighten a wrought-iron one that has been bent. The old engines here had a rather small rocker, and a crooked one at that, yet they had no trouble with them. Cast-iron guides were also used.

WROUGHT-IRON PARTS,

such as the rods, eccentric blades, valve stem rods, etc., were only machined where they came in contact with other pieces. The valve rod has only the hole drilled in each end, the keyhole for valve stem, and the sides of the back boss turned off; the rod itself is rough and painted. Side and main rods are the same, the eccentric blades having only the ends finished, the link hangers the same.

Some of the old engines had a long reverse lever, and the reach rod running from the lower end along the side of the ash-pan to the arm of the tumbling shaft, which was straight and extended down.

THE DRIVING-BOXES

had strips of brass cast into them, which made a cheap construction, but they gave trouble by getting loose, and in cutting.

THE CHEAPEST ENGINE TRUCK

I have ever seen is made here, and has given satisfaction for years. They use only a 24 inch truck wheel, which is pretty small. The truck is of the floating-box style; the pedestal jaws are cast-iron, the wearing faces of which are chilled, the top, where it is bolted to the frame, being the only place planed. The sides of the box are cast against chills, and it has no machine work on it at all; the cellars are cast neatly, and go into the box right from the foundry. The top frames are simply two pieces of flat iron cut off to the proper length, placed together and drilled. The truck is a rigid one, having a cast-iron center, which, of course, admits of cheap frame construction that could not be used in a swing truck. The brasses are cast, the sand taken off the face roughly on an emery wheel, and lead lined. No reamer is used in any holes, turned bolts are driven into well-drilled ones, and no fine work is expended on them. These trucks have given such good satisfaction for years, and have cost so little for repairs, that Mr. Wilson uses them for his best engines, his only improvement being in the use of a steel tired wheel, he has used some Allen wheels, but the new ones have the Boies steel wheel. On the inside of the cellars of this truck they place a piece of $\frac{3}{16}$ sheet-iron that is cut out to fit the axle, it is held up in front by a small tap bolt into the cellar casting, at the back there is another tap bolt through a slot in the strip, this admits of raising the strip as the brass wears away and drops the cellar away from the journal, and serves to keep out dirt, and keep the packing in.

THE NEW ENGINES

are something to be proud of, both in design and workmanship. They have a splendid wagon top boiler, and the design conforms more to the style of well-known builders. Cast-iron Laird guides are used, cast-steel rockers and the wrought parts are painted instead of finished, but they are so neatly forged that at twenty feet distance an expert would not note the difference. They have extensions and straight stacks.

BUSHINGS.

Everything that is subject to wear is bushed, rods, link motion, tumbling shaft arms, etc. The plan is to do little machine work on these engines during future repairs. The tumbling shaft has a bush on each end held by a set-screw, and the box has a bush as well. The tumbling shaft ends can be made true in ten minutes by simply changing bushes, and it need never see a lathe.

BALANCED VALVES

designed in the shop, with two sets of round packings on top, are used; the valves are enormously heavy, and one would think that they would jerk the valve stems off, yet the new engines have got up to more than sixty-five miles per hour without trouble.

These engines are 18x24 with a 62-inch wheel center.

THE FOUNDRY

is rented to a firm of contractors, who do the company's work by the pound. The use of a foundry is of great help to a shop, and many kinds of work and many cheap processes are rendered possible by its use, that are out of the reach of the shop without one. One pit in the shop has a good drop table, there are racks between pits for the different parts of stripped engines. The shop is roomy, there are cranes where needed most, the light is good and the place clean.

A NEW SCHEME

In the rod gang's place we noticed a self-adjusting main rod brass scheme that is being made for trial under the direction of the inventor. This consists of a heavy eccentric located between the brass and the rod end, with provisions for turning it, and holding it when turned. The inventor says they will start with the brasses $\frac{1}{16}$th open. It looks as if he would soon have the brasses hopelessly loose in the strap—it has been in use some time on stationary engines. Some of the different classes of work are under the care of a foreman, thus all the tire, pin, axle and other driving-wheel work are seen after by one man. E. Eich is foreman of machines, and C. E. Trenton foreman of the pits.

THE BOILER SHOP

is under the care of our correspondent, Jas. Heron, who seems to be the right man in the right place. He has been in charge but a few weeks, but has already introduced changes and improved methods wonderfully. Heron is one of the few boiler makers who do not have to have a wooden template designed in the drawing-room for every piece he makes. He lays off each piece when it is flat, and punches every hole that goes into it before it is bent or flanged. On some back heads they were punching when I was there, I noticed even the gauge-cock holes were punched as well as those for other attachments, and the mud ring, this is not usual.

SYSTEM.

The plates for an entire boiler are brought in on a large push car, rather high, one sheet on top of another; the foreman lays them off, and as they are finished they are lifted to another car or by a crane or trolley, and the first one is punched long before the last one is laid off.

Mr. Heron has a system of templates—that's what he calls them—that are simply long steel straight-edges drilled full of holes. With these and a pair of dividers he lays out a complete boiler. He will explain it all to you if you go there, but I can't explain it. (Heron has promised to do so soon.)

All irregular-shaped sheets are trimmed with a punch; shears are not used. The punch is one of Mr. Heron's own make—a design he has used for some years.

THE PUNCH

is shown in the sketches herewith, and is oblong, seven-eighths of an inch wide and two inches long. A side view of the tool is given in cut marked "front," and, as will be seen, there is a round bit at one end that does not come out of the die while at work. The tool is started from the edge, or from any hole large enough to admit the "tit," and this acts as a guide to the work. Fig. 3 shows how the work can be turned under the tool, making a round or square turn, an obtuse or an acute angle. This cut also shows the form of the punchings.

With this punch they cut out the back heads, flue sheets, throat plates, etc., and it leaves a smooth edge that needs no other trimming. While I was there they cut out a back head in eighteen minutes.

One of the greatest advantages of the punch is that it leaves both pieces straight and flat, the outside pieces being useful for patches. This tool can be used in any punch that is strong enough for the work, and it does such nice work that, if tried, you will never again use a round punch for dome holes, etc.

ANGLE IRON SHEAR.

Boiler makers who have much tender and ash-pan work to do know what trouble and annoyance the cutting of angle irons by hand is. Mr. Heron does this work with a shear, and the ends look as if they had been sawed. This tool is here shown by rough sketch. The point of the tool strikes the iron first, using all the power of the machine to cut the heavy part in the corner.

LARGE ROLLS.

They have a new set of heavy rolls, made by a well-known maker, that we have had occasion to criticise before, not on general principles, but because of little faults that detract from their usefulness. Railroad shops, as a rule, cannot afford more than one set of rolls, and these should be adapted to every variety of work they have to do. This make of rolls will not close together enough to permit of the rolling of a smoke-stack, roundhouse jack or any such work of thin iron. The operating levers are so arranged that one man cannot handle them without moving, and the tilting screw frame is so heavy that in an accidental starting of the lowering gear recently the tail of the top roll was badly bent. In most rolls this screw is only held by a couple of long bolts, that would break long before the massive roll tail could get a four-inch crook in it—a case where a device is made too good.

ATTACHMENTS TO HYDRAULIC RIVETER.

At the end of the shop there is a tower and crane for handling work for the big riveter. When I was there they were using the riveter for a punch, and a very good one it made, being able to get to the center of a very large sheet. They are building a little attachment for this machine, for reaming or drilling out holes. It will be very useful, especially in repair work, to clear out bruised holes or those that do not come exactly fair.

FLANGING FORMS

of cast-iron are used, and so constructed that the crane does not have to let loose of a piece that is being flanged, and the entire flange is turned at a single heat. It is an advantage in heating a sheet, say the back head, to have it punched first, as the fire goes through the holes and gets the whole sheet hot evenly, while with a blank sheet the edges are burning before the center of the sheet is half hot enough.

THE BLACKSMITH SHOP

is a very large one, and under the charge of another ingenious mechanic, in the person of Mr. Geo. Tutbury. This gentleman does more and heavier work on his "bulldozer" than any one I have yet seen. The formers used for this work are kept in a storeroom of their own, and are very ingenious.

Some of the heaviest work they do are equalizers for floating box trucks. These are about five feet long, an inch thick, and five and a half wide. They are bent edgewise, and done very neatly. They are kept from buckling by lips on the opposite sides of the two jaws of the former.

An endless variety of car irons are bent up here and punched. Handles for Janney couplers, having four bends are made by the hundreds; draw-head yokes, very heavy, are formed, and brake beam hangers, with several bends, are made four at a time.

Nosing irons of one-sixteenth inch stuff, bent at a very sharp angle for the edges of unloading boards on stations, were formerly heated and bent by hand at an expense of fifty cents each, are made now on the machine, cold, at a cost of a cent or two each for labor. Heavy keyholes in draw-bar bolts are punched on the bulldozer by clamping them between dies that leave an opening just large enough for the punch.

The usefulness of the bulldozer would be very much enhanced if the builder would make the frame a little deeper at the back end. Even light work that is high has a tendency to tip over, making it very hard to do accurate work, and rendering some otherwise simple jobs impossible.

NO LARGE STEAM HAMMER

is used, but a heavy steam helve hammer takes its place. It does good work for a tool of its kind, but a direct steam hammer would be far better.

A GAS FURNACE

for heating iron for the formers is in use, and a very neat device it is, doing away with the smoke and dirt of several large fires.

THE TIN SHOP

is located over the machine shop in a gallery, and is well supplied with tools. In one corner I noticed a pile of several hundred signal lamps for switches, etc., a class that have been discarded. In the shop there were piles of neat malleable iron castings of the bodies of new four-light lamps. In this tin shop they were making a lot of copper wire steam chest joints, and putting them together in a way that was, to me at least, new. Instead of cutting the ends at an angle the ends were left square and a slit sawed into each end for about a quarter of an inch, and a little piece of copper sheet slipped into the slits. This brings the ends up fair and a smart tap with a hammer holds the ends solid while being brazed.

EXTREMES MEET.

A person originally designed by Providence for a clown, as I was, can't go around a place like this without seeing something that strikes him as comical. I was looking for it—just as a boy with new boots hunts a mud puddle—and found it in the tool-room. General Foreman Black had just been showing me their truck and how they cheapened work by making paint take the place of polish, and had me all enthused with the subject and its details when we stepped into the tool-room. The gear cutter was at work on a pile of nice castings of spur and pinion wheels *for hand cars*—think of it! The road commenced this practice years ago, before cast gears were as good and cheap as they are now, and the roadmaster still insists on cut gears.

THE CAR SHOPS

are very extensive, and are well fitted up. They are under the supervision of Mr. B. K. Verbryck, Gen'l M. C. B., ably assisted by Sam'l Pullman, M. C. B., in immediate charge. They have a very neat and efficient iron-clad storehouse for paints with the oils located in the cellar. There seems to be plenty of room and good facilities.

I noticed an 80-foot sleeper in the paint shop, that would not have let the doors shut if there had been another coat of paint on the draw heads.

The cars are painted better and more pains taken with the ornamentation than usually seen. Mr. John Rattenbury is the master car painter, and some of the handsomest work I have ever seen is the pearl inlaid pictures of locomotives and cars turned out under him as advertisements for the road—they are works of art.

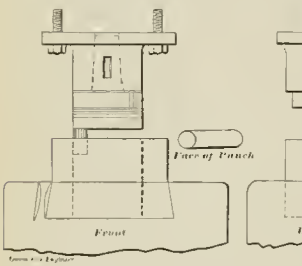

FIG. 3.

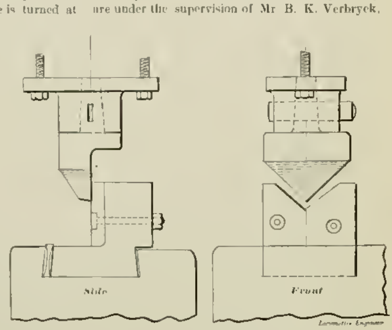


THE ROUNDHOUSE

is under the care of an old runner, E. W. Kenyon. The house is a modern one, where the engines head in, and is about like other roundhouses. They use here a cast-iron smoke-jack that lasts about five times as long as a sheet metal one.

A POINT.

In this shop they put their extensions on in one piece, and in putting in a new boiler the front end is not riveted to the boiler. It is otherwise finished and is then fitted to the cylinders and fastened there, giving the men more room and time to work. When they are ready for the boiler they set it on, slip the joints together, and rivet it fast.

AIR ENGINES

Small, compact oscillating engines are used for driving cylinder borers, etc. Air is supplied by two brake pumps located in the boiler house. There was a Westinghouse and a New York pump side and side. Starting at nothing, the Westinghouse pump would fill the large drum to working pressure in twelve minutes. The New York pump took twenty four minutes to do the same work. G. F. Wilson, Sup't of Motive Power, and General Foreman John Black have little to be ashamed of and much to be proud of in this shop; it is above the average. J. A. H.

The Newport News & Mississippi Valley lost a locomotive and an engineer on January 8th by the explosion of the boiler. Inspect.

The Clean Man and the Dirty Angels.

BY JOHN ALEXANDER

When I first went firing, down in my native district, where Bean is king, there was a man on the road pulling a mixed train, by the name of Clark—'Lige Clark.

Being only a fireman, and a new one at that, I did not come very much in contact with Clark, or any of the other engineers, excepting my own—James Dillon, whose story I have told you.

'Lige Clark was a character on the road, everybody knew "old 'Lige"; he was liked and respected, but not loved, he was thought puritanical, or religious, or cranky, by some, yet no one hated him, or even had a strong dislike for him.

His honesty and straightforwardness were proverbial. He was always in charge of the funds of every order he belonged to, as well as of the Sunday-school and the church.

He was truthful to a fault, but, above all, just.

"'Cause 'tain't right, that's why," was his way of refusing to do a thing, and his argument against others doing it.

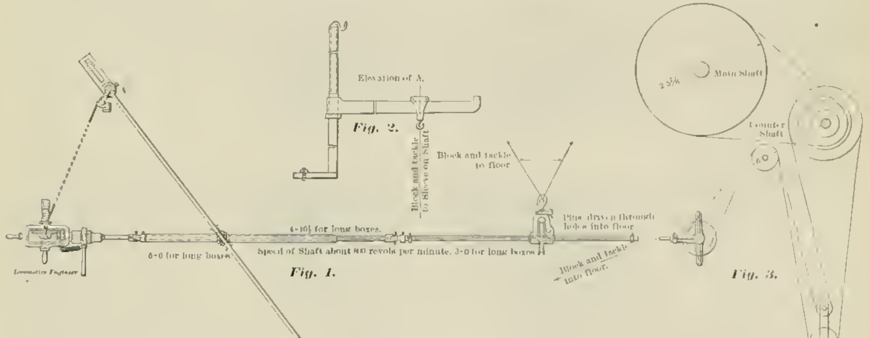
After I got to running I saw and knew more of 'Lige, and I think, perhaps, I was as much of a friend as he ever had. We never were chums. I never went to his house, nor he to mine, we were simply roundhouse acquaintances, used to talk engine a little, but usually talked about children—'Lige had four, and always spoke of "doing the right thing by 'em."

he always got up and said: "Them air declarations ain't right, an' I wouldn't ask any railroad to grant 'em", or, "The declarations are right; of course I'll be glad to take 'em."

When old 'Lige declined to hear a grievance it was modified or abandoned, and he never took a request to headquarters that was not granted—until the strike of '77.

When the war broke out 'Lige was asked to go, and the railroad boys wanted him to be captain of a company of them, but he declined, saying that slavery was wrong and should be crushed, but that he had a sickly wife and four small children depending on his daily toil for bread, and it wouldn't be right to leave 'em unprovided for. They drafted him later, but he still said it "wa'n't right" for him to go, and he paid for a substitute. But three months later his father-in-law died, up in the country somewhere, and left his wife some three thousand dollars, and 'Lige enlisted the next day, saying, "'Tain't right for any man to stay that can be spared, slavery ain't right—it must be stopped." He served as a private until it was stopped.

Shortly after the war, 'Lige was pulling the superintendent over the road, when he struck a wagon, killing the driver, who was a farmer, and hurting his wife. The woman afterward sued the road, and 'Lige was called as a witness for the company. He surprised everybody by stating that the accident was caused by mismanagement of the road, and explained as follows: "I pull the regu-



SCREW-STAY TAPPING MACHINE.

Screw-stay Tapping Machine.

At the Montreal shops of the Canadian Pacific they use a very efficient home-made machine for reaming and tapping out holes for stay bolts.

The machine was designed to reduce the delays and annoyance from breakage of flexible shafts.

Our engraving shows at the right, Fig. 3, the arrangement of the rope-driving device, which is a very good one, giving the operator plenty of "go-and-come." This is, however, independent of the machine.

The slip joint in the center of the machine is supported by a trolley on the swinging arm of a small crane, as shown at *A*, and also in Fig. 2, the drill head, shown at the left, being supported by a cord attached to a weight and suspended in a small sheave hung in the hook on top of the crane.

The drill head is geared as shown, and has convenient handles for its manipulation. There is also a small clutch that enables the operator to stop and start the drill at pleasure without shifting belts or disturbing the driving gear.

The outer end of the knuckled driving rod carries the driving pulley, which is made fast to the floor by a small tackle, the tension of the driving rope and weight keeping it up.

With one setting the boiler maker can tap all the holes in the side sheets of a boiler. This machine runs at a high speed, and does very fast work.

We have received numerous letters on the air pump question since the publication of the answer, which, of course, we cannot use.

'Lige had a very heavy, full beard, that came clear up to his eyes, and a mass of wavy hair—all iron gray. His eyes were steel gray, and he had a habit of looking straight at you when he spoke.

On his engine he invariably ran with his head out of the side window, rain or shine, and always bareheaded. When he stepped upon the footboard he put his hat away with his clothes, and there it stayed. He was never known to wear a cap, except in the coldest weather.

Once in a while, when I was firing, I have seen him come in, in winter, with his beard white with frost and ice, and some smoke-shoveling wit would dub him Santa Claus.

'Lige had a way of looking straight ahead and thinking of his work, and, after he got to running express, would go through a town, where other trains were side-tracked for him, looking at the track ahead, and at the trains, but never seeming to care that they were there, never nodding or waving a hand. Once in a while he would blink his eyes, that was all. The wind tossed his mane and hair, and made him look for all the world like a lion, who looks at, but appears to care nothing for the crowd around his den. Some one noticed the comparison, and dubbed him "The Lion," and the name clung to him. He was spoken of as "Old 'Lige, the Lion." Just why he was called old I don't know, he was little more than forty then.

When the men on the road had any grievances they always asked 'Lige to "go and see the old man." 'Lige always went to lodge and to meetings of the men, but was never known to speak. When the demands were drawn up and presented to him,

lar Atlantic express, and should have been at the crossing where the accident occurred an hour later than I was; but Mr. Doe, our superintendent, wanted to come over the road with his special car, and took my engine to pull him, leaving a freight engine to bring in the express. Mr. Doe could have rode on the regular train, or he could have had his car put into the train, instead of putting the company to the expense of hauling a special, and kept the patrons of the road from poor and slow service. We ran faster than there was any use of, and Mr. Doe went home when he got in, showing that there was no urgent call for his presence at this end of the line. If there had been no extra train on the road this farmer would not have been killed; 'twa'n't right."

The widow got pretty heavy damages, and the superintendent tried to discharge 'Lige. But 'Lige said "'twa'n't right," and the men on the road, the patrons, and even the president agreed with him; so the irate super. gave the job up for the time being.

A couple of weeks after this, I went to the super.'s office on some business, and had to wait in the outer office until his Grace got through with some one else. The transom over the door to the Holy of Holies was open, and I heard the well-known voice of 'Lige, the Lion.

"Now, there's another matter, Mr. Doe, that perhaps you'll say is none of my business, but 'tain't right, and I'm going to speak about it.

You're hanging around the yards, and standing in the shadows of cars and buildings half the night, watching employes. You've discharged several yard men, and I want to tell you that a lot of the roughest of them are laying for you My advice to you is to go home from the office They'll hurt you yet. 'Tain't right for one man to know another is in danger without warning him, so I've done it, 'twouldn't be right for them to hurt you You are not particularly hunting them, *but me;* but you won't catch me."

Mr. Doe assured the Lion that he could take care of himself, and two nights later got sand-bagged, and had about half his ribs kicked loose, over back of the scale house.

When the trouble commenced in '77, old 'Lige refused to take a request for an increase of pay up to headquarters; said the road could afford to keep us just where we were, which was more than some were doing, and 'twan't right to ask for more. Two months later they cut us 10 per cent., and offered to pay half script. Old 'Lige said that 'twan't right, and he'd strike afore he'd stand it; and in the end we all struck.

The fourth day after the strike commenced I met 'Lige, and he asked me where I was going to hunt work I told him I was going back when we won. He laughed, and said that there wan't much danger of any of us going back, we were beat, mail trains all running, etc. "'Tain't right, Brother John, to loaf longer'n you can help. I'm going out West to-morrer"—and he went.

Some weeks afterward, Joe Johnson and I concluded that, contrary to all precedent, the road was going to run without us, and we also went West, but by that time the country was full of men just like us.

When I did get a job it was drying sand away out to the front on one of the big roads. The first engine that came up to the sandhouse had a familiar look, even with a boot leg stack that was fearfully and wonderfully made There was a shaggy head sticking out of the side window, and two cool gray eyes blinked at me, but didn't seem to see me; yet a cheery voice from under the beard said, "Hello! Brother John, you're late, but guess you'll catch on pretty quick There's lots of 'em here that don't know nothin' about railroading, as far as I can see, and they are runnin' engines, too. 'Tain't right."

The little town was booming, and 'Lige invested in lots, and became interested in many schemes to benefit the place and make money. He had been a widower for some years, and with one exception his children were doing for themselves, and that one was with his sister, and well cared for. 'Lige had considerable means, and he brought it all West. He personally laid the corner stone of the court-house, subscribed more than any other workingman to the first church, and was treasurer of half the institutions in the village He ought to have quit the road, but he wouldn't, but did compromise by taking an easy run on a branch

'Lige was behind a benevolent scheme to build an hospital, to be under the auspices of the church society, and to it devoted not a little time and energy.

When the constitution and by-laws of the institution were drawn up, the more liberal of the trustees struck a snag in old 'Lige He was bound that the hospital should not harbor persons under the influence of liquor, or prostitutes 'Lige was very bitter against prostitution. "It is the curse of civilization," he often said. "Prostitutes ruin ten men where whisky does one. They stand in the path of every young man in the country, gilded tempters of virtue, honesty and manhood; 'tain't right that they should be allowed in the country."

If you attributed their existence to man's passions, inhumanity and cruelty, or woman's weakness, he checked you at once.

"Every woman that becomes a crooked woman does so from choice; she needn't be if she didn't want to. The way to stop prostitution is for every honest man and woman to refuse to have anything to do with them in any way, or with those who do recognize them. 'Tain't right."

In this matter 'Lige Clark had no sympathy nor charity. "'Twan't right"; that settled it, as far as he went.

The ladies of the church sided with old 'Lige in his stand on the hospital board, but the other two men wanted the doors of the institution to be opened to all in need of medical attention and care, regardless of who they were or what caused their ailment. 'Lige gave in on the whisky, but stood out resolutely against the soiled doves, and so matters stood until midwinter.

Half the women in the town were outcasts of society—two dance-houses were in full blast—and 'Lige soon became known to them and their friends as "The prophet Elijah, second edition."

The mining town over the hills at the end of 'Lige's branch was booming, too, and wanted to be the county seat. It had its church, dance-halls, etc., and the discovery of coal within a few miles bid fair to make it a formidable rival

The boom called for more power, and I went over there to pull freight, and 'Lige pulled passengers only. Then they put more coaches on his train, and put my engine on to help him, thus saving a crew's wages. Passenger service increased steadily until a big snow-slide in one of the gulches shut up the road. I'll never forget that slide.

It happened on the 26th of January. 'Lige and I were double heading on nine coaches of passengers, and when on a heavy grade in Alder gulch, a slide of snow started from far up the mountain side, swept over the track just ahead of us, carrying rocks, trees, telegraph poles and the track with it We tried to stop, but 'Lige's engine got into it, and was carried sideways down some fifty or sixty feet. Mine contented herself with simply turning over, without hurting myself or fireman—much to my satisfaction.

'Lige fared worse. His reverse lever caught in his clothing, and before he could get loose the engine had stopped, on her side, with 'Lige's feet and legs under her. He was not badly hurt, except for the scalding water that poured upon him. As soon as we could see him the firemen and I got hold of him, and forcibly pulled him out of the wreck. His limbs were awfully burned—cooked would be nearer the word

The passengers crowded around, but did little good. One look was enough for most of them. There were ten or twelve women in the cars. They came out slowly, and stood timidly away from the hissing boilers, with one exception. This one came at once to the injured man, sat down in the snow, took his head in her lap, and taking a flask of liquor from her ulster pocket, gave poor 'Lige some with a little snow.

I got the oil can and poured oil over the burned parts to keep the air from them; we needed bandages, and I asked the ladies if they had anything we could use for the purpose. One young girl offered a handkerchief and another a shawl, but, before they were accepted, the cool woman holding 'Lige's head got up quickly, laying his head down tenderly on the snow, and without a word or attempt to get out of sight pulled up her dress, and in a second kicked out two white skirts, and sat down again to cool 'Lige's brow That woman attended 'Lige like a guardian angel until we got back to town late that afternoon; the hospital was not in shape yet, so 'Lige was taken to the rather dreary and homeless quarters of the hotel

As quick as it was known that Elijah Clark was hurt he had plenty of friends, male and female, who came to take care of him, but the woman who helped him live at the start was seen no more; yet every day there were dainty viands, wine or books left at the house for him—but pains were taken to let no one know from whom they came.

One day a month after the accident I sat beside 'Lige's bed, when he told me that he was anticipating quite a discussion there in the evening, as the hospital committee were going to meet to decide on the rules of the institutions. "Wilcox and Gorman are set to open the house to those who have no part in our work and no sympathy with Christian institutions, and tain't right," said he. "Brother John, you can't do good by prolonging the life of a brazen woman bent on vice."

"Don't you think, Lige," says I, "that you are a little hard on an unfortunate class of humanity, who, in nine cases in ten, are the victims of others' wrong doing, and stay in the mire because no hand is extended to help them out? Think of the woman of Samaria."

"They are as a coiled serpent in the pathway of mankind, Brother John, fascinating, but poisonous There can be no good in one of these creatures."

"Oh, yes, there is, I'm sure," said I "Why, 'Lige, don't you know who the woman was that gave you brandy, held your head, and used her skirts for bandages when you were hurt?"

Old 'Lige raised up on his elbow, all eagerness "No, John, I don't, but she wan't one of them. She was too tender, too thoughtful, too womanly. I've blessed her from that day to this, and, though I don't know it, I think she has sent me all these wines and fruits. She saved my life. Who is she, do you know?"

"Yes. She is Mollie May, who keeps the largest dance house in Cascade City. She makes lots of money, but spends it all in charity; there has never been a human being buried by the town since she has been there. Mollie May is a ministering angel to the poor and the sick, but a bird of prey to those who wish to dissipate."

The hospital was opened on Easter, and the first patient was a poor consumptive girl, but lately an inmate of the Red-light dance house

'Lige Clark did not run again; he became mayor of the little city, had faith in its future, invested his money in land, and died rich four years ago.

'Lige must have changed his mind as he grew older, or at least abandoned the idea that to crush out a wrong you should push it from all sides, and thus compress and intensify it at the heart, and come to the conclusion that the right way is to get on the inside and push out, thus separating and dissolving it. For before me lies the second annual prospectus of a now noted institution in one of the great cities of the continent, and on its title page I read, through the dimmed glasses of my spectacles

"Industrial Home and Refuge for Fallen Women. Founded by Elijah Clark. Mary E. May, Matron."

THREAD INDICATORS.

Thread Indicators.

The pipe fittings of the Consolidated Car Heating Company, of Albany, N. Y., are the heaviest and best we remember to have seen. They have a very neat way of designating right and left hand threads that would seem worthy of a more general adoption. The distinction between right and left-hand threads is made by casting ribs on the body of the fitting. Where these ribs stop short of the end it indicates a right-hand thread, where they extend to the end they indicate left-hand threads. Our illustrations explain themselves.

Air Ships versus Railways.

The last and present generations have been so prolific in producing scientific and mechanical revolutions that an incredulous age is becoming credulous, and probability has become a synonym for possibility. This is evidenced by the large area of space which the daily papers are giving up to speculative articles regarding the "Mount Carmel air ship," a model of which is now in a promising condition at the exposition building in Chicago. Whether the promises will ever be fulfilled or not is problematic, but then, so is the air ship. The inflated character of this aerated vessel and of the capital stock of its company—a mere \$20,000,000—indicate beyond peradventure that one or the other will go up, but whether the ship or the company is a matter of painful uncertainty. The pathetic cry of the inventor and promoter, that the railways looked down upon him and did all they could to hamper his efforts through professional jealousy, may be changed to a taunt of triumph when he looks down upon the railways from his private supermundane train, flying over the first and only genuine air line in existence.

It must be confessed that the local railway men are at least curious regarding the Mount Carmel air ship, although hope deferred has made them somewhat skeptical. There is a tantalizing fascination in dreaming of something which will deliver them from the self-assumed powers of granger legislators and the exuberant follies of an ephemeral Farmer's Alliance, so that the inventor of the air ship is in error when he cries against railway prejudices. Railway managers are really prepared to hail him as their Moses, *if* his air ship will run on scheduled time and demonstrate that roadbeds, bridges, ties, rails, switches, crossings and many other annoying and forever failing characteristics of mundane railways are unnecessary.—*Railway Age.*

The Semaphore signal was adopted from the English, but our American railroads were too stingy to buy decent sized lamps for night work. Signal lamps ought to be large and bright, a plain lens is better than a corrugated one, and a lamp of decent size with a chimney will give about four times the light the common 4 inch glowworm in common use does. The English signal, with its seven and eight inch lens, puts our measley little nuisances to shame. The prevailing price for little, no good, lamps is about what ought to be invested in the lenses alone.

An Austrian railroad, having two branches partly completed, whose present terminal stations have no turntables, applied to the government authorities for permission to haul freight trains on these branches with the locomotive reversed—tender ahead—which is forbidden by the government regulations. Permission was granted on condition that the speed prescribed in the time-tables should not be exceeded, and that a trainman be posted on the tender at the head of the train, to watch the track and the signals.—*Ex.*

One of the managers of a great watch manufacturing concern recently made a careful estimate of the number of watches required on railroads in New England, and finds that it averages ten watches per mile of road. This proportion would probably remain true of the eastern States but in the central and western it would fall below.

An elevated railroad engine on the Third Avenue line in this city was thrown off the structure into the street, on Sunday, the 11th. The crew jumped upon the structure and avoided the fall, no one was hurt. The accident was caused by a collision at a cross-over switch.

We will give \$2 for a complete copy of the third annual report of the American Railway Master Mechanics Association.

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 22,000 engines and 250,000 cars. This includes 160,000 freight cars, which is about 16 PER CENT. of the entire freight car equipment of this country. Orders have been received for 100,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

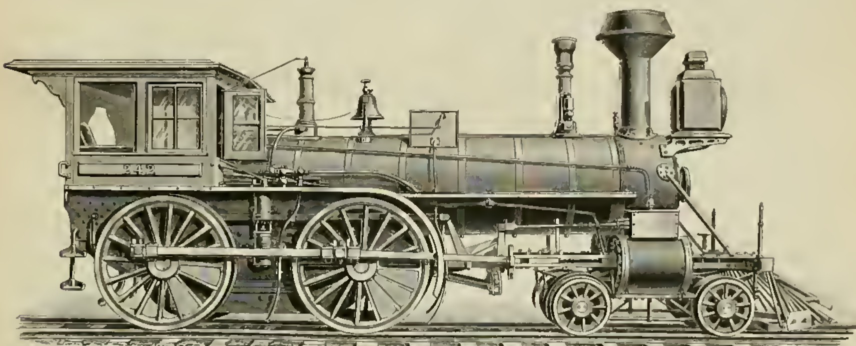
The Eddy Engines on the Boston & Albany.

There has been in use on the Boston & Albany road, or the roads that now compose the B & A., for upward of forty years, a class of engines designed and built by Mr. Wilson Eddy, who was for more thirty years master mechanic at Springfield, Mass.

These locomotives were, and are, peculiar to this road and to this maker, yet they had and have peculiar merits, else they had not survived all these years, as between 80 and 100 of them are still in service.



OLD EDDY ENGINES OF THE BOSTON & ALBANY R. R.

Mr. Eddy was born in 1813, served his apprenticeship in the noted old machine shops at Lowell, Mass., where he worked on the first iron planers built in this country and the first locomotives built in New England.

The noted Major Whistler, who early identified himself with the building of the first railroads in this country, and then went to Russia, where he developed the railroad system of that empire, and died there, after many years of service, had charge of what is now the western divisions of the B. & A., and in 1840 employed Mr. Eddy as foreman of the Springfield shops.

The road used English engines and eight or ten "crabs," built at Baltimore by Winans. These crabs had upright boilers like the "grasshoppers" but had horizontal cylinders and no walking beams, or "legs." A few Lowell engines, modeled after the English engines, were also employed.

In 1849, Mr. Eddy drew the plans for his first engine and commenced to build it, but the facilities were meager, and the engine was not in steam until early in 1851, Mr. Eddy having been made master mechanic in 1850. This engine was named after the president of the road, "Addison Gilmore." She had a single pair of drivers 6 feet, 9 inches in diameter, and cylinders 15⅝x26.

This engine was so constructed that it was not easy for the fireman to get out to the chests to oil the valves, and Mr. Eddy extended pipes from the chests back to the cab and put the oil cups there—setting a pattern that has been followed from that day till this. Had Mr. Eddy taken out a patent on this little scheme it would have been worth something to him.

This engine was one of several that competed for a prize in the summer of '51, and carried off a gold medal, still preserved by Mr. Eddy, the engine having gone over a nine-mile course in 11 minutes and 29 seconds. This was the first engine built in this country with horizontal cylinders. The Gilmore had the first frame ever built with a splice ahead of the jaws, to admit of repairs without tearing the engine all to pieces; this splice was used in all of the 136 engines that Mr. Eddy made.

During the two years the Addison Gilmore was being built, Wm Mason visited the shop many times, as he was preparing to build locomotives. Mr. Mason traveled a good deal, and his first locomotives combined the good features of most every builder in the country, among other things the spliced frame, and this useful plan became known as the Mason splice, and is to this day, although Mr Mason himself never claimed it, as it was running on Eddy's engine two years before Mason turned out a locomotive.

Mr. Eddy soon commenced to build eight-wheelers like the cut, and those with smaller wheels for freight service. He resigned in 1856 and went to Russia to take charge of a locomotive shop, but came back the same year and resumed his old place.

None of his engines had a dome, all were straight boilers with escape pipes as shown, on the left side of the boiler, just ahead of the sand box, there was a manhole plate bolted on and calked, but seldom used, the dry pipe was four inches inside diameter, of copper, and perforated along the top, the throttle being a plain slide in the T pipe in front end, the rod extending through the pipe to the back boiler head; the oil cup just back of the stack was for the purpose of oiling the throttle valve. The fire-box was four inches wider than any other make, as the frames between the boxes were only ¾ of an inch thick and bolted flat against the boiler by numerous tap bolts. The expansion of this part of the frame was little if any different from the boiler, and no trouble was experienced here, but provision had to be made for the expansion of the boiler above the frame—most boilers are fast to the cylinders at the arch and slide on the frame at the fire-box end, or swing on expansion links. This boiler was fast at the fire-box end, so Mr. Eddy let it slide at the cylinder end. The cylinders and frame were bolted to a triple thick arch extended down, no saddle being used; the boiler sheet, ahead of the forward flue sheet, was fitted inside the smoke-box and riveted there. When the engine was completed the rivets were all cut out except five or six at the top, a band of thin iron was put around the joint and held by ¾ bolts in ⅞ holes, what expansion there was was accounted for here.

The most peculiar feature of these engines was their short steam ports, eight inches long for freight and ten for passenger; some large freight engines 18½x28, with a 52" boiler, had but 8" ports.

Mr. Eddy contended then, and does yet, that there is as much danger of making a port too large as there is making it too small—he believes there is a "just right" point, and thinks 8 inches for freight and 12 for passenger not far from the proper proportion. His ports were all 1¼ wide, however, and he used a fairly long travel, 5, 5½ and 6, giving a quick valve opening. Mr. Eddy never hesitated to run his engines in competition with other engines, and while others might run faster or possibly haul more cars, he never failed to transport the same load with the expenditure of less fuel.

Back in the '70's the R. I. Locomotive Works built a mogul engine, 18x26, for the B. & A., and it was tried against two 8-wheeled, 18x26 Eddy engines, one with the same wheel and the other with a six-inch larger wheel. The R. I. engine, named "Brown," had 14" ports, the others, the Virginia and Adirondack, 10" ports.

At the first trial on the Western division, between the Brown and Virginia, the Brown had valves with ⅞ in. outside lap, no inside lap. On the second trial on the Eastern division, and also the third on the Western division, the valves of the Brown were changed to ⅞ in. outside and 5-16 in. inside lap. The valves of the others had ⅞ in. lap outside, and cut out 1-16 in. lead on each end inside. The throw of valves was in both cases 5 inches.

On the first trial between the Brown and Virginia, five round trips were made between Greenbush and Pittsfield, 105 full loaded line cars were taken east, and 175 (a large number of which were empty) were taken west by each engine. The fuel consumed by the Brown was 30,850 lbs. of coal, costing $107.97. By the Virginia, 23,924 lbs., costing $83 73.

On the second trial between the Brown and Adirondack, nine round trips were made between Springfield and Boston, 224 cars, less 24 from Worcester to Boston, were taken east, and 320, less 5 from Worcester to Springfield, west by the Brown; and 223 east and 307, less 3 from Worcester to Springfield, west by the Adirondack. The fuel consumed by the Brown was 106,150 lbs., costing $371.52, by the Adirondack, 83,090 lbs., costing $290.81. The average time upon this trial was (going east), to Charlton Summit, 1 hour and 4 minutes each trip in favor of the Adirondack and from Boston to the same summit, 1 hour, 30 minutes in favor of the same engine. On the third trial between the same engines, 14 round trips were made between Greenbush and Pittsfield; 317 full loaded cars were taken east, and 387 west by the Brown; 317 cars east and 372 west by the Adirondack. The fuel consumed was 86,148 lbs. coal by the Brown, costing $301.52; and 69,676 lbs., costing $243.87, by the Adirondack.

Thus, it will be seen that in the 37 days' trial, the Mogul burnt 223,148 lbs. of coal, costing $781.01; Springfield engines, 176,690 lbs., costing $618 41. In favor of the latter, 46,458 lbs., or $162 60.

Mr. Eddy claimed that the cause of the saving in his engines was on account of the lessened load carried on the valves, less friction in the engine and the wide fire-box.

In his later engines he used one large, cast, escape pipe behind, and none in front.

The engraving shows one of his passenger engines still in service on the road. They carry the homeliest and best sand-box ever put on a locomotive, giving absolutely no trouble and requiring no repairs. The front escape pipe has a muffler on top, the rear one a safety valve.

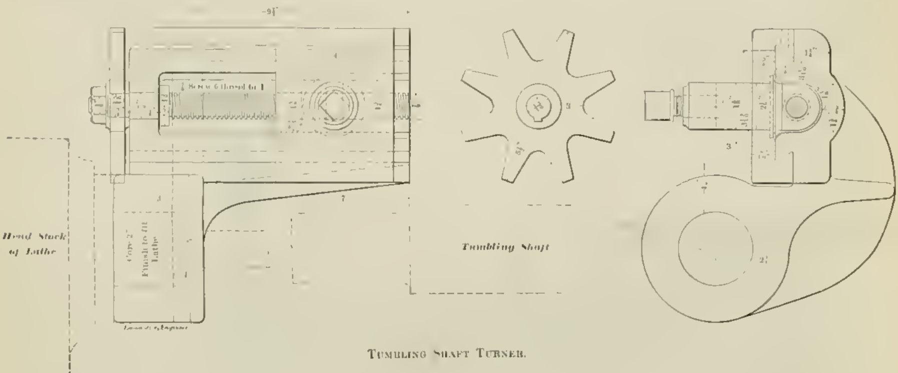
On top of the bell standards there are places to carry signal lamps, the B. & A. carrying all signal lamps there or on top of the boiler. Rigid center, side bearing trucks were used, and oil pipes were outside the jacket. Once Mr. Eddy established a plan he adhered to it, he never would change his independent cylinders for the saddle plan, yet loose cylinders was one of the troubles they had to contend with, especially as the engines got old and the arch sheets began to cut away.

This engine has air-brakes and injectors, but his engines had, before the day of injectors, eccentric pumps worked from the back axle.

While modern practice does not follow many of the peculiar and particular ideas early introduced in these engines, they were, no doubt, among the best engines in service when first built, and are to this day successful and economical machines, and their forty years of service are the very best arguments on their designer's side of the question.

Mr. Eddy retired in 1880 and was succeeded by his son, W. H. Eddy, who is still M. M. of the Springfield shops, where his father put in the best 40 years of his life.

These locomotives are now, and have been for years known among the men on the road as the "Eddy Clocks."



TUMBLING SHAFT TURNER.

Lathe Attachment for Turning Tumbling Shaft Bearings.

The engraving on this page shows a very simple little tool for turning up the bearings on tumbling shafts, or other similar work that is too large to swing in a lathe.

As will be seen, the main casting of the device is screwed on the lathe spindle in place of the face-plate, the tumbling shaft is held between the centers, the arms preventing its being turned, and the tool revolving around the work trues up the bearing.

The tool-post is on a slide operated by a screw as shown, the screw is turned by a star wheel on its end, that strikes a projecting lug held by a tap bolt on the bottom of the head-stock.

The sizes being given on the engraving render further description unnecessary, and will enable any bright mechanic to make one of the tools, if desired.

This device was gotten up at the West Chicago shops of the C. & N. W. road, and is in use in the principal shops of the system.

Engineer Robert Brown, of the New York Central, was killed in a collision caused by a misplaced switch at East Rochester, N. Y., February 4. He was one of the best-known engineers in the country, having been one of the early runners on the Rock Island, Illinois Central and U. P. He carried a handsome watch and chain presented to him by the engineers who ran with him out of Chicago. He had been on the Central for the past twenty years.

The Staff System of Running Trains in a Hole.

President Clark, of the N. Y., N. H. & H., was over to Europe last year, and there saw in operation the English plan of running trains over a short piece of single track, known as the "staff system." There is a brass "staff"—and only one—usually with a key on the end of it, and when an engineer has this staff in his possession he knows there is no one on the track, and he has the absolute right. Once over the ground the staff is left in the possession of the station agent, switch tender, or put into a box, and the next train, going in an opposite direction, can take it and go over the line. This is used on short lines, over bridges and through tunnels where the train service is light and not worth the expense of keeping operators at each end of it.

On his return to New England Mr. Clark decided to use the staff system on about seven miles of single track out of New London, while the second track was being built.

The system was introduced with a hurrah, and many of the papers told all about its advantages, even going so far as to show a picture of the staff. The plan didn't work first-rate from the start, and the dispatchers commenced to help it out with train orders—the way the trains should have been handled from the start.

But if this was done the staff part of the scheme got moldy from disuse, so orders were given to run by the staff only.

The traffic over this part of the road is considerable, and trains were not evenly divided in each direction, so a switch engine was often obliged to run over the line for the sole purpose of "toting" the precious staff.

Not long ago a train slowed up at the end of the bridge to receive the staff, and the engineer made a grab for it as he passed, but missed it, and the staff fell into the water.

The engineer, very properly, refused to proceed without the scepter of royal authority, and so the single track line was tied up while all hands fished for the staff. After some hours the key to the situation was recovered, and the train proceeded on her majestic way, and several other fellows who had trains waited long and patiently for their turn at the "brass barber pole."

All this shows that the staff system is a great success for American conditions, for no sooner was the staff recovered from the water than the train was off. Had a telegraph operator been dropped into the Thames for an hour or two he would have been useless when recovered, and a new one would have had to be sent on to take his place. Score one for the staff.

Extensive tests on several roads, notably the Santa Fe, have proven that the most successful composition for lining truck brasses with, is composed of six parts of lead to one of antimony.

The office of mechanical engineer on the Santa Fe has been abolished. Big Four ditto.

The Old-time Flyer, Lightning.

The engraving on this page is a faithful reproduction of an original lithograph, made more than forty years ago.

This style of engine—driver back of fire-box, and extra carrying wheel—have been quite extensively used in Europe, and are known by their designer's name, "Crampton."

This engine was built at Schenectady, N. Y., by the Norris Locomotive Works, then located at that place, for the Syracuse & Utica Railroad.

She had cylinders 16x22". The drivers were 84" in diameter, the carrying wheels were 48", and the front truck wheels, 42". All these wheels were solid forgings, the first of their kind ever made in America.

Her boiler was only 42" diameter at smallest ring. There were 116 2"-tubes, 10' 3" long. The fire-box was 54' long, 36" wide, and 54" deep inside. There was a three-inch water space all around the fire-box.

The frames were of the old double style, the main frame being 6" x 1¼", set edgewise. The outside frame was 4"x1½".

The center of the boiler was 64" above the rails.

The Gooch link was used, and the gear arranged to cut off at any point from one-eighth to seven-eighths of the stroke. The complete engine weighed twenty gross tons.

At the top of the driver, behind the name plate, there was located an odometer that recorded the number of revolutions of the drivers.

This engine ran before the days of rubber hose, and used the old, combined ball and slip joint on the feed-pipe connections between engine and tank. This engine had a glass water gauge—one of the first.

As will be seen, steam came direct from dome to steam chests in copper pipes, and the exhaust was conducted to the stack under the boiler.

The load on the drivers could be varied by changing the fulcrum pin between the equalizer and the frame. The extra notches are shown in the equalizer and frame through the driver.

The "Lightning" was an exceptionally well-made machine, but had too small a boiler, and was too light for much useful work. She made her first trip in December, 1849, and remained in service only about a year. Her fastest record was 16 miles and 88 feet in 13 minutes and 21 seconds, hauling eight 8 wheeled cars. Sam'l Draper, engineer. This was on February 2, 1850. She was cut up at the Schenectady Locomotive Works in 1854.

A neat little book of outline drawings of four classes of locomotives, with dimension lines for keeping data of sizes, has been issued by Coodbaugh, McMann & Pomeroy, of 45 Broadway, this city. The books are very useful to locomotive engine and shop men. They will be sent free to those who mention this paper.

Northwestern Shops at Chicago.

The writer had about an hour's spare time to put into the Chicago & Northwestern shops, at West Chicago, on a recent trip west. We got only a few snap shots.

This shop is unlike most other railroad shops, in that it has all the room needed, and to spare. The road owns 240 acres of ground where the shop stands, and the buildings are not crowded up like a ten-dollar man in an eight-dollar coat. The yards around the shops are roomy, and lots of the ground is still left for pasture. The buildings are good, and the shops all the way through are far better than the average, but it has been the policy of the management to build their own machine tools, to an extent that has filled the shops with tools unlike any others in existence, to say the least.

Many of these tools do excellent service, and fill the bill, but they must have cost double what standard tools could have been had for. Mr. William Smith, the new superintendent of motive power, is one of the kind of men who believe in getting well-known and tried tools, where he can buy the cheapest, and will probably build only such machines of their own design as are not on the market.

They were building a couple of double headed bolt cutters when we were there, that have some features of their own. They do a nice class of work with dies, their stud threads for steam-tight work resembling lathe work, and giving them no trouble whatever.

There is a large and well-equipped tool-room in this shop, and a special tool shop back of it, where all taps, dies, drills, reamers, and, in fact, all small tools, are made. This is a department seldom found in American railway shops.

This shop has built many locomotives, but the pressure of repairs is too great for that now. The road operates 800 locomotives. The first of 60 new engines are beginning to arrive now.

They make a good and a cheap engine truck here, the plan of setting up and drilling the frames and jaws being shown on another page. These trucks have a large, rigid center, but it is made in two pieces, fitted together with heavy bolts in slotted holes, so that the center bearing can be shifted sideways to keep the flanges from cutting.

The boiler shop is large, and the work seems to be done with a view to good work, regardless of the cost.

Much of the line in the Northwest goes through a country where good water is as scarce as gold, and boiler repairs are heavy. Flues average a life of from three to four months, and fire-boxes do well to hold out for three years.

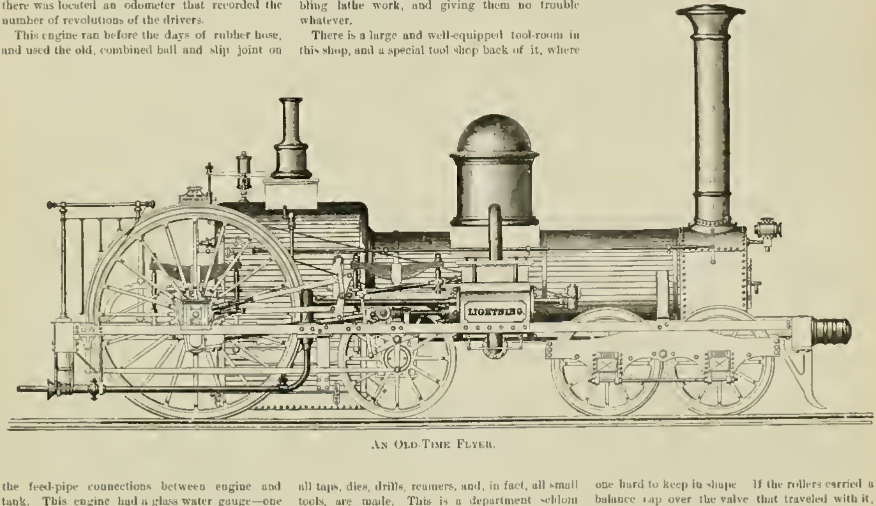
Some experiments have been made here with a Nathan lubricator that very much simplifies the cup for three feeds—one for the air pump. In the regular three-feed cup the front, or gauge glass, of the cup is used for the air-pump feed, and there are several extra inside and outside pipes. On this road they took one of the old cups, without the third feed, and tapped a hole into the side of the elbow valves on one glass, screwed in extra valves, and put a glass between them. The top valve was connected by a small copper pipe direct to the steam pipe of the air pump, the lower valve regulating the feed. This retains the handy gauge glass in the front of the cup. Mr George Royal, of the Nathan Manufacturing Company, with his usual promptness, secured this device for his firm just as soon as it popped its head up.

The blacksmith shop is a very large one, the road doing their own axle and other heavy work.

Outside the roundhouse we noticed a pressed wrought-iron boiler front. It had been taken off on account of difficulty in keeping a tight joint at the door.

One engine in the house had an extremely wide steam chest, containing a new device for reducing friction between the valve and seat. At each end of the ports there was a rack of cut teeth set. Each end of the valve had an overhanging projection, on the under side of which a corresponding rack was cut. Between these two, a toothed segment of a wheel oscillated, carrying the valve slightly clear of the seat, without steam. When working steam, the valve face just touches enough to make a joint. This engine, it is claimed, is doing good work, and handles easily, but it would seem that the plan called for too nice a job for locomotive work, and one hard to keep in shape. If the rollers carried a balance cap over the valve that traveled with it, and had its steam tight joints on the sides and ends, it would seem to us to be more promising.

All the engines coming out of the shop have the Henney variable exhaust, the invention of one of the division master mechanics. It is illustrated in another column.



AN OLD-TIME FLYER.

"A Hoodooed Hoodoo."

The lodge of Locomotive Firemen at New Haven rent their hall of the order of Elks. Recently the boys bought a "Hoodoo model," and asked the old he-Elk where they could put it. He told them to put it into the banquet room, but to get a case made for it so that it would not be injured. The carpenter employed made a box to go over it that would take up the least room, and when it was done and stained it looked just like a coffin set up on legs. A few days after it was in place, the old he-Elk sent for the secretary of the lodge and asked him what in the name of the everlasting gee-whiz they had in that casket. Said he: "We tried to have a little banquet after initiation last night, but the boys couldn't enthuse with that thing there, and the whole thing was solemn as a church, so the lodge voted that I tell you to please remove the remains or get a new hall—we don't keep a vault."

The Cushing Draw-bar Stop.

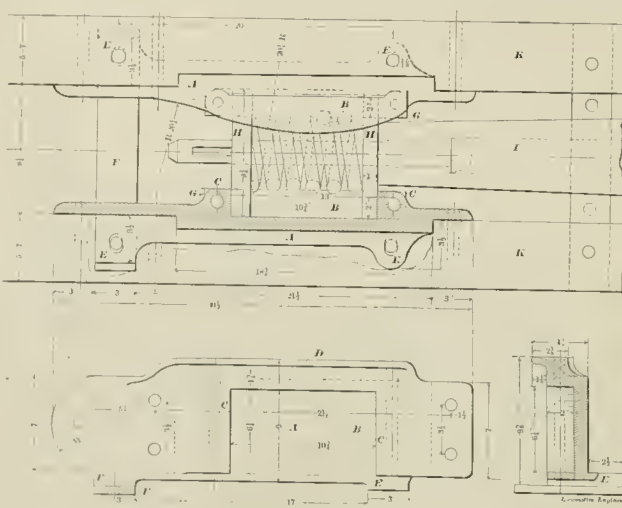
When George W. Cushing was Superintendent of M. P. of the Reading he found endless trouble with the draught rigging of freight cars, the very large locomotives used there having a tendency to develop weak spots in draught rigging. Mr. Cushing went from there to the U. P., and, finding the same trouble, set about to devise a remedy.

The great trouble seemed to be the weak construction of the frame work that transmitted the shocks from the draw-bar to the frame of the car. The draught timbers were light, and the stops being in two pieces, bolted ahead and behind the spring, had a tendency to pull their bolts through the timbers, and otherwise get themselves into bad shape.

Mr. Cushing devised a double stop, with spring pocket, having part of its side let into the timbers, and securely bolted thereto, extending along the top and bottom were heavy strengthening ribs, and the two stops were tied together by heavy wrought-iron straps, so that there should be no spreading of the timbers.

The lower side of the pocket was left open for the insertion of springs, but the back end of the bar and the spring were supported by carrying strips bolted below the stops, that prevented the loss of springs where draw-bolt was broken and head pulled out. This stop reduced the expense of car repairs on the U. P. very perceptibly, and in order to protect the road Mr. Cushing took out a patent on the device. Since he left the road there has sprung up a demand for the stop, and Mr. Cushing has been more or less busy for some months overseeing their application to a large number of freight cars built at Pullman and other shops. The stop is highly spoken of on the U. P., where a great many are in use.

Mr. Cushing intends returning to railroad work when the right opportunity offers, but is not the sort of man that sits down in the winter and wishes it were spring; you will find him busy with this stop at his office in the Rialto Building, Chicago.



CUSHING DRAW-BAR STOP.

The Wear of Driving Wheel Tire.

J. N. Barr, Supt. of Motive Power of the C., M. & St. P. road, has been making some experiments to determine the cause of uneven wear in driving wheel tire. At a recent meeting of the Western Railway Club, Mr. Barr gave the results of his test, from which we condense the following:

At first sight the most natural conclusion is that the tire varies in hardness, or resistance to abrasion, and this undoubtedly is the cause of a portion of the trouble, but from an extended series of observations, the writer is compelled to conclude that a material portion of the trouble lies outside the tire itself. This conclusion has been arrived at from the following observations:

First—The tire of several locomotives showing serious flat places have been slipped around on the center, then turned up and placed in service. The flat places in every case formed again at the same place relative to the center, but in a different place on the tire.

Second—Observations made on a large number of tires running in a sandy district showed that the flat places grouped themselves with a close approach to uniformity, occupying nearly the same position with reference to the pins and counterbalance.

The above clearly indicates that there are cases of irregularity in the wear of tire, due to the forces which are in action in operating the locomotive, and it is the purpose of this investigation to partially determine the nature, extent and influence of these forces.

Mr. Barr took a 16x24 locomotive, having 62" drivers and a weight on all four of 54,000 pounds, carrying 160 pounds of steam, 130 steam chest pressure, cutting off at 6", and determined the weight on each wheel at 40 miles per hour, for each tenth degree of the wheel. He found that for a point covering 90 degrees of the circle and laying in front of the crank-pin the tendency of the counterbalance and reciprocating parts was to overcome the adhesion and slip, thus wearing the tire.

The left-hand tire wore the most, and all the tires wore more or less unevenly.

A change of steam pressure, speed, or cut-off changes the wear and its position on the wheel. Many tables were compiled and details given, but these are the important points. The paper concludes as follows:

1. Flat places on driving wheel tires are not entirely due to lack of uniformity in the wearing quality of the same.

2. The flat places have a tendency to group themselves where the coefficient of slip is greatest.

3. They vary in depth with the pressure on the rail, and when the pressure does not exceed 11,000 lbs the imperceptible slip produces but little abrasion.

4. Imperceptible slip does not appear at random on any part of the wheel, but in special localities, as fixed by the maximum values of the coefficient of slip.

5. The counterbalance should be as light as possible compared with the reciprocating parts, consistent with smooth riding.

6. The weight of the reciprocating parts should be as light as possible.

The 19x26 "hogs" on the N. Y. Central are in great disfavor with the men, they pull lots of cars, but are unwieldy in getting out of the way. Big engines are money savers if the road is not so level that they can pull fifty or more cars; trains of that length are heavier than links and pins can stand, and break-in-twos cost money, and cause endless delays.

A Big Jump.

Early in February, a 20x26 consolidation engine on the Boston & Albany got away from her crew at the top of a long hill and started off down grade with the throttle open. The telegraph was put to work and a switch was opened some ten miles away, that would send the runaway up a high coal chute, and, it was hoped, stop her without damage. She sailed into town at a moderate speed, mounted the coal chute gracefully, and jumped off the end, some eighteen feet to the ground. The bridge jumper lit on her feet, so to speak, and sank well into the soft ground, but the tank, not to be outdone in agility, turned a somersault, alighting on its back, and in so doing smashed the cab. Nothing of importance was damaged, although broken frames and bent axles were expected. The engineer, who had been knocked off by the engine's being struck by a train being switched behind her, followed on foot to the next station and there got a hand-car, and together with the fireman arrived in time to pull the fire; the injector being on at the time of the accident prevented any trouble from low water. The rumor among the men that the company had decided to name the engine "Steve Brodie" has been denied.

When Angus Sinclair was a boy in the telegraph office of the old home road in Scotland, he had the "engine fever," and used to spend his spare time around the engine sheds, where he soon struck up an acquaintance with the firemen, who used to swell him up with pride by allowing him to do sundry chores for them on the way to the trains. He learned rapidly, and one evening was elated more than usual when one of his stoker friends got down to oil and told him to "fill up the fire"—a common expression then. Angus had not written his pamphlet on combustion at that time, and translating the stoker's instructions literally, he "filled up the fire," and the fire-box as well, while his friend was busy elsewhere, and the engine started out with a mail train—losing two hours. The stoker has it in for Angus yet.

The rapid introduction of pressed steel parts of cars and locomotives has given the roads a great many pieces of half the weight and double the strength of castings. Every pound of weight gained in car construction is a source of economy as long as the car is in service, but we are inclined to doubt the economy of using pressed steel for locomotive work. In the first place there is not the objection to weight that there is in cars, and the cost for doing repairs are greater. Bent wrought-iron or steel front doors, etc., cost much time and patience to straighten out, and serious crimps can only be repaired by a forming press—which no road could afford to keep.

It would be a hard matter to find a substitute for cast-iron that would facilitate and cheapen locomotive repairs, especially those parts liable to breakage in every-day service.

You can learn to estimate the weight of castings by getting some idea of the cubic inches contained. Four cubic inches will average a pound.

The Coupler War.

The New England Railroad Club, with J. N Lauder, of the Old Colony, in the lead, have stood bravely up in meeting and said their little say about the M. C. B type of coupler. Mr Lauder lays a good deal of the ills he suffers to the railroad papers. This is hardly right, as the M. C. B. coupler was given a send-off by the Car Builders' Association, pushed, especially by the P B R, that had adopted the Janney before it became the standard. The papers bowed low before the M. C. B. type—for advertising only—and defend it against the world

It is altogether likely that if there were no link and pin couplers to mix in, the hooks would do far better than they do now, but there is no denying the fact that they are a great expense and an awful nuisance. If every master mechanic and master car builder in this country were to stand up and tell just what he honestly thinks of the M. C. B. coupler, we venture to say that it would make the hook coupler men sick—exceedingly sick

We admire Mr Lauder and the New England club, they believe they are right and are not afraid to say so—that would be admirable even were they wrong—and it is quite likely they are not.

Long Island Notes.

Cooke's are building some new passenger engines for the Long Island. This road does an enormous passenger business in summer, and a comparatively light one in winter, and these engines are designed to burn soft coal in winter and hard in summer, they have long fire-boxes on top of the frame, and when rigged to burn soft coal about three feet of the front of the grates is bricked over. They are 8-wheelers, 17x24, weighing 90,000 pounds, with Master Mechanic Thompson's cab set over the forward driver, and an iron summer kitchen on behind it. The crank-pins are hollow, and have small holes drilled from the face of the bearings through to the large hole in the center, this hole is about an inch in diameter, and does not go clear through the pin; it is filled with cold tallow, and a brass plug screwed into the end. When the pin gets warm the tallow melts, and gets in its work A great deal of trouble is experienced here from sand.

The new shops at Jamaica Plain are very neat and substantial, and fitted with overhead cranes, some new tools and a great many old ones.

This road still uses double vacuum brakes, but will in all probability soon commence to put on air. If they had not been shut out from exchange of cars with other roads, air would have been a necessity long ago. The road runs an awful lot of old rolling stock—the majority of passenger cars remember all about the war

In the car shop, getting "slicked up," was Austin Corbin's new palace on wheels, known as the "Oriental," equipped with air, vacuum, steam heat, hot and cold water, bath room, kitchen, dining room, wine cellar, and bridal chamber It is one of the finest cars ever built, but Mr Corbin can afford these little luxuries—the patrons of his road cannot. If we ever get a private car like this we'll name it the "Accidental"

The Long Island road are taking out some copper fire-boxes that have been in service for six years, this is just the life of steel boxes there. Copper costs more to begin with, but at the end is worth considerable as old copper, while steel is practically worthless.

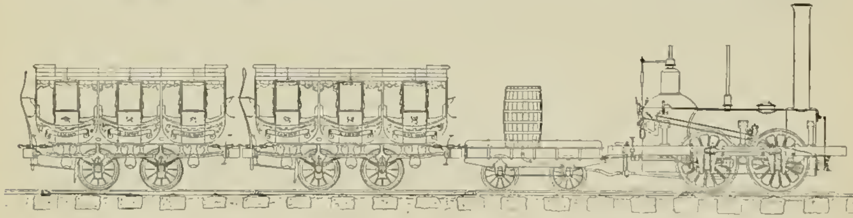
The First Railroad Train in the State of New Jersey.

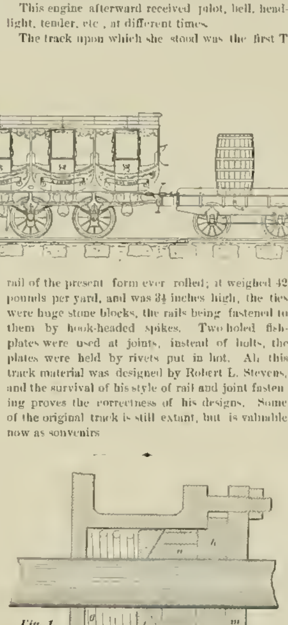
The outline sketch below, from an old daguerreotype, shows the engine and train of the Camden & Amboy road at Bordentown, N J, as it was inspected by the legislature of the little State, on the 12th day of November, 1831. The engine was the famous "John Bull," just over from England, and now in the National Museum at Washington This engine was run under steam at the Railway Exhibition in Chicago, in 1883

The "John Bull" was on this, her bridal morn, under the charge of Mr Isaac Dripps, now a resident of Philadelphia. The tender shown was improvised from a push car and a whisky cask, the hose having been made of leather by the village shoemaker

This engine afterward received pilot, bell, headlight, tender, etc, at different times.

The track upon which she stood was the first T rail of the present form ever rolled; it weighed 42 pounds per yard, and was 3½ inches high, the ties were huge stone blocks, the rails being fastened to them by hook-headed spikes. Two holed fish-plates were used at joints, instead of bolts, the plates were held by rivets put in hot. All this track material was designed by Robert L. Stevens, and the survival of his style of rail and joint fastening proves the correctness of his designs. Some of the original track is still extant, but is valuable now as souvenirs





Lewis & Whaley's Metallic Packing.

The packing illustrated herewith has been in use on engine 20, New York & New England Railroad, for the past ten months, making 30,000 miles without trouble, it is also in use on other engines on the same road. Fig. 1 shows the general arrangement of the packing. Fig. 2 is an outer end view of the packing rings *d*, Fig 3 being a cross section of the same on the line *X*; Figs. 4 and 5 show the coned brass washer *f*; Figs. 6 and 7 show the brass gland *h*, against which the packing abuts, and makes a steam tight joint, as at *a* in Fig 1.

A spiral spring keeps the packing against the gland The packing rings are held together by a flat spring *e*, Fig 2, this gives a uniform tension to the rings. The packing is made smaller than the box, so as to admit of vibration of the rod. It is the invention of E. F. Lewis and F T. Whaley, whose addresses are Norwich, Conn.

"Way 'long about '56," said the old-timer, taking a chew of fine-cut, "the Erie were about the best road in America, and though we weren't getting but sixty dollars a month, the engineers were mighty independent and uppish like. Once when old man Minot was general superintendent, there was a plug-puller there of the name of 'Yankee Dan.' Dan were runnin' one of the old inside Hinckley's with a hook motion; on these engines the two eccentrics on a side were cast together, and when one slipped they both did. One day Dan came into Susquehanna with one side slipped just enough to make her sound like a peg-legged soldier walkin' on a plank road The president was standin' on the platform with some of the stockholders, and when the train stopped and Dan got off to walk into the eatin' house the old man sais, 'Ain't your valves out a little, Daniel?' 'Nope,' sais Dan without stoppin', 'they was both in the chests when we left Port Jervis.' He'd be hung for that now"

After long tests in actual service, the Illinois Central have decided to return to the use of case-hardened iron for crank-pins, and use iron in place of steel for axles.

Big Work by a Little Engine.

The Benedict & Burnham Manufacturing Co., of Waterbury, Conn., have quite an extensive yard about their factory, and a little H K. Porter & Co. locomotive that is the especial pride of Chief Engineer Crane Hearing that Mr Crane had indicated the engine lately, we wrote him about it, receiving the following answer

Replying to your favor of the 7th, the locomotive mentioned has 9x14 cylinders; is a tank locomotive with four drivers 30" diameter, and with the tank two thirds full of water, weighs 11 tons.

It is used for shifting purposes in our yard, and as our yard would not permit of the necessary speed to take the diagrams, I took it outside where there is a short track, and as the stiffest spring I had was only 40, I was limited to about 80 pounds pressure. To get the proper load I put on a brake until the engine had a sufficient amount.

We have one grade 184 feet on a curve of 100 feet radius. It will start and haul about 40 tons on this grade, but in the ordinary work about the yard will handle from 100 to 200 tons very nicely. It has hauled over 400 tons on a fairly level track with slight curvature. Usual steam pressure, 125 to 130 pounds.

With a flat car rigged up for an excursion, and weighing altogether about 10 tons, it made 6 miles in 10 minutes. Average grade slightly ascending

It rides very smoothly up to about 25 miles per hour, and fairly well at 35, but beyond that it jumps so badly that another pair of wheels would be necessary. Of course, it was not intended for any such speed, as it was simply built for a shifting engine

You notice that the lead is less as the lever is hooked up, which is contrary to the generally accepted idea

The builders, H K. Porter & Co., say that this is on account of their being obliged to put the fire-box over the driving axle on this size, and the eccentrics on the other axle, in such a way that it produces this effect.

As excessive lead and compression make a hard riding engine, it is possible that this feature of the valve motion makes this engine ride so easy, with the drivers making over 300 revolutions per minute. The steam distribution is such as shown by the cards that it is doing about all that is possible.

Waterbury, Conn. W. E. CRANE.

[The cards are reduced just one-half. The lead could be made to increase instead of decrease, if the links were so connected to the eccentrics on forward axle that the hooking up of lever would move the straps on the eccentrics in the opposite way from which the eccentric ran.]

Correspondence

Air-pump Valve Stops.

Editor The Locomotive Engineer.

"A Reader" asks how we get the length of main valve stop, without taking off the steam cylinder, as they run in length from $\frac{5}{8}$" to $1\frac{1}{4}$". In reply I will say that if they use the Westinghouse 6" or 8" air-pump in Wilmington, the main valve stops don't vary $\frac{1}{16}$" in length—at least I have never found one to vary that much, and I have been in the business over ten years. I have a lot of stops turned up with small end that goes in casting about $\frac{5}{8}$ long, and the end that the main valve rests on, about $\frac{13}{16}$" long and $\frac{3}{8}$" diameter. I find they all "go." W. F. RELYEA

Syracuse, N. Y.

Big Passenger Engines.

Editor The Locomotive Engineer:

The B. & O. has recently put in service three very large passenger locomotives; they are 8-wheelers, 21"x24" cylinders, 78" wheel, with a big boiler and long fire-box. They were built for the fast runs between Washington and Philadelphia, they are not yet fully "suppled up;" yet one of them is credited with having run a mile in forty-six seconds, with four cars. In a description of the Mt. Clare shops of this company, which appeared in a recent number of your valuable paper, this road is "showed up" in anything but bright colors, and while I acknowledge the corn, I think that we might have been allowed credit for the few little improvements that have been recently introduced. It is true that we have been somewhat behind the age, but the present management shows a disposition to get there, and I hope that we will eventually come out all right. The compound is back on passenger, and doing fairly well, but no better than the simple engines.

Baltimore, Md. ROBERT H. ROGERS.

For Air-pump Doctors.

Editor The Locomotive Engineer:

I said last month I would give the "boys" a tough one in the next paper. So here it is, and in a few words: I had a pump that would blow very bad on the upward stroke only. The rings in main piston, reversing piston and main steam valve were all good as new, and there was nothing about the pump that was loose or broken. Now what made that pump blow? I put on a new top head, and that stopped the blow. So you see it was all in the head, but where? W. F. RELYEA.

Syracuse, N. Y.

Grief on the Reading.

Editor The Locomotive Engineer:

I saw in a recent number reference made to the explosion of an engine belonging to this company, at Philadelphia.

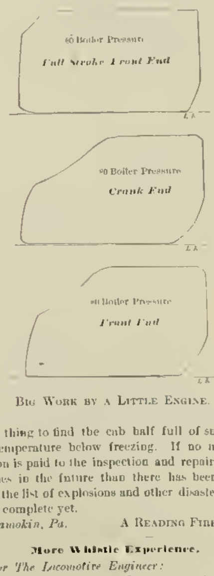
I am a fireman on one of their dirt burners, and simply want to say that it is a wonder that more of them don't go up, judging from the condition the engines are run in.

Take, for instance, Shamokin. When they want an engine to assist any of the through trains from Sunbury or Snydertown to Locust Summit, some 30 miles, the caller is sent for the engineer and fireman. When they arrive their first job is to find out what engine they get. Generally, the men have to wait for fires to be cleaned or for some engine that has been sent out of the yard on account of low steam. At last the crew get an engine of some sort—and we have many breeds—and the cry is: "Get out! get out of here, or I will mark you back on the list."

The engineer yells at the fireman to hurry, and asks if the flagman is ready—but there is no flagman. The scraper is lost—but no one dare stop for one. There is no headlight chimney, and when you run to the storehouse to draw one you are asked how you broke the other, and told that there must be a great deal of carelessness. In the cab there is a cloud of steam, because the injector valves need packing; the gauge cocks are blowing and the blower sizzing in the cab and the front end of pipe stopped up by a chunk of dirt.

All of these annoying matters must be cured or endured as best you can on the road. We hear nothing from start to stop but "Hurry up, hurry up!" Nothing is cared for, the only thing is to get over the road somehow. If locomotives are cared for on this plan, what can you expect? Our engines here are considered well fixed for the winter, but you can see cabs without glass, half of them closed up by sheet-iron or old coats. It is no unusual thing to find the cab half full of snow and the temperature below freezing. If no more attention is paid to the inspection and repairs of our engines in the future than there has been in the past, the list of explosions and other disasters is far from complete yet.

Shamokin, Pa. A READING FIREMAN.



BIG WORK BY A LITTLE ENGINE.

More Whistle Experience.

Editor The Locomotive Engineer:

J. A. N.'s inquiry in January number about whistle extinguishing lantern, reminds me of a similar case in the long ago.

For some cause the block was taken from the whistle, and the sound changed from a shrill to a course one. The first night after the change, the engineer had a time with the gauge lamp—could not blow the whistle without darkening the cab. The stopping of surplus vent on top of cab was resorted to, but to no purpose. And yet, by opening and closing the valve rapidly—keeping it open as long as desirable—that whistle could be sounded as many times during the night as necessary, and never affect the light. Does the vacuum theory hold good in the above instance? Give us more light.

Greenville, S. C. "SWAMP RABBIT."

[The writer has run locomotives that would lower and finally extinguish lights in their cabs by long use of the whistle, and had never heard of any other theory than that of the induced currents taking away from the lamp some of the necessary oxygen. This theory would seem to be at fault in this case and the one cited last month. Still we see no other cause that the phenomenon can be charged to; even should it be proven that it is the vibration of the air in a certain manner, that would not prove that the vibration itself did not lessen the supply of oxygen. Who knows something about this?]

The Reason it is Hard to Get Better Engineers.

Editor The Locomotive Engineer:

It has long been my intention to write a few lines for your spicy paper, on the subject of employing firemen and engineers. Probably I am a crank on this subject, but I maintain that railroad companies are alone responsible for the incompetent crop of engineers now growing up, and the number of incompetents has reached such proportions, that only time and patience will effect a reform. Now I am not writing particularly of men in this latitude, but we have our proportion of the class referred to, as few observing men will deny. The cause lies far back, and can be traced to carelessness of those having power to employ men in their departments. Time was, not far back, when any man was thought good enough to throw coal into an engine. Generally, his physical build had a great deal to do in procuring an applicant a position, in preference to a smaller man, physically, but probably larger, intellectually.

The great mistake has been in not recognizing the fireman as the future engineer, and in not expecting every fireman and engineer to pass an examination in reading, writing and arithmetic, the standard to be set by superintendent of machinery. Up to five or ten years ago, the man that could keep her howling was considered an A1 man. Now, this is no longer a practical test of an intelligent fireman, and it has also been demonstrated that the careless fireman is the indifferent engineer. After this is discovered, the first thought amongst officials is to gradually weed out the incompetents, but they run against a snag in the brotherhoods the first move they make; for after a man fires six months or a year [in the firemen's, and the same in the engineer's], he is eligible to membership in these organizations, and he veils his incompetency behind a big B, and, generally, the poorer the man, the bigger the B; the master mechanic discovers this after he concludes to discharge a man. He finds his ideas differ from those of the committee that waits on him, as to what a competent man is, and he concludes not to discharge the man; or if he does, he courts trouble, and possibly a strike; so it has come to that pass that a man may be known to be useless, and a detriment to a company, and still continue in the employ of said company, and a master mechanic or superintendent of machinery will generally think twice before ordering a man discharged. A reform can only be brought about in this matter by officers exercising more care as to the class of men employed, giving preference to the best and brightest, and by putting a premium on brains, and by organizations refusing to admit everything that makes application for admission, without any test as to intelligent service rendered in their department. COMMON SENSE.

Jamestown, N. D.

Throwing Water with Light Throttle.

Editor The Locomotive Engineer:

I would like to ask your opinion about an engine that works water when working light throttle, but does not when she is working hard. Engine has large wagon top, and carries water good, but as soon as I work her easy she will spit considerable. I find no indication of dry pipe leaking; besides, we have some others that do the same thing, and in a recent conversation with the traveling engineer of two southern roads, I have been informed that a great deal of trouble exists on their roads from this source, and mostly from engines with single nozzles.

If you will be kind enough to give us your opinion about this, you will oblige several readers of the paper here. JOSEPH NELSIS, Engineer

Springfield, Ill.

[It is very likely that your trouble comes from condensation, and the collection of water in the exhaust passage. When your engine is working hard, the force of the blast carries all of the water out of the nozzle with the exhaust steam at each pulsation. When working a very light throttle, and cutting off close, what water there is in the exhaust steam collects in the lowest bend in the exhaust passage, until the area of opening is so small that the steam commences to pick up the water and carry it out with it. You will probably cure the disease by drilling a quarter inch or three-eighths hole into the bottom of exhaust passage in each saddle. These holes will prevent the collection of water in the passages at any time, and do much to keep the engine clean and comfortable, and the leakage of steam from them will hardly be perceptible.]

Running with One Eccentric Rod Down.

Editor The Locomotive Engineer:

I am a regular reader and would like a decision through the columns of your valuable paper in regard to a breakdown. In making my trip with a passenger train on the D. S. S. & A. Ry., east from Duluth, a set-screw worked loose and dropped through eccentric into collar of strap, and broke eccentric straps and eccentric rod in two places—left back-up eccentric—leaving me with both go-ahead eccentrics all right. Now I had serious doubts whether I could handle my train with one side or not, taking into consideration the condition of the road, having one car more than the usual train, being seventy miles from the end of my run, and twenty miles of the seventy up hill, and the road heavy with snow. Under the circumstances I immediately concluded to work both sides of my engine; I therefore put reverse lever in extreme forward notch, and blocked link down solid on link block and secured block from falling out if it did work loose, by tying bell cord several times around the link, and started working my engine in full motion. I brought my train in all right, and only losing about forty five minutes over the regular schedule time in the seventy-mile run. Having had some argument with the master mechanic, and more with the boys, I concluded to ask your advice under same circumstances. L. L. HOOD.

Duluth, Minn.

[Not knowing the exact conditions, it is difficult to tell what was best to do or not to do. The danger in a case like this is from the lower end of the link swinging far enough to strike something; for instance, back of truck frame; the success of your experiment would seem to prove your good judgment in this case, you guarded against excessive slip and a "cramp" by the use of the block. We think under the circumstances you did right.]

Putting Water into Red-hot Boilers.

Editor The Locomotive Engineer:

In Bro. Sinclair's "Testing Red-hot Boilers," page 29, *National Car and Locomotive Builder*, for February, he says: "There is a prevalent belief among people who ought to be better informed, that should a steam boiler get hot through shortness of water, and feed water be suddenly injected upon the hot plates, an explosion is almost certain to follow." He then cites several experiments where steam was generated in different boilers, boilers then blown out without drawing fire, and allowed to stand a sufficient length of time to heat crown sheet red-hot; cold water was then forced into it with a steam fire engine. Result: No terrific explosion—nothing except a gradual cooling of plates, "only this, and nothing more." Query: Would the result have been different had the experiment been tried on a consolidation engine hauling twenty loads up a 100-foot grade, with 180 pounds boiler pressure, crown sheet exposed until it became red-hot, and a sudden injecting of cold water upon it? I don't think Bro. Sinclair would have nerve enough to "stand within five feet of it, with his hand on it most of the time," but would prefer to view it from a safe distance through a field glass.

One of the first lessons taught me when I began firing, was the necessity of keeping the crown sheet covered, of course that was some years ago, but the rule must still be observed. I would not advise any of the readers of THE LOCOMOTIVE ENGINEER to experiment any along this line, for fear they might not be able to "collect their scattered thoughts" and tell the result. Don't you think so?

Albany, N. Y. SID.

[The dropping of the crown sheet is to be expected under these conditions, but does not occur once in ten times. Water always tends to cool and stiffen the sheet; heat softens it, and when there is pressure above, a hot sheet is easily forced off the stay bolts; the very common belief that sudden contraction brings the crown down is wrong—it is heat and pressure; the sudden injection of cold water might tend to suddenly increase the pressure and thus aid the rupture.]

Some Driver Brakes and the Men Who use 'Em.

Editor The Locomotive Engineer:

I read your item on the crippled driver brakes with some amusement.

The main trouble with steam driver brakes is that most of them have no way of getting off except by the weight of the toggle, so in order to admit of their application and release during the same week the boys do not pack the piston. This allows a mist of steam to waft heavenward just as you are making a flying switch or a bad coupling, and your ears must tell you whether the switchman has got the target over, or the gafter got safely out from between the cars. In cold weather you will find many plug-pullers, like me, using the bar in preference to taking chances. The American Co. have recently put a sort of bonnet on their brake cylinder, and use a spring to hurry the release. This keeps the company doctor from lots of practice.

Engineers hate to see steam escape from any valve except the pop.

When the first driver brakes were put on the Cumberland & Pennsylvania, they tried two kinds—the vacuum and the steam. The 19 was in for repairs and got the steam brake. The vacuum was put on the 18, nights. The first morning the holes were drilled in cab bracket, a few bolts in place and the hangers up. The second morning the vacuum pan, or "kettle," as the boys called it, was up, the diaphragm shoved into it, and the connecting rod banging loose in the hanger. Some of the boys "'lowed" that it would be connected to the crosshead and vacuum pumped up. The third morning it was complete, but the engineer did not know how to use it until he was told by the M. M., and then hardly understood it.

The other engineer was made of different stuff and wrote the steam brake company for instructions, got a book and studied up, and when his engine came out he was the only man that knew how to handle it right. The boys at once named the steam brake the "jim crank" or the "wind jammer," while the vacuum is known only as the "old suck."

Mt. Savage, Md. HANK.

Using Compressed Air for Everything.

Editor The Locomotive Engineer.

I met my friend "Doc" the other day, while the passenger train he was drawing was stopping at the eating house for dinner, and he was mad all over because he had to run his air-pump so fast to keep up the pressure. I tried to console him by saying that lots of pumps had to run faster than his did, and that some engineers let their pumps run full speed from choice. "That don't make any difference with this pump," says he, "it is in first-class order, and there is plenty of air going into the reservoir, but they use it for everything under the sun after it gets past there. In the first place, it is piped up into the water tanks in the sleepers, and pumps the water into the wash basins by forcing it out of the tank. Some of them don't get the pipes just right, and the consequence is that the water gets back down into the train pipe, then the first cold night the air pipe is froze up solid, so we can't use the brake past that car. I have been caught that way once, so it is no fancy statement. Then they run the air pipe up into the reservoir of the gasoline lamps, and use it there to light up the coaches. There ain't much used for that, of course, but every little helps to make it harder to keep up the supply. One of our cars has got a patent step that lets down close to a station platform, and when you get a signal to go, how do they raise it up again? Why, with air pressure of course. Look at the private car back there, it has got some sort of a trap under it to shut off the steam from the heating apparatus in case of a wreck, but for the life of me I can't see what they want to shut off the steam for. That uses air, too. Then they have a reservoir of water in the corner of the car, with a pipe leading into the Baker heater, and some kind of a dingus in it to let the water into the fire in case of a smash-up. That's all right, for I don't care where the air goes after a smash up takes place, if they can use it to put out the fires, good enough.

"I hear a fellow has got up a machine for calling the stations, which works a sign in each car to show the name of the next station. What works it? The air, to be sure. I suppose we will have one on this train before long, and if they make one to ventilate the cars, and carry out grips for good-looking girls, the brakemen won't have a soft time. Oh! no! The bell ringer on the engine works with air, too, and that's pretty fine. I like it lots better than steam—it's cleaner, easier to regulate the ringer, and if the packing leaks a little around the piston rod, it don't hide your view ahead or cover your window with water, like a steam ringer does. Ike, the traveling engineer, is going to have a sand pipe put on this engine with an air attachment in it for running a nice, fine stream of sand on the rail whenever you want it; the M. M. of the Fitchburg Railroad got it up. I saw one working the other day when I was down at Fitchburg; it is fine, you can have just enough run on the rail to keep you from slipping.

"I wouldn't kick so hard about this air business if it was not for one thing—when you set your brake light and easy, the leaks under the cars for all of these fixings take some more air out of the train pipe, and sets it too tight, then it has to be let off before we get to the stopping place, and that makes me hot. I don't calculate to set the brake but once for any ordinary stop, but a leak in the train anywheres beats me. Some fellows set it and let it off again two or three times in making a stop, and, of course, they run by most every time. I have no patience with that kind of business. The air signal is all right; I thought it was a nuisance at first, but on a long train it beats a bell cord all hollow. If it is put on all right, and all the joints tight, it won't bother you any, but some of them have to whistle on their own hook pretty often—that makes a fellow think something is wrong; I don't know what makes them do it.

"Have you seen the electric headlight yet? One of our boys told me that you could not see colored lights very plain with it, is that so? I don't believe it, for it don't seem reasonable. The next time you are near one, find out for me, will you? My idea of the electric headlight is to use an incandescent globe instead of an arc light. I don't see why an incandescent lamp set in our reflector where the burner comes won't work as well as a kerosene lamp, and give ten times the light. They say the little loop in the lamp won't stand the shaking on an engine. They are used on street cars which ride ten times as hard as the front end of an engine. You can carry a storage battery on the engine that will run one of these lamps for three or four days. One of our sleepers used to be lit up that way, and they had twelve in it going at once."

The conductor came along just then, gave "Doc" his tissues, and off he went, leaving me to meditate on what he said. It is a fact that some inventors in the car department seem to think that compressed air is like salvation—free, and the more you can use the better you are, and that any new labor-saving contrivance for a passenger coach is not perfect till it is made to go with air. If all the pipe fittings are made in the best style, the check valves between the train pipe and these patent fixtures tight, and sure to always drop in their seats, it is not much matter if a little air is used, when these extra pipes are connected to the auxiliary reservoir it must operate to gradually release the brake if there is a leak. Leaks of all kinds cost money, and make bad work, whether in air pipes or fire-boxes. The electric light costs so much for original plant and running repairs when in service, that companies don't think but once when the cost is compared with the kerosene burner they now use, which costs so little.

Port Huron, Mich. C. B. CONGER.

About the Size of Injectors.

Editor The Locomotive Engineer:

In answer to a question about the size of injectors in a recent issue, you made a mistake in saying that the size was determined by the size of "combining" tube. The size is always determined by the "delivery" tube, the smallest in the instrument. But I write to put your readers right about this supposed "standard" for sizes.

The old Giffard instruments were numbered as you state, by the number of millimeters the delivery tube was in diameter. The Messrs. Sellers followed this plan in their instrument of '76, and stuck to it reasonably close. Conditions were changing all the time, and when it was found that an injector was slightly weak in its water supply an easy remedy was found in reaming out the tubes.

The Sellers self-adjusting instrument will throw more gallons of water per hour under varying steam pressures than can any instrument without the self-adjusting feature, providing the delivery tube is the same size in both instruments.

The tests made of the '76 or self-adjusting injector some years ago rather established a standard of capacity in gallons per hour, and the other makers enlarged the delivery tubes of their instruments to bring the capacity up. This increase of size varied, being controlled more or less by differences of construction or design.

The Hancock inspirator people made a departure from the usual practice and numbered their instrument by the number of 100ths of an inch in the diameter of the delivery tube, and their locomotive sizes range from 10 to 50.

The Rue Co. used to prefix one (1) to the number of their Little Giant, to distinguish the locomotive pattern from the stationary; thus a number six became 16, and there are still in use many of their older instruments so numbered; they soon dropped the extra number, however. The new, re-starting Sellers will not throw as much water as the old with the same sized tube, and so they had to be enlarged to take the place of the old ones. So you will see that the original plan of measuring the size of an injector has been virtually abandoned for the more practical one of determining the number by the actual capacity in gallons—the size of the delivery tube always governing this capacity.

There should be a standard established for locomotive injectors that would simply call for a certain number of gallons per hour at some given pressure—say 140—then a No. 7 of any make would throw a given amount of water, and railroad master mechanics, engineers, etc., would not be bothered by the differences in range and capacity as now, although there is not as much difference as one would expect where a matter of this kind has been allowed to settle itself. Trusting that this will put you and a great many interested parties right in the matter, I am an

INJECTOR MAKER.

About Increasing Lead.

Editor The Locomotive Engineer:

I notice an answer in your issue of February, 1891, No. 12, J. B. Horner, Shamokin, Pa., in which you say *Yes*, in answer to Question 1, which is: "Does the hooking back of the reverse lever increase the lead on the valves of a locomotive?" Do I understand you to mean that when the reverse lever is brought nearer the center of the quadrant that the lead is increased? That is the way I understand your answer and I think you are wrong. Please answer in your March number and oblige

Shamokin, Pa. JOHN MCELIECE.

[The shifting link always changes the lead when the point of cut-off is changed. It can be put up in such a way as to decrease the lead, but probably not one locomotive in five hundred is so hung. Engines with a stationary link and shifting block maintain a constant lead—the shifting never does.]

Two Useful Kinks from the Chicago & Northwestern Shops.

Editor The Locomotive Engineer:

I send you two blue prints that may be of interest. One shows a frame that our engine trucks are built on, which requires little or no explanation.

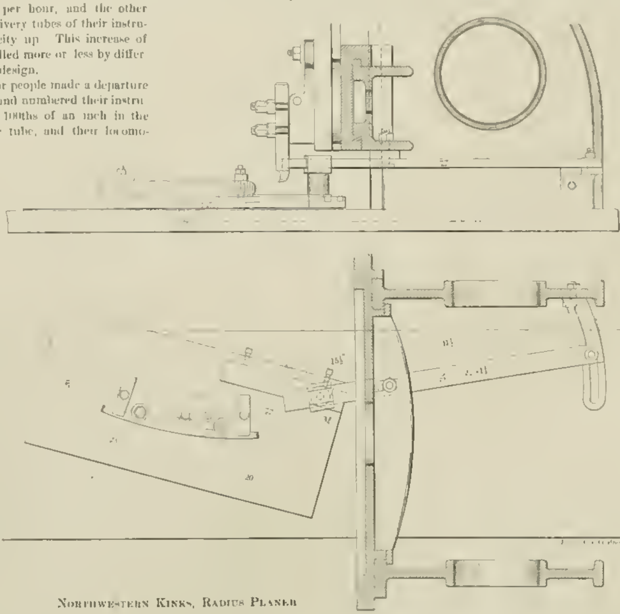
Under a large bracket-drill built on a column of the shop, there is a track on which our big jig travels. There are four solid upright castings that fit between the jaws of the frame where the box goes. We place the jaws against the casting and adjust the set-screws from behind, pinching the jaw tight up against it, afterwards we put the frame on, and a clamp, shown at A in elevation (on page 49), swung on a loose bolt through the casting, binds the jaws and frame all together. We have two different sized trucks that we build: one has a large box, and the other a small one; for the small box, the jaws come up against the casting, and for the larger box we have liners that we put one on each side of the casting. That makes the jaws the size we require.

After the top plate is put on the frames and one side drilled and reamed and the bolts put in, we have the center clamped down with two clamps on either frame. We then take an eye-bolt with a cotter through it, drop it down over the center pin, and overhead we have a crane that hoists the whole thing up and turns it around—the drill press being of a very ordinary type, and built to clamp so as to render it stationary.

We place one end of the truck under the drill press, and after one hole is drilled the truck is simply pushed along on small wheels running on a rail bed that is laid to accommodate them, so that the hole comes directly under the press, and all that is then necessary is to feed it down.

With regard to the blue print of radius planer, I presume you will readily understand this with little explanation. We turn up a center, as shown on blue print, about six inches in diameter, this is let half way through the plate for fastening the work on; the plate is merely placed on top of this round center, without anything to hold the plate in position, excepting simply its own weight. The bar, of course, swings the plate with the travel of the table. The desired radius is obtained by moving the bar back from the table, either in or out. When one becomes accustomed to it, it can be set very quickly. The man that works ours has marked the back end, so that by placing the bar at a certain mark a certain radius is secured. Of course, a good plan is always to run the radius over before starting the cut. It is a very convenient tool for various kinds of work in a repair shop.

Chicago, Ill. MECHANIC.



NORTHWESTERN KINKS, RADIUS PLANER.

Our Re-cousined Pooh Bah.

Editor The Locomotive Engineer:

I've been waiting over three years now for one of our men to die so as to write you about him, but he don't seem to have any idea of dying afore I do, so I'm going to get out his obituary in advance.

I used to think he was a character, and studied him, then I came to the conclusion that he had no character and studied him more; he's an "amoosin' old cuss," but, bless you, my boy, what a row he kicks up everywhere he goes.

He was raised a pet on the same road our General Manager came from, has some sort of pull, and wears a title something like service inspector, though he seems to be something like an extra tail, hitched on to the motive power department.

Our G. M. is a nice old fellow, but he wants to have things so that no officer under him can make a move without his approval, and every move must add a star to his crown; he "brooks no rival near the throne," therefore The Tail is a valuable appendage.

The Tail has five cousins, two sons, four brother-in-laws and a nephew, in good, easy jobs on the road. One daughter pounds a type-writer and chews gum in the old man's office, and another has married the claim agent.

For all this, you never did and can't to-day mention a good berth on the road but what The Tail will tell you of a cousin or a something-or-other of his that would fill the bill and have something to carry, save the company 'oodles of money, and make the traveling public so glad that they would sit down on the cold ground and laugh for joy.

The Tail examines firemen before they are set up, and his word goes with the "old man," and I give the boys, who expect promotion, a pointer that the escorting of the younger Tail girls to a show, the purchase of a few whisky-sours for the Captain Tail, or the agitation of the propriety of presenting the general assistant-everything with a gold-headed cane, will go much farther with him than knowledge of valve gear or train rights.

I was in his office lately while two young men were examined.

The first fellow that came in was one of our best firemen, decent, sharp as a pickerel, and deserving of promotion.

The Tail started in thus:

"Well, young man, can you run an engine?"

"I think so."

"That's no answer. What's lead?"

"Opening of valve when engine is on dead center."

"Who told you? You've been studying for this. What's coal?"

"Composed of different substances, principally carbon."

"What's a parallelogram?"

"A figure whose opposite sides are parallel."

"If you was getting up an engine to pull 100 cars on a level, what size cylinders would you use?"

"I don't know; don't expect to build any engines this fall."

"Well, what size stack would you use?"

"I don't know."

"Don't know?"

"No."

"You're a bright one, you are. What size stack do they use here?"

"Sixteen inch."

"Sixteen inch; that's right. Used that on the Hudson Bay while I was traveling engineer. Six-

"Yep, betcherlife they can't play three ball with us."

"Well, Jim, what's steam?"

"Hot water."

"Pretty hot, ain't it, hey, Jim?"

"Yep."

"What's coal?"

"Stuff to burn."

"Yes, course it is. What's the difference between anthracite and bituminous coal?"

"Different kind."

"Yes, yes. Say, Jim, what's lead?"

"To put into valves."

"Yes, course. How old are you, Jim?"

"Thirty-two."

"Yes, yes. Well, Jim, I just ast you a few questions to see how you was gittin' along. You go over into the stock yard and run Biles' engine to-night, and I'll git ye on the road pritty soon. Well, yes; don't care if I do, Jim, smoke it after supper."

Exit firesy No. two.

"Likely young feller, that," says The Tail to me; "make a good runner, too, you bet. Father fired for me on the Hudson's Bay, married a sister of

fired and sued for trespass if they walked across the company's right of way.

He sat up behind me last Saturday as the best engine in New England was skimming 61 miles an hour out of four mail cars, and said:

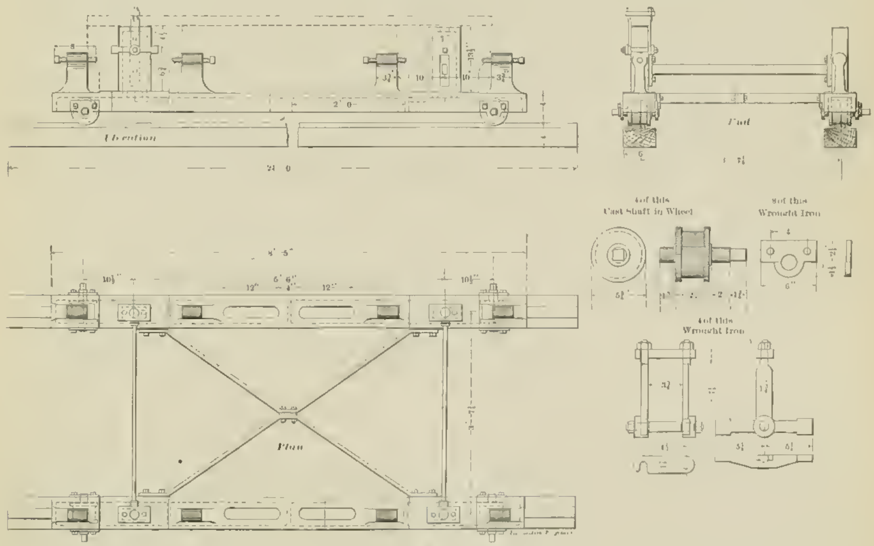
"Too small cylinder, Alexander; too darn small, running line and line, and only three-fourths lap on a five-inch travel. I just wish I was master mechanic of this road. I'd show 'em something. This engine wants a short stroke, big cylinder, twenty-two by twenty-two, and a seven-and-a-half or eight-inch travel. They could take down half their coal chutes then. But, Lord, the old man is slow to move things."

I was sorry, Mr Editor, we got into the passenger station at the Hub just here, or the old Tail would have had a place picked out for his wife—possibly running my pet engine. JOHN ALEXANDER.

Lamp and Whistle Question—A Reasonable Explanation.

Editor The Locomotive Engineer:

I would like to say in reply to R. W. Pope's letter in the February LOCOMOTIVE ENGINEER, that the reason why the whistle of a certain locomotive



NORTHWESTERN KINKS, TRUCK TEMPLATE.

teen inch is the right sized stack for any engine. You'd better study up a little. How old are you?"

"Twenty-four."

"Too young, too young altogether. I wa'n't set up till I was thirty. What's the best, single or double nozzle?"

"I suppose it depends on the service; one kind seems to do as well as another."

"Tut, tut, man. The Hudson Bay abandoned single nozzles thirty year ago; they ain't no good. You seem to have no very good idea of what a thing ort to be."

"Single nozzles work well on this road."

"They do, hey? That's all you firemen know. Why, my dear sir, I'll guarantee to save two ton of coal a day on every engine if the old man would let me introduce double nozzles. Done it right on the Hudson's Bay. But look here, young fellow, you want to post up, and maybe after awhile we can put you to running. Good morning."

Exit bright young man, feeling mean and misjudged.

Enter second fireman.

"Hello, Jim; glad to see you. Want to be examined, hey? Well, that's all right. Say, you fellers got the best of Mart and Bill on that run last night, didn't yer?"

mine. That man knows more about water than any man in New England. If I could get the old man to make him superintendent of water supply on this road, he'd make a turning over in that office—you bet he would—and save this company ten thousand dollars a year—do it just like a darn. Heard you was off the track last night. What was the matter? Broken rail, so? There is a damnably managed department. Pete White don't know no more about keepin' up track than I know about preachin'. What they want to do is to get a man like Ike Merrill on the Hudson Bay. Why, he forgets more about track every day than Pete White ever knew; takes right hold himself. Great Scott, but wouldn't he make things howl here! You wouldn't see four or five dude clerks in that office long. Yes, Johnson is roadmaster now. Ike's keepin' butcher-shop in Collins; but, Lord, he'd be willin' to take hold of the place. You ort to mention this to the old man, John; it would be a good thing for the road—a big thing, sir. I can recommend Ike, he's my wife's father."

The Tail, being general factotum, goes out on the road as sort of engineer in general, and paralyzes firemen by telling them that if they had fired or cleaned their engines on the Hudson's Bay as they do here, whilst he was traveling engineer, they would be

put out his office lamp, is that the pitch of that whistle was a harmonic of the tone that would be produced by the lamp chimney if it were used as an organ pipe, so that when that whistle was sounded, the air in the lamp chimney vibrated in *sympathy* with it.

This law of tones is well understood by organ builders, and if any engineers have trouble with their cab lamps going out when the whistle is sounded, I think they can remedy it either by changing the pitch of their whistle or the lamp chimney for one of a different length.

Grand Rapids, Mich. D. EMERY.

To Save Work in Valve Setting.

Editor The Locomotive Engineer:

Brother L. C. Hitchcock is correct on valve motion, but he will save himself time and trouble if he will only use centers on one side and quarter on the other, and he will find out he has the same results. E. A. CAMPBELL,

Houston, Texas. Supt. M. P. & Machinery.

Phelan's Air-brake Practice is meeting with quite a sale in Australia. One of our club raisers there recently sent in an order for 60 copies.

Chances for Economy in Higher Pressures or in Compound Locomotives.

Those who are inclined to the belief that there is little or no economy in compounding locomotives, generally end their argument by the assertion that simple engines could be made just as economical, if a very high pressure were carried.

A great many of our roads have increased the boiler pressure up to 170 or 180, and one English road has some boilers carrying 200 pounds per square inch.

We have not yet heard of a compound locomotive for which a considerable saving of fuel was not claimed, and, in most cases, proven. The best example extant is the little Forney engine on the Brooklyn elevated, that was compounded by the R. I. Locomotive Works The tests this engine has undergone prove that she is saving from twenty five to thirty-five per cent. of fuel over the simple engines of her own class, but there is a good reason for this showing, and it is larger than the same makers, or any one else, can hope to get on a surface road, in express service. The elevated engines are employed more than half the time they work steam in starting and getting their train up to speed. This calls for the working of the engines hard, the lever in the corner for a few turns, then gradually hooked back a notch at a time until, when cutting off at a quarter or a third of the stroke, they must be shut off for the next stop—stations being only five blocks apart. This sort of use of a simple engine is very wasteful of steam and fuel, as any one can see.

Now, the compound engine works steam expansively, even while in the corner, and though she starts a train slower, makes up for this when she gets it going; the construction of the engine obliges the runner to work her expansively even in starting, prevents a fierce blast from tearing the fire, and gets more useful work out of the steam.

This compound locomotive shows a very high saving of fuel, because the engines she runs against are so wasteful of it

The Webb compound on the P. R. R. shows a large saving over the regular engines of the road, and, we believe, partly from the same reason. Webb's compound locomotives do not show as high a saving of fuel over his own simple engines as it does over ours. Why? Because his simple engine is more economical than ours.

A comparatively high pressure of steam can be carried with good results on the boilers of compound locomotives, because by expanding the steam in two cylinders a large percentage of useful work can be got out of it.

The same pressure in a simple locomotive is not economical, because it has to be released from the cylinder before it has done as much work by expansion as it would do in the compound locomotive's cylinders. Too much heat is thrown away in the exhaust, the fire has to be forced harder to furnish this extra heat to waste, and everything about the engine and boiler must be made heavier and stronger to stand the pressure Again, the chances for wasting steam are greater with high than moderate pressure—every leak is intensified, and there are more leaks.

High-pressure steam for economy should call for a shorter cut-off, but the limit of cut-off for effective work, easy riding, and the prevention of excessive compression with the link motion is found between the quarter and third stroke marks—6 or 8 inches for 24-inch strokes.

If we are debarred from an earlier cut-off, we must wire-draw the steam more by throttling. We may gain a little here by superheating the steam in wire-drawing, but we reduce the pressure at the chests—why not carry the lower pressure in the boiler? It is certainly cheaper on repairs, and safer.

The new "Class P" passenger engines on the Pennsylvania carried 180 pounds pressure, and the boys had to "hit 'em" to make time. But two of these engines blew off their dome caps, and, pending a change of pattern, the pressure was slacked back to 140 on all the class, and they have made the time just as well as before

There must be a pressure for every locomotive that is just right, taking into consideration her size, weight, service required, and not forgetting the link motion—which cuts a large figure. We are inclined to think this happy medium exists, for the simple reason that by going to extremes, in either direction, trouble is encountered.

Suppose we had fifteen pounds pressure, and there was no such thing as friction, this pressure would move the pistons through the cylinders, and when the exhaust took place a very large amount of heat would be wasted, and yet no useful work could be done.

Now, on the other hand, if we had one thousand pounds pressure, we would be unable to use it in the cylinders, because we would not have the weight to maintain adhesion, everything would have to be extra strong, and the dead weight carried to stand the pressure would be more than doubled from present practice; we could not cut off much earlier than we do, and steam would have to be reduced to the cylinders; the cylinder condensation would be greater than at a later cut-off, and the excessive heat would make the lubrication of the valves and pistons almost impossible.

Do the best we can, the development of power by any heat engine is wasteful, in so far as we get the use of but a small per cent. of the heat in the fuel consumed.

In the use of steam, we are a good deal like the small boy who hitches his little sleigh on behind the four-horse sled, and is dragged along, consuming but a small part of the passing power

Compound locomotives can carry higher pressure and get more work out of steam than can single expansion engines, and when simplified and adapted to our work, will become as popular for locomotive work as is the triple expansion engine for marine work—because they will haul more tons a mile, or one ton more miles for a ton of coal burned, than simple engines will.

The present form of locomotive with excessively high steam pressure will not become as popular, because the railroads will measure its work by the tons of weight moved a mile, or the miles a ton of weight is moved for a ton of coal consumed—and it will not be able to compete with the machine that makes its second expansion of steam in a cylinder instead of in the smoke-stack.

Five Thousand Dollars Reward.

It has become a very common practice, of late years, for railroad officers to get out flaming handbills, after a wreck, offering five or ten thousand dollars reward for the arrest *and conviction* of the miscreant or miscreants who placed obstructions on the track, or misplaced a switch.

Sometimes, no doubt, these posters are gotten out to terrify meddlesome people in the district where a wreck has occurred, but in many, if not most cases, the sole reason for their existence is to shift the responsibility for the fatalities from the shoulders of the road, or its management, to the shoulders of some unknown and undiscoverable "miscreant."

When an engineer or fireman, or both, are killed, it opens a cheap way of settling with the family, if the road can make the wife and children think that the dear one was ruthlessly murdered by an assassin in ambush, whom the more than interested railroad would give $5,000 to get and send up—or hang

"Miscreants, to us unknown," are charged with about twenty crimes for each one committed.

The writer recently walked through a yard in a small town on the line of a road that had up a "$5,000 Reward" notice. There were stub-rail switches, with broom ended rails from four to six inches, apart. One switch stand we inspected had the bridle rod connected to the stand with a bolt not less than a quarter of an inch smaller than the hole it was in, and the slack of the rig, from the padlock to the rail—by actual measurement—was one inch and an eighth. Four out of seven ground switches were so made that the center of the rail rod connection was *above* the fulcrum, instead of below it. Such a switch will throw itself under a train There was enough slack in switch-connections to cause a disastrous wreck any time—one of the $5,000 kind.

Every freight train that passed had flat wheels enough under them to break dozens of rails any frosty day. Brake beams were small wooden ones, and many running without safety hangers.

This road has power brakes only on its passenger cars, lights its cars with oil lamps, and heats them with stoves. It has half-protected drawbridges, uses little, four-inch switch-lamp lenses, that are invisible about ten car lengths away in good weather.

This road keeps enginemen and train crews on duty from sixteen to thirty hours continuously, and its officers are the very kind who call a washout "an act of Providence," and foster the framers of resolutions that say, "It has pleased God to remove from our councils our beloved brother," etc., etc. They are the first to lay a case of bad switch, or rail-spreading wreck, a burned bridge, a broken wheel, or brake-beam "pile-up," to that unknown quantity, the "miscreant," for whose arrest and conviction they would gladly give $5,000.

The widow or mother of the victim of these wrecks generally sign a clearance for from $250 to $1,000—miscreants come higher, and are very rare

A little intelligent investigation of the cause of wrecks by the men most interested—the enginemen—and quiet advice from them to the proper officers of where there are dangerous places or practices, would do a good deal to prevent these fatal wrecks by the stitch-in-time process, and when they did occur it would probably put the responsibility where it belongs, instead of charging it up to Providence, or the $5,000 "miscreant" aforesaid.

Book Review.

CONSTRUCTIVE STEAM ENGINEERING A Descriptive Treatise, embracing Engines, Pumps and Boilers, their Accessories and Appendages. By Jay M Whitham, M E., C. E John Wiley & Sons, New York. Price, $10.

This work treats of the constructive features of steam engineering; it does not discuss the subject of designs, but illustrates and describes the distinctive features of almost all the popular builds of engines, pump, boilers and general steam appliances. The work shows the latest and best devices used by the most successful builders, and does not advocate, like many works, untried plans and devices designed by the author because they were different from anything else.

The book is a bound catalogue of standard makes of steam machinery, compiled by a disinterested and unprejudiced mechanic No better work on machine design can be got out than one showing the latest and best forms made by the most progressive builders.

The work is large, having 900 8vo pages with 795 illustrations, many of them folded plates The work does not treat of locomotives.

COMPOUND LOCOMOTIVES By Arthur T Woods, M M. E, Prof. of Mechanical Engineering, University of Illinois R. M Van Arsdale, publisher, 140 Nassau St, New York Price, $2

This work is made up of twelve chapters on the subject of compound locomotives, contributed by the author to the columns of the *National Car and Locomotive Builder* during 1889 and '90, making a book of 170 pages, containing quite a number of engravings illustrating the distinctive features of the different forms of compound locomotives now extant

One very useful feature of the work is a list of all the patents granted on the compound locomotive from 1882 up to August, 1890.

The author has not "theorized" very much on the subject, but has rather confined himself to a brief statement of what the different experimenters have done, and the results of trials of their devices

The work will be especially useful to master mechanics and mechanical engineers who contemplate experiments in the direction of compounds.

ASKED & ANSWERED.

(20) E. L. Baltimore, Md., asks:

Why is it necessary to have a vacuum pump connected with the passenger car steam heating apparatus as used on the P R. R system? *A*.—The pump is not necessarily a vacuum pump; it is used to pump the water of condensation out of the train pipes and radiators, and put it back in the tank, thus maintaining a circulation

(21) Y. B., Durham, N. C., asks:

Can a locomotive's drive wheel be properly counterbalanced for various speeds, and how? *A*.—Strictly speaking, no. Speed is not usually taken into consideration in determining the weight of counterbalance; no doubt there is one certain speed at which any engine's counterbalance is nearest right

(22) J. F. M., Salida, Col., asks:

Please state in your question column what book or books you would advise a person to get in order to find the exact positions to set the saddle on the link. *A*.—Auchincloss on Link Motion, sold by E & F N Spon, 12 Cortlandt street, this city.

(23) Young Engineer, N. Y., asks:

Why does lead increase with the link motion, when lever is cut back? *A*.—Because the relation of the rest of the valve gear to the eccentrics is changed just as if the eccentric were advanced on the shaft. By lifting the links, the straps and entire motion are set *back* on the eccentrics. The shorter the eccentric blades, the more movement takes place and the more lead will increase.

(24) Inquisitive, Weldon, N C., asks:

Why is it that elevation from sea level causes water to boil with less degrees of heat? *A*.—Water boils when the tension of its vapor is equal to the pressure it supports. As the pressure is increased so is the boiling point, as it is decreased the boiling is also decreased. Simply stated, because there is less pressure on the water; the pressure of the atmosphere is 14.7 pounds per square inch at sea level and becomes less at greater heights.

(25) B. & O., Mt. Clare, Md., write:

We are using the Westinghouse improved automatic freight brake, and often are obliged to cut out cars on account of air leaking through the exhaust, or, in other words, through the pressure-retaining cock on top of roof. What causes this? *A*.—The alleged leak is probably simply the air releasing through the cock, as this is the only place it can release when car is fitted with retaining valve Many accidents have been caused by men cutting out cars because they thought the air ought to escape at the top of the car only when the retaining valve was turned on. The fault is with the men, not the device.

(26) J. H. D., Kalkaska, Mich., asks:

1. Why are the top guides worn the most? 2 Which is the stronger, a double row of horizontal rivets or the zig-zag rivet plan? *A*.—There is more pressure on the top guides when the engine is running ahead; engines that back up all the time wear the lower guide the most. The crosshead and guides are to keep the connection between the piston and main rod from going up or down out of the direct line Just think for a moment where the force is applied and the resistance met, and you will see where the pressure on the guide is in either case 2 The staggered rivet seam is the stronger

(27) Tar Heel, Weldon, N C., writes:

I am running an engine with eccentrics 5½" throw. Suppose I turn ⅛" off of this eccentric all around. Will it shorten travel of main valve, and how much? *A*.—No Just think for a minute yourself; the *size* of the eccentric makes no difference with the throw; if your eccentrics were ten feet diameter the distance from the *center of the axle* to the *center of the eccentric* would not be changed, and this alone determines the amount of throw If you made two eccentrics, or rather wheels, one ten feet and the other ten inches in diameter, and put the shaft in the center, neither would move an eccentric blade, because there would be no eccentricity—but set each axle out an inch, and each will have two inches throw.

(28) J. S. L., Des Moines, Ia., asks:

Will a locomotive pull more than half a train with main rod disconnected on one side. If so, why? Do you not think it would be better to take a train that you are sure you can handle without taking chances of doubling hills with an engine working on one side? *A*.—A locomotive on one side can pull more than half her usual train, because the boiler will furnish steam to work one cylinder very much harder than it is possible to work both when coupled together, and the engine has use of all her adhesion The difficulty is to get train started, and the weight of load should be regulated somewhat by the number of stops, and where they are A train so heavy as to require a double should not be taken under ordinary circumstances. A locomotive on one side is more or less unmanageable, and liable to stop on the center in the way of important trains.

(29) A H. Tucker, Chillicothe, Mo., writes:

Will you please answer through the "Asked and Answered" column the following: What is the minimum quantity of water that a Sellers No 7 injector of the "76" pattern will supply to a locomotive boiler at a boiler pressure of 140 pounds per square inch, feed water at ordinary temperature? What is the maximum quantity? What is the size of the delivery tube opening? *A*. The No 7 Sellers of "76" will deliver at its minimum capacity, with 140 pressure, about 94 cubic feet of water per hour, and at its maximum capacity 201.5 cubic feet per hour It will heat the water about 100 degrees The size of delivery tube is seven millimeters. All injectors are numbered by the size of the smallest tube in millimeters One millimeter is .03937 of an inch, to find the size of any injector in decimals of an inch multiply .03937 by the number of the instrument.

Ever since the Santa Fe road built across the Southwest there has been a curious practice followed in regard to the employment of Mexican labor. A wiper received $1.35 per day, unless he was a Mexican, in which case he received $1.75. When Mr. Player went there he made the pay uniform, and all the Mexicans struck. It is peculiar that this practice was carried on for so many years, and no one seems to know the reason for the original favoritism

John Wiley, the well-known scientific book publisher, is dead He was eighty-three years of age.

Who Is Responsible for the Harlem Tunnel Disaster?

On the morning of February 20th two empty passenger trains at the Grand Central station in this city, were put together and taken by a switch engine toward Mott Haven, where the trains are switched and cleaned. This particular morning was very foggy and signals hard to see, and before the heavy train of empties was through the tunnel, it was run into from the rear by one of the New Haven trains, and six car cleaners were killed—some of them being roasted alive.

Between Fiftieth street and Ninety-eighth street on the Harlem Railroad there is a tunnel under Fourth avenue, being about half open to the streets by an open cut in the center of each block, there are four tracks through this tunnel—the two central ones for the line roads, the outside tracks for local traffic—it is used by the Harlem, the New York Central and the N Y, N H & H. roads; all trains on this piece of track being under the superintendent or general manager of the Grand Central Depot.

The Harlem road uses the left-hand track instead of the right, and the signals are located upon the left of the track, so that they are on the firemen's side.

The road is blocked by what is known as the Syke's system of signals, the switches and signals being interlocking. There is an electrical device that locks signals in the danger position, and the signal cannot be taken off until released from the other end of the block—it is said by those who ought to know, that in order to hurry traffic it is customary for the operators to resort to a trick of their own whereby they can unlock the signals by using a pencil, and that two trains are allowed in blocks at the same time very frequently

The New Haven train was running at a high rate of speed and the shop train very slow when the crash took place—one car was completely telescoped and at once caught fire, burning dead and alive alike until the arrival of the city firemen, who put out the flames.

The daily papers have made a great howl about the New Haven road not using steam heat, but it is very evident from the wreck that the fire was intensified, if not caused, by the oil in the head-light.

The collision occurred at Eighty fourth street, in the block extending from Seventy-second to Eighty-sixth street.

The engineer either ran by the distant and home signals at Seventy-second street, or else the signal was not against him Either the engineer or the signal man at Seventy-second street is guilty of a misdemeanor, and on the final decision the cost of the accident will fall on the road employing the man adjudged guilty.

Let us look into the why and the wherefore of this business. But first let us say that we have no interest in the matter further than to see exact justice done, if the engineer is guilty of gross carelessness let him suffer and his road pay, or if the signal man is to blame, on him let the hand of the law descend. We are sorry to observe, however, that the matter, as far as the public are allowed to see, has settled itself down to a contest between the legal talent of the two roads, to see which can shift the cost of the accident upon the other.

The signal operator in his tower has charge of the operating of the signals in such a way that no two trains can get into the same block, or in such a way that the trains will not run into each other, his reputation with his superior officers depends upon how little he delays trains, and there is a constant incentive to be as attentive to the prompt removal of a signal that will stop or delay trains as possible.

With a young and ambitious man there is a constant temptation to take a few chances, to be "fly," depending considerably on the engineers and the air brake to lessen the danger of collision, and there is no direct check on this tendency, as cases are not reported and success emboldens the experimenter The signal man is in no personal danger, and "lightning only strikes once in a thousand times."

How about the engineer? He is in the greatest personal danger, his years of training on a locomotive tell him the consequences in case of collision, and he knows full well that his chances of escaping unhurt are but about one in ten. No sane man is going to jump into a furnace or down a well. Aside from that, his fireman is just as much interested, for he takes the same chance, and knows full well that not only their success but their very lives depend upon their being *sure*, not only about the engine, the brakes and the orders, but, above all, the signals, not only that they are *not* wrong, but that they *are* right.

In the Harlem tunnel there is no firing allowed—the fireman has no duty but to look out for signals—they are on his side. In thick weather he must stand in the gangway and stoop down to see the distant signal at Seventy-second street, because it is so low.

Bad weather often obscures these signals, and in order that there may be an additional safeguard a large gong is so arranged as to ring continuously while the home signal is set at danger. Every one who has had experience on a locomotive or train knows that such a thing as a noise like this gong being "drowned by the roar of the train" is utterly impossible.

On this particular morning Engineer Fowler and Fireman Wellington started with train No. 10, known as the New Haven local; they were five minutes behind the shop train. Fireman Wellington was in the gangway on the lookout for the dwarf distant signal at Seventy-second street; the engineer had to go to the left side of the engine to see the signal, and the fireman also reported the signal "clear." Both men positively declare that they saw the home signal at "clear," and say no bell was ringing; the conductor says the bell was not ringing when the train passed, and several passengers say they heard no bell.

The signalman and a track walker who was with him are just as positive in their assertion that the signal was at danger and the bell ringing. It is not possible that the engine crew were asleep; they had been less than five minutes away from the terminal station.

No sane man would pass that danger signal knowingly—it is too much like suicide—personal danger prevents the engineer from taking chances, while there is no personal peril to check the assumption of risk in the signal man.

President Depew, of the N. Y. Central, says the accident was caused by the N. H. train running too fast—the time card calls for high speed in this tunnel. This train's time is thirty miles per hour, and the officers of all the roads brook no delay; there is not a day in the year when there is not some train that runs fifty miles an hour in this tunnel. Manager Platt, who controls this short piece of busy road, says the signals do sometimes fail, but on the side of safety, and acknowledges that it is possible for an operator to unlock the signals, and the rules provide for this in the use of a "twelve bells" signal that signifies, "Have unlocked you"; this is to be used when the block system is out of order.

From a personal investigation we are satisfied that the signals were at "clear," no matter in what condition the operator thought them. He may have cleared another signal thinking he was clearing one of the main tracks. We are also convinced that two trains are sometimes allowed in the same block, and this fact ought to have been known to the operating officers. While the block system used was the best one once, it is not the best now, and has a disadvantage in that it can be tampered with. There are in successful use systems of block signals that are operated by electricity or air and electricity, that are entirely automatic, being set and released by the trains themselves. They cannot fail except they go to danger, and there is not the chance for human forgetfulness, carelessness, or design in their handling, that exists in the old hand-operated block signal.

A road, crowded as this one is, should be provided with absolute blocks automatically operated by the positions of the trains themselves. The practice of running trains on the left-hand track with the signals on the opposite side of the track from the engineer is a very dangerous arrangement.

If any one erred in judgment or made a mistake, it looks as if it must have been the signal man, and not the engineer, but these two men are not entirely to blame—the road with the poor signal system is a partner in the crime, and signal men only get $52 per month.

Whether the car stove caused the fire or not, we hope the New Haven road will have to pay a big fine for using them in New York against law—they are dangerous, and no good road ought to, or will, insist on stoves.

It is only fair to say, however, that the New Haven officials had given an order, before the wreck happened, for the most expensive steam heat appliances extant—as good as money can buy—they commence on March 2d to put on the Consolidated Car-heating Company's Disk Drum System, using the Standard Sewall Coupler.

There is another element that ought not to be overlooked, and that is the use of "rules" for the government of employes that are habitually ignored by the men, and must be, in order to get trains over the road on time. These rules are intended and used only to shield the road from responsibility and the payment of damages in case anything happens. Rules being daily ignored are winked at by the officers. There may have been none of this in the tunnel disaster, but there are very few roads in the country where a good hunter could not find from one to a dozen of these rules that should be obeyed and accidents avoided—yet if a man obeyed them he would be taken off his run, as a man who could not make time. Have you a rule of this kind on your road?

Valve open Valve closed

VARIABLE EXHAUST NOZZLE.

Variable Exhaust Nozzle.

Annexed engraving shows a very simple and practicable form of variable exhaust nozzle invented by Mr. D. Hanney, a mechanic in the Chicago & Northwestern Railway shops at Chicago, and used on some of the locomotives on that railway. A valuable feature about the invention is that it can be easily operated from the cab, and by that means easily adjusted to the requirements of steam making. Another good point about the invention is that the exhaust orifice is not distorted in shape by being opened or closed. An expanding nozzle is particularly valuable for locomotives engaged on suburban business if the men in charge could only be induced to operate it. A careful test of this nozzle was made with one of the suburban engines, and a material saving of fuel was effected by its use. The saving recorded was about 20 per cent. After making allowance for the saving that always ensues when men are working under the consciousness that they must do their best, there appears to have been a margin of saving, due to the variable exhaust nozzle, which should induce railroad companies to adopt it.—*National Car and Locomotive Builder.*

At the Illinois Central Shops.

The old shops of the I. C., on the lake front in Chicago, are landmarks to every railroad man who has spent any time in the greatest railroad center in America.

The I. C. is a big road, running almost due north and south from New Orleans up into Wisconsin; they own almost 2,000 miles of track, and control, through stock ownership, or lease, 600 miles more. There are in service 500 locomotives, and over 18,000 cars.

The shops in Chicago are old ones, and have a great many old tools and appliances, but there are also many new ones, and a practical man can see at a glance that there are minor improvements going on that are tending to facilitate the handling of material and save time. Overhead tracks and trolleys are being built, and cranes placed in the most convenient places.

W. H. V. Rosing has recently been promoted from chief draftsman to be assistant superintendent of motive power, and to him has been given the care of the shops.

The first novel thing that catches the eye as you go into the machine shop is a jig for milling out steam ports in cylinder castings on a large radial drill. The jig is simply a cast-iron plate or template bolted over the valve seat, having ports cut out of it, of the proper proportions. The cylinder is fastened on the bed of the drill, and the radial arm set at right angles to the bore, and a milling tool the desired width of the ports put in, in place of a drill; the blank above the cutting edges, or the shank, fits the slot in the plate bolted above the seat, and this guides the tool, the automatic feed of the machine feeding it from end to end. For the exhaust port they do not change tools, but feed the same small miller right around the port.

On the driving-wheel lathes they use a very neat and handy hoist to lift the wheels to the centers. This device consists of two hangers to take hold of the axle, a bar for them to hang on between the face plates, and two boxes to support the bar, the whole rig being placed on the lathe itself. The boxes are simply two square pieces of iron, with a hole through them for the bar, which is long enough to reach from one face plate to the other, and heavy enough to support a pair of wheels. The square pieces have squared shanks about ten inches long, that drop into the ends of the large radial slots in the face plates. The hangers hook over the bar, and the lower end terminates in a fork large enough to go over any axle, and a heavy key is put through the fork below the axle, to lift the pair of wheels. In the center of these hangers there are turn-buckles to adjust their length. The wheels are rolled up behind the lathe, the boxes put into slots on the upper quarter of the face-plates, the cross-piece put on, and the hangers adjusted the proper length and keyed to the axle, then the lathe is started up, and the wheels roll up inclined timbers until they are above the bed of the tool, and then swing clear; the lathe is stopped with the boxes on top, and the centers run into the center holes in the axles, the turn-buckles slackened, and keys knocked out of the hangers, and the whole rig taken off in just about as much time as it takes to tell how.

Where no crane is at hand, this is a very handy device for the work, costing little, requiring very little machine work and no patterns, and enabling the latheman to handle all his own work alone.

They bore out driving-boxes very successfully in the quartering machine, a field of usefulness not often given that machine.

In the machine shop there is a very ingenious tool gotten up here for making tin car seals, stamping the initials of the road and a number into the tin, which is fed in—in sheets of the proper size

In this shop each swing crane—and there are several—are so set as to serve three or four tools each.

This road has a good many kinds of engines, most of them having some of the peculiar features found of benefit to the road. The water contains a large percentage of lime, and forms scale very readily, and there are peculiar washing-out facilities used. On the left-hand side of each boiler just ahead of the crown sheet, and on a level with it, there is a cock screwed into the boiler shell This cock is a check, the pressure in the boiler tending to keep it shut, there is a cam, however, operated by a rod to the cab, that will open it when there is pressure on the boilers, this allows it to be used as a blow-off cock

Inside the boiler there is a pipe extending from this check across the boiler, the opposite end being closed, and a number of flattened jets screwed into the back side of it. Outside the check there is a pipe, with a hose coupling extending below the running board. When the boiler is washed out, the hose is connected to this pipe, and the pressure from the pumps lifts the check, and the jets direct the water under the crown bars and wash the sheet clean. On the belly of the boiler, near the front end, there is another hose connection, and an elbow inside the boiler that directs the stream back, this is used after the general washing, to drive the scale loosened from the flues back into the water leg, where it can be taken out of the hand-holes.

A great many of the engines have their checks in the front side of a steam dome placed well ahead. These domes formerly had an alleged water purifier in them. A sort of basket, containing iron turnings and small scrap, was supposed to receive the deposit of lime; the dome caps were taken off periodically, and the scrap changed, but, while there was always more or less deposit on the scrap, the practice was abandoned as being too much bother for the results obtained, the checks being left in the dome.

All driving-boxes are cast around strips of brass that form the bearing, these are dovetailed, but sometimes come loose when they are driven out and shimmed up, or new ones put in.

They have here a class of heavy suburban engines that do remarkably good work. They are four-wheel connected, have a pony truck in front, and a four-wheeled truck under the tender, which is framed with the engine

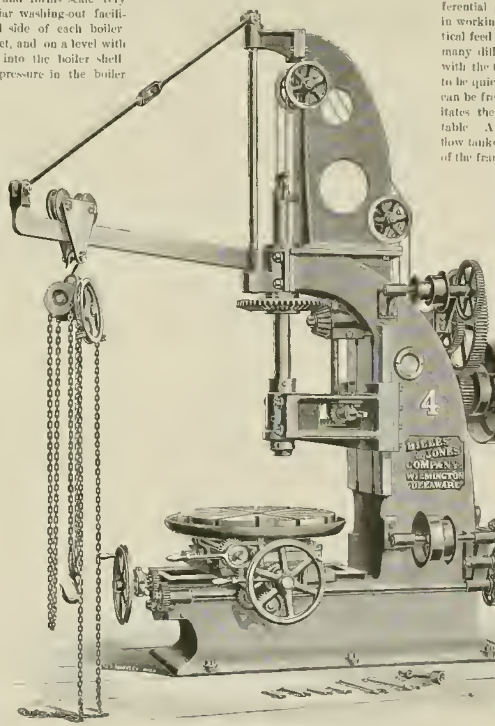
To prevent dirt and the rusting and pitting of the sheets of the tender, the manhole is placed on top of a large cast-iron elbow that is flanged to the back of the tank, when this is run over, the water goes upon the ground, and the coal space is free and dry. The pony trucks on these engines have a long equalizer on each side, extending back between the steam chest and the saddle.

Out in the graveyard there are some old-timers of small caliber that have died of the grippe, and on stilts a dome boiler of the vintage of '46 reminds you of the "merry old days that were."

The new engines are mostly of the Brooks build, and are very nice engines indeed; they have inclined fire-boxes, with a section of level grates at each end, and a section in the center on an incline, all shaking, they are well liked by the men, who have dubbed them the "toboggan fire boxes."

The standard grates used run lengthwise of the box, and are simply straight bars with projections on the sides, and in shaking move fore and aft

All piston heads are cast solid, with four core holes; these holes are tapped out, and stays screwed through and riveted down.



A NEW DESIGN OF VERTICAL MILLING MACHINE.

Jerome packing of their own make is used.

All eccentrics are four-inch face and 16 inches in diameter, so that but one size of eccentric and strap need be carried in stock, and they can be kept on hand finished

In the roundhouse, the valves on wash-out plugs are moved by an eccentric held open or closed by a weighted lever, which is easy and quick to handle

The buildings are mostly of stone and brick, but have been in use for many years, and are therefore not so modern as you could wish, new shops will probably be built at no distant day, further out. Plans were in the drawing room, to which chief draftsman D. J. Durrell was putting the finishing touches, for a very fine plant at Water Valley, Miss., to take the place of the shops recently burned there.

On some of the engines the New York air-brake is used, at the time of our visit we noticed a mechanic filing back one of the stops on the engineer's valve, the system of levers in the valve having developed lost motion enough to make this necessary

On all the engines running into the city there is a blower valve, located so that when the throttle is closed, the blower is started enough to prevent black smoke, the amount of opening given the blower being regulated by a thumb-screw on the throttle lever.

A New Design of Vertical Milling Machine.

The well known builders of locomotive and car-shop machine tools, Hilles & Jones, of Wilmington, Del., have recently put on the market a heavy vertical miller, originally designed for locomotive work. The machine has some new features that will, no doubt, be duly noted at a glance by practical men.

There is a self-supported radial crane, with a differential pulley block and trolley for convenience in working The spindle is arranged to have a vertical feed by hand, which is very useful in facing many different pieces. The worm which engages with the table has a pivoted shaft which allows it to be quickly moved out of gear, so that the table can be freely revolved by hand This greatly facilitates the work of setting pieces to a line on the table A rotary pump, with the necessary overflow tanks, which are attached to the opposite side of the frame from that shown in the cut, returns the soda water which is used in keeping the cutters cool. There is an unusual vertical height in this machine, the vertical motion of the spindle being 20 inches

This allows a great variation of work to be handled, which otherwise would have to be done on a slotter, or by hand. The merits of vertical milling are well known to most of our readers, and need no special commendation in this description.

Baldwins are now delivering twenty-seven locomotives to New South Wales, Australia. The price was $10,000 each.

The Bennington & Glastenbury Railroad in Vermont has the steepest grade on which ordinary traction locomotives are used in the United States. For some distance the road rises at the rate of 250 feet to the mile.—*Railway Register*.

What is the matter with the Calumet branch of the Denver & Rio Grande, with its eight miles of over 300-foot grade—part of it 400?

The Employes' Relief Association of the Philadelphia & Reading reports an increase of membership during the year to November 30, of 1,500, and it is stated that *ninety-eight per cent* of all the employes of the company are members of the association, which would seem to indicate that membership is in some degree compulsory—a point which was considerably controverted in the newspapers during the earlier months of the association's existence. The total contributions to November 30 last were $44,833; payments for deaths and disablements, $275,488.—*Ex.*

The St. Paul & Duluth road give any employe, engineman, machinist or wiper $10 extra for every cracked side rod found—none get away for want of thorough inspection Eight have been discovered in the past two years. It pays the company to find them before rather than after they let go. It is a regular practice on some roads to pay $1 extra for cracked or broken wheels found by car inspectors.

Engineer Louis C. Todd, of the Boston & Maine, has been promoted to the position of master mechanic of the Passumpsic division, and all the boys on the road are pleased and propose to help him to be a success.

They Advertise Advertising.

It's funny how inconsistent human beings can be when they set themselves about it. A shoemaker who wouldn't think of prescribing medicine for himself, and a blacksmith who wouldn't think of making his own shoes, and a merchant who wouldn't think of shoeing his own horse—each because he knew nothing of the trade or art he wished to employ—will all separately and independently sit down to write an advertisement of his own wares or his own work, and when the "ad." fails to attract the amount of custom or trade wanted, our amateur advertisers will each and all hold up their right hands and swear, legally and illegally, that "advertisin' don't pay."

Now, if either of these worthies wanted to build a house he would seek the advice of some one who knew something of house building or get a work on architecture. If he wanted to paint his house mouse color, he would get a painter to mix his paint, or consult a standard work on color mixing. But let it come to the expenditure of money for advertising, and he takes up his pen with as much unconcern as a drunken blind man has for wigglers in the water he drinks. Advertising is a business, and there are men who make it a study, their work is shown in the highest class periodicals of the country—the advertising in some of our magazines being almost as interesting and attractive as is the text—some of it more so.

One concern in this city publish, at 10 Spruce street, a paper called *Printers' Ink*, that is as brimful of kinks and suggestions on advertising as this paper is on locomotives repairs. The little paper costs $2 per year, but it is worth $2 per issue to any live advertiser. The advertisements in railroad papers are too prosy, and not changed often enough. We heartily wish that our advertisers would get a few pointers from *Printers' Ink*, and then commence to bother us to change and rearrange their ads. It would pay them, and it would pay us.

Fast Trains Wanted.

W. Barnett LeVan, a mechanical engineer of Philadelphia, recently read a paper before the Franklin Institute of that city, in which he said:

"It is well known, and has been shown by experiments by M. Regray, superintendent of the Eastern Railway of France, that the fractional losses in locomotives amount to about 35 per cent. of the total indicated horse-power of locomotives coupled by parallel rods. Single locomotives always run more freely and with less internal resistance than coupled ones. The adoption of single locomotives in England has made a saving of over three pounds of coal per mile, or about ten per cent. of the entire passenger locomotive coal bills. The coupling of locomotives tends to keep down the speed. The objection in this country to single locomotives is the traction of one pair of driving-wheels, but by the introduction of steel rails and that of the steam-sanding apparatus, locomotives can now carry as much as 20 tons on a single pair of driving-wheels, where before 14 tons was the maximum load. The fast trains between Philadelphia and New York and those to Washington average about 200 tons weight, drawn by coupled locomotives, the average coal consumption being 50 pounds per train mile. Why not adopt the single locomotive of the English type and reduce the time between Philadelphia and New York to 90 minutes and the coal consumption to 30 pounds in place of 50 pounds per mile? Whatever railroad managers may think of the economy of running light and frequent trains, at reduced fares, there can be no doubt that they are a popular want. The cost of moving trains at any given speed is, all other things being equal, almost exactly in proportion to the weight moved. It can be stated positively, in view of the data before cited, that passenger trains of reduced weights, and drawn by single locomotives, according to the English system, and affording all requisite comfort to the traveling public, can be run between New York and Philadelphia in 90 minutes, and involving a consumption of coal of but a fraction over one-half of that now consumed in making the 2-hour run."

A fair trial of the single coupled engine is needed in this country, just to show what it will do; the results may be startling, but the type will only do for fairly light trains. Instead of howling for faster time, without offering any suggestions on how to get there, Mr. Le Van seems to be something like Blifkin's widow, "Knew what she wanted and wasn't afraid to ask for it."

Credit When and Where Due.

To the Trainmen on —— Division:

Another year has passed without serious accident on this division. Since October 1st, 1888, we have been singularly fortunate in this respect, and I doubt if any road in this country, with as large an amount of traffic, can show so clean a record for any division. During that period you have handled nearly 700,000 cars with a remarkable degree of safety, and while recognizing the excellence of the road-bed, and the good fortune which continues to "stand by" us, I must give all credit to the trainmen whose prudence and good judgment have made it possible. Do not let past success cause you to relax your vigilance and care, but rather redouble it, in the hope of adding another year to the record.

Y. Z. BLANK,
Division Superintendent

The above bulletin was recently posted on the boards of one of the busiest pieces of track in New England. It is manly, and gives credit for work done and results accomplished to the men who wrought—there is none of the "I did so and so" in it. We don't know why—unless it be the enlargement of the bump of modesty—but this officer specially requests us not to give his name or road away.

Better Than a Kick.

Upon the retirement of Master Mechanic McGrayel, on the first of the month, the engineers presented him with a fine bookcase and desk, and the following memorial:

CHICAGO, ROCK ISLAND & PACIFIC RAILWAY—DES MOINES & FT. DODGE DIVISION.

JOHN MCGRAYEL, Esq., Grand Junction, Ia.:

DEAR SIR: We, the engineers of the D. M. & F. D. Division of the C., R. I. & P. Ry. Co., deeply regretting your departure after (17) seventeen years service, as master mechanic, desire your acceptance of the accompanying memorial, in testimony of our affection and respect for you as a gentleman and a mechanic, and as a faint expression of our appreciation of your kindly efforts to render our connection with this division not only pleasant and agreeable to ourselves, but profitable to the company. Deeply regretting that our connection must be severed, we shall gratefully remember our association in the past, and hope always to be held in pleasurable remembrance by you.

J. F. THOMPSON,
M. LEACH,
M. SMITH,
Committee.

Painting the Forth Bridge.

As some curiosity has been expressed as to the quantity of paints and oils used in the construction of the Forth Bridge, the officials of the company requested Messrs. Craig and Rose, of London and Glasgow, who held the contract throughout, to make up a statement of the amount actually supplied, and these were found to be as follows: Machinery and illuminating oils, 980,072 gallons, paint oils, 35,527 gallons; paint, 250 tons. It is computed that the quantity of oil used would have been sufficient to float one of Her Majesty's first-class cruisers, and sufficient paint to cover 1,100 acres, or nearly two square miles of surface.—*Ry. Press* (London).

Some Patent Office Statistics.

The patent office of the United States received 40,201 applications for patents during the fiscal year ending June 30, 1890, which, with the re-issues, designs, trade marks, etc., made up a total of 46,140. There were 25,857 patents granted, and enough labels and trade-marks registered to bring the total up to 27,493. There were 3,403 patents held because the final fee was not paid, showing that some inventors, and, possibly, some inventions, are poor. During the year 11,885 patents expired.

During the 54 years ending in 1890, there were 742,583 patents filed, and 91,165 caveats. There were 475,785 patents issued, and the receipts of the department were $25,349,584; expenses, $20,554,110, leaving a clear gain of $4,095,474. We wouldn't mind running a patent office ourselves.

A Business Way to Do Business.

Our attention has been called to the following neat circular, which shows the estimation the paper is held in and the business ability of Mr. Wade. It would pay any master mechanic's clerk to take this matter up in the way Mr. Wade has—a cash commission is paid for clubs.

OLD COLONY RAILROAD CO.,
OFFICE SUPT ROLLING STOCK,
BOSTON, February, 1891

DEAR SIR: I am getting up a club and I wish to call your attention to THE LOCOMOTIVE ENGINEER. It is a practical illustrated paper for railroad engineers, firemen and mechanics.

This is no job to fleece you; but you will thank me for bringing the paper to your notice.

The superintendent of rolling stock and master mechanic of each division have subscribed and endorsed the same. Shall I add your name to the list? The publication is a monthly, and the subscription price is low, being only $1.00 per year, and will be sent to your address.

By filling out the coupon at the bottom of this circular, enclosing the same in the envelope, and forwarding to me, I will send your name to the publishers at New York.

You can enclose $1.00 with the coupon, or send the coupon and forward the $1.00 later on.

Respectfully,
JAMES H. WADE,
Clerk, Office Rolling Stock Dept.

MR. JAMES H. WADE:

DEAR SIR.—Enclosed find $1.00 for my subscription for THE LOCOMOTIVE ENGINEER.

Name........ Fireman or Engineer.

No........ Street, Town of ....

State of. ....

Magnitude of the Telegraph Business.

There are 842,812 miles of telegraph line in the world, of which the United States operate 254,110. This is lines, not wires. There are 807,589 miles of wire in the U. S. alone. In the U. S. 254,110 miles of poles and cables, 25,591 telegraph offices, and 42,447 employes. The Western Union controls 678,997 miles of the wire. Last year this company alone transmitted 55,878,762 messages. The cash receipts were over twenty two million, and the net profits over seven million.

Russia has the next largest system to the U. S., she owns 88,280 miles of lines, 172,360 miles of wire. The smallest system is that of Paraguay, there being only 100 miles of lines there. The enormous number of 300,000,000 messages are transmitted annually over all the lines of the world.

Many of the oldest of us can remember when there was not a mile of telegraph wire on the earth. We move fast in this age, and see much; but does it make mankind better or happier? The higher the so-called civilization, the meaner men get, the more they will do against their fellows in order to dominate it; the wider the gulf between the rich and poor. No half dressed savage in the wilds of darkest Africa can compete with the civilized men, taking them in the aggregate, of to-day, in cruelty.

Substantial Improvements.

During last year the Illinois Central purchased 89 fifty to sixty-ton engines, built 65 new passenger coaches, which are of the latest design and finish, 1,500 thirty-ton coal cars, 1,000 twenty-five-ton box cars, 10 fifty-foot baggage cars, 10 postal cars, 150 refrigerator cars. It has built and is now building 18 iron bridges, and has replaced 22 wooden bridges with stone culverts. It has built several new depots, and repaired many of the old ones. It has purchased and laid 32,000 tons of seventy-five pound steel rails, and 4,000 tons of sixty-pound rails. It has ballasted with stone and gravel 160 miles of track. It has equipped 100 engines and 2,500 freight cars with the latest improved Westinghouse automatic air-brakes.—*Ex.*

Compound Tubing.

George H. Everson, of Pittsburgh, Pa., has patented a process of rolling tubes that promises remarkable results for many kinds of work.

One of his processes is to reduce a tube by rolling; this process practically polishes the tube inside and out, makes it stronger and lighter; tubes of this kind are used by a factory in Pittsburgh, who make steel carriage and wagon wheels. The other process the inventor uses to roll a lining or a cover or both of a different metal upon or into a tube.

He takes a steel tube and lines it with brass, copper, tin, or any metal, and can cover it with any other metal, rolling the two metals so closely that they are practically solid.

A steel tube covered with copper might be just the thing for locomotive flues in bad water, the covering of copper resisting the action of the salts and making a nice joint in the flue sheet, while the steel lining will resist the cutting action of the cinders drawn through the flue.

Description of the Southern Pacific Compound, by a Sacramento Paper.

The blindest worshipers of the extension arch could not wish for warmer praise than this. Listen to him:

"The combination engine is about completed, and a test of it will probably be made to-morrow or next day. These locomotives have never been used by the company, though on eastern roads they are said to have proved a success. The locomotive in the shops here is an ordinary eight-wheel connection, but with an added front-end extension to the boiler. An ordinary locomotive was taken, and the addition made to it. The purpose is that the steam may be used twice, the combination being of high-pressure and low-pressure exhausts. If it is a success, it will afford a saving in steam and consequently in fuel, by no means a small item in so extensive a system. There will be no added power in the combination locomotive, but the company will be more than pleased if the saving spoken of is effected."

Don't suppose this reporter is any further off than we should be in trying to describe the ladies' costumes at a ball, but a fellow can't help thinking that, perhaps, the reporter had been drinking a little.

Speaking of small steam pipes, ports, etc., the other day, Mr. Wilson Eddy, one of the oldest M. M.'s in this country, said to the writer: "A good many years ago I took an old engine in the shop and lengthened her boiler and frame twenty-five inches; the coppersmith lengthened the dry pipe, but put in a thin piece of metal. After the engine had been in service a few days the engineer complained that she was loggy and would not swing her train after getting it started. The valve gear was looked over, steam ports examined, and cylinder heads removed, to no purpose. The engine would start just as many cars as any other, and pull them at slow speed, but she would not swing 'em. Upon examination of the dry pipe it was found collapsed on account of the thin piece in the splice. The pipe was closed up with the exception of an irregular strip that we estimated to be not over one inch in area, yet this engine pulled a full train over the road in this condition for some time."

More than thirty years ago the Housatonic Railway, of Connecticut, ran trains of cars whose ends were covered and the two cars joined by flexible hoods, into the sides of which the passengers entered by doors—in fact, the modern vestibule. How Sessoms, Pullman, or any one else can get a broad patent on this device, much less successfully defend it in the courts, is a wonder. Pullman has just as much right to patent the idea of roofs over cars.

Edward B Gibbs, of St. Louis, Mo., is introducing his patented improvement on extension smoke arches. He uses a modification of the Barnes extension, such as shown in this journal for February, 1890. The improvement consists of two ¾-inch nipples, screwed into the front of the base of the exhaust stand. The jets of steam, it is claimed, prevent the cinders from igniting and kill all fire. For this reason, very large screens and a larger nozzle can be used.

Jacob Myers, for more than forty-four years a locomotive engineer, died at the age of 75, on February 8th, at Saratoga, N. Y. He commenced running in 1846, on the old Rensselaer & Saratoga road, remaining twenty-two years. Since 1868 he has run on the Adirondack road.

To find the proper size of rail for given weight of locomotive, multiply the number of tons on one driver by ten, the result being the lightest rail advisable.

Clinton B. Conger, for some years past mechanical engineer on the board of railroad commissioners of Michigan, has been appointed road foreman of engines of the C. & W. M., and the D., L. & N. railroads, a responsible position that he is eminently fitted to fill.

Those who argue that a standard sized stack for all sizes of cylinders and boilers is right, might just as well argue that a certain sized bearing was "the proper thing, regardless of the weight to be carried, or the speed attained.

CALCULATIONS

For Engineers Firemen and Machinists

A work of instruction and reference 336 pages, with 150 diagrams and illustrations, 9 inches x 6, printed on heavy paper; sold in 10 monthly parts at 25c each, or in one handsomely bound volume for $2.50, postpaid

Theo. Audel & Co., Publishers, 91 Liberty St.,
(Room 3), New York City.

NOTE:—This work teaches practical men how to advance themselves to the highest positions. "He who reads (this work) must learn."—Ald Collins, Inspector. "I would not part with the H. B. C. for five times its cost."—Jno. J. Jennings. "I have found it to be the best ever put before the public."—Chas. Spiel, Chief Engineer.

Notwithstanding

belief to the contrary, locomotive boilers can be — and are — washed out, refilled and steam raised in one hour. To attempt such work and use the old, crude devices is impossible. A small, cheap jet instrument is made by the Rue Manfg. Co., 116 N. 9th St., Philadelphia, that, taking cold water from the mains, throws a powerful stream of hot water for washing and filling up, thus avoiding danger of sudden contraction. It also has an attachment for testing boilers with hot water up to five or six hundred pounds. A man can carry it, requires no foundation and has no moving parts to break or wear out. Costs less than pump foundation.

Look into this.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

AIR BRAKE PRACTICE.

SECOND EDITION.

BY J. E. PHELAN.

A book of 107 pages which can be carried in the pocket, and which covers the practical work of operating Air Brakes intelligently, explaining how and why they do certain things under certain manipulations and not under others. Tells how to handle, inspect, repair and adjust all the different systems of air brakes in use. Explains both the Hodge and Stevens System of Levers. Contains full directions for applying Driving Brakes to old equipment, and gives road kinks that are alone worth the price of the book.

Two large Removable Plates show the latest form of Air Brakes, complete and in detail, in perspective and section, so plainly that no one can fail to understand.

SENT POSTPAID TO ANY ADDRESS FOR $1.25.

☞ If no one has got up a club in your neighborhood for this book, and you will take the trouble to gather in anywhere from 10 to 100 Subscribers, write for Club Rate Circular.

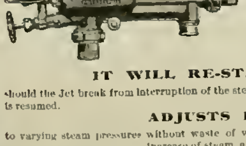
The Self-Acting Injector of 1887.



Range of Capacity over 60 per cent., and can be regulated, therefore, to work continuously for light or heavy trains. Never fails to promptly lift hot or cold water.

No service on a locomotive sufficiently severe to permanently stop its working.

IT WILL RE-START ITSELF

should the Jet break from interruption of the steam or water supply, as soon as the supply is resumed.

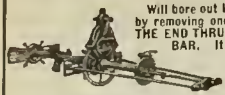
ADJUSTS ITSELF

to varying steam pressures without waste of water. Increases quantity of water with increase of steam, and vice versa.

Very easily operated—Started by pulling out the lever, and stopped by pushing the lever in. Descriptive Circular and Price List sent on application to Office and Works.

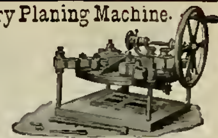
PHILADELPHIA, PA.

Patent Portable Locomotive Cylinder Boring Machine.



Will bore out Locomotive Cylinders IN THEIR PLACES by removing one or both heads, as desired, and piston. THE END THRUST IS ALWAYS IN EXACT LINE WITH BAR. It is fed with constant feed of cut gears.

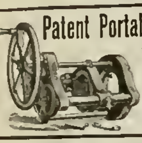
Portable Valve Seat Rotary Planing Machine.



Will face off the Valve Seats of Locomotives and other Engines in a rapid and accurate manner. No lost time; no breaking of the edges; the only machine requiring no use of files or scrapers after machine has faced off the seat.

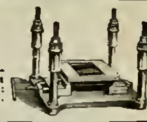
Pedrick & Ayer, Philadelphia, Pa.

Patent Portable Crank-Pin MACHINE.



Will quickly and accurately true up Crank Pins, taking off that part that is eccentric only, leaving the fillets at the corners. It will feed either way and fit any size pin. Is built strong and powerful. Circulars with full description on application.

Patent Portable Valve Chuck.



Used in combination with Valve Seat Rotary Planing Machine; quickest and easiest way of facing a valve; obviates use of planer; adapted to roundhouse and repair shop work. Adjusted by the four graduated columns.

THE HILLES & JONES CO., Mfrs.,
WILMINGTON, DEL.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formulæ patented by Mr. G. W. Lord. For decree of court, etc., address G. W. LORD, 330 Union Street, Philadelphia, Pa.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. IV, NO. 4 NEW YORK, APRIL, 1891. $1.00 per Year or 10c. a copy.

It All Depends.

"I see some of the roads out of Chicago have made a cleaning out of their passenger conductors again," said the old-timer, sitting down thoughtfully on the editor's hat. "Same old story over again. I guess they won't never let up till they can get up some plan to do away with cash fares and tickets.

"Mebbe you don't remember a few years ago when the Pennsylvania put on ticket pickers and then got up a sort of a grab bag, nickel-in-the-slot-affair that was strapped to the conductor—he had to drop a ticket or a receipt for fare paid into the slot in the presence of the passenger—don't remember it, hey?

"Well I was pulling a con then, and he were a good one, but he flared up and quit—wouldn't stand it. He hadn't been running but seven or eight year, but he had saved money enough to buy a hotel, and no slouch neither, right in old Philly.

"I was in to see him not long ago and had a good talk about old times, and he sais to me, sais he

"'Frosty, old boy, they couldn't git me to wear their dam harness, they couldn't git me to go through my train with no sub-treasury attachment and an affydavy fare, like a convicted shop-lifter—not by a damsite.'

"Just here his clerk sold a cigar, and taking a quarter from the customer, jabbed a key on one of them regestering typewriter things that jumps up a card saying 'ten cents,' give the man his change, and went at something else.

"'What's that, Jim,' sais I.

"'Cash register,' sais he.

"'What fur?' sais I.

"'Why to keep them roosters from stealing my eye teeth out,' sais he.

"'Same plan as the old ticket box, hey, Jim,' sais I, laffin'.

"'Well, suthin,' sais he, kinder thinkin' like. 'But, Frosty, these hotel clerks are slick ones—steal while you're lookin' at 'em. You got to keep your eye on 'em just like a "do not" order, or they'll skin you; but you look kinder tired, old man, less have suthin'"

Makes an awful difference, Mr Editor, 'whose cretur gets hooked,' don't it?

New Forney Locomotives for the Manhattan Elevated Road.

To a railroad man familiar with the little, red engines that haul New Yorkers back and forth, a description seems much like a description of his own home; but the number of letters we constantly receive from far and near, asking about these engines, their size, weight and service, shows that the average railroader knows little or nothing about them.

MANHATTAN ELEVATED LOCOMOTIVE.

The engraving on this page was made directly from a photograph, and shows one of the latest engines put in service, and one having some new features.

The Manhattan Company now controls and operates the four lines of elevated road, on the Second, Third, Sixth and Ninth avenues, in New York City.

There are 32.40 miles of double track road, supported on iron pillars in the street, the height averaging about twenty feet above the pavement, but running higher in places. Much of the road is double lines of single track, supported on a single line of iron posts for each track, but in the latest built lines the tracks are together over the center of the street. Counting the 24.98 miles of sidings, all the trackage amounts to 89.78 miles.

The gauge is standard 4' 8½", and 70 pound steel rails are used. On each side of the rails there are 8 x 8 timbers bolted to the cross-ties to insure derailed rolling stock from going far astray.

The company has 300 locomotives and 1,100 cars, and does only a passenger business, at five cents uniform fare, the longest ride possible being from South Ferry to 155th street, a distance of a little over ten miles. The average number of passengers carried daily exceeds half a million, and has exceeded 700,000. The total yearly earnings are upward of ten million dollars. Stations are about six blocks apart, on an average, being only five in the lower part of the city, and farther apart up town.

Four and five car trains are run, during the busy hours as close as one minute and five seconds apart. A maximum speed of twenty-five miles an hour is made, the stops being so frequent as to prevent a higher average rate of speed than fifteen miles per hour.

The strength of the elevated structure limits the admissible weight for locomotives to 47,000 pounds, so that, as a rule, great pains are taken to make parts as light as is consistent with strength.

The road being built entirely over crowded streets, no water or oil can be allowed to drip, the noise of the exhaust must be chocked down, and muffled pops and escape pipes used, so that, perhaps these little engines have more pieces than a decapod.

The engines are never turned around, but run either end ahead, there being a four-wheeled truck under the tank, and no truck at the cylinder end.

The cylinder saddles are hollow and deep, and are the receptacle for some of the drip, the outlet to the cylinder cocks being piped into it. The overflow of injectors and drip cocks goes to the ash-pans, which are water-tight.

Under the cylinders and guides there are pans, as shown, to catch the drip.

The sand-boxes are located under the running board. No bells, pilots nor foot-steps are in use.

Eames' vacuum brakes are on all wheels under the engine and train, the escape of steam from the ejector being muffled by the device shown on top of the cab.

The cabs are of thin steel, lined with wood, this lining and the tank deck being all the wood used.

The exhaust pipe of these engines is large, and a long, cast-iron cone is drilled full of small holes and put into the pipe, point down. The area of the opening of the holes is equal to the port area. This device is to muffle the exhaust, and is known in road parlance as "the bug."

The boiler is of the Belpaire form, 42" diameter, with a fire-box 53¼"x31¼" and 43" deep, set on top of the frame. There are 154 tubes, 1¾" diameter and 6' 3¼" long. The grate area is 16 square feet, heating surface, 430 square feet. The drivers are 42" diameter, truck wheels, 28"; the rigid wheel base being 5', and the total wheel base 16'. The tank carries 1,600 pounds of coal and 512 gallons of water. These engines weigh 45,500 pounds empty.

The main axle journals are 5¼" in diameter and 6¼" long. The cylinders are 12" bore and 16" stroke; steam ports, 8¼"x¾"; exhaust ports, 8¼"x1¾"; travel of valve, 3¼"; throw of eccentric, 3¼", outside lap, ⅝".

The latest order of this class of engines are now building at the Baldwin works, some of the order having been delivered.

The new departure in these engines has been in lightening parts by the use of steel and wrought-iron in place of castings.

The driving wheels are forged wrought-iron, the frames are of steel, the front-end door, cylinder-head casings, etc., being of pressed steel. They still use a cast-iron stack, weighing about 600 pounds, however.

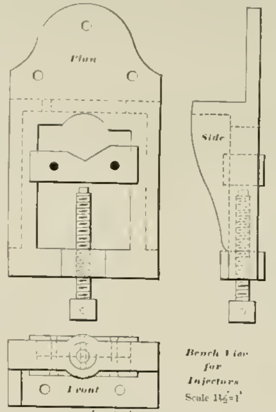
These little engines are double crewed, and average about twenty hours' work per day each, developing an average of 145 horse-power in doing their regular work.

The average consumption of fuel, which is anthracite coal, is 45.7 pounds per mile, 40.9 miles for a ton being averaged.

Crews do not always work continuously, but do not put in over eight hours' service for a day's work without extra pay. Engineers get $3.50 per day; firemen, $2. Each crew averages about 70 miles per day, and in that distance make 208 stops. Over 3,600 trains are run daily.

An Injector Vise.

The accompanying engraving represents a very handy bench vise for injector work in use in the



Boston & Albany shops at East Albany, N. Y. The body or frame of the vise is made of cast-iron; the slide or crosshead is wrought-iron, made in two pieces, and riveted together. The screw has a loose handle, like any other vise screw.

This device gives a sure grip on an injector, and has no tendency to crush the work, while it holds the instrument vertically so that the mechanic can see into the opening and get the tubes in and out to the best advantage. This feature will be appreciated by men who are working with a common vise, and giving themselves the rickets stooping over to see into the injectors.

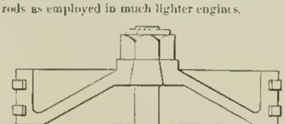
Thos. B. Purves, Jr., general foreman of this shop, says this kink saves them lots of trouble, and that they would lend the pattern to any one who wants to make a vise.

A Suggestion in Piston Design.

The more our railroad mechanics investigate the counterbalance problem, the more apparent it becomes that lighter reciprocating parts are necessary.

There is little doubt that we have been, unconsciously, perhaps, going to extremes in the matter of weight—seem to have simply increased some sizes in proportion to the total weight without regard to the work to be done or stress to be borne.

Almost all designers are doubling the size of the main pin and its connections in very heavy engines, yet they leave the same sized front end of main rods as employed in much lighter engines.



With the introduction of good cast steel, crossheads and piston heads may be made much stronger and lighter than has been possible with cast-iron.

The sketch shown herewith illustrates a form of piston in very extended use in marine practice, and tests made in England some two or three years ago showed this form of piston to be 30 per cent. lighter than a solid head, or the thick, cellular style, and having the same strength; this was for cast iron.

Two years ago the British steamship Leander had a piston of this shape put in, that was made of cast-steel; it was 78 inches in diameter and only 1¼ inch thick in the arched web.

This form of piston would have advantages for locomotive work other than in its lightness; one of these is that when placed on the forward center, and the cylinder head removed—both heads would, of course, have to conform to the shape of the piston—the piston fastening, be it nut or key, would be outside of the cylinder, where wrenches or other tools could be used upon it. Another advantage is that the piston rod packing will be in the sunken back head, and out of the way, admitting of larger packing and requiring less room at the ends of the guides, admitting of shorter guides where this would be an advantage. This piston may possibly have been used for this purpose, or have been suggested for use—we claim no originality—but it's a good thing, anyway, and will help reduce the weight of heads, and if this don't help the counterbalance, it will prevent excessive wear in the cylinder by the drag of the head.

There may be a few old engines where the arched cylinder head cover would be in the way of the front truck wheel, but they are few.

At it Again.

Under the heading, "What is an Engineer?" the *Railway Age* gives us the following:

"A quiet agitation regarding a narrower limitation to the word 'engineer' has again been started in engineering circles, with the prospect that some definite action will be taken in the matter by interested members of the profession. 'Engineer' as a term of significance is too ambiguous. It may mean a mechanical draftsman, a bridge builder, a patent counselor, a machinist in charge of a stationary engine, a locomotive operator, or followers of a dozen other pursuits.

"The words 'locomotive' and 'mechanical,' for instance, when modifying 'engineer,' respectively characterize a trade and a profession, a subordinate and his superintendent, yet both are *engineers*. One or the other should do the graceful thing, and yield.

"If the locomotive engineers are willing to take the initiative they might choose to be called 'locomoteers' or 'engine drivers,' or even 'motormeers,' the official title of electric operators. But if the professional men should be asked to give up their birthright, what characteristic term could they adopt which would embrace the tripersonality of the mechanical, civil and electrical engineer? It would at best be pseudonymic, for 'engineer' should designate the profession, and not the trade."

Engineers who run locomotives can stand to be called "runners" away ahead of "motormeers" or "locomoteers," but what is the matter with the now universally accepted term "locomotive engineer"? There are in North America more than 50,000 men entitled to that name, and perhaps a single thousand designers and master mechanics, who could be called locomotive engineers because they design or superintend the building of locomotives. Mahomet had better go to the mountain—it's easiest.

On a recent visit to a Central-Hudson shop we found machinists putting brass brackets into the exhaust ports. These brackets are screwed to the bottom of the exhaust port passage by two tap bolts, and the top comes up between the bridges and forms a cross-brace or tie between them. Several engines cracked their bridges or broke them out entirely, causing the expense of new cylinders. An unsupported bridge, only an inch wide and eighteen or twenty inches long, must spring considerably under pressures of 150 or 160, and springing means breaking.

We are in receipt of quite a number of letters from enginemen telling of cases where they have been let into blocks with other trains, and of instances where operators claimed that they could not release the signals so that they could go to danger. The block system of signals is just coming into use in this country, and it is important that its faults be understood and remedied, and that the habit of "monkeying" with the device, or in any way preventing its use rigidly for the purpose designed, must be frowned upon, and checked before faults of handling are charged against the apparatus.

The U. P. management have ordered all operators to withdraw from their order, or quit—why not tackle an organization of their size?

The First Water Grate.

There have probably been forty patents in as many years of the water grate, as used on hard coal burning locomotives, and a few that burn soft coal.

To those who think that to them or some of their friends belongs the credit for the original idea, it may be of interest to look back a few years—quite a few.

At the Museo Borbonico, at Naples, Italy, there are carefully preserved many copper and bronze tools and utensils exhumed at Pompeii, and among them a small vertical boiler of copper, this has a fire-box and smoke flue through the top, a door on the side, and *water grates* composed of small tubes of copper crossing the fire box at the bottom.

Pompeii was destroyed by an eruption of Mt. Vesuvius, A. D. 79—more than 1800 years ago.

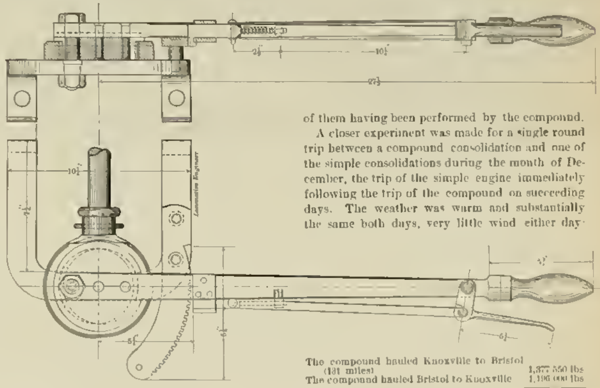
A Good Place to Work.

In Switzerland a Sunday law has been enacted applying to all railroad, steamboat and tramway companies and post-offices. Working time must not be more than twelve hours a day, even on occasions of increased traffic. Engine and train men must have at least ten hours' unbroken rest, and other employes nine hours. They must also have fifty-two days off yearly, and seventeen of these must be Sundays. No reduction in wages is to be made for such rest days. All freight traffic on Sunday is prohibited, except for live stock. The penalty for the first infraction of this law is not less than 500 francs, but a repetition means 1,000 francs, and even the willingness on the part of an employe to work on a rest day does not enter into consideration. *Ex.*

Illinois Central Throttle and Reverse Lever.

The engraving of the throttle lever and latch used on the Illinois Central, which will be found on this page, shows a departure from usual practice in the manner the throttle stem is attached to the lever.

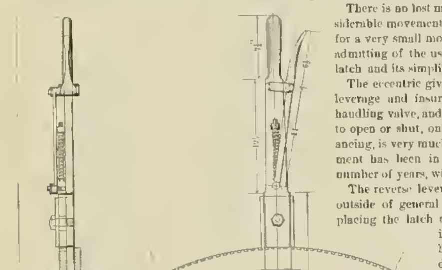
As will be seen, the throttle stem head is enlarged and has a very large hole in it, into this hole an eccentric fits, the eccentric turns on a pin that is also the pivot at end of the lever, the eccentric being fastened to the lever by a couple of rivets.



There is no lost motion in this rig, and considerable movement of the lever is required for a very small movement of the stem, thus admitting of the use of coarse notches in the latch and its simplification.

The eccentric gives the runner a powerful leverage and insures a comparatively easy handling valve, and the tendency of the valve to open or shut, on account of improper balancing, is very much reduced. This arrangement has been in use on this road for a number of years, with very gratifying results.

The reverse lever shown has two features outside of general practice. The first is in placing the latch on the side of the lever instead of in front or behind, the sector being double.



This admits of the use of six or seven teeth at once, and the latch is prevented from working loose on the lever by the long bearing permissible. If the latch is placed on the inside, or next the boiler, in those classes of engines with the boiler through the cab, there is nothing to catch the clothing of the engineman, and the notches of the sector will not get full of dirt.

A short bell crank arm is formed on the lower end of the lever, and a coiled spring, protected by a cast-iron case, is located under the deck and connected to the lever as shown. This gets the spring out of the way and prevents jerking of the lever, as the pull is all one way upon it instead of being transmitted in jerks, as is the case where the counterbalance spring is on the tumbling shaft.

In describing the Eddy engines in last month's paper, credit was given to Mr. Eddy as the first builder who placed the cylinders horizontal. The article should have read the first builder in New England. Norris built 8-wheelers with horizontal cylinders and spread trucks as early as 1850, and the "crab" locomotives built by Winans had horizontal cylinders, but vertical boilers and a geared connection to the wheels.

The first patent granted by the U. S. government bore date July 31, 1790, and was issued to Samuel Hopkins, for a process of making potash and pearlash; it was signed by George Washington. Only three patents were granted in the first year. They average 75 a day now.

The Compounds on Fuel.

In some recent tests on the E. T., V. & G., the Schenectady compound ten-wheeler showed a saving of 31.2 per cent above that of simple engines of its class. The test covered considerable time, and a number of engines were used against the compound, thus comparing it with average practice, there were 151 runs of 131 miles made, 42 of them having been performed by the compound.

A closer experiment was made for a single round trip between a compound consolidation and one of the simple consolidations during the month of December, the trip of the simple engine immediately following the trip of the compound on succeeding days. The weather was warm and substantially the same both days, very little wind either day.

The compound hauled Knoxville to Bristol (131 miles)		1,377,550 lbs
The compound hauled Bristol to Knoxville		1,196,000 lbs
Total		2,573,550 lbs.
The simple engine hauled Knoxville to Bristol		1,290,710 lbs
The simple engine hauled Bristol to Knoxville		1,128,020 lbs.
Total		2,418,730 lbs.
Work of the compound in excess of the simple, in lbs		154,820 lbs.
Work of the compound in excess of the simple, in per cent.		6.4
COAL USED.		
Compound		23,080 lbs
Simple	29,728 lbs	
6 per cent for extra work done by the compound	1,783 lbs	
Total for work equal to the compounds		31,511 lbs.
Difference between engines		8,431 lbs
Saving by the compound		26.7 per cent.
WATER USED		
Compound used ...		19,200 gal
Simple used ..	24,535 gal.	
6 per cent for excess work of compound ...	1,472 gal	
Total ...		26,007 gal
Saving by the compound ..		26.2 per cent.

The worst example of alleged steam heating of trains can be seen on the Manhattan elevated road in this city. The cars are heated fairly well, but it is almost impossible to find two steam heated cars coupled together without finding a cloud of steam around the platform, caused by leaky couplings. This system use a coupler having a trap in it, but its use is obsolete—the leaks could easily drain away four times as much water as is condensed. The steam often obscures the platform at stations, and makes it dangerous for passengers getting on or off the trains. The Manhattan Co. has 1,100 cars, and it is said that their annual repairs of steam hose alone amounts to about $7,000. On the Suburban Rapid Transit road, which is an elevated system above the Harlem River, Supt. Wetmore uses an all-iron steam connection between his cars, that costs but $38 per car, and is tight.

The heavy ten-wheelers built for New South Wales by the Baldwin works, have straight boilers, with copper fire-boxes and stays, and Vauclain's patent wrought-iron driving wheels. They have solid-ended rods, and a screw reverse gear.

The Hoosic tunnel, on the Fitchburg road, is 4¾ miles in length, and is brilliantly lighted by electricity from end to end. The locomotives burn coke. The tunnel is remarkably clear of smoke and steam. There is a large ventilating shaft near the center 1,028 feet deep.

The total number of freight cars in the United States at the end of 1889 was 1,060,164. Assuming that all those built in the railroad shops, and that over 28,000 of those built by private works have gone to fill vacant numbers, there were, at the end of 1890, 1,135,000 cars in the United States.

Locomotive Running Repairs.

By L. C. Hitchcock.

FLANGE WEAR.

Probably one of the most difficult matters with which roundhouse foremen have to contend in the line of running repairs is the wear of driver and truck wheel flanges. It is difficult in this way: where a wheel has been allowed to run to one rail more than to the other until the flange has become sharp, and a groove worn in the face of the tire, it is oftentimes a very difficult matter to get the tire to bear on the rail out of this groove.

The flange of a driving tire wears sharp owing generally to one of two causes. Either the engine is low on its springs at that point, or the drivers are not square with the engine frames, or, as it is generally expressed, they are out of tram with the engine frames In cases where only one driving tire is wearing the flange sharp (as often occurs) there is very little doubt that the engine is low on that spring, and is crowding that flange to the rail, though if the wear is noticed on either of the front drivers it may be caused by a weak engine truck spring on the side where the flange is cutting. As soon as the marks on a tire indicate that the flange is running close to the rail it should have *immediate* attention, for this is one of the jobs which it does not pay to put off until a more convenient time, for if action is taken as soon as the difficulty is discovered the proper remedy may be applied, viz.: either raising the engine at the proper points or throwing the wheels in the proper direction, and the trouble be easily overcome. But where a person is careless, and neglects to apply the remedy as soon as the need of it is discovered, it takes but a very short time for the rail to wear a groove in the tread of the tire and wear the flange sharp, and where this exists to any extent the safety of the traveling public demands that the drivers be removed and the tires be turned. And in a majority of shops this means taking the engine out of service for a week or ten days, at the least calculation, whereas, had it been taken in time, the whole difficulty might have been remedied in twenty minutes or one-half hour.

In cases of driving flange wear, the old adage, "A stitch in time saves nine," is certainly true. Cases are quite numerous where one of the back driving flanges will begin to cut. Where this occurs, the height of the engine at this point, in comparison with the height the engine stands from the other driving-boxes, should be noted. It will generally be found that the engine is low at the driver, which carries the cut flange, and removing or clipping up the driving spring will remedy the evil; but after the flange is made to run free from the rail it should be carefully watched for some time, to see that the engine does not settle at this point, for it will wear itself away faster than would be imagined if allowed to come in contact with the rail the second time.

Suppose that both drivers on one side of an eight-wheeled engine are cutting, and the distance between the bottom part of the spring saddles and top part of the engine frames are about equal on each side, it would be safe to conclude that the main axles are not square with the frames. The first thing to ascertain in a case of this kind is whether the center casting, which rests in the engine truck center casting, is in an exact central position between the engine frames. In case it is not centrally located it should be changed to that position, for when it is out of center it often causes both the driving flanges and engine truck flanges to wear sharp. And right here let me say that I am not an advocate of what is commonly called a swing beam engine truck, that is, one having a movable center casting, for my observation leads me to believe that engines having the swing beam trucks wear the flanges of both the engine truck wheels and forward drivers more than do engines having the rigid trucks, when the engine is kept away from the side bearings of same.

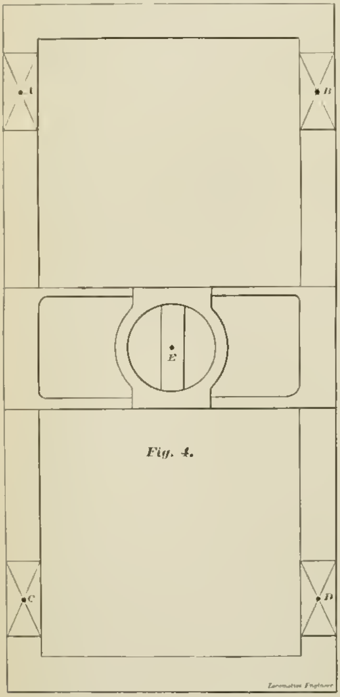


Fig. 4.

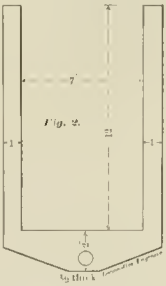

Fig. 2.

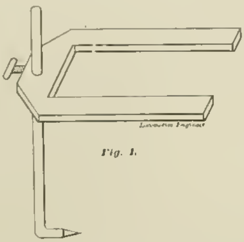

Fig. 1.

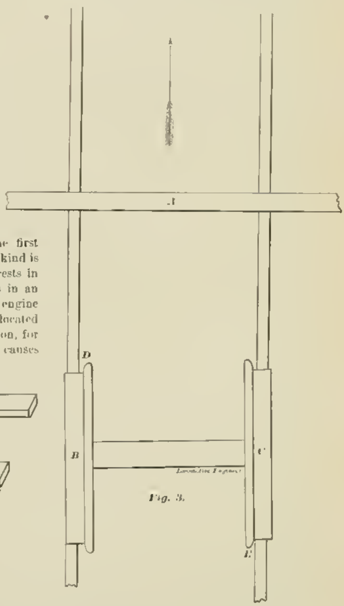

Fig. 3.

Now to return to the case in hand. Should the center casting be centrally located the trouble is surely not there, and to ascertain if it is caused by the driving axles being out of square with the engine frames, first set up the wedges until the driving-boxes will just move between the shoe and wedge, then clamp a straight edge about eight feet long flatwise on top of the engine frames, just forward of the tumbling shaft boxes, and perfectly square with the frame on each side Now see that the distances from the main centers to the top of the engine frames are equal on each side of the engine. To ascertain this, use a small tool shown in Fig. 1, made of ¼" steel. (See Fig. 2 for dimensions.) Place the driver so that a spoke will be in a perpendicular position, and directly in line with the center of the spring saddle, then pass a leg of the tool mentioned on each side of the spoke and saddle. Hold the flat side of the legs firmly on top of the frame and set the pointer to the main center; now remove the gauge without disturbing the pointer and try the other side. In case the two distances are not the same, raise the low side of the engine until they are the same, then prick-punch the back edge of the straight-edge you have clamped forward of the tumbling shaft boxes an equal distance outside of each frame, and from these punch marks tram to the center of the forward driving wheels, and I think that you will find the center of the driving wheel having the cut flange farther from the straight-edge than that of the opposite driver. Perchance this can more readily be understood by reference to Fig. 3, representing in an exaggerated manner the position of a pair of drivers under the conditions mentioned. The forward part of the engine being indicated by the dart, the straight-edge *A* clamped to the frames Now if wheel *B* is farther from the straight-edge, when placed as described, than is wheel *C*, the flange of wheel *B* will be crowded to the rail at point *D* when the engine is moving forward, and the flange of wheel *C* will hug the rail at point *E* when the engine is running backward; but as engines usually run forward more than backward the left drivers in the case under consideration would show the greater amount of flange wear. To remedy the evil, either the right drivers must be thrown back, or the left wheel forward, to bring a line through their centers parallel with the straight edge, and a good way to proceed is to either remove liner from the left shoe or to plane from the face of it about two-thirds the amount that the wheel center shows out with the straight-edge. Then add to the wedge the same amount of liner that was either planed from the face of the shoe or was taken from it by the removal of liner Now if the distance between the forward and back drivers were the same on both sides of the engine, this same operation must be performed with the left back shoe and wedge; this will bring the drivers again in tram, and both pairs will be square with the engine frames, and I think would give no more trouble.

Should the engine truck wheel flanges begin cutting, see that the engine truck springs hold the forward part of the engine level, and that the male center casting is centrally located between the engine frames, as previously mentioned. If so, take off the pilot and run the truck out. If it is a truck with a swinging center casting, place a piece of thin board tightly within the casting, and on this board get the exact center of the casting. Now drop the binders and jack up the frame until the bottom of the jaws is nearly to the top of the boxes. Then scribe on top of the frame the face line of each jaw. This may be done by the use of three short straight-edges. Next place the center casting in an exact central position between the ends and sides of the truck frame. Now, referring to Fig. 4, see that the distances from the points A to E, B to E, C to E and D to E are equal. If they are not equal it shows that either the jaws are not bolted to the frame in the proper positions, or that the truck frame is not square, and one or both pairs of truck wheels are not square with the frame, producing the same evil which exists with the pair of drivers represented by Fig. 3, and means should be taken to make the distances from central point E to the center of the truck-boxes equal. After this is accomplished ask the master mechanic to allow you to block the casting in this position, the results obtained from thus blocking it would, I believe, be very gratifying to you both.

If the trucks under tenders are squared in the manner just described, and the tenders are kept level on their springs, and away from the side bearings, I think that there will be very little trouble caused by the wheels having sharp flanges.

wipers as "the ingine wid two chimblys," and Uncle Amos was boring the snout of a long can toward the eccentrics, said snout having some nine particular crooks to miss everything. Mike looked at Uncle Amos, set down his grip and walked around the engine on a tour of inspection. When he got around Uncle Amos withdrew the spout of his can like you would take a corkscrew out of a cork, and said.

"Be you the man sent down to run her whilst I'm off?" "Yes," said Lillis, "but I'll tell you what I'll do, old man, you just stay with the pesky varmint and I'll take the ten days!" And he went home on the next train.

We must know the names and addresses of writers, but not for publication necessarily. Letters signed "Old Timer," "Kicker," or "Young Runner" alone are used to kindle fires. Always write on one side of the paper.

An Early Passenger Coach.

The accompanying engraving represents a form of car once used for passenger and freight service on the South Carolina road.

This road was one of the first in this country, being the first to use an American built engine.

The car here shown was the invention of one George S Hacker, an inventor of more or less merit, to whom the invention of the fifth wheel of common wagons and carriages is accredited. The patent on this car was number 1937, dated January 21st, 1841; our engraving was made from a tracing made from the original drawing on the 9th of February by Chief Draftsman W. J. Wilcox, of the S. C. road.

Tubular cars are advocated as something new at frequent intervals, but this car seems to have been in actual use many years ago, and there are a great many people still living in the South who have ridden in these old hooped tubes.

mare's nest to paralyze its opponents. Instead of taking anything like average American practice, they cite the two Erie locomotives tried against the Strong, by a Strong employe, making out an advertising and glorifying report to boom the double barreled boiler and gridiron valve machine designed by Mr. Strong.

Mr. Dean made out a large percentage of saving for the Strong, and, in order to do this, Erie men allege, made the performance of the other engines none too good. The officers of the Erie road say nothing for publication on the subject, but do not hesitate to say in private that Mr. Dean's report is not fair to their engines at all.

Less than a year ago, Mr. Ross Kells, Supt. of M. P. of the Erie, reported to the American Railway Master Mechanics Association's committee on valve gears as follows:

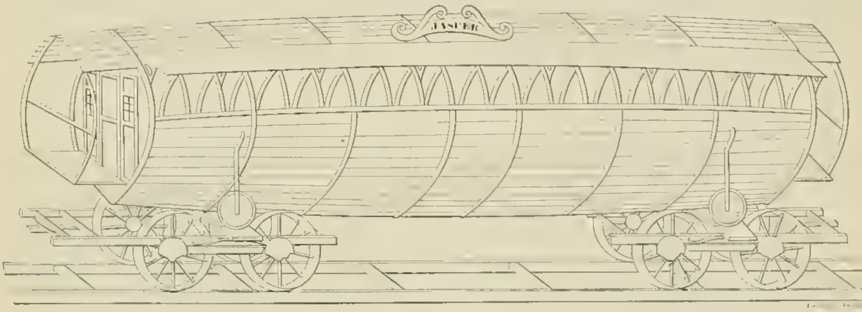
"We have only made one test of a locomotive equipped with a valve motion, other than the link, and that test was to determine which of the two designs was the most economical on the basis of coal consumed per ton per hundred miles. We found on this test that our regular link motion locomotives were fully as economical on coal, and much more economical on maintenance of valve gear."

This refers to the test by Mr. Dean.

The Erie engine compared to the Strong was a hard-coal burner, with a fire-box 11 feet 6 inches long. This engine was tried against the Strong with hard coal. The Strong could not burn this fuel well, and so the other engine was fired with soft coal. In practice, when one of these engines is used as a soft-coal burner, about one-third of the grates are bricked over, the engine burning a better fire, and steaming freer than when the full length of the box is used. Again, the Erie road is what may be termed a "coal road." Fuel is cheap, and little attention is paid to economizing it.

Yet our English friends have hunted long and diligently for an "awful example" to hold up in comparison with their best practice.

Comparisons should be fair on both sides.



Preferred the Disease to the Cure.

A long time ago the Denver & Rio Grande road owned an old English engine of the Fairlie make. She had four cylinders, eight connected wheels, no truck or tender; there were two sets of flues, a fire-box in the center of the boiler, and a stack on each end. The fire-doors were on the side of the boiler, the coal on top, and the water in side tanks. In the cab there were two throttles, and a lot of other dinguses that it wasn't safe to touch unless you knew just what would happen afterward.

Every man who had run her had added something—none carried anything away. The running gear underneath was sort of a scrambled scrap heap, and all new men had a chart to oil by.

The old Fairlie served a purpose in her day in appeasing a lot of English stockholders, but soon started down the scale from passenger to freight, construction, and the scrap heap. At the construction stage of the game she was in charge of an old-timer, Amos McKenna by name, who managed to get along with her pretty well—especially laying on sidings.

But one day Uncle Amos and the Fairlie had a chill at the same time, and a regular train found them on the main line with no flag out, and reported it; the division superintendent ordered the crew suspended for ten days.

Mike Lillis' engine was in the shop, and Mike was losing time, so he was glad when he got orders to loaf on construction for ten days—Mike hadn't seen the Fairlie then.

When Mike got off at the little desert station, he saw for the first time the locomotive known to the

The Webb Compound Again in Harness.

The Webb compound locomotive is in express service between New York and Philadelphia again, and doing remarkably good work. She made the ninety miles the other day in two hours and four minutes, hauling eight heavy coaches and making seven stops.

We recently saw a letter from a prominent Pennsylvania official, in which he said: "I am not at liberty to give exact figures as to the saving of coal shown by the Webb engine over our regular passenger locomotives, but will say that it has been considerably over 25 per cent."

Hunting for "Awful Examples."

For some time past there has been a triangular discussion going on between two American and one English engineering paper as to the relative value of the locomotives common to the two countries. When arguments ran low, each side commenced to promise some showing of facts and figures after a time, to prove the ground taken in each case.

The Engineer, of London, has just opened up its

Mr. Phillip Hoffecker, master mechanic of the Lehigh Valley road at Weatherly, Pa., died on February 19th. Mr. Hoffecker was one of the oldest master mechanics in this country, and was employed in building the Beaver Meadow road before it owned any rolling stock. He became M. M. of this line, and remained in the place after the L. V. got the road. He was the originator of the 12-wheeled locomotive—eight wheels connected and four-wheeled truck. He paid particular attention to his foundry, and driving wheel and cylinder castings turned out were so smooth and clean cut it seemed a sacrilege to put a tool into them.

The Belt Railway of Chicago have in use a section of track south of Sixty ninth street that is laid with the Standard steel tie. This track has been down fifteen months, during which time 37,500 trains passed over it without perceptible wear or distortion of the track. These ties weigh but eighty two pounds each.

In all countries of Europe, excepting Spain, there are laws against the use of cast iron wheels under cars or locomotives in passenger service.

Varnish.

Varnish is varnish, and that's about all you can tell about it, except what the maker says and the price he asks—and sometimes makers will overdo both these.

There is no short, easy test for varnish that is reliable. Those that are in use are a good deal like Ikey Ichabod's plan for telling a singer from a female canary bird. He said: "Put sugar on a wet cracker and stick it into the cage, and if a *she* comes up and pecks it, why it's a *she*; but if a *he* comes up and pecks it, why it's a singer, dontcher see?"

The only way to test varnish is to use it. On the C., M. & St. P. road, they varnished some 200 cars some time ago with two kinds of varnish, half one, half another make. This is a good test, but sends the cars out on a big system where they are not often seen by those who are conducting the experiments, and as one end of a car got shabby first, many had to be taken in early for re-varnishing.

Mr. Wetmore, of the Suburban road in this city, painted several boards just as he does his cars, then varnished them with different makes of varnish, and hung them out to the weather; the results were surprising. If we should tell just what they were, there would be one varnish maker pleased, and about four would say we lied. The best varnish was the highest priced—like anything else.

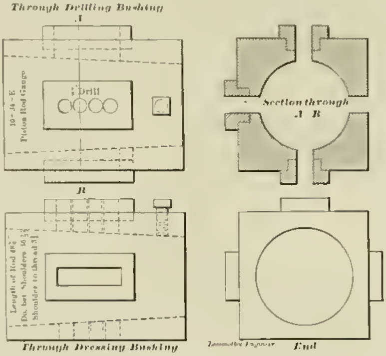
At roundhouses where there is no stationary boiler, an efficient fire extinguishing apparatus can be devised to attach to a locomotive injector. A steam ejector with hose attached, located between two stalls, and having an easily attached or detachable connection to the blower, or an independent steam cock, is better and easier taken care of. All yard engines should be equipped with "squirts" for fire purposes.

Piston Rod Gauge.

The piston rod gauge shown herewith was designed by Thomas B. Purves, Jr., general foreman of the B. & A. shops at East Albany, N. Y., and is a time saving device that prevents lots of guesswork and measuring in the finishing of piston rod ends, insuring interchangeability when rods are kept in stock. The gauge is made of cast-steel bored out the correct taper to fit the rod when finished. There is also a taper plug, not shown, that just fits this hole, that is used as a gauge to bore out crossheads and piston heads.

Once the taper on end of rod fits the gauge, the latter is fastened to the rod by the set-screw shown, and the keyway is then cut out, first by drilling through the guide holes shown, and then by chipping and filing. The guide pieces are hardened steel, pressed into place, and, as will be seen, admit of dressing out the keyway perfectly central on the rod without any laying out at all.

The gauge is plainly marked with the dimensions of rod throughout, and, of course, a separate gauge is used for each size of rod, the gauge in this case being for the Baldwin consolidations that pull freight over the B. & A.

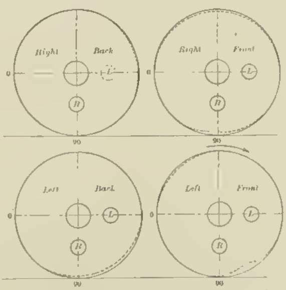


Device to Measure Uneven Wear of Tire.

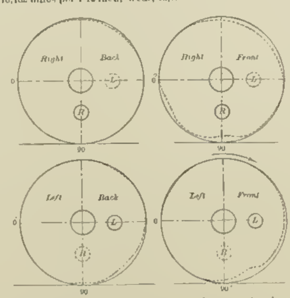
W. H. Lewis, master mechanic of the Chicago, Burlington & Northern, has designed an ingenious device for showing the wear of driving wheel tire. He recently described it before the Western Railway Club as follows:

"I have given the subject of counterbalancing locomotives some considerable study, and I feel a great interest in the matter. About a year ago, when this subject was before the club, I noticed a reluctance on the part of the members to enter into the discussion of the flattening of tires which took place in certain localities, particularly where they had a sandy road bed. I have made an apparatus by which I can take a perfect picture of the flat spots and their location. The instrument consists of a revolving disk attached to the tool-post of a driving wheel lathe, and geared to the head block of the lathe, so that it makes the same revolutions as the face-plate. The pencil bar attachment is first set at the inside of the tire, with the point of the pencil at zero, or the center mark on the paper. Then by moving the pencil bar to the tread of the tire, and allowing the lathe to make one revolution, it describes a circle the radius of which represents the thickness of the tire, and at the same time locates accurately the position and depth of the flat spots."

The accompanying diagrams are reproduced from full-sized ones taken by this apparatus, there



Engine No. 8.—Passenger mileage between turnings, 75,152 miles per 1-16 inch; wear, 18,788



Engine No. 11.—Passenger mileage between turnings, 46,413

being also a true circle drawn to show the size of the flat spots more clearly. This true circle, together with the axle and crank-pin circles, are drawn by hand.

These tire pictures were taken from 8-wheeled passenger locomotives, having cylinders 18x24, with 54,500 pounds on the drivers. We reproduce the cuts from the *Railway Review*.

Correspondence

Who Invented the Cast-iron Brake Shoe?

Editor The Locomotive Engineer:

You asked in a recent number, who invented the common cast-iron brake shoe. The cast-iron brake shoe was patented by Stephen Morse, Feb. 23d, 1858.

WILSON EDDY.

Springfield, Mass.

Burning of Oil in Chests and Cylinders.

Editor The Locomotive Engineer:

I am firing on a fast passenger run, and I notice that after oiling the valves there is a strong smell of burning oil, just after the lever is pulled up. I know there is a vacuum in the cylinders, which increases as the lever is pulled up, and which draws the hot air and gases through the stack into them. And I think that if the throttle was opened just enough to fill the cylinders with steam before the lever was pulled back, that more good would be got from the oils. Please give your opinion.

Portland, Me. FIREMAN.

[Burning cylinder oil generally indicates a poor quality of oil, or hot rods or pistons caused by cutting. The partial vacuum in the chest is not increased by hooking up; compression in one end of the cylinder will lift the valve off its seat, and equalize matters; the mere hooking up of the lever will generally throw oil and vapor out of the oil cups, indicating a pressure. Opening the throttle before hooking up would make the lever handle harder, and the first steam admitted will wipe off all the surplus oil, any way.]

Air-pumps with Lung Trouble.

Editor The Locomotive Engineer:

I was called out in the yard recently to see what was the matter with an air-pump. It would pump 20 or 30 pounds of air, keep to work, slowly, but would not increase the pressure. I put the brake valve at full release, and opened the cock back of tender, this relieved the drum of pressure and gave the pump an easier job, but it did not run faster at all, which as good as said that it could not get rid of the air it pumped, or was not getting steam enough to run it, the latter not being probable at all. I took off the air-pipe connection to the air cylinder, and the instant the nut was slackened the pump commenced to run fast. The pipe was almost stopped up by oil and dirt; this was burnt out, and the pump was cured. At another time an engineer called me to see his pump, it would not make more than a couple of strokes, when it would stop. By opening the waste cock the pump would make a stroke or two slowly, steam blowing out of the waste cock hard; this told me that something was wrong with the exhaust, the pump could not get rid of her steam. Slacking off the nut of exhaust pipe caused the pump to race. The end of the pipe had become clogged with cinders in the front end.

WM. LANSING.

Cedar Rapids, Iowa.

Low Water Alarm for Locomotive Boilers.

Editor The Locomotive Engineer:

Almost everywhere you go you will find some sort of device in use on stationary boilers to give alarm in case of low water.

Why would not something of the kind be a good thing for locomotives?

I am sure that the locomotive engineer has his attention called away from the water supply more than his brother in the basement.

LAYMAN.

Boston, Mass.

[Once in a while the locomotive engineer gets water down too low for comfort or safety, but the introduction of some device to cause an alarm when they get water too *high* would be worth more money to the railroads.]

A Kicker Against the Eddy Engines.

Editor The Locomotive Engineer:

I would like to have you give a reader of your paper a few points about those "Eddy clocks" which you try to enthuse over. Why is it necessary to allow anything for expansion at *front* ends of boiler and not at the *back?* Is it because the smoke-box is hotter than the fire-box?

Why do engines designed for freight service require different size openings than for express? One would think that steam should be used to the best possible advantage in all engines. Would it not have been better to have done away with the usual steam pipes and used the oil pipes to have furnished steam for the cylinders? They could have been made a little larger and saved putting pipes inside of boiler, and that would have saved the "screw patch" to get into the boiler.

Am glad to know that all that is required to make a sand box perfect is to shape it as ugly as possible, which makes the sand so homesick while in it that it waits very impatiently to get a chance to get out. Who can blame it? It is possible that such good results are obtained from these engines on account of the two cannons (one with the bell muzzle) on top of boiler. If so, what part of the work do they perform in getting trains over the road? Why is an 8" port right for a freight engine and 12" for passenger, regardless of size cylinder they are to have? Why do you claim that there is so much saving in having the fire-box 4" wider than ordinary engines? and if that 4" does so much good, why does not the "Wooten fire-box," which is 8 feet wide, show some saving in proportion to its width? If it would, you would be able to start a coal yard from the savings of such a fire-box.

Why have the B. & A. R. R. Co. quit making these wonderful engines? Hope you will not think it too much trouble to explain these things to anxious minds. As soon as these things are all made plain, there will not be any more use for the *Indicator*. *Hand-books of the Locomotive* will be dead stock. Experts will be looking for jobs in hydraulics, and all the rest of us who have spent much of our lives trying to improve the locomotive will know that our time has been worse than wasted, as it has assisted many to waste much time and money for their employers. Why were not these wonderful engines known to the railroad world before this time? "INDICATOR."

Boston, Mass.

[We will leave our correspondent to the mercy of those who know all about the service rendered by the engines mentioned, who can, and no doubt will, tell him what he wants to know.]

That Leak Through the Pressure-retaining Valve.

Editor The Locomotive Engineer:

I think your answer to B. & O., in the March issue, went about a "millimeter" shy of explaining the cause of the trouble complained of.

I had about six or eight months' experience once in "switching air ahead" myself—or, in other words, in handling an air-brake engine in freight service, where only a part of the cars were equipped with air-brakes—and I think we had more trouble from leaks through the exhaust opening, and through the bleeding valves, than from any other source. This leak through the exhaust port was almost always attended with application of the brake, more or less severe on the car affected, and, through a sort of a dual regard for the life of the fireman and the coal record, I used to "cut the cars out."

One day I struck that prince of all educators in railroading—the "way freight"—and, armed with an engineer's "best friend"—the monkey-wrench—I proceeded to investigate one of these refractory subjects, while the boys were unloading freight.

I took off the triple valve and took it apart, and found the spring that holds the emergency valve up to its seat jammed in such a manner that the valve would not seat, and the air, of course, opened the check valve below, and admitted air from the train pipe direct to the brake cylinder, and, the slide valve being in release position, it would, of course, escape through the exhaust.

With only a few air cars in the train, and a good pump, and a pretty free flow of air through the emergency valve, you can see that the brake would set with nearly full train pipe pressure. I also found inside of the valve casing quite a quantity of sand, which, as the strainer was in place and in good condition, I concluded must have come off the inside of the valve casing casting.

So I opine that the trouble is very often with the triple *valve* and not with the *men*.

Chillicothe, Mo. A. H. TUCKER.

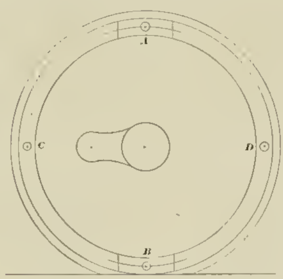
[In a great deal of personal tribulations of this kind we have always found the trouble in the brakesmen trying to "stop the leak." Our first correspondent did not state that the escape of air was continuous. He has since stated the trouble more fully, and we have told him to look just where Brother Tucker puts his finger. We want to say right here that this idea of looking up and locating the true cause of trouble is highly commendable, and should be more widely followed.]

Taking Dead Centers—The Trouble with Measuring One Side Only.

Editor The Locomotive Engineer:

In your March, 1891, issue, Bro. E. A. Campbell says that I can save time and trouble while setting locomotive slide valves by using centers on one side and quarter on the other. I do not clearly understand him; had he said use centers on one side, and quarter for the other, I would have concluded that he meant to equally divide the space on the tire between the two center marks.

To illustrate, let *A* and *B* represent the dead center marks obtained, as described by me in your February, 1891, issue, then the points *C* and *D* would be the quarter marks, and when the valve tram would reach from the mark on the wheel



cover to one of these quarter marks, the opposite side of the engine would be on the center. Is this what Bro. Campbell meant? If not, will he please explain in detail what he refers to in your March issue, for if there is anything new, I wish to "catch on," and have all readers of THE LOCOMOTIVE ENGINEER do likewise. I have worked in the manner just described, but never found much advantage over taking centers on both sides the same, as you have to walk from side to side of the engine in either case, and I thought that the method of quartering the wheel would not be so readily understood by novices.

Minneapolis, Minn. L. C. HITCHCOCK.

Why the Emergency Valve Opened for a Service Stop.

Editor The Locomotive Engineer:

I took a ride on an accommodation train one day lately, and found out something about the automatic brake that I wanted to know.

The train consisted of one coach, one baggage car, five box cars, and ten street stable cars. The stable cars had the quick-acting brake, and every time the engineer made a stop everything stood on end at the rear; this was not slack, but the emergency stop.

After two bad stops I went over to the engine and asked the engineer what was the matter. He said he reduced the air very carefully, and yet it seemed as though the quick-action valves worked every time he tried to stop.

We had some time to wait for other trains, so I arranged with him to set the brakes when I gave him a signal. He was to reduce the pressure but five pounds on the gauge—he had the new equalizing discharge valve—and then put the valve on lap.

I went back and turned a train pipe cock between the fifth and sixth car, and then gave him the signal. When he reduced the pressure the brakes went to work just as they should, proving that the trouble was further back. I cut the back cars in again, waited till the pressure equalized, and signaled for brakes. At once the quick-action opened with a vengeance, and the brakes applied full. I was not satisfied, and went to the engine and applied the air myself very slowly for service stop, reducing but five pounds, but the quick-action went to work just as before.

I then watched each brake separately, and found no difference, except in the one on the sixth car; this brake did not move out as soon as the others did for service stop, but waited a second or two, and then went on full, the others following it. this I figured was caused by the sudden reduction of pressure caused by the opening of one quick-action valve.

We cut the air out from the auxiliary of this car, and removed triple valve, and found the trouble. The small brass pin that goes from the piston rod to the little graduating valve, to pull it open, had broken off, and did not unseat for the service stop reduction, so when the reduction was made the piston moved out until the stop on its rod came to the large slide and delayed there until the difference between the train pipe pressure and the pressure in the auxiliary was great enough to move the large valve, this threw open the quick-action valve, and the reduction in train pipe, caused by it, threw on the others as described.

I have known of similar trouble with brakes, and engineers complaining that the emergency goes on for a service stop, but they are generally charged with bad handling of the valve. I have little doubt that a similar derangement of one valve in many has caused a great deal of annoyance and trouble. I have never seen a similar case spoken of in print, and am anxious to help my brother air-brake doctors to locate diseases by the symptoms.

Cedar Rapids, Iowa. WM. LANSING.

Those Pressure-retaining Valves.

Editor The Locomotive Engineer:

Your answer to Question 25, in last month's issue, on the cause of escape of pressure from pressure-retaining valve, does not cover the case for those here.

I recently found two from which pressure escaped all the time so bad that the pump could not supply the leak. E. TAYLOR.

Baltimore, Md.

[The trouble is in the triple valve, then; if it did not let the air to the exhaust passage it could not escape at the retaining valve; some valve leaks, is off its seat, or broken—probably the quick action valve.]

Counterbalancing for High Speeds—A Letter from the Inventor of the Shaw Locomotive—A New Design Under Way.

Editor The Locomotive Engineer:

I was much pleased in reading, in your last issue, an account of some experiments being made to determine the cause of uneven wear in driving wheel tires, by J. N. Barr, superintendent of motive power of the C., M. & St. P. road, and I sincerely hope that he may continue his experiments until he has fully determined the cause by exhaustive trials, and settle it beyond question.

I have been skirmishing along that line for some time. Seventeen years ago I took this subject up, and did not have far to look to discover what, to my mind, was the difficulty, viz., the counter weights.

And up to this time no one has been able to find any other reasonable cause, and never will. The outcome of my investigation was the introduction of the now well-known Shaw locomotive, in which there is no evidence of imperceptible slip or uneven wear of tires.

There has been a great deal of ignorance displayed and nonsense written on this subject, but no careful investigator, who has made any real experiments, has ever arrived at any other conclusion than that the trouble was caused by the counterweights. And there is but one remedy, and that is to take them out, they do no real good at high speeds, and cause a terrible misunderstanding among the main members of the machine.

A locomotive having a speed of translation of say fifty miles per hour at the center of rotation, its counterweights have a speed of about one hundred miles per hour at the top of the wheel. Now if there is no slip (as some suppose), then it must come to rest at its instantaneous axis—the point in contact with the rail—during one half revolution of the driving wheel, which is impossible according to the laws of motion, therefore we have that imperceptible slip going on (under high velocity) continuously.

It has been said by one of our leading railway journals that the Shaw locomotive is too complicated for general use, and it is not likely that the engineering world will ever go so far looking for a remedy for unbalanced mechanism. I do not know what they mean by that, without they expect to do it with the ordinary counterweight, which none of us will live long enough to do or see done.

I know it is difficult to convince railroad men that there is anything better than what we have now in use, especially those who say they can balance their locomotives with the valve gear—and that is what a leading railroad officer recently declared.

The objection to the original four-cylinder Shaw engine was complication, but that has been overcome by the use of one cylinder on a side, as in ordinary locomotives. The deadly paralleled rod is avoided as well by use of a different means of coupling the wheels.

This engine will also have a new valve gear, which I will soon explain to you, for the benefit of those who see untold virtues in the shifting link.

I hope soon to construct a locomotive on my latest plan, and have no doubt but that I can satisfy Brother Le Van by taking an express train from New York to Philadelphia, "ninety miles in ninety minutes." There is nothing unreasonable in his plan, and I am firmly convinced that the time will be made regularly at no distant day.

HENRY F. SHAW,
West Roxbury, Mass. Mechanical Engineer

The First Locomotives with Horizontal Cylinders.

Editor The Locomotive Engineer:

Latterly I have seen accounts of two or three different engines having the *first* horizontal cylinders ever built in this country. Allow me to add a little history to the list. In June, 1847, I was braking on the Reading Railroad, between Port Richmond and Palo Alto, Schuylkill County. In the roundhouse at Schuylkill Haven, there was, at that time, lying an engine built by Ross Winans, of Baltimore, and named Baltimore, and she had horizontal cylinders. I cannot tell you when she was built, but she had run on the Reading road before my advent there. In the following December I was in Baltimore and saw Ross Winans' spur wheel engines at work in Mount Clare yard, for the B. & O. R. R., that looked as though they had been at work for a year or two, and they had also horizontal cylinders.

E. J. RAUCH
New York City.

Relyea's Puzzle and a Kink.

Editor The Locomotive Engineer:

I see in the March number that Mr. Relyea kept his promise, and I will give the readers a few of the defects that I have found that caused the air pump to blow as he describes. First, there is a steam port through the head, and bushing to reversing valve, that in a well-fitting bushing, but only has $\frac{1}{16}$" metal to hold the steam pressure, and this often blows through at this point.

I have, for the past three years, been increasing the metal at this place by putting a ring on the bottom of bushing.

Also, a loose reversing valve stem will cause a pump to blow on the up stroke of piston; also a short reversing valve bushing, or cap, not making a perfect joint at top of the bushing.

I will give the air pump men a plan of a more convenient way of handling the pump in the shop than I have seen anywhere in my travels. I have a portable bench, 20" high, with two brackets made of $\frac{1}{2}$"x3" iron, 8' high, bolted to bench, 12" apart. To these I bolt the pump to be repaired, and I find it quite an improvement over a loose block on the floor, as is mostly used.

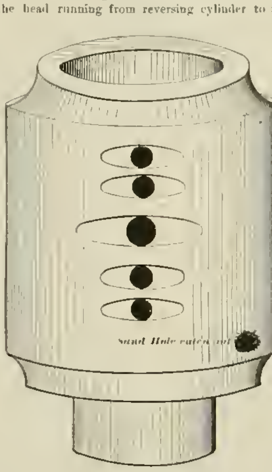
C. E. N.
Mandan, N. D.

Relyea's Air-pump Puzzle.

Editor The Locomotive Engineer:

I want to take a whack at Relyea's pump-head problem. I think the blow on the upward stroke was caused by a loose reversing cylinder; they are made tapering for a short distance from the top, and the head is also made tapering in the chamber where the cylinder is placed, so that it will conform to the taper of the cylinder, and form a tight joint. But if the cylinder is too small in diameter it will strike on the shoulder at the bottom before it strikes on the taper. And as there is an exhaust steam port running through the side of the cylinder, communicating with the reversing valve bush, for allowing the steam to exhaust from the top of the reversing piston while the pump is making its upward stroke, the reversing valve should and does cover this port at one end; but if the reversing cylinder was loose steam would leak through from the top of reversing piston into a groove that is cut alongside of the reversing cylinder near its bottom, and cause the blow on the up stroke. During the down stroke this port in reversing cylinder is closed by reversing piston.

One other thing that would cause a blow: In the head running from reversing cylinder to re-



versing valve chamber are three ports, nearly horizontal, the top one for live steam to top of reversing piston, the other two exhaust ports. These are divided by partitions of iron; if through a flaw or sand-hole these ports should become connected with the lower exhaust port, it would cause the blow.

F. B. ARMSTRONG.
Camden, N. J.

The Answer.

Editor The Locomotive Engineer:

I thought the best way to explain my last air-pump "conundrum" would be to send you a drawing of the reversing valve bush, showing how it was cut with steam, causing it to blow through into the cylinder.

W. F. RELYEA.
Syracuse, N. Y.

Air-brake Trouble—Red-hot Pipes—The Engineer's Valve.

Editor The Locomotive Engineer:

I would like to ask Mr. Relyea, or some other "air-brake" man, if he has ever seen the discharge pipes from the air-pump to main air reservoir get red-hot, and what, in his opinion, is the chief cause of it?

Engineers have them get hot sometimes, and cool off again, without anything being done to pipe or pump.

I would like to ask the name of the inventor of the engineer's brake and equalizing and discharge valve. While I am talking about this valve, I would say I can seldom find any one who will say anything in its favor, though I know of one person who says that it is the best thing that was ever put on an engine. I think the great trouble lies in the engineers not fully understanding the principle of it. Engineers, almost without exception, are running them in release position, thereby having no excess. Some say, if they run them in running position the brakes leak on—some say, because all cars in their trains have not got the quick-action triple valves on. Now the last reason given is a poor one: for, no matter what kind of a triple valve is used, the excess pressure is what releases the automatic brake, and if the old-style triple valve is used, they need the twenty pounds excess more, I should say, than where the quick action valve is used. This is my view of it. Am I right?

F. B. A.
Camden, N. J.

[There is little doubt that the greatest trouble with the engineer's brake and equalizing and discharge valve comes from the runners not being posted on its principles and operation. The claim that brakes leak on when running in proper position (running position) is a mistake, unless there is an escape of air from the train pipe, that brakes sometimes "leak off" when valve is "on lap," we do not doubt. Much nicer and more accurate braking can be done on long trains with the equalizing valve than can be done by either old style. The excess pressure feature is a very useful adjunct, especially where drum capacity is small, and where cars are picked up on the road. There are few engines that pull long trains of 20 to 50 cars, that have drum capacity enough. A large volume of air is not affected so much by the addition of cars, or the use of the brakes for service stops. With a good pump and reliable governor on a locomotive having two drums, the excess pressure valve loses some of its virtue, and can be got rid of easily, but with small drums it is in the nature of a necessity.]

Shut-off Valves in Steam Pipes.

Editor The Locomotive Engineer:

I have often wondered what was the reason valves were not put in convey or steam pipes to the steam chests. It seems to me that by the valves standing open, and steam passing through, the seats would not melt, and the stem could be packed with asbestos packing, fire could not burn it out, and the stem could protrude through the smoke arch, so it would be handy to shut off. In case you would break a chest, you would not have to break the joint and put in a thin piece of iron, and in case you would have to disconnect, you need not clamp the valve stem or block the crosshead so carefully. Could these valves be put in or not, and if they can, why are they not put in?

Wellston, Ohio. MERRY DEVINE.

[We are afraid the introduction of shut-off valves in steam pipes would be like every man carrying an instrument in the pocket to observe eclipses with—hardly enough use for it to pay, and a piece of smoked glass answers so well when the eclipse comes. It would be impossible to prevent the flow of steam from cutting out seats, and "the game would not pay for the candle." It is very seldom that a break occurs where it is not possible to block the inlet passages at the valve seat. Some shut-off scheme probably could be used if it would pay, there is no need of it at present.]

The Modest Man and Other Things of Interest on the B. & A.

Editor The Locomotive Engineer:

That superintendent who gave his men proper credit for good work done need not have been so modest, and I want him known, so give him away. His name is W. R. Robeson, Jr., and he holds forth at East Albany, N. Y., on the Boston & Albany.

We are all pleased over the show up you gave the "Eddy clocks"—they were better than they looked. On the Boston division the boys call 'em the "corn-poppers," and the wrought iron driving spring box between the wheels has long been known as the "hog trough."

We are breaking driving springs on a class of engines that have a push down driver brake; some think the brake helps break them, as they usually let go while it is on.

W. E. ANDROS.
Albany, N. Y.

The Electric Sand-box.

Editor The Locomotive Engineer:

A new wrinkle for these parts has recently appeared from the B. & O. shops in this city, viz., the substitution of electricity for sand, with which is combined a plan to increase the power of the engine to which it is applied, by one-third. The locomotive on which this experiment is being tried is an 8-wheel passenger, of the long fire-box type, built at the company's shops in 1886. The dynamo for generating the electricity is placed on top of the boiler, in the place generally occupied by the sand-box (which is minus on this engine) and driven by a small tri-cylinder engine immediately behind it, and in front of the dome. Electricity is conducted from the dynamo to the tires of the drivers, and as they become thoroughly magnetized their attraction to the steel rails is supposed to prevent slipping, and greatly increase the adhesion of the engine to the track. It is claimed that a locomotive loses one-third of its power by slipping in starting a heavy train, which is to be obviated by the use of this contrivance. So far, however, the results reached have not been as satisfactory as might have been desired, in fact, some of them say that a pinch of sand is worth twenty dynamos on a wet rail, and in starting out. All parts of the engine that are not to be charged are carefully insulated. A non-conducting substance (probably compressed paper) is placed around all her rod bushings, between the wheel centers and driving-boxes, and all precautions are taken that nothing will be magnetized but the tires. This plan has probably been tried before, but this is the first time on this road. The question of electricity *vs.* sand, is an interesting one, if nothing else. The sand-box has been an important accessory to a locomotive for some time, has been extremely useful for the purpose for which it was intended, and from an economical point of view has cost next to nothing. But these are not reasons why something much better should not supersede it. But whether that "something" is the dynamo on the "806," I am unable, at present, to say.

Baltimore, Md. ROBERT H. ROGERS.

A Lucky Coupler, Even the Angels Want It.

Editor The Locomotive Engineer:

Having read the article, "The Coupler War," in your valuable paper of March, will you permit me to explain in your columns why the vertical hook coupler has made so many coupler men sick?

It is the fact that the hooks now in use are weak in structural form; the metal is not distributed so as to strengthen the weak points, and the miserable and costly excuses of uncoupling attachments now in use are continually broken or non-workable.

The vertical hook is the only device yet invented that avoids the high car carrying the low car, and it would cost a trifle in comparison to attempting to keep cars to a uniform height.

The Ferguson hook is at least 50 per cent. stronger than any hook now in service made of same quality and weight of metal, and the uncoupling attachments are so simple that the angels would hail their adoption with delight, as they would prevent the expletives now considered necessary to do work with these old devices. GEO. J. FERGUSON.

Greenville, Tex.

[Perhaps the angels would kick, if they had to face the repair bills.

Did Engineer Hood do Right in Running With one Eccentric Rod Down?

Editor The Locomotive Engineer:

On reading about the exact conditions of engineer L. L. Hood's accident on D. S., S. & A. railway by breaking the left back-up eccentric, I venture to give my opinion.

In the first place I think he did wrong by putting reverse lever in extreme forward notch, and blocking link down solid on link block, thus giving the valve a little more than its usual travel, and allowing steam to get into the other port.

Second, having lever in extreme notch would allow the bottom end of link to come in line with top end, or other eccentric rod, and would bind and break the other eccentric, or whatever was the weakest part on that side.

Third, when he came to the conclusion to leave up his other eccentric and block his link, if he had put his lever in about half its distance of forward motion, and then blocking, instead of putting it in extreme notch, he would have been using better judgment; for which I will give my reasons.

When the lever would be in about half its distance in forward motion it would give the valve and link a shorter stroke, and would not let the link travel so far as to get in line with the top end, and bind; for when the lever is in extreme notch the link would travel so far, the bottom end would come in line with top end, and you cannot move link or lever, with the block in or out, without taking a bar and prying bottom end of link down, and my opinion is that it was more by good luck than through good management that he came in all right by using his way of blocking.

It would have been better to take down both eccentrics on that side under these conditions, and did the best he could, for with the block he was putting double the work on the other eccentric that it was made to do; and if he had paid a little more attention to the eccentrics, and had those set-screw holes plugged up, as they ought to be, the accident would not have happened.

A READING ENGINEER.

Marquette, Mich.

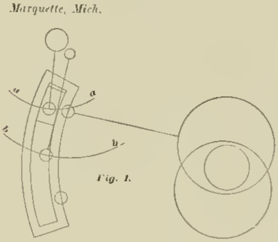


Fig. 1.

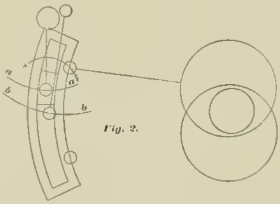

Fig. 2.

[Putting lever in the extreme forward notch does not let the top of the link strike the block, as long as his link hanger was up he was safe here. Increasing the travel will not admit steam to the other port. As to the lower end of link swinging up so that the top connection would come in line, forward or back of the link block pin, and bind, the tendency that way will be least the way Hood disconnected. Take a look at the skeleton sketches on this page. Fig. 1 shows the manner in which the engine was run, the eccentric blade connection is just opposite the die or link block, and the movement of the eccentric strap has little tendency to swing the link, and this tendency is counteracted by the hanger that obliges the center of the link to swing on the radius *b b* (which is nearly like that of the lower arm of the rocker *a a*), the weight of the link and the block that was fitted into the lower end of the link. Had the blocking been done as you suggest, shown in outline in Fig. 2, the link block would have been between the forward eccentric blade connection and the suspension stud, and the movement of the eccentric strap would have had a tendency to move the top of the link in the direction of the arrow, and around the link block pin; this, of course, would have greatly strained the hanger connections, and probably broken some thing. By disconnecting the lower or back-up blade, no more extra work is put upon the forward motion one than would be in working the engine full stroke, when all right; in that case the back-up blade merely prevents the lower end of the link from swinging—the top blade does the work. Any plan that will insure the lower end of link from swinging can be used, but nothing will succeed unless at full stroke, for the reasons pointed out. No fault could have been found with Hood if he had taken down both blades and disconnected his engine, but under the circumstances he did the best thing. Your last point has nothing to do with the question—the damage was done, and the question was to come the nearest to regular service with the least delay and risk that the circumstances would warrant.]

Why Truck Flanges Cut.

Editor The Locomotive Engineer:

I have been keeping track of a lot of engines with all manner and shapes of trucks, with a view to finding out something about the cause of flange wear. I want some information on this subject, and will make a few assertions just to call out some discussion or some history of experience.

We have a lot of modern swing-motion trucks, with steel-tired wheels, under 8-wheelers, about as many more with rigid center trucks, some resting on small center bearings only, some on large centers (24 inches), Mason style, and others that have a small center, but are side bearing. You would naturally think that the easiest truck to round a curve would wear its tire least, but the old-fashioned side-bearing trucks and the old Mason centers seemed to do better than the small center bearing or the swing motion.

Three years ago I put some engines with each kind of truck on one of our divisions, that is practically without a curve—and the flanges wore nearly, if not quite, as badly as on the crooked divisions. As before, the wide center and the side-bearing trucks did the best—why? By riding on the different engines I came to the conclusion that the cause of flange wear—where the engine is in tram, and the truck frame square—is not on account of the curves, but on account of the constant vibration of the truck. The swing-motion truck crowded the rail one side or the other at every low joint, and was constantly changing from side to side at every move of the engine—as the fireman expressed it, "it wiggles." The rigid, small center truck did the same, while the side bearing truck ran steadily and stiffly, and every time the engine lurched the side-bearing or the weight on one edge of the wide center at once brought the front of the engine back to center, and had things running in line. On the swing truck the engine came back to center slower, and was easier to move out.

I came to the conclusion that flanges wear more from "wiggle" than from curving. What do the readers of THE LOCOMOTIVE ENGINEER think?

A SOUTHERN MASTER MECHANIC.

Wants Us to Have a Sure Thing.

Editor The Locomotive Engineer:

I have read the paper since its first issue, and think enough of it to send for the bound volumes for the three years. There are some men in this country that have never read it—some don't want to read anything about a locomotive—the place to learn is to be on board of one, etc., etc. I differ from a good many that way; I read and re-read all I can find that will better me in my calling, and I have been running a locomotive in road service for fifteen years. I think if the managers of our railroads would subscribe for your paper and furnish each engine crew with a copy, and have them receipt for them, same as the time card, it would be like bread cast upon the waters—it would return to them tenfold at the end of the year in net earnings for the company.

If they would scatter them through the shops and roundhouses, and read them themselves, it would do some of them good. I send you eleven names, including myself, for three bound volumes each, for '88, '89, and '90. We all like it here.

Fond Du Lac, Wis. G. F. MCEVOY.

[Bro. McEvoy's plan would no doubt be a pleasant thing for us and many of the "boys in blue" (overalls), but we don't expect to see this kind of a millennium. We are satisfied with "friends like these," who know a good thing when they see it, and are willing to pay for it.]

The Rogers Locomotive Works are building three heavy decapods—10 wheels connected—for the C., B. & Q.

CONTENTS

Making Changes.

When you are promoted to take another man's place, don't think that your reputation depends upon how many changes you can make in the existing order of things. This is especially true where your predecessor has been a successful man and has left to better himself.

Look around you, study conditions, and perhaps you will find a good reason why some things are different from what you are used to or would advise. A fairly well-organized place will run itself for awhile, you simply get on and ride, keeping your eyes open.

Don't make too many reforms at once, make those that show results first, without antagonizing the men under you. Old hands are very valuable to a new head.

Never make a change except with a view to economy, safety, or increased efficiency—never for the simple sake of change. A manager's success depends very much more upon what he *don't* do than upon what he does.

The Reason Compound Air-pumps Will Show No Economy.

There has been considerable talk of late about the economy of compound air-pumps, or other forms than the ones in general use.

That these pumps will supply a given pressure of air with the expenditure of less heat, or, in other words, less steam, no one will dispute; but here come in the conditions of service that make the economy useless.

When a locomotive is running the brakes are released, and the pump governor has the pump choked off—it is simply pumping enough air to supply the leaks. Brakes are never applied except when the throttle is shut, and when the brakes are applied the governor at once sets the pump going to supply the place of the air used, and it simply uses steam that would otherwise escape at the safety valve.

In nine cases out of ten there is much more steam wasted at the pop than the pump uses.

Complicating the pumps to save steam is the opposite of economy—it will cost too much to maintain them.

Advantage of Drop Tables Over Cranes for Repair Work.

Cranes have become very stylish of late for locomotive repair shops, and many master mechanics have figured on how much they could save if they only had a big traveling crane in the shops.

Besides the large investment of a crane, it has a disadvantage in that it takes power all the time to operate it, or the shafting running it; it requires a man in attendance all the time, and is a candidate for some repairs and considerable oil.

For manufacturing it is all right and will pay, but for repair shop practice we do not think it any better nor near as economical as a good drop table.

The table uses no power except when actually at work; there is no attendant, not one-tenth the investment planted, occupies no room when not in use, is not in the way of belting, and is fully as efficient in getting the running gear out from under a locomotive as is a crane.

A well-arranged table with hydraulic or air cylinders for moving an engine makes the table work quick and easy.

For running repairs, where it is desirable to remove a pair of drivers or a truck, there is nothing quicker and easier than the Vreeland transfer jack, and no large roundhouse is complete without it.

Pressed Steel Parts—Diversity of Sizes.

At the March meeting of the N. Y. Railroad Club, Mr. Chas. T. Schoen read a very interesting paper on the use of pressed steel parts for car work. Among other things he mentioned the fact that the cost of pressed steel parts was greatly increased on account of the great diversity in sizes used, his works having on hand, in less than three years' experience, some seventy-odd dies for center plates alone, and half as many for stake pockets and corner bands. He blamed the motive power and rolling stock officials in a measure for not adopting and adhering more to standard sizes.

Geo. W. West, Superintendent of M. P. of the N. Y., Ontario & Western, however, stated that his road was using pressed steel parts made by the speaker's house, and that they never were consulted as to whether sizes in stock would do, but were asked to furnish cast-iron centers, etc., so that the steel could be made to interchange.

Mr. Blackall, Superintendent of M. P. of the D. & H. C. Co., stated their road had the same experience, and he did not think it fair to lay it all to the motive power men.

The Master Car Builders ought to have a standard size for all these small parts, and the cost of repairs would be reduced by adhering to it.

We must not forget, however, that there are over one million cars running in the United States, and in substituting steel for iron in old work it is very necessary that the pieces be so built as to go on in place of the old cast-iron parts. No road can afford to throw away center plates or stake pockets to come to a standard, while there is just as much service to be got out of an old piece as a new one for running repairs.

Mr. Schoen gave some very interesting figures on the economy possible by reducing dead weight of cars by the employment of pressed steel in place of cast-iron.

Eugene V. Debs.

Eugene V. Debs, by far the ablest labor speaker and writer in America, has resigned his position as grand secretary and treasurer of the Brotherhood of Locomotive Firemen, and editor of their *Magazine*. Debs has not yet vacated his office, but stands ready to do so when his successor is appointed. To the honesty, intelligence, ability and untiring energy of Eugene V. Debs, the B. L. F. owes its present prosperity, and probably its existence, and we do not doubt but that the members of the order give him full credit. We were in the order ourself when the sun didn't shine very often.

It is to be regretted that Brother Debs has decided on this step—it will be hard to fill his place—but as far as he is personally concerned, he has the necessary qualifications to leave more fame and fortune behind him than can be found within the necessarily prescribed limits of one order.

Eugene V. Debs is not a man who needs the offer of a "place"—he will make a place for himself.

He has not, as yet, publicly announced his plans, but it is pretty generally understood that he will start a paper. If he follows any old plan, or cites any precedents to go by, it will be the first time he has done so; and if he does not show us something new, crisp, clean and sharp, he will fail to continue on the lines he has long ago established.

Eugene V. Debs is a labor agitator, and is proud of it. He is as honest as daylight, and does not hesitate to aid what he thinks is right, and kick what he thinks is wrong—find it where he may.

When he dips his pen in gall and reaches for a victim, he flays him alive—there is no mistaking what he means. Sometimes we have thought he fought too courageously, defeated the ends he sought by bearing down too hard, but we have only to think how, years ago, he borrowed money of his mother to pay up the debts of the Brotherhood, we have only to think of the millions of dollars that he has collected in pittances, and paid to the widows and orphans of the order, without the loss of a penny; we have only to think of the money, meals and encouraging words he has given to suffering brothers or "the tramp"; we have only to think of the sleepless nights and days he has worked over his books and his copy to keep up the spirit and interest of the order, when we love him more and more.

He has made mistakes and made enemies—only the fool has no enemies—but he has already contributed a lifetime of good to his fellow man.

Eugene V. Debs has a warm place in the hearts of thousands of American railroad men, who stand ready to aid him in any undertaking he may put his hand to—he can have half our shirt "on sight."

ASKED & ANSWERED

(30) Young Machinist, Chicago, Ill.,

Wants to know the value of lap of valve and the functions of the eccentric. The subject is too long for this column. Buy Forney's Catechism of the Locomotive; price, $2.50. It will tell you all you want to know in such simple language that you cannot fail to understand, if you think of the subject as you read.

(31) E. Gibson, Wilmington, Del., asks.

1. At what point is the crank pin when it receives its greatest strain? 2. At what point is the pin when an engine is most liable to slip? *A.*—1. At the beginning of the stroke, because the pressure on the piston is greatest there. 2. Slipping takes place most when the crank-pins on each side are below the center, the most wear generally showing almost directly in front of the right-hand crank-pins.

(32) W. H., Pine Bluff, Ark., writes:

A locomotive is working hard with 25 loads, throttle half open and lever near the corner, she breaks off five cars and starts ahead with them. The throttle nor lever have not been touched, yet the exhaust is easier and lighter. Why? *A.*—The exhausts take place closer together and sound lighter, and after the engine has gained speed there is not the time for the cylinders to fill with steam that there is when moving slowly and cutting off so late in the stroke. Steam does not have time to get in, thus less is used, and the exhaust is lighter.

(33) J. H. D., Kalkaska, Mich., asks:

1. How much more will an engine pull up a grade two hundred feet to the mile with 120 pounds of steam than it will with sixty? 2. What would be the percentage of the hauling capacity of an eight-wheeled Baldwin engine on a grade 66⅔ feet to the mile? *A.*—1. In this case grade does not enter into the problem; it is simply a matter of pressure, the engine's hauling power will depend upon the mean effective pressure, which in this case will be about double for the higher pressure. 2. About 19 or 20 per cent of its capacity on a level, conditions varying the capacity very much.

(34) J. P., Ishpeming, Mich., asks.

Does smoke enter the cylinders when engine is running with steam shut off, especially when air-pump is working? *A.*—No. The tendency is to pump the air out of the chest and steam pipes into the nozzles, and there is, under the circumstances named, a partial vacuum in the chest, proven by the "suck" on the oil pipes. Where there are no relief valves this vacuum is generally governed by the weight of the valve, which will lift when the pressure under it becomes strong enough. The packing will usually leak enough to supply the needed air. When the motion is reversed is when smoke and cinders go down the nozzles to the cylinders and chests.

(35) H. Williams, Moosic, Pa., asks.

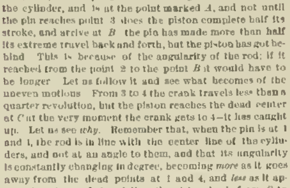
How do you figure the horse-power of a locomotive? *A.*—It is customary to allow half the boiler pressure for the mean effective pressure, which is the average pressure from the beginning to end of stroke. The following rule is used for any engine, and where used for a locomotive the result should be doubled, because a locomotive has two cylinders. *Rule.* Multiply the mean effective pressure in pounds on a square inch of piston by the length of stroke of piston in feet, multiply this product by the area in square inches of the piston, and again multiply this last product by the number of strokes made by the piston in one minute, and lastly, divide this total product by the 33,000, the quotient will be the indicated horse-power. Probably the following formula will help to impress this rule on the memory: Let *I. H. P.* stand for indicated horse-power; *P* for the mean effective pressure in pounds on a square inch of piston; *L* the length of stroke in feet; *A* the area of the piston in square inches; *N* the number of strokes made by the piston in one minute. We then have

$$I.\ H.\ P. = \frac{P\ L\ A\ N}{33{,}000}.$$

Here it must not be understood that the word *P L A N* has any particular relation to the horse-power of an engine, but the letters forming this word should simply be understood to be symbols of the factors which enter into the calculation, neither does it make any difference in which order we take the factors, but placing them in the order here given, they form the word *PLAN*, which may help to impress the rule upon the memory. The divisor 33,000 stands for that many foot-pounds. An engine which raises 33,000 pounds through one foot in one minute is said to exert one horse-power. This unit of horse power was established by Watt, and has been in use ever since.

(36) Not Posted, Philadelphia, Pa., asks

Please explain through your paper what is angularity in side and main rods, and what effect it has on the engine. *A.*—Side rods have no angularity, because they are always parallel to the piston that moves them. What is known as the angularity of the rod affects the motion of the piston, and makes it necessary to change the motion of the valve to correspond to the irregular motion of the piston. The accompanying outline sketch of the crank-pin, piston and main rod will help to make the matter clear. It is perfectly plain that when the crank-pin is at 1 or at 4 the piston will be at *D* or *C*, the extreme end of the cylinder. As the piston and crosshead are keyed solidly together, we will consider only the motion of one, as in this case their motions are exactly the same. The angularity of the rod always decreases by increasing the length of rod; so in this case we show the rod but half the usual length, as compared to the proportions of other parts; this will serve to show the effect of angularity more plainly. Now, suppose we start the pin from 1 in the direction of the arrow; at 2 the crank has traveled over one-quarter of its path, or 90° of the circle, but the piston has failed to get to the center of the cylinder, and is at the point marked *A*, and not until the pin reaches point 3 does the piston complete half its stroke, and arrive at *B*; the pin has made more than half its extreme travel back and forth, but the piston has got behind. This is because of the angularity of the rod; if it reached from the point 2 to the point *B* it would have to be longer. Let us follow it and see what becomes of the uneven motions. From 3 to 4 the crank travels less than a quarter revolution, but the piston reaches the dead center at *C* at the very moment the crank gets to 4—it has caught up. Let us see *why*. Remember that, when the pin is at 1 and 4, the rod is in line with the center line of the cylinders, and not at an angle to them, and that its angularity is constantly changing in degree, becoming *more* as it goes away from the dead points at 1 and 4, and *less* as it approaches them. Let us follow the piston back from *C* to the center of the cylinder at *B*. You will see that the pin has only got to 5; the constantly increasing angularity has made the piston travel a full half stroke before the pin has



got to the quarter, the piston reaches *A* again when the pin gets to 6, the quarter, but the moment the pin gets past 6 the angularity of the rod commences to decrease till it reaches 1 again, which it does by the time the piston is at the end of the cylinder at *D*. You see, the pin has to travel from 5 clear around to 3, in order to make the piston go from the center of the cylinder to the back head and to the center again, while it only has to go from 3 to 5—a considerable shorter distance—to make the piston go from the center of the cylinder to the front at *C*, and back to the center. Something is working unevenly. What is it? The fly wheel, in a stationary, and the moving weight of engine and train in a locomotive, act as governors that prevent uneven impulses given to the pistons from affecting the regular rotary motion of the crank-pin, and, as that is coupled to the piston by the main rod, the result is that the pistons travel unevenly; not only do they stop and start at each end of the stroke, but they make one-half their journey quicker than they do the other half. In a full revolution of the crank the piston will always travel the *least* while the crank is making the half revolution farthest from the piston, and travel the *most* while making the half revolution nearest the piston. In locomotive practice it is customary to place the center line of cylinders slightly above the center line of the wheels, and this increases the angularity on the lower half of the crank-pin's path, and decreases it in the upper half; but this change is so slight that locomotive builders, as a rule, ignore it. The motion of the valves of a locomotive are derived from eccentrics fixed upon the axle, and coincide more nearly with the motion of the main pin than the piston, so that something must be done with the valves to equalize the point of cut-off for the uneven motion of the pistons. In the ordinary link motion this is done by changing the point of suspension, or saddle-pin, of the links.

The Coming Locomotive—A Reply to Mr. Sinclair's Criticism of Single Engines.

Facts outweigh the profoundest and most ingenious speculation.

Angus Sinclair, in *The National Car and Locomotive Builder*, says, "To talk of employing 'single' driver locomotives at this day is trifling with a serious subject." Before making the above statement, it would have been well had Mr. Sinclair made sure of his facts.

Mr. Sinclair further says, "Mr. Le Van is not a railroad man, and never has had anything to do with the designing of locomotives." . . . Will Mr. Sinclair tell us what constitutes a railroad man? Mr. Le Van has designed and built a locomotive. Has Mr. Sinclair ever built and designed one?

It is not the province of a railroad man to build and design locomotives. That work comes under the head of dynamics, and should be referred to the engineering branch of the company. The best evidence of this is found in the manner that the majority of locomotives are designed and constructed by "railroad men." In engines so designed and constructed, the high-pressure steam from the boiler is passed into a large rectangular steam port, and, after being expanded four or five times, is forced through an exhaust nozzle, one-fourth the area of the inlet, or, in plain terms, it is let in at the big end of a funnel, and expected, after expanding to four times its volume, to get out of the small end in less than one-half the time occupied for its inlet.

He further says, "The question of running fast trains has presented itself to Mr. Le Van in a one-sided and rather impracticable fashion."

Mr. Le Van's experience has been that of every ordinary mechanic; he served an apprenticeship under Stillman, Allen & Co., of New York City, as a machinist, and attained a fair ordinary common education, and for the last forty years has been continually and exclusively engaged in designing, constructing and superintending different kinds of machinery and boilers, having had three years' experience as a marine engineer, and was a manufacturer of steam engines and other machinery, including that of cotton, woolen and paper-mills for over ten years. I have also been employed as an expert by the City of Philadelphia, in relation to their pumping machinery for its water supply, and have for the last twenty years been employed as an expert in regard to the construction and operation of machinery in patent cases, and similar suits in our courts. I have also been a member of the Franklin Institute for the last thirty years, and one of its board of managers for thirteen years, and also a member of the American Society of Mechanical Engineers since its organization.

In the course of my business experience I have for a number of years visited New York City once a week, and consequently know "the conditions under which railroad trains are operated," . . . . "and the existing conditions that require the steam to be shut off and speed reduced." . . . English railways have just the same conditions to contend with in the above respect as the Pennsylvania and other roads.

In the race to Edinburgh, in 1888, the locomotives had the same contention to deal with; on the east coast route the speed was restricted to ten miles an hour through Peterborough, Darlington, Maspeth and Berwick, and through six other towns from ten to twenty-five miles an hour, beside other delays, and still the average speed was 54½ miles an hour with a 200 ton train.

Then again, Mr. Sinclair knows, as well as Mr. Le Van does, that the Pennsylvania Railroad Company runs both the States of Pennsylvania and New Jersey legislatures, and can have only such restrictions imposed as they may want.

In the spring of 1884, Mr. Le Van read a paper before the Franklin Institute, and also before the American Society of Mechanical Engineers, in which he undertook to establish the fact that the distance between New York and Chicago could be covered in seventeen hours, or at an average speed of fifty-five miles an hour. This paper was submitted, prior to the reading, to the general manager of the Pennsylvania Railroad Company, who said there would be no difficulty in carrying it out as stated. The race from London to Edinburgh, in 1888, shows conclusively that there is no difficulty in so doing, as the above speed was exceeded on that occasion for a distance of 400 miles, covering thirty days runs.

It is a well-known fact, and no one knows it better than Mr. Sinclair does, that the English locomotives use much less fuel for the load moved than our American locomotives do; and one of the best evidences of this fact is close at hand, by comparing, namely, the fuel consumption of the English locomotive now running between Philadelphia and New York, with the consumption of fuel by one of the best American locomotives on the same road, and *doing similar work*.

Now this locomotive is virtually a "single" locomotive. Mr. Webb's object in introducing this locomotive was to secure, in the first place, a greater economy of fuel, and, secondly, to do away with parallel rods, the "weak link in the chain of mechanism at high speeds," they being "the principal drawback to a coupled engine." Mr. Webb, by his arrangement, at the same time obtains increased adhesions, with the freedom of a "single" locomotive.

Mr. Sinclair says, in a paper on "Economy of Fuel," read before the Master Mechanics Association, "While I stand second to none in admiration of the American locomotive, I think there is a possibility of making it lighter on fuel." The

Webb locomotive hauls five cars and makes seven stops in 124 minutes, between New York and Philadelphia. The coupled locomotives can do no better, and consume nearly 30 per cent. more fuel. The former having 1,400 square feet of heating surface, and 19 square feet of fire surface; the latter having 1,205 square feet of heating surface, and 85 square feet of grate surface.

Twenty years ago, Mr. Patrick Stirling, superintendent of the Great Northern Railway of England, built, and up to present date continues to build, and run "single" locomotives with great success, as well as economy of fuel, and they are noted in England for their efficiency. The traffic is exceedingly heavy, and the trains are run at a high rate, the average speed of the Flying Scotchman being 50 miles an hour, and no trains in England make better time. These trains average, including engine and tender, 228 tons weight, and the coal consumption per mile averages 22.6 pounds. Mr. Stirling conducts his traffic at a higher rate of speed, and with equal punctuality, with his eight feet "single" locomotives, than does Mr. Webb of the Northwestern with coupled locomotives, and the economy of fuel of the former over the latter is very remarkable.

In the race from London to Edinburgh, "single" locomotives on both the routes carried off the palm, and the most interesting feature was the run from London to Crewe—158 miles—without a stop, and by a locomotive twenty-five years old, and a *single* at that, having cylinders 17x24 inches, with 7-feet 7-inch drivers, and 1,098 square feet of heating surface, and 15 square feet of grate surface. Taking modern locomotives as a standard, this is a small locomotive, being only 22½ per cent. of weight of the load hauled; the average speed was 54 miles an hour.

Mr. Johnson, superintendent of the Midland, England, since 1887, has adopted the "26" class of "single" locomotives for his flying trains; cylinders, 18x26 inches; driving wheels, 88 inches in diameter; heating surface, 1,240 square feet; grate surface, 20 square feet. The loads hauled by these locomotives average 244 tons weight, with a coal consumption of 26 pounds per mile, and average speed is 48 miles an hour.

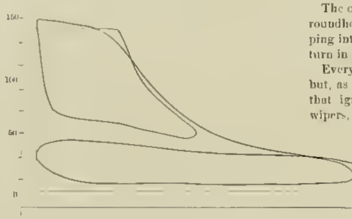
At the present time all of the best railways in England are adopting "single" locomotives for their fast trains. The advantages of English locomotives over American locomotives for fast speed and economy in fuel is in their adoption of large diameter driving wheels, and large exhaust nozzle area, the former reducing the number of revolutions per mile, thus producing a slow draught, allowing the products of combustion time for passing through the flues, so as to give up the greater portion of the heat evolved, thus effecting a higher evaporation per pound of coal burnt, and the latter reducing the back pressure on the pistons, the occurrence of which is the great drawback to high speeds; the trouble is not to get the steam into the cylinder, but to get it out quickly.

It is undeniable that for trains within their adhesive powers no class of locomotives can run with so much freedom and steadiness, and with so little *wear* and *tear* to the machine, and permanent way, at very high speeds, as the single driving wheel locomotives.

Mr. Sinclair says: "The conditions under which railroad trains are operated will, however, prevent them from imitating English practice. If the ninety miles run from Jersey City to Philadelphia could be made without the engineer being required to shut off steam more than once, the fundamental condition on which British fast train operating is based would be paralleled, and a large wheeled locomotive with limited adhesion would be in her proper element. As the existing conditions require the steam to be shut off, and speed reduced ten or twelve times, the designer of locomotives provides the kind of engines adapted for lifting the train quickly into speed, and nothing else will do."

Now Mr. Sinclair, like those he calls "railroad men," will build locomotives suited to start their trains with, *which involves not three per cent. of the work to be performed, therefore making them wasteful for the ninety-seven per cent. of the power to be developed to haul the moving load.* This is why the English locomotives excel ours in speed, and are so much more economical in fuel than the American locomotives. Their trains and locomotives are adapted for each other, and this is why the former towers above the latter, as the Eiffel does above the Washington monument.

Mr. Sinclair says: "Trains are becoming so heavy that two pairs of drivers and a four-wheel truck will not carry the weight of the boiler and cylinder necessary to provide the required power." Now the fact is that three fourths of the trains running between New York, Philadelphia and Washington, on both the Pennsylvania and Baltimore & Ohio railroads do not exceed 225 tons weight, including locomotive and tender, which can be hauled at the rate of fifty miles an hour by a first class single locomotive with a coal consumption not exceeding thirty pounds per mile. And this is just what the best English railway companies are doing, including the Great Western, which is operated for forty-nine per cent. of its gross receipts; the Midland, the passenger traffic furnishing thirty per cent. of the gross receipts, and which pays *six per cent.* dividends on its ordinary stock. The Great Northern for the last twenty-five years has used singles for its fast passenger traffic, with a coal consumption not exceeding twenty-three pounds per mile, also the Caledonian, Manchester, Sheffield & Lincoln, and several other lines are arranging for singles. Mr. Worsdell, of the Northeastern, has in all his late fast compounds adopted single drivers 7 feet 7½ inches in diameter. With a special train of eighteen six-wheeled carriages a speed of about ninety miles per hour, the highest on record by several miles, was obtained. Indicator diagrams were taken on this trip; one set was taken at a speed of eighty-six miles per hour on the level. The speed was carefully measured by a stop watch and mile posts, the quarter-mile posts being frequently registered during the trip, the shortest time was just over ten seconds per quarter mile. The following indicator diagram was taken at a speed of seventy five miles per hour



Total weight of locomotive, tender, and train, 310 tons, 6 cwt., high-pressure cylinder, 20 inches diameter; low-pressure cylinder, 28 inches; stroke, 24 inches; driving wheels (single), 7 feet 7½ inches; high-pressure cut-off, at 47 per cent.; low-pressure cut-off, 67 per cent. of the stroke; total indicated horse-power, 1041.4. Heating surface in flues, 1,016 square feet; heating surface in fire-box, 123 square feet. Total, 1,139 square feet. Grate area, 20 square feet. Coal consumption, 28.4 pounds per mile.

The highest indicated horse-power on this trial was obtained at a speed of eighty-six miles an hour, namely, 1,068, boiler pressure, 175 pounds. From the above it will be seen that Mr. Sinclair's statement, that "Locomotives with single pair of driving wheels had their day . . . the American locomotive . . . did admirable service, but the indications are that its days as the motive power for fast passenger trains are nearly over, the mogul and ten-wheel locomotive are slowly taking the place; they will eventually monopolize," is simply ridiculous in the extreme.

With the introduction of steel rails, and that of the steam sanding apparatus now in general use on the majority of the best flying trains in England, it has been demonstrated that a single pair of driving wheels can carry as much as twenty tons, where before fourteen tons was the maximum load. The latter improvement has brought the single locomotive into the front rank for fast train service. To accomplish sixty miles in sixty minutes consecutively the compound system and a single pair of driving wheels will have to be resorted to. The race in 1888 between London and Edinburgh showed that the best average consecutive miles per hour was fifty five and one-half miles. Therefore, compounding will have to be substituted so as to utilize all the power developed by the boiler, as well as the heat units now wasted in the high back pressure due to excessive compression.

WM. BARNET LE VAN.

Philadelphia, Pa.

A Pie eating Ghost.

Way back in the early days on the Rio Grande—1875 was pretty early in the early days—the management bought an English locomotive, one of Fairlie's double enders.

This peculiar old scrap was odd in every way—devilish odd. She had four cylinders, two stacks, etc. Her cab was something between a freight car and a pump house, and was located in the center of the boiler. This cab was some two feet wider than any other cab on the road—if it hadn't been, this tale would never have been told.

On top of this cab there was a cheap, cast iron bell that made a noise something like the rattle of a big bunch of keys.

After the first year none of the regular men would fire the Farlie, except a little Cornishman who answered to the name of Fairlie Jim.

Early in his career Jim had been laid off ten days for not ringing the bell at a crossing, so he made up for lost time by ringing the old rattle-box on the Fairlie all the time when not actually putting in a fire. He soon became noted for perpetual bell ringing; night or day, in the yard or on the road, Jim jingled the bell and leaned lazily out of the side window.

But one day the Fairlie was sent over a new division, where no calculations had been made for her wide cab, and a steam pipe to a pump where some bridge work was going on did not clear enough, and Fairlie Jim's head was taken off, and the bell stopped.

The old engine was brought back to the Denver roundhouse and stored away in an odd pit, dropping into a season of slothful idleness awaiting her turn in the shop.

Everybody wanted to go firing out there then, but, as usual, the roundhouse foreman thought that ignorance was the proper qualification for wipers, and yet he wanted wipers to become firemen and firemen to become engineers; so the majority of the wipers were ignorant, and, being ignorant, were superstitious.

There was one bright young fellow wiping, and praying for his turn to go firing; he was smart, but he did not look it. There was a spirit of fun in him, and by pretending ignorance and the belief in all signs and other forms of superstition, he managed to keep his co-workers talking and telling something for his especial edification.

The night foreman was a fun-loving young man also, and helped his friend the wiper enjoy himself.

When the Fairlie came in, after killing Jim, our wiper friend told the crew all about her and Farlie Jim, and added, much to their amazement, that every night at exactly twelve o'clock Jim came to the engine and rang the bell; he elaborated his lie as interest grew on it, and by ten o'clock had all hands truly excited, but somewhat incredulous, then he slipped away and told his friend—the foreman.

This worthy at once attached a string to the Fairlie's bell and ran it where it could not be seen to his desk.

Promptly at 12 o'clock the cracked tones of the Fairlie's bell rang through the house, and our wiper friend, assuming great fright, dropped his torch and dove for a door, closely followed by the crew of night hawks. The man who appeared to believe his own story led the frightened crowd into the supply yard, where tons of castings, timber, piles of wheels, tires, pumps, pile drives and trucks were concealed in the darkness, ready and willing to throw the wayfarer down and then jump on him.

When the bell stopped they all came back slowly, rubbing their chins, except one man—probably he's running yet. The next night the ghostly bell-ringer came back, but he was not satisfied with merely ringing the bell.

Our jokers had heard of another peculiarity of Jim's—he was an awful pie eater. Shortly after the gang got to work the next evening the humorous wiper asked a neighbor if he had any pie in his lunch the night before, and when he received a reply in the affirmative simply shook his head and kept still. When asked to explain he, apparently with great reluctance, told that he came to the house the night before sure that he had a piece of pie in his lunch pail, but that after the ringing of the bell he could not find it, and told what an awful pie spoiler poor Jim had been.

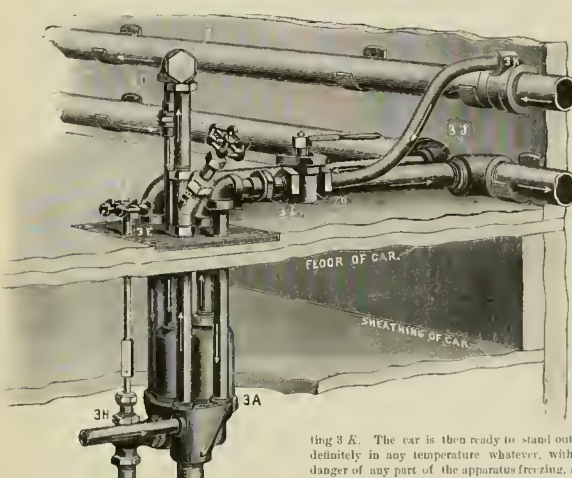
That night our wiper led the retreat again, and his side partner who did the ringing also lifted the pie out of every pail—their own included.

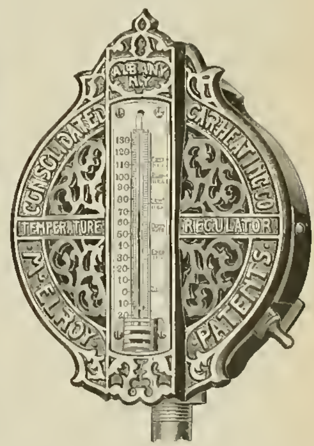
Our wiper told his comrades that he would be mortified to death to have it get out that he was scared lest he should see poor Jim—so they all agreed to keep still and wait for developments.

The boys lived on pie for a fortnight when the Fairlie was put into the back shop for repairs, just in time to save the two jokers from chronic dyspepsia.

Public Test of the Commingler Storage System of Car Heating and the Automatic Temperature Regulator.

On March 11th and 12th the Consolidated Car Heating Company, of Albany, N. Y., gave an exhibition of their heating devices on the trains of the





Delaware & Hudson Canal Co. running between Albany and Troy.

A large delegation of railroad officers and newspaper men attended. This company control several systems of car heating, only one of which was in use on the trains mentioned, their direct steam system being in extensive use, however, on other trains on the roads centering in Albany

The attraction of the exhibit was the McElroy Temperature Regulator for automatically controlling and regulating the heat in a car by the temperature of the air in the car itself.

In the commingler system of heating, direct steam is used to heat the car up at first, the water of condensation finally filling up the pipes and automatically changing itself to a hot-water storage system.

The commingler is a small device shown on the left of this page—two are used on each car.

Into this commingler 3 *A* steam enters from the train pipe, through the regulating valve 3 *B*, at very low pressure—about two pounds—and thence makes its way into the heating pipes of the car, following the course shown by the arrows in the cut. As heat is given out the steam condenses and the water of condensation returns to the lowest part of the system—the commingler 3 *A*—where additional steam is continually and noiselessly injected into the water. In this accumulating water heat is stored and mildly radiated therefrom.

When the piping is full the surplus condensation overflows through overflow fitting 3 *K*, and thence through the trap cock 29, down the pipe connected therewith to the drip, where it falls to the ground. The trap cock 29 takes the place of a thermostatic trap. The drip cannot freeze, as it is in metallic contact with the base of the commingler 3 *A*, which base is directly connected with the train pipe, and so is always heated with steam.

By opening the drain valve 3 *H*, controlled by the wheel 3 *F*, the water of condensation is drained from the system and the apparatus then becomes a simple direct steam system. When steam is first turned on the car is quickly heated by direct steam; wheel 3 *F* is then turned, the drain valve 3 *H* is so closed, and the direct steam system gradually and automatically converts itself into a hot-water circulating system.

At stations or elsewhere, if it is desired to avoid any drip, the trap cock 29 is shut, and not a drop of water can escape

When the car is laid off for the night, or for more than three or four hours (for three or four hours it will keep warm from stored heat), the drain valve 3 *H* and the regulating valve 3 *B* are opened, and the entire system is quickly emptied of water, air entering up through the drip pipe and overflow fitting 3 *K*. The car is then ready to stand out indefinitely in any temperature whatever, without danger of any part of the apparatus freezing, and is also in readiness to be quickly heated by direct steam, when again brought into use Like apparatus is placed on each side of the car, thus allowing each side to be heated separately One automatic regulator controls both comminglers.

The automatic temperature regulator (cut on right) is made in ornamental form and occupies but little space. A thermometer attached always shows the temperature of the car. The regulator is attached to the side of the car, at about the center, and is enclosed in a strong metal case of brass, bronze or nickel, as may be preferred. It can be placed in any car already piped for steam, with slight labor and with little or no change in the piping of the cars.

The temperature regulator is actuated by a fluid placed between two diaphragms which are brazed together at their edges. The fluid has a boiling point at sixty-eight degrees Fahrenheit and remains passive below that temperature. At sixty-eight degrees the fluid boils and exerts a pressure upon the diaphragms to force them apart. Suitable mechanism is employed to communicate the movement of the diaphragms to a vertical steel rod three-eighths inch in diameter, which is connected to a valve of special design admitting steam from the train pipe. This rod is enclosed within and protected by a half-inch iron pipe extending from the regulator to the special steam valve. No steam is admitted to this pipe, it serving merely to hold the parts which it connects in rigid adjustment and to prevent any interference with the rod. The movement of one-quarter inch takes place in the steam valve under a change of temperature of five degrees. The regulator closes readily against sixty pounds steam pressure.

These regulators are set to maintain a temperature in the car of seventy degrees Fahrenheit, unless ordered for other temperatures. They are made for sixty-eight, seventy, seventy-two and seventy-four degrees.

Every regulator is provided with a lever, shown at side in cut, which admits of a change of four degrees in the point at which the regulator will hold the temperature of a car. The standard regulator is designed to hold the temperature at seventy, with a possible range between sixty-eight and seventy-two degrees, depending on position of such lever

After the exhibition the editor of this paper made a trip over the D. & H. C. Co. in a train heated by this system and controlled by regulators. Every ventilator in the four cars was open, the air was fresh and pleasant and the temperature steadily stood at sixty-nine, not only by the thermometer on the instrument, but by two others at the ends of the cars. The trainmen do not touch the heating device, it cares for itself.

The idea of regulating the temperature in a train by an automatic device that takes notice of every disturbing element and meets it, instead of regulating by the hand of a green brakesman and the whims of the passengers is a grand improvement.

Patent Centennial Celebration.

Elaborate arrangements have been made to celebrate the beginning of the second century of the American patent system, at Washington, on the 8th, 9th and 10th of April next. President Harrison will open the celebration, and the literary exercises will be presided over by some of the most eminent inventors in the country Twenty addresses upon the different phases of invention will be delivered by men who are famous as masters of the subjects they will discuss. A national association of inventors and manufacturers of patented articles will be organized There will be a grand reception at the Patent Office by the Secretary of the Interior and Commissioner Mitchell, at which at which it is expected Cyrus W. Field, Thomas A. Edison, George Westinghouse, George M. Pullman and others will assist. There will be a military parade, a grand excursion to Mount Vernon, a planked shad banquet at Marshall Hall, near Mount Vernon, and the Navy Yard, the National Museum, the Patent Office, and other interesting national establishments will be open to the visitors.

This is the first time in the history of the republic that the inventors have celebrated.

The Head Liars.

Not long ago there was an important meeting of railroad presidents in this city to fix up some of their broken agreements, and President Stickney, of the Chicago, St. Paul & Kansas City road, among other forcible remarks, said:

"I believe that all the presidents here are honorable gentlemen, and, as private individuals, I would trust them with any amount of money. But as heads of railroads they are a lot of scoundrels, and I wouldn't believe them under oath, neither would I trust them with a cent out of my sight."

Not one of the gentlemen present seems to have resented this charge, and therefore practically acknowledged its truth.

Very few who know anything about it deny that the management of a great railroad property on the modern lines laid down calls for the perpetration of almost, if not all the crimes in the calendar—robbery, corruption, and bribery, to say the least—yet the worst of this is called "sharp financiering" or "good management." As the heads of our railroads are the virtual management, they are responsible for all questionable practices—and there are enough of them daily to send a banker or grocer to prison if he but slightly imitated them.

If an engineer or trainman is caught telling a lie about a little mishap on the road he is discharged. But the great big president will deliberately sign a cast iron contract just for the fun of breaking it to injure another line. President Stickney seems to have known who he was talking to.

Engineers Made to Order.

The Mexican executive has applied to Congress for authorization to spend what may be necessary, for the purpose of establishing in the Federal district a school for the practical training of young men in the handling of steam engines in general, but more particularly of locomotives. This school will be under the control of the Department of Public Works. The course of study will comprise the elementary branches of mathematics, mechanics, and natural philosophy, mechanical drawing, French, English, etc., but its salient features will be the acquisition of a practical acquaintance with the materials of which steam engines are manufactured, the mode of putting them together and taking them to pieces, of operating locomotives, practice in handling locomotives of peculiar pattern, and instruction in the rules governing the running of trains. A period of training in railroad shops, in foundries and mills will also enter the curriculum. After satisfactory examination in the branches named, pupils will be given a certificate of fitness.—*Ex.*

Granger Legislation.

A bill has been introduced in the Missouri legislature, which provides that no engineer shall be allowed to run a locomotive without first having three years' practical experience, and also to allow only those engineers having good moral characters to handle the levers. The bill does not undertake to explain how an engineer is to get three years' experience without running a locomotive.—*Ex.*

If the bill said three years' experience as a locomotive engineer *or fireman*, it would be well enough, and do no harm, if it did no good. Experience on the foot-plate is the only safe way to make engineers, but experience alone will not make an engineer of a basswood tobacco sign—some brains are necessary.

Original Inventors (?).

The *Times* advocates supplementary audible warning signals in the New York tunnel as a means of preventing mistakes in visual signals, as an original proposition. Considering the fact that the *Press* advanced this suggestion immediately after the tunnel accident, the palm for "cheek" belongs to our Mugwump contemporary, but not the palm for originality.—*N. Y. Press.*

Considering the fact that there were just such signals in use in the tunnel at the time of the accident, and that both these papers described it half a dozen times, it's hard to tell who made the original proposition, or has the most "cheek."

Verdict of the Coroner's Jury in the Tunnel Accident.

The following is the verdict of the coroner's jury which investigated the New York tunnel disaster:

The coroner's jury, summoned by Coroner Ferdinand Levy to inquire into the cause of the death of Helen T. Supple, Wm. Anton Zeilner, John H. Hencke, Michael Mullone, John B. Flynn and John Murray, in the Fourth avenue tunnel, on the morning of February 20, 1891, do find:

First—That the preponderance of evidence shows that the signals were properly set at danger at the time the New York, New Haven & Hartford train, called 10 Y, passed them in the morning of February 20, and the jury believe that, owing to the density of the atmosphere in the tunnel, due to the presence of fog, smoke and steam, Engineer Fowler, of the New York, New Haven & Hartford Railroad Company, did not clearly see the signal. It is further believed by the jury that Engineer Fowler did not hear the gong, if it rang on the day of the accident when his train passed the danger light.

Second—We find the New York, New Haven & Hartford Railroad Co., its officers and directors, are immediately responsible for the death of Helen T. Supple and the others heretofore mentioned, because of the failure of Engineer Fowler to distinguish the danger signal at Seventy-second street, and thus causing the collision with the "shop" train; and we further find that the New York, New Haven & Hartford Co., its officers and directors, are immediately responsible for the death by suffocation and burning of John Murray and Jas. B. Flynn, which was caused by the upsetting of a car stove in the Boston & Albany car, under the charge of the New York, New Haven & Hartford Railroad Co., and setting fire to the wreck by reason of the collision.

Third—We would urge the legislature to compel the New York Central & Hudson River Railroad Co. to make additional openings in the tunnel, in order to provide for better ventilation and light in said tunnel, as from personal examination we find that the present ventilation and light are inadequate; and we do further believe that the use of anthracite coal when additional openings are made will contribute to the safety of the traffic. We further believe that the present system of the use of one man in the signal cabs in the tunnel is insufficient for safety, and we earnestly recommend the employment of two at all times.

We further recommend that each outgoing and incoming train when passing through the tunnel be advised of the train immediately preceding it, and also its reasonable headway. And we further recommend that a uniform rate of speed be adopted for all trains and engines passing through the tunnel.

As will be seen, this jury put the blame of the accident upon the New Haven Road, and assume that the signals were right, and the engineer passed them while at danger.

The principal officers and directors of the consolidated road have been placed under heavy bonds.

Chauncy M. Depew has been on the witness stand, and pictured out all the horrors that may arise when an accident occurs to a steam-heated train, and condemned, *in toto*, the very practice the New York Central road has been proud to lead in—they refused to interchange cars with the P. R. R., because the latter were not steam-heated, and therefore unsafe. Mr. Depew has been hot on one side, and cold on the other. He has told a story apparently to help pull President Clark out of a bad hole—Mr. Clark dug the hole himself and ought to be left in it.

If one of Mr. Depew's engineers or conductors was called up before him, and contradicted his own story and his own actions half as bad as Mr. Depew himself has, Mr. Depew would probably come to the conclusion, if he did not then and there announce, that the man lied. To say the least, the president of the Central Hudson has set a very bad example to his men, and placed himself in a position that will cause him the loss of a large measure of the public respect.

On the Georgia Pacific and several other southern roads, they have in use a new form of boiler check, of which the men using them speak highly. Both checks are screwed into a large cast chamber located on top of the boiler, this chamber has a large valve at the bottom, that can be used to shut off connection with the boiler, so that one or both checks can be ground in, cleaned or renewed, with steam on. It is claimed that by locating the checks above the water line there is no trouble from their being held up by scale, and the pipes are so arranged that they empty themselves of water, and are in no danger of freezing up.

Very stringent orders have been issued to passenger conductors of railroads in the Chicago and Ohio River pool to examine carefully all mileage books presented by passengers, and take up those that look as though they came from a scalper's office. If the possessor of a map-of-Ireland face presents a book made out to Ikey Offenheimer, for instance, the conductor is expected to adjust his eye-glasses carefully, and after scrutinizing the face and the face of the book inform the passenger that he's onto him. Any dereliction of duty is likely to be followed by dismissal. On the theory that railroads have nought to do with scalpers this rule would seem to be a tough one to ticket brokers, but as it is a well-known fact that general passenger agents sometimes deal with these gentlemen, it may not be so great a hardship after all. It all depends.—*Cincinnati Times-Star.*

We have received from Eugene V. Debs, editor, a handsome bound volume of the *Locomotive Fireman's Magazine*, for 1890. The *Magazine* is the best "official organ" of any association of workingmen in this or any other country. It is run absolutely and entirely in the interests of its order, and, while we sometimes differ from the opinions expressed by its editor, we give him credit for being heart and soul in his work, and doing at all times what he thinks is best for the order. Bro. Debs has announced his intention to retire from the editorship, and if he does, his successor will do well to occasionally look over the files of the *Magazine*, and keep close to the general lines laid down there. Eugene V. Debs can always refer with pride to the ten volumes of the *Magazine* he created—there is not a dead letter in the set.

On the Connecticut River road they use quite a number of St. Johnsbury feed-water heaters. This heater is a box located just back of the cylinder saddle, and between the guides. The feed water is forced through a lot of brass tubes that are surrounded by exhaust steam, taken from the passages in the saddles. This heater heats the water, no mistake about that, but it takes, like all the rest of them, from Peter to pay Paul, in every case where used, the nozzles have been closed to make the engine steam. There is another fault, the friction of the water through the tortuous passages of the heater pipes puts a great deal of work on the pump, requiring more power to drive it, and making it necessary to pack constantly.

The Sewall steam hose coupler is fast becoming the standard coupler of the country, being already in use on 52 roads, representing a mileage of 37,562 miles, and having 7,080 passenger cars. McElroy and other couplers of the Consolidated Car Heating Co. are in use upon roads having a mileage of 8,188 miles, and having 2,557 passenger cars. These figures show the Consolidated Company's couplers now in use on a total mileage of 45,750 miles, and by railroads having 9,637 passenger cars, which are already equipped, or are to be equipped, for steam heat. It is to be hoped that the master car builders and the master mechanics will decide on a standard coupler, before there gets to be five or six thousand devices in the field.

A largely signed memorial has been presented to J. H. Olhausen, general superintendent of the Central Railroad of New Jersey, by the commuters, thanking the road for the introduction of the splendid new cars, and the Pintch system of gaslights, all of which tend to make life more endurable for them for about two hours per day. The new trains of the Central are praiseworthy, and the new engines are just as deserving. It is splendid stock. The spectacle of patrons thanking a railroad for good and efficient service in this day and age of kicking grangerism stands out like a diamond ring on a tramp's thumb.

Pullman will send a large force of carpenters, upholsterers and painters to Australia, to put together and finish the new cars he is building for that country. The cars are sold outright.

The Alabama Locomotive Works have been incorporated. Home office, Alabama City, Ala., capital stock, $1,000,000.

Examination of Locomotive Engineers and Firemen.

The Master Mechanics Committee appointed to investigate the subject of "Examination of Locomotive Engineers and Firemen, on their duties relating to the use of fuel, care of the locomotive, and ability to deal with disorder or disability of machinery, to what extent practiced and best plan for conducting the examination," request answers to the following questions:

No. 1.—Do you examine engineers employed from other roads on anything except time card rules? If, so what plan do you pursue and of what does the examination consist?

No. 2.—Do you examine firemen, candidates for promotion? and if so, what line of examination is followed?

No. 3.—In hiring men for firemen, what age do you consider the limit past the age of 21 years?

No. 4.—Do you advise the first year in service, as fireman, be on switch engine?

No. 5.—What do you consider the shortest time a fireman should serve in that branch of service before he is allowed examination for promotion to engineer? If a fireman fails in an examination, how do you deal with him?

This subject is very closely connected with the economical operation of locomotives, and it is highly desirable that the committee should receive sufficient information to advise them of the practice followed on most railroads. Any information on the subject that a member may have, and which is not drawn out by the questions, will be gladly received by the committee.

Answers to be sent as soon as possible to W. H. Thomas, Superintendent of Motive Power, East Tennessee, Virginia & Georgia Railroad, Knoxville, Tenn.

Purification or Softening of Feed Water.

The committee to report at the next annual meeting of the Master Mechanics Association upon the best means of Purification or Softening of Feed Water, have issued the following circular:

1st. Have you had any experience with mechanical devices? If so, with what result?

2d. Have you tried chemicals, and with what result?

3d. Have you found practical, and do you recommend for use, any of the mechanical or chemical devices for purifying water? Please tell briefly what your experience has been with any method that you have tried, and also make any suggestions or recommendations that will be of use to the committee.

Replies to be sent to W. T. Small, 749 Dayton ave., St. Paul, Minn.

A patent has been taken out by a Californian for a coin-operating device for unlocking reversing car seats. With a device like this in use for lights, the use of the drinking cup, and the occupation of the toilet-room, the companies might possibly get along without asking fare. If some inventor will get up a device that requires the insertion of a four-hundred dollar bill before a farm hand, with a Buffalo overcoat, and two drinks of whisky, can open a car window in front of a woman with a sick baby, we will head a list of "eminent citizens" that will build him a monument nine hundred and eighty-four feet high.

Considerable time and trouble are expended on every cylinder made, to lay out, and mill out, the exhaust port exactly true with the other ports. There is absolutely no use in doing anything to the exhaust port more than to clean it out and get rid of the sand around the opening. Its being milled out true does no good at all; it is the steam port and edges of the valve that do all the admitting, cutting off and releasing the steam, the exhaust port is merely a hole, and a cast hole is just as good as a machined hole—and lots cheaper.

One of the new elevated engines being built at Baldwin's will have Swinerton wheels, with flat spots half an inch long. It is now claimed that some thoughtless person put the driver brake on and exterminated the flat spots on the last pair of wheels tried. This thing dies hard on the elevated. If good nursing will put life into it there may be some days elapse before the final funeral; but, seriously, why not make the wheels square? It is said the Wright design of four-cylinder compound will also be tried.

Adolphe Viart has recently been invested with the silver palms and violet ribbon of "Officier de l'Academie," the highest honor France can bestow upon artists and men of literary genius. This man has been for more than thirty years a wheel tapper and greaser on one of the French roads at Vernon, in Normandy. He wrote poetry at night, and was unknown until a man with money heard of him and helped him publish his verses. He is known now as "the greaser poet."

A committee of citizens are circulating a petition in Philadelphia, asking for a stringent ordinance against the use of soft coal as fuel on locomotives or motors run within the city limits.

None Too Soon.

General Manager H. S. Haines, of the Savannah, Florida & Western, has issued a circular to employes that concludes as follows:

To FLAGMEN: Never forget that you are placed at the rear of the train to protect life and property, and that it is in the darkness of night, in fogs and storms, that your prompt attention to duty is most valuable.

It is better for your own piece of mind that you should get wet or be left on the road cold and hungry, than for you to see life lost, perhaps your own friends mangled and crippled, or engines and cars broken up in a collision, through your own carelessness or laziness, or because you did not go back when you knew that you ought to.

To ENGINEERS AND CONDUCTORS: Your attention is called to this circular, see that your flagmen understand it and act upon it. Pay strict attention to giving whistle signals or verbal instructions to flagmen, also as to dropping fusees in ample time, when you know in advance that you intend to stop at an unusual place. You will thereby assist your officers in protecting your own lives, as well as the lives and property which it is your duty to protect. You will also add to the reputation of the railroad company which employs you, and in which, I believe, you take as much pride as I do.

Of the class of railroad accidents that can rightly be charged to negligence of employes, there is little doubt that fully ninety per cent. is due to insufficient flagging or to no flagging at all.

Pedrick & Ayer, of Philadelphia, have sent us a combined memorandum and pocket book—empty, as usual. This is the neatest and most expensive vest pocket book we have ever seen given away as an advertisement. It's a daisy.

John Hickey has resigned as General M. M. of the Milwaukee, Lake Shore & Western, to become superintendent of motive power of the Northern Pacific, Mr. W. T. Small having resigned.

Bound Volumes and Back Numbers of THE LOCOMOTIVE ENGINEER—Vols. 1, 2 and 3.

Bound Volumes for 1890 are now ready for delivery. Price $2.00 postage prepaid. Bound Volumes for 1888 and 1889 still on hand, at same price.

Unbound Volumes of each year now ready, and mailed to any address in the United States, Canada and Mexico at regular subscription rate of $1.00 a year. Single Copies, 10 cents each.

Address, THE LOCOMOTIVE ENGINEER, 96 Fulton St., New York.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

AIR BRAKE PRACTICE.

THIRD EDITION.

BY J. E. PHELAN.

A book of 107 pages which can be carried in the pocket, and which covers the practical work of operating Air Brakes intelligently, explaining how and why they do certain things under certain manipulations and not under others. Tells how to handle, inspect, repair and adjust all the different systems of air brakes in use. Explains both the Hodge and Stevens System of Levers. Contains full directions for applying Driving Brakes to old equipment, and gives road kinks that are alone worth the price of the book.

Two large Removable Plates show the latest form of Air Brakes, complete and in detail, in perspective and section, so plainly that no one can fail to understand.

SENT POSTPAID TO ANY ADDRESS FOR $1.25.

☞ If no one has got up a club in your neighborhood for this book, and you will take the trouble to gather in anywhere from 10 to 100 subscribers, write for Club Rate Circular.

TOOLS FOR LOCOMOTIVE BOILER WORK.

The Cut shows our PATENT PLATE BENDING ROLLS,

Specially adapted to this work.

The HILLES & JONES CO., M'frs., WILMINGTON, DEL.

Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast iron bedplate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started, stopped or reversed instantly.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formula patented by Mr. G. W. Lord. For decree of court, etc., address G. W. LORD, 830 Union Street, Philadelphia, Pa.

Engines of the "Royal Blue"—The Fastest Train in America.

What is popularly known as "American conditions" has prevented the attainment of very high speed for very long distances, and, while some of the fastest time ever made for a few miles has been credited to American locomotives, the English have always run their express trains faster than we have

The fastest trains now running in America are the five-hour "Royal Blue" trains between New York and Washington, a distance of 227.6 miles, being run at an average speed of 45.5 miles per hour, but the conditions calling for more than 60 miles per hour for much of the way. These trains are run by the Central Railroad of New Jersey, the Philadelphia & Reading, and the Baltimore & Ohio, and run over portions of the three roads to reach the national capital from the greatest metropolis of the continent. Thirty-one miles, from New York to Bound Brook over the C. R. R. of N. J., sixty miles over the Reading from Bound Brook to Philadelphia, and the remainder over the B. & O., are the proportions of trackage operated by each road. The "conditions" to be met are extremely difficult for the attainment of high average speeds, and that these trains are so seldom late is a credit to the respective operating departments, and the engine and train men.

To begin with, the Central road has the ferry from New York to Jersey City—one mile, and across the crowded North River. This occupies twelve minutes from the time the five-hour time is commenced until the train is actually started from Jersey City.

The road is four-tracked, and protected with automatic block signals, but runs through many small places, not extra well protected, has a number of heavy curves, a drawbridge over Newark Bay over 10,000 feet long, a grade crossing of the P. R. R. at Elizabeth, and an undulating road with grades averaging from ten to forty feet per mile. The fastest trains always stop at Elizabeth for passengers, and at Plainfield on signal, and yet they are required to run the 30.1 miles in 36 minutes—52 miles per hour.

The Reading road is a double track, not protected by block signals. It is rather crooked in places, but has very slight grades. The fast trains stop at Trenton Junction, Jenkintown, and Girard avenue, make a circuitous entry into Philadelphia, and cover the intervening 60 miles in 73 minutes—50 miles per hour

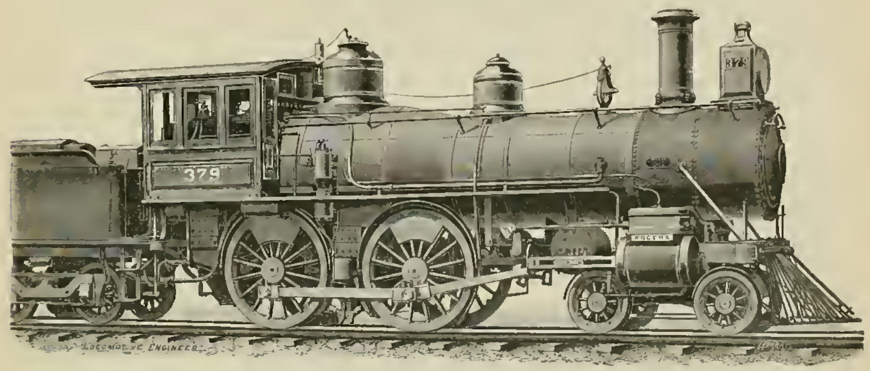
The B & O. road is double track, and comparatively new The track is good, but has numerous curves The road is hilly, the grades averaging about 20 feet, the heaviest being 42; but the Philadelphia division starts and stops at tide-water The trains always stop at Wilmington, and, on signal, at one other station At Havre de Grace they must run slowly over a 6,000-foot bridge. At Canton the engine and train are run upon a large transfer boat, and are ferried more than a mile across the river, when, for three miles, the train runs through yards and the streets of the city to the Baltimore station, into which it heads Another engine takes hold of it from behind and pulls it to Washington, 40 miles away, making one stop *en route*. The fast trains are taken over this piece of difficult road for a distance of 136 miles in 2 hours and 55 minutes, or at the average speed of 47 miles per hour.

So the reader can plainly see that to make this kind of time, including all stops, ferries and slow-downs to scoop water, etc., that all of the roads have to run the trains considerably more than a mile per minute between stations.

THE TRAINS

The "Royal Blue" trains are a step in the right direction toward the attainment of high speed. They are lighter than the usual trains on American railroads Only four cars are hauled on the fastest trains. They are two day coaches, one parlor car and a dining car, with a small baggage compartment in one end. The cars are painted "Royal Blue"—whatever shade that is—and on the sides, in the center of each, there is painted a large and handsome shield, showing the State arms of New Jersey, Pennsylvania, Delaware or Maryland—the States through which the trains are run, these trains are vestibuled throughout, and make a very handsome appearance.

The interior is finished in mahogany. All the cars are provided with a commodious smoking room and a wash-room for gentlemen, and a large toilet-room for ladies, just as sleeping cars are. They are lighted by the Pintsch system of gas lights, are steam-heated throughout, and a porter is provided for each car. In the day coaches the Hale & Kilburn seats are used, which are more comfortable, but not quite so elaborate as the pivoted sofa



ENGINES OF THE FASTEST TRAIN IN AMERICA

chairs in the parlor car—for the use of which a small extra charge is made.

The diner is somewhat smaller than those usually seen on long runs. They are elegant, however, and the service as good as the best. They have six tables, seating twenty-four persons. The kitchen is near the center of the car, and beyond it there is a short baggage compartment.

The coaches are 65 feet long, and weigh 70,000 pounds each. The parlor car is the same length, weighing 74,000 pounds, and the diner weighs 80,000, making the total weight of train 294,000 pounds. These trains were built by Pullman, and are the joint property of the three lines operating them.

THE LOCOMOTIVES.

Each road uses a different locomotive. All of them give good results, and doubtless the officers of each road think they have the best.

The engraving on the first page shows the class of locomotive used by the Central of New Jersey. They are typical American locomotives, originally designed by the Baldwin Locomotive Works, by whom the greater number have been built. The one shown was built by the Rogers Locomotive and Machine Works, at Paterson, N J. These engines are of the following general dimensions:

Cylinders, 19''x24''.
Diam. of drivers 78'', centers 62''.
Engine truck wheels 38'' diameter, Paige steel tired.
Tender truck wheels 36'' diameter, Paige steel tired.
Steam ports, 1⅝''x18''.
Exhaust ports, 3''x16''.
Bridges, 1¼''
Allen-Richardson valves, 5½'' travel, ⅞'' outside lap, 1/16'' inside lap.
Driving axles journals 7½''x8½'' (have been increased on later engines now building at Cooke's).
Engine truck axle journals 5½''x8''
Tender truck axle journals 5''x8''
Boiler, 56'' wagon top, ½'' steel plates, shallow fire-box for anthracite coal with grate of waters tubes and pull bars. Box 125'' long x42'' wide x53'' deep front x48'' deep back. Tube plate, ½'' crown; sides and back all ⅜'' steel. Crown bars, 230 flues 2'' outside diameter 144½'' long No. 13 w. g. Working pressure 145 lbs. per sq. in. Dry pipe, wrought-iron, 8'' outside diameter.

Weight on drivers	81,004
" " truck	28,856
" tender	77,050
Total weight	187,810 lbs.

Rigid wheel base, 7' 6''; total wheel base, 21' 8''. Tender fitted with water scoop.

The writer recently rode on one of these engines on the fastest train between Jersey City and Bound Brook. The yard limits were passed at a comparatively slow rate of speed. Three slow downs occurred, and two stops, yet the run was made on time. More than 10 miles out of the 31 were made at a speed of over one mile per minute, and on the straight track, slightly down grade, into Bound Brook, we made two consecutive miles in 51 seconds each—a speed of 70 miles per hour. This was the highest speed attained on the trip over the three roads. These engines burn anthracite coal, carry 145 pounds of steam, and hold their steam pretty good.

This run is so short that it is not necessary to take water, but enough coal is carried for two round trips. If the engines were stripped to do their best, a great deal of dead weight in fuel and water could be taken off.

Only three minutes are allowed at Bound Brook, Philadelphia and Baltimore to change engines, and the men are so spry that no delays occur on this account.

The train was pulled from Bound Brook to Philadelphia by a Wootten fire-box, eight-wheeler, built by Baldwins. These engines differ in form from ordinary engines only in the peculiar form of boiler, having a very wide fire-box, with the grates above the wheels. We did not get a chance to ride on this engine, but timed her over the whole division. She made exceptionally good time all the way, and between Langhorne and Philmont was only using 56 seconds to get over a mile of track—this is 64 miles per hour. She ran for many miles within a second of a mile per minute.

The B. & O. engines shown in our full-page supplement are the latest example of fast express engines in this country. They are large for the trains hauled, but it takes power to get high speeds. The introduction of 78-inch wheels was a step in the right direction. Probably no better or faster engines than these can be found on the continent. The following are the complete specifications furnished by the builders, the Baldwin Locomotive Works, Philadelphia, Pa.:

Class 8—34 C, 34 to 36.] [Drawing No. 4.

SPECIFICATION

No. 5,497.

Of a high-speed passenger locomotive engine, having two pairs of coupled wheels, and a four-wheeled center-bearing truck, for the Baltimore & Ohio Railroad Company

DIMENSIONS.

Cylinders, 20 inches diameter and 24 inches stroke.

Driving wheels, 78 inches diameter.

Gauge, 4 feet 8½ inches.

Fuel, soft coal and coke.

Total wheel base, 21 feet 11 inches.

Driving wheel base, 7 feet 6 inches.

Total wheel base of locomotive and tender, 46 feet 10 inches.

WEIGHT.

Weight in working order, total 116,000 pounds, on driving wheels, 76,000 pounds.

Weight of tender, with fuel and water, about 70,000 pounds.

BOILER.

Made throughout of flange plates of homogeneous cast-steel, ½ inch thick, riveted with ⅞ inch rivets, placed not over 3 inches from center to center, all longitudinal seams butt-jointed, with double covering strips. Throat sheet ⅝ inch thick. Throat sheet ⅛ of an inch thicker than shell of boiler, to prevent undue thinning where flanged. All parts well and thoroughly stayed, and extra pieces riveted to inside of side sheet, providing double thickness of metal for studs of expansion braces. All plates planed at edges, and calked with round-pointed calking tool, insuring plates against injury by chipping and calking with sharp-edged tools. Boiler tested with hot water to 180 pounds pressure per square inch, and by steam to at least 20 pounds above working pressure; working pressure, 140 pounds; waist, 58 inches in diameter at smoke-box end; made wagon top, and with one dome placed over wagon top; tubes, of iron, No 12 wire gauge, with copper ferrules on swaged ends in fire-box tube sheet, 251 in number, 2 inches in diameter, and 11 feet 10 inches in length.

Heating surface flues, 1,544 square feet.

Heating surface, fire-box, 143.45 square feet.

Total, 1,687.45 square feet.

Height to center of boiler, 8 feet 3½ inches.

Height to highest part of boiler, 11 feet 5⅝ inches.

Height to top of stack, 14 feet 8⅞ inches.

Fire box, 107¼ inches long, and 33⅝ inches wide inside. F., 67⅝ inches deep; B., 52⅝ inches deep; of homogeneous cast steel, all plate thoroughly annealed after flanging; side and back sheets, 5/16 inch thick, crown sheets, ⅜ inch thick; flue sheet, ½ inch thick, water space, 3 inches sides and back, 4 inches front; stay bolts, ⅞ inch diameter, screwed and riveted to sheet, and not over 4½ inches from center to center, sliding fire-door opening, formed by flanging and riveting together the inner and outer sheets; tool guard to be cast on lower part of fire-door frame. Fire-brick arch, with crown sheet, supported by crown bars, each made of two pieces of wrought-iron, 5½ inches by ⅝ inch, set 1¼ inches above crown, placed not over 4½ inches from center to center, and bearing on side sheets. Crown bar bolts, not over 4½ inches from center to center, screwed through crown sheet, with head on under side. Crown stayed by braces to dome and outside shell of boiler.

Cleaning plugs in corners of fire-box.

Balanced puppet throttle valve of cast-iron, in vertical arm of dry pipe.

Grates, rocking finger.

Ash-pan, with double dampers.

Straight pattern, steel base, smoke-stack.

Smoke-box, extended, with netting, deflecting plate and spark ejector. Nozzles, double, 3¼'' diameter.

FRAMES.

Of hammered iron, made in two sections.

Front rails bolted and keyed to main frames, and with front and back lugs forged on for cylinder connections.

Pedestals forged solid with main frames, and protected from wear of boxes by cast-iron gibs and wedges. Pedestal cap lugged and bolted to bottom of pedestals.

ENGINE TRUCK.

Center bearing swiveling, four-wheeled truck. Truck frame of wrought or cast-iron, with braces of wrought iron; fitted with fixed center bearing

Four cast-iron center, steel-tired wheels, 36 inches diameter.

Axles of hammered iron, with journals 5 inches diameter and 10 inches long.

Springs of crucible cast-steel, tempered in oil, connected by equalizing beams resting on top of boxes.

MACHINERY.

Of close-grained iron, as hard as can be worked, each cylinder cast in one piece, with half saddle, placed horizontally; right and left-hand cylinders reversible and interchangeable, accurately planed, fitted and bolted together in the most approved manner. Valve face and steam chest seat raised above face of cylinder to allow for wear. Steam ports, 19x1⅝ inches; exhaust ports, 19x2¾ inches; bridges, 1¼ inches. Cylinders oiled by Detroit sight-feed lubricator, placed in cab, and connected to steam chests by copper pipes running under jacket. Pipes proved to 200 pounds pressure.

Two Sellers re-starting injectors, No. 10.

U. S. metallic packing for piston rod and valve stems.

Pistons of cast-iron, fitted with approved form of steam packing.

Piston rods of iron or steel, ground and keyed to crossheads, and securely fastened to pistons.

Guides, double bar style, of steel, fitted to wrought-iron guide yoke.

Crossheads of cast-steel, with brass bearings.

Shifting-link motion, links, sliding blocks, pins, lifting links, and eccentric rod jaws made of hammered iron, well case-hardened; sliding blocks, with long flanges, to give ample wearing surface; rock shaft of wrought-iron; reverse shaft of wrought-iron; slide valves, Morse balanced, with vacuum valves.

Driving wheels, four in number, 78 inches in diameter; centers of cast-iron, turned to 72 inches diameter.

Tires of cast-steel, 3 inches thick when finished; back pair flanged, 5⅝ inches wide; front pair plain, 7¼ inches wide.

Axles of hammered iron; journals, 8 inches diameter and 9½ inches long.

Driving-boxes of cast-iron, with brass bearings.

Springs of crucible cast steel, tempered in oil.

Equalizing beams of wrought-iron.

Connecting and parallel rods of steel or hammered iron. Connecting rods forged solid. Parallel rods with solid ends and heavy brass bushings. Bushings put in by hydraulic press, and well secured from turning in rod.

Lubrication of all bearings carefully provided for, and oil-cups attached where required.

Adjustable needle oil-cups on rods and guides

Wrist-pins of wrought-iron.

Feed water supplied by two 10½ Sellers 1887 injectors.

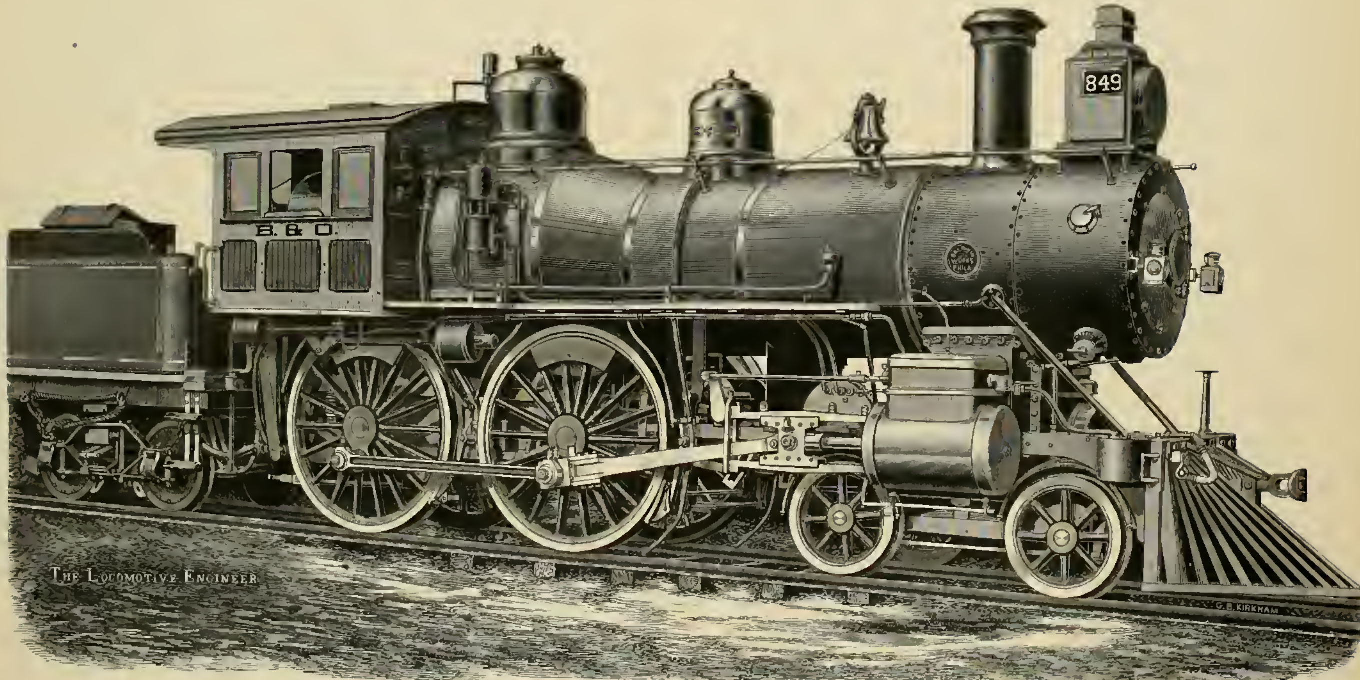
ACCESSORIES.

Cab with ventilator, substantially built of clear, yellow pine, well finished, and fitted together with joint-bolts and corner plates. To be provided with suitable windows and doors, conveniently arranged, and glazed with first-quality double American crystal glass.

Pilot of wood braced with iron, with wrought-iron bull nose.

TOOLS.

Engine to be furnished with one 28 sand-box, stand for head-lamp, bell, whistle, blow off cock, blower and two 3'' Crosby safety-valves, steam gauge, cab lamp, gauge cocks; also a complete set of tools, consisting of two heavy jack-screws and levers, one heavy pinch bar with steel point and heel, complete set of wrenches to fit all nuts and bolts on engine, including two monkey-wrenches, one set of driving-box packing-tools, one machinist's hammer, one soft hammer, three cold chisels (two flat and one cape), one long-spout quart oil-can, one two-gallon oil-can, one tallow-pot, one torch, engineer's arm-rest, one extra fusible plug, one bell cord, cab seats, cab seat cushions, one



LOCOMOTIVE OF THE "ROYAL BLUE"—THE FASTEST TRAIN IN AMERICA.

DESIGNED BY THE BALDWIN LOCOMOTIVE WORKS.
PHILADELPHIA, PA.

poker, one scraper, one slice bar, and one scoop shovel.

Headlight to be furnished by R B Co.

Westinghouse automatic brake, applying to forward side of each driving wheel, and to tender wheels. Westinghouse train signal

FINISH.

Cylinders lagged with wood and neatly cased with iron, painted. Cylinder head covers of hydraulic-forged steel, polished. Steam chests with cast-iron tops ; bodies cased with iron, painted. Dome lagged with wood, with iron, painted, casing on body and cast-iron top and bottom rings.

Hand-rails of iron. Running board nosings of angle iron. Wheel cover nosings of iron. Boiler lagged with wood, neatly jacketed, and secured by iron bands.

GENERAL FEATURES OF CONSTRUCTION

All principal parts of engine accurately fitted to gauges and templates, and thoroughly interchangeable.

All finished movable nuts and all wearing surfaces of machinery made of steel, or iron case-hardened.

All wearing brasses made of phosphor bronze or ingot copper and tin, alloyed in proportion to give best mixture for wearing bearings.

All threads on bolts to United States standard.

TENDER.

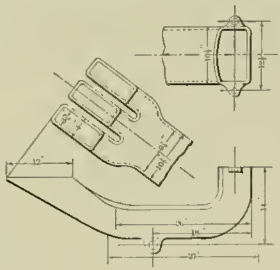
Provided with water scoop and Janney coupler. Tank of steel or iron, strongly put together, with angle-iron corners and well braced Top, inside, and bottom plates ¼" thick, outside plates $\frac{3}{16}$" thick, riveted with three-eighths inch rivets, one and one-quarter inches pitch Capacity 3,500 gallons (of 231 cubic inches).

Shape of tank, U-square top.

box end of the tubes, which must be scraped off.

One of the best recommendations of these engines is that the men like them; they all say that they ride well, steam well and can "get there" The only criticism from an engineman that we heard, and it seems a reasonable one, was that the roof of the cab was six or eight inches too low for comfort and a good lookout, but the height at the eaves is regulated, we understand, by the size of some tunnels on the line; the center, however, could easily be raised.

The using of a bald tire ahead is done to conform to the ideas of those in authority on the road, and not those of the builders; there is little doubt that the engine would be safer, easier on the track and on herself with flanged tires on the forward drivers. These engines have repeatedly made the run from Washington to Baltimore, 40 miles, in thirty-nine minutes, and have made up fourteen



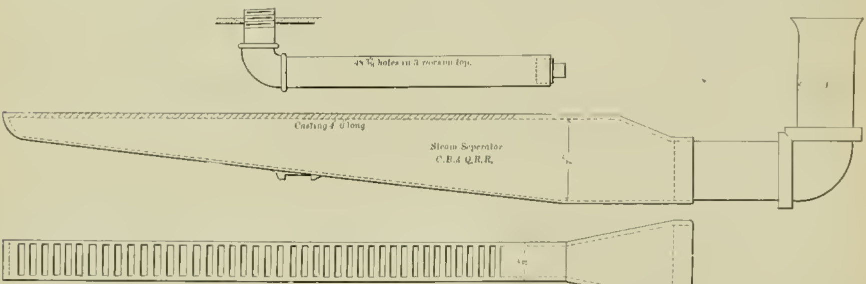
equal of an ocean steamer for convenience and elegance, a veritable traveling palace hotel—the "Royal Blue" aims more to comfort and cleanliness, a light train, powerful engines and fast time, and it is to be hoped is but the beginning of a regular move in this direction by many of our roads running between large cities.

To our friends abroad who are inclined to pick up all odd or outlandish forms of experimental locomotives made in this country, and criticise them as typical American engines, we can say the B. & O engine shown herewith is the latest and best form of American express locomotives built and operated in this country.

Curious Devices to Put into Locomotive Boilers.

Much that is interesting, amusing and instructive has been given to the world by men who have made a study of the peculiarities of different species of animals, birds, reptiles, insects or plants—when man knows what a certain animal or plant or element will do under certain circumstances he can figure intelligently on the outcome of any plans he has that deal with the subject or thing the habits of which are known—if he is in the dark on the subject he is liable to make several grotesque devices or expensive mistakes before he finds out which way the animal will jump when approached.

It has occurred to us that some student of nature, art or science might do a good thing by giving us something on the habits and peculiarity of steam. What is it, anyhow? Does it swim or fly? Is it hot or cold? Can it be tamed and taught to do tricks? Can it be taught to crawl through a gimlet hole, and to dodge the bore of an auger? How does it produce and rear its young? What will make it



CURIOUS DEVICES FOR BOILERS.

Tender frame substantially built of oak, strongly braced.

Two four-wheeled center-bearing trucks, made with wrought-iron side-bars and two cross-beams of wood or channel iron; additional bearings at sides of back truck Springs, crucible cast-steel, tempered in oil.

Boies steel tired wheels thirty-six inches diameter. Brakes on both trucks.

Axles of hammered iron or steel ; outside journals 3¾ inches diameter and seven inches long Oil-tight boxes with brass bearings.

We have published the complete specifications of this engine because it will be interesting to preserve with the engraving, and serve to explain it.

On our trip over the B. & O this engine made many miles above the rate of sixty miles per hour, and in one instance covered two miles in one minute and forty-eight seconds—66 miles per hour.

These engines burn coke with a slight mixture of soft coal to insure its quickly kindling, about one ton of soft coal is taken in the bottom of tender and the tank then filled with coke, the fireman using the coal when and where needed. This fuel burns nicely, emitting no smoke, and giving off only a light dust, thus by the two first roads using hard coal and this one coke the trains are kept clean and comfortable. To burn coke the brick arch had to be abandoned, as the coke has a endency to form a light, crusty clinker on the fire-

minutes on the run between Washington and Philadelphia.

The writer examined the train sheet on this division and found a detailed report of every minute's delay to the "Royal Blue" trains for a full month, and there was not a minute charged to these engines for any cause—this is remarkable service

None of the roads mentioned keep a very close record of fuel; to be sure so many buckets, or cars, or chutes are charged up to the engines, but at best it is guesswork, so that any figures given from the general fuel account would be misleading one way or the other—the men on the B & O. say that the new engines are the most economical machines in the service, and that they are capable of handling the present trains in twenty minutes better time than they do.

The worst feature in the Central of N J. engines is a small driving-box, they heat pretty regularly and all the fast engines have water pipes that throw a small stream of water on each box all the time the engine is running. The B & O.'s have an inch longer box and don't turn the axle in it so many times in a mile, and give no trouble from heating.

The introduction of the "Royal Blue" trains is the first reasonable move made in America toward faster travel. The American ideal seems to have been for extra comfort, elegance and weight for the best trains—the Pennsylvania Limited is the

weak and tired, and what will kill it? This last is the most important question.

Perhaps if something definite were known of its habits there would be more concerted action in the attempt to catch, tame and train it for useful work, instead of so much indiscriminate killing just for the hide and tallow.

Some of the latest steam traps are shown herewith; they have peculiar functions to perform, or else C., B & Q. steam has peculiar habits. The device shown is called a "steam separator"—not a threshing machine—and there are a pair of them in each new boiler put on that road. They are about eight feet long, over all, and are supported in the boiler by heavy loops of strap-iron from the top of shell; they have forty-two slits in their top, each slit being one-quarter of an inch wide and 2⅜" long; these are cast in, and are on an angle, as shown. These are put in the boiler so that this angle slotted water goose extends back over the crown sheet, and the open pipe at the other end extends up into the dome. The form shown is that used for engines with Belpaire fire-box where the wagon top is slightly higher than the barrel of boiler, where dome is located, and this goose is supposed to carry the live steam around to keep the throttle valve dry and happy.

Another breed of the same species with a perfectly straight top are used in straight boilers—it's curious that steam won't go along the top of the boiler to the dome, and will crawl through a sifter and up a pipe to the same place.

There is a theory about the impinging of the wet steam upon the south sides of those angled slots, and the slipping up and falling back into the boiler of the wet part, and the escape of dry and dusty steam to the dome, but we are not capable of understanding it. At the base of the dome there is an iron plate ⅜ thick, made in halves and punctured copiously with ⅛ holes, we are unable to state the exact use of this screen door, it may be to prevent the escape of the dry steam from the separator, or to prevent wet and low caste steam from coming up from the slums and mixing with the pure, refined article—probably the latter.

New engines of the C., B. & Q. also have a steam catcher, shown in Fig. 2, to supply steam to the fountain in the cab, this is simply a piece of pipe drilled at the top with forty-eight small holes; this device has some merit, but takes steam lower in the boiler than would a direct connection, and will, in all probability, be as bad if the water in boiler surges badly in quick stops; when there is no steam being used through the cab cocks, this pipe will fill with water, and go where it can do no good, and may do harm, through the first cock that is opened. We are unable to see—from our meager knowledge of the habits of steam—why each of these enormous watering troughs will not fill with water when the engine is at rest, only to be thrown out at the top of the dome when a current is established. It would seem to a layman that if some of these instruments of torture were removed, that reasonably dry steam could be induced to crawl along the upper part of the boiler—like a fly—and enter the dome of its own free will and accord.

It is improbable that it is the intention to carry water so high in these boilers that there will be no steam room between it and the top of the shell. If the dome of these boilers was removed altogether, and these two steam driers could be run tandem, and were connected direct to the dry pipe, and the throttle placed in it, far drier steam could be furnished than that now dried in the separator, and delivered to the hatchery—the dome.

The closer the steam can be kept to the fire, and in contact with the circulating water, the hotter and drier it will be.

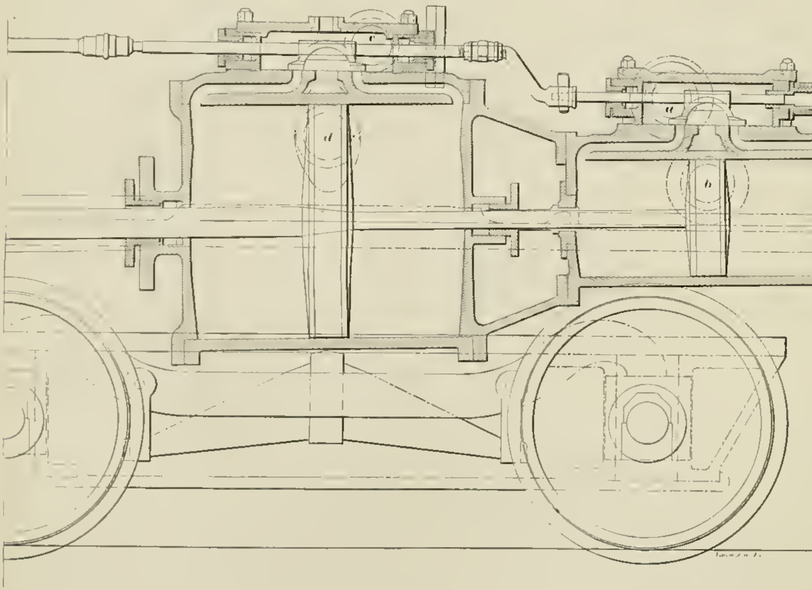
The upper figure shows a device used on the great Pennsylvania's new Belpaire boilers. It is called the "trap for sewer gas" by the men, and is a sort of a Black Maria for conveying to the proper asylum demented, imbecile or idiotic steam that don't know enough to come in out of the wet when it has all the chance in the world.

Schemes like these have been tried for years, and will be tried for years to come, and we really think something on the habits of steam during its spawning season would not be amiss.

The First Compound Locomotive in America.

Since the compound system for locomotives has been forced upon the attention of the railway mechanics of the world, there has been more or less of a rivalry among certain inventors to be known as the originators of the system, and not a few have contended for the distinction of building the first in America.

We believe that the engravings shown herewith, from the original drawings, represent the really first in America, and, perhaps, in the world, and this was no odd or obsolete design, but a mechanical affair, and one that has some advantages over any other compound yet built; moreover, this compound locomotive was in actual service for some years.



The first compound marine engines used in this country were designed and built at the Shepard Iron Works, Buffalo, N. Y., for the propeller "Susquehanna," which at once showed such results that many other boats had their engines rebuilt to compounds, and all the new power was of that pattern. At that time Mr. E. M. Ketchum was draftsman for these works, he made the drawings for the first compound marine engine, and also has the distinction of planning the first compound locomotive.

Mr. Ketchum is now employed in the custom house, at Buffalo, and has many of the original drawings of compound engines, and was so kind as to loan the original locomotive drawing, from which these cuts were made. The plans were drawn in 1866, and early in 1867 the Erie Railroad Company sent a yard engine to the Shepard Iron Works to be changed into a compound. The cylinders were taken off, and two new ones substituted on each side, making a tandem compound.

The high-pressure cylinder was fast to the head of the low-pressure cylinder, and also, by a side flange, to the frame, the piston rod was extended into it, and, by an ingenious device shown plainly in the cut, one gland was made to pack the piston rod in both cylinders.

The valve stem was extended beyond the yoke, and through the front of the chest, and by an offset connection drove the forward valve, the high-pressure cylinders are 12x24, the low-pressure cylinders being 24x24.

This plan admitted of the changing of old locomotives without disturbing their valve gear, cross-heads, rods or any other part except cylinders and saddles.

The plan view shows the arrangement of the pipes; steam was taken from the steam pipe in front end by pipe *a* direct to side of chest, as shown at *a* in sectional view, and was conducted from exhaust passage *b* through pipe *b* (in plan) to the chest of the low-pressure cylinder, the exhaust from the low pressure cylinder escaping through the regular nozzle. With this plan the work on each side of the engine was exactly the same; the breaking of one chest or one cylinder did not call for the throwing away of the others on that side, and no receiver was required.

This engine ran for about two years in the yard at Buffalo, and went from there to Hornellsville, where she did further service, but was finally broken up. We are unable to find that any record of this engine's work was kept, and little, or no experimenting was done to determine what her comparative fuel consumption was.

The locomotive was at a standstill just at that time, and the compound principle was not understood; on the road it was simply "a new contraption to make extra trouble." The designer and his engine were ahead of the age, and had to wait; the compound locomotive was a long time getting here, but she has come to stay.

A locomotive built on this plan to-day would be far from a bad design, and would have some advantages over any compound now built in this country.

The original patents, eight in number, were granted to Perry and Lay, in 1867.

The Canadian Pacific recently received dispatches that the "Empress of India," the first steamer of the road sent on the round-the-world trip, had arrived on exact time at Hong Kong. The vessel remains at that port two weeks, and then starts on the last lap of the journey for Vancouver. The "Empress of Japan" sails from Liverpool April 11th.

Steam Jacketing.

A correspondent who, some time ago, sent us a plan for a compound locomotive for our opinion on its merits, writes

* * * "As you will remember, I had an internal high-pressure cylinder, surrounded by the low-pressure cylinder, with a space like a steam jacket, having a low pressure piston in form of a ring. You thought I did wrong in blanketing my high pressure cylinder with exhaust steam. I have been looking over cut of triple expansion Corliss engine in *Power*. His engine is steam-jacketed over heads and barrels of cylinders, and the steam passes *through the jacket to the cylinders*. It looks to me like a worse case than mine would be for condensation, and, to judge from the loss of temperature in contact with so many surfaces, there was not much left for the pistons—yet the engine showed up 1,000 horse-power."

The stationary engine referred to, by making the jacket on the cylinder virtually part of the steam pipe, maintain the temperature of the cylinder the same inside and out, while our correspondent proposal to put live steam into his high-pressure cylinder, the outside being in direct contact with exhaust steam of a much lower temperature, there would be a constant loss of heat

The advantages or disadvantages of steam jacketing, in every form and shape, is very much in the dark, and no very exact knowledge exists on the subject In one instance it shows apparent economy, while in another it shows loss But, for obvious reasons, in no case can economy be attained by the use of steam in jackets of a lower temperature than that used in the cylinders.

Cover the Slot.

Where a valve rod is very short, as on ten-wheelers, with long eccentric blades, a knuckle joint is objectionable, and will soon wear badly, it is, moreover, little better than a stiff rod, as far as its wearing the packing is concerned A great many engines are built with slotted boss on the valve rod, in which a box on the end of the rocker works, the rod having a bearing on the yoke back of the rocker connection

Where such a construction is resorted to, the flanges of the box should be so deep as to entirely cover the slot in the rod in all positions This will keep out dirt and cinders, and prevent the careless leaving of wrenches, nuts, or packing hooks in the convenient slot, to say nothing of the security of fingers in case the reverse lever was moved while some one was wiping in the vicinity of the slot

Norfolk & Western Ideas.

On some heavy engines recently turned out of the Rogers Works for the Norfolk & Western they use a reverse lever whose latch engages with a screw instead of the common sector or quadrant; the lower end of the lever is slotted to admit of the lever rising and falling slightly, the screw being straight. The lever can be handled the same as a plain lever, and the runner can also adjust the point of cut-off by the screw, which is operated by a hand-wheel on the back end.

These engines have two blower valves, one each side of the boiler head, and the cylinder oil-cups are located one on each side, this is a bad cab arrangement; an extended handle would have made the blower accessible to the engineer without putting in an extra valve, and it would be far better to put the two oil cups together, as it is entirely unnecessary for both men to oil valves at one time, taking their attention from their work, the fireman can oil two almost as easy as one, and the engineer ought to have his attention on the tracks and signals or his brake These engines have the Belpaire boiler, and ahead of the cab on the flat wagon top the angle valves to the injector steam pipes are located—the injectors being located near the side of wagon top—but these valves are connected to the opposite injectors, the right-hand valve supplying the left injector, and the left valve the right injector, this calls for a big cross of crooked copper pipes on the top of the fire-box without any apparent good to come of it

Going Up.

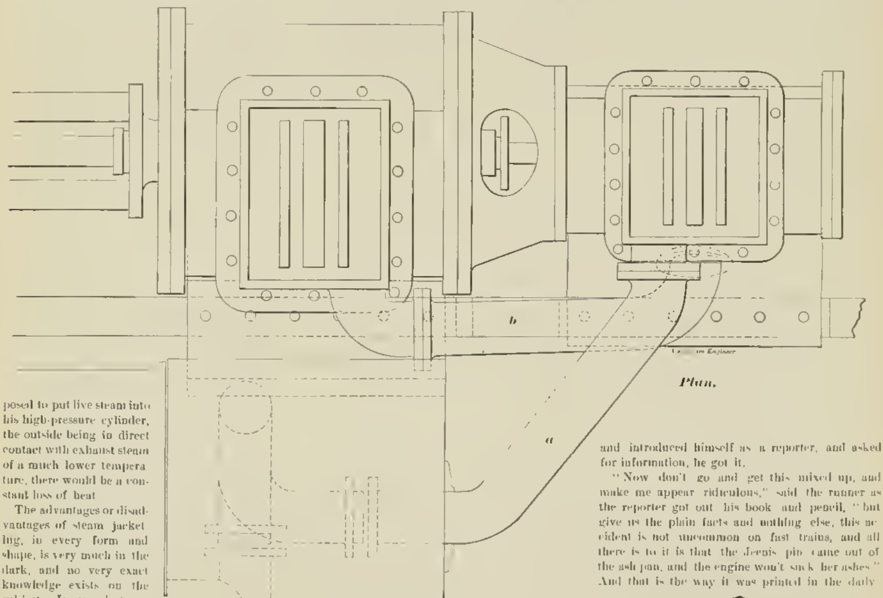
Joseph Billingham, traveling engineer of the Gulf, Colorado & Santa Fe road, has been promoted to the position of master mechanic at Temple, Texas. Bro. Billingham is a practical runner, and a member of the Brotherhood Engineer James McDonough, who represented his division at the Pittsburgh convention last fall, has been made travelling engineer to fill the place left open by Mr. Billingham. Of this appointment General Master Mechanic Ward says in his bulletin

His duties will be to inspect and report the condition of all engines, to examine the methods of firing, and instruct firemen in their duties concerning the consumption of coal, oil and waste, etc He will see that engines and tenders are kept clean, and that tools and small stores are in their proper places; in fact, he will have general supervision while on an engine, and his instructions will be respected and obeyed by engineers and firemen He is authorized to inspect all engine houses, and require the same kept in good condition, and the surroundings neat and clean. He will receive his instructions from the master mechanic, and report all cases of neglect or extravagance to the master mechanic or the division master mechanic Foremen of engine houses, engineers, and all concerned are requested to render all the assistance in their power to enable him to carry out his instructions

A Bad Breakdown.

Not long ago a Pennsylvania engineer had to stop on the road and disconnect his engine, and, of course, the passengers crowded around to see what was the matter This particular engineer had been cured of the chills by reading daily paper reports of accidents and railroad happenings, and felt grateful to the average reporter for the fun so unconsciously given. So when a young man came up and introduced himself as a reporter, and asked for information, he got it.

"Now don't go and get this mixed up, and make me appear ridiculous," said the runner as the reporter got out his book and pencil, "but give us the plain facts and nothing else, this accident is not uncommon on fast trains, and all there is to it is that the Jenuis pin came out of the ash pan, and the engine won't suck her ashes" And that is the way it was printed in the daily



FIRST COMPOUND IN AMERICA

Some Truth About War.

The slightest international question that arises is made the basis for a talk about war Many men are foolish enough to express the opinion that a war would be a "good thing" It would make business lively. Does the thinking citizen realize that for all the "lively business" he or his posterity must pay for with a heavy interest? Only a fool or a knave would wish for a war The money loaners of the world are the ones who profit by war The ruling classes make war an aid in suppressing the masses As long as they are able to create wars, they are safe from the democratic masses

What the masses of England, Germany and the United States have the most to fear in the future is that the moneyed aristocracy will plunge them into a war that will check or destroy the advance they have made in their own emancipation It will be the last desperate resort to stem the tendencies of the age. Workingmen should never let the patriotic cry blind them from looking below the surface and learn why it is necessary The aristocracies of the world would gladly bring on war, that their position might be more secure Compel them to do the fighting and there would be no war.—*U P Employes Magazine.*

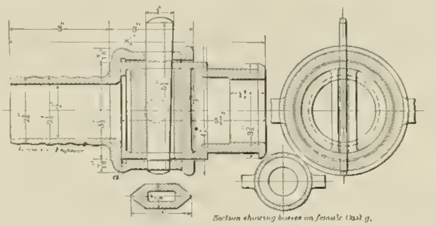
Standard Hose and Feed Pipe Coupling of the Norfolk & Western.

The accompanying engraving makes plain the details of one of the simplest and best water hose connections we have seen.

The usual threaded form with rubber gasket, cone strainer and coal pick brands on its ears, is familiar, and shortcomings well known. It is hard to keep tight, and a mean thing to work at when in a hurry or in snow

The coupling here shown is very simple, and is very quickly and easily opened and closed, requires no gasket, and there are no threads to cross.

As will be seen, the female casting is smooth, with two slots through it for a key, and has bosses to facilitate getting it off or turning to match the keyway. The male casting has a rib across it through which a keyway is made; this keyway, of course, does not open to the water space. When the hose coupling is shoved over the male casting, which is screwed to the feed pipe on the engine, a joint is made at *a*, and the key is dropped into the keyway, and, being of slight taper, a light tap with a hammer secures it against possibility of jarring loose. The key is easily loosened by a tap of the hammer from underneath, and the coupling pulled apart.



Standard Hose and Feed Pipe Coupling.

This device has been in use for some years on the Norfolk & Western, with satisfactory results

How to Prevent Streaking of Dome Casing and Jackets.

To any one who has any pride at all, be he fireman, engineer or master mechanic, it is always a source of annoyance to see a new dome casing or boiler jacket streaked up with some compound from inside, that runs from the seams down, and in Russia iron generally takes the finish off and leaves a white streak.

Jackets are almost invariably put on so that the lap is from the top, the upper sheet outside, like shingles. This is to make it shed water from the outside, but rain never does harm—it is all done by moisture from within.

If a boiler seam leaks it is worse, but if there is no leak there will be some moisture sweat out of the lagging, and this is charged with some substance that cuts the planished surface of Russia iron like acid.

A little hot water running down outside a dome casing cuts off a strip of paint like a knife.

All this trouble can be avoided by putting the jacket and casings on right The upper sheet of a jacket should always lap *under*; this will conduct all the moisture, acid, etc., to the bottom, where a few holes should be punched for its escape.

This plan of lapping jackets was in use years ago by the R. I. Locomotive Works and their jackets so made never streaked up.

The side sheet or band of dome and sand-box casings should go *outside* an internal lip on the cover or top, and *inside* the base casting.

Any master mechanic who will take the trouble to try this plan will be gratified at the results, and the firemen and engineers will rise up and call him blessed.

The streaking not only looks badly, but causes lots of unnecessary work.

The Serve's Ribbed Tube.

The accompanying illustration shows a cross section of actual size of a form of tube invented by a French engineer, and now in use in the boilers of some forty locomotives on the Paris, Lyons & Mediterranean Railroad, and also in several lines of river steamers in France; they are also being tested on the Metropolitan Railway of London.

Elaborate tests of the efficiency of these tubes have been made by the French Admiralty, and far better results claimed than can be had with plain tubes

This form of tube is much stronger to resist crushing strains, and the plain part or outside of the tube can be made thinner, the ribs absorb a very great quantity of heat, and convey it through the exterior to the water.

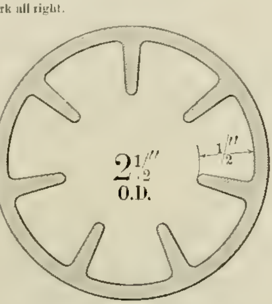
At first sight one would think that these ribs would get red-hot and burn out, but experience has proven that they do not.

To test this point, the manufacturers covered a steel tube, inside and outside, with an alloy of tin and antimony. They then surrounded this tube with a larger plain one, allowing but three-quarter inch water space between the two. A strong blast was kept going an entire day through the ribbed tube horizontally, the flame jet projecting three feet beyond the ends. Upon examination after the experiment, it was found that the heat had made no impression on the alloy, the melting point of which is far below the degree of heat necessary to produce a visible red on iron or steel.

This size, 2½", is the smallest size made in steel or iron; all sizes are made in copper and brass.

It is claimed that these tubes make extraordinarily strong hollow stay bolts. When used for this purpose the ends are thickened so as to admit of their being threaded. When used for flues the ribs are removed for three inches from the ends, to admit of expanding.

The manufacturers claim that no difficulty occurs in keeping these tubes clean with the ordinary appliance. Of course any blower flue cleaner would work all right.



The Serve's Ribbed Tube.

These tubes are made in Liverpool, England, and sold in this country by Charles W. Whitney, 81 Fulton street, this city.

We have in our possession a curious railroad ticket. It is in the shape of a two-dollar bill, and looks like one, having the regulation green back. The face reads: "The South Carolina Railroad Company. Fare Ticket. Good for the fare of two passengers twenty-five miles. Charleston, July 1st., 1873." It was engraved by the American Bank Note Company, and is a very nice piece of work. They have only been out of use for a few years.

The Pennsylvania engineer who rode at the head of General Sherman's funeral train, rode—or walked—behind the General in his march to the sea—"Endurin' de wah."

Correspondence

Why Emergency Valves Stick Open.

Editor The Locomotive Engineer:

Regarding the continuous flow of air to the exhaust in the quick-action triple valve or pressure-retaining valve when used, would say, the usual cause of this trouble is owing to the rubber-seated emergency valve being held unseated by cinders or other foreign matter. As a rule, obstructions of this character can be removed by giving the quick-action movement.

The most prolific source of cinder, sand, etc., in the triple, is owing to accumulations in the hose couplings as the result of the hose being left hanging down, and very much of this annoyance of leaking triples can be obviated if the hose were hung in the dummy coupling when not in use.

Chicago, Ill. K.

[A quick-action triple valve without a good strainer at train pipe connection is not complete and safe for service.]

The "Eddy Clocks"—"Practice" Tells Some Facts About Them.

Editor The Locomotive Engineer:

"Indicator" appears to be anxious to *learn something* about the "Eddy clocks," which goes to show that he is not entirely lost to the good things of this world. Will give him a few points that may do him good. For the past forty years the maker of these engines has been known to the railroad world as "Old Eddy," and the amount of *slurs* about him and his engines are "legion," and there were many who desired to show him and his employes how far behind the times they were, but the "unlucky" ones who met him on the "field of honor" with their "new-fangled notions" wish they had not.

About 1866 an M. M., who had lived near where the "clocks" were made, and whose engines came into close contact with them, became superintendent of the "Grant Locomotive Works," and it has been asserted that he did not enjoy a full night's sleep until they had secured an order to build some *fast* express engines to compete with the above "clocks." The old engineers who had always run the Eddy engines were so enthused over the new engines that they could hardly wait for their arrival.

They finally came, bringing a "streak of blow" of what they were going to do, and how sorry they were to hurt the "Old Man's" feelings, but it was their duty.

These engines were all that "Indicator" could wish, as far as theory and hand-books were concerned. Their dimensions were as follows: Cylinders, 16x24, wheels, 5½ feet, steam ports, 16 inches long, 1¼ wide, valve travel, 6 inches, and they were not loaded down with cast-iron cannon, but had a real dome all covered with brass, cylinders and steam chests ditto. In fact, they were the ideal locomotive for heavy fast passenger service, and were the envy of all engineers until they were put to work, and then their ability to perform the work required was found wanting.

A complete failure, as every knows who was in any way connected with the B. & A. R. R. at that time.

Mr. Eddy's nerves stood this shock much better than had been expected by such persons as think that a railroad company can haul their trains over the road with an indicator, assisted with a few hand-books of the locomotive in case of breakdown.

For some years the Eddy clock was allowed to tick along in its usual way, and when any one did slur them it was at low breath. But the best will sometimes forget, and when the Mogul "mania" became epidemic around Boston there appeared another chance to down the aforesaid "clocks" and their designer. After straining several brains to their utmost, the engine "Brighton" was brought forth. "A Mogul, the coming engine," which would reduce the cost of hauling freight wonderfully, on account of reducing the number of trains, etc.

At this time the clocks for freight service had 16 x26 cylinders with 5 foot wheel, four wheels connected, which was considered by the friends of the Mogul to be only a waste of money for freight use. The "Brighton" was to pull 50 per cent. more cars without any additional cost, either in fuel or labor. But when this Mogul got over to Pittsfield it was found that 13 cars up the hill to Dalton (8 miles) in 50 minutes was the best it could do, and that one of the Eddy freight engines could haul 14 cars up the same hill in less time, which was doubted by some of the "Mogul's" friends.

At this stage of the game the old man had a new passenger engine ready to turn out of the shop (the same as the one shown in your paper), and he took it over to Pittsfield to see what it would do pulling freight up the hill where the Mogul was working. This engine (the "Sacramento") was new, and he thought this a good chance to limber it up. It was coupled to 14 cars and went up the hill with them in thirty minutes, which was considered satisfactory by Mr. Eddy.

The Brighton was to haul thirty cars from Albany to Pittsfield, but was found to be only able to haul seventeen. After much figuring and theorizing according to the "Mogul" mania, it was found out that it was not the number of wheels that a locomotive had that did the work, but that the cylinders and boilers had a part to perform in getting the trains over the road. After this important discovery was made the Mogul's friends had some new engines made with larger cylinders and smaller wheels (same as the Brown), and were sure *that* was what would drive the Eddy engines off the railroad, not thinking it was possible to make a *larger* clock than was up to this time in use. But they reckoned without their host, as one can see by your article about that trial. Up to this time the fight was all one-sided, and would have continued so if a break-down had not occurred, which proved what an old 16x26 cylinder, 5-foot wheel clock could do on passenger train.

When the "Young Owl" train was put on, in the '70s, its time from Albany to Pittsfield was one hour and thirty-nine minutes, but it had never been made by any engine that they had tried on it. They had the Masons, the Grants, etc., which had never lost less than three minutes on the run; but when the regular engine gave out one night they coupled on the old Mississippi (a freight engine), which ran the train over in one hour and thirty-four minutes, this set some of the theorists to figuring once more.

Now "Indicator" wants to know why these engines are not still being made, and why steam ports of same size are not used at present, etc., etc.

Will say that it takes a much smarter man to answer a question than to ask it, and before trying to answer his question will ask one or two.

Why do ladies wear a large bird-cage on their back, called a bustle? why wear high-heeled shoes and a hundred other nonsensical things? I will tell you in one word, and that is—fashion, just fashion.

There were many good points about the Eddy clock that you did not mention in your article, and will give you a few of them. They were made with an independent valve seat which could be taken up when the chest was taken off, placed upon a planer to be faced the same as the valve, and required no hand-work. The frames were bolted solid to boiler, which prevented the necessity of repairing expansion braces with new bolts, etc., every time engine went into the shop. Their driving springs were arranged so they didn't "gouge" into the boiler all of the time, and they could be put in and taken out much easier than any other style yet seen. The boiler was without dome, which made it the strongest possible with the least cost. By using the small ports in cylinders it reduced the friction to a minimum, with least clearance. As long as the openings on cylinders are larger than the "exhaust nozzles," there will be no trouble in getting steam through them.

There is the same time to get steam into cylinder as there is to get it out of the exhaust nozzle, and the pressure is much greater when going in, and there is no use of steam pipes being larger than to allow what steam the boiler can make to pass through readily. There can be no more steam used in the cylinders than can be made in the boiler, and when the time arrives for the use of *facts* in place of *theory*, these engines will be known so well that "Indicator," with his books, will have plenty of time for a vacation—for it takes something besides *theory* to get heavy trains over mountain roads on time. "PRACTICE."

East Albany, N. Y.

A Wrong Idea of the Water-brake.

Editor The Locomotive Engineer:

There is an interesting little engine running here on the Deadwood Central, and she has a little water-brake. She is a 12x18 inch cylinder, three pairs drivers, no engine truck and no tender. She carries her water over the top of the boiler, and her coal under the seat-boxes. She has always burned wood until very recently, because it is only about two months now that she has had any connection with the outside world.

She was hauled here by ox teams, and has been pulling passenger between here and Lead City, 3½ miles, for about two years.

Her water-brake is attached the same as any other. A pipe tapped below water line of boiler leading from the cab is teed and taps the two exhaust cavities from the back side of the saddle. "Betsy" has seven per cent. grades to descend, 360 feet per mile. When she starts down, the engine is reversed, the water turned on, and cylinder cocks left closed; she shoots the water out her nozzle into the front end. They have found it necessary to put a drip pipe on the smoke arch to drain the water away.

The men who run her say she never gets any water into her cylinders on the valves. Her valves and cylinders wear as nice as any engine could. This is something different than is ordinarily claimed for the water-brake. Anything on the water-brake question will be of interest here.

Deadwood, So. Dak. BLACK HILLS

[If the lever is kept in the reverse position from direction the engine is running, she will certainly pump water from the exhaust passages to the steam chests and cylinders, and this is what the water-brake is for, to lubricate and cool the moving parts. The cylinder cocks should be opened, and no more water used than can be comfortably worked through them, the speed being regulated by changing the position of the reverse lever. There is great danger of knocking out cylinder heads by closing the cylinder cocks and handling the lever close to the center.]

Air-pump Lore—Hot Pipes—How to Start a Pump.

Editor The Locomotive Engineer:

That cut of mine last month didn't illustrate very well. I wanted to show that steam had cut out metal around the steam port and down into the space below the bushing, thence to the cylinder. E. C. N., of Mandan, N. D., had it right.

In reply to F. B. A., will say that I have seen pipes cherry red. It is caused by contracted passages, and too rapid pumping of the air. It is the friction of the air in the pipes that produces heat. This is usually the result of poor judgment, as a rule, of man in charge of pump.

An air-pump should be started just as you would your engine when getting her out of the house.

Of course it is sometimes necessary to run pumps fast, to supply leaks, etc., but there is no excuse where leaks could be cured by the simple use of a wrench.

I presume we will soon have plenty of fresh "conundrums" here, as we are to have the "train signaling apparatus" in use on or about June 1, on the N. Y. C. W. F. RELYEA.

Syracuse, N. Y.

Lamps and Whistles—More Experience.

Editor The Locomotive Engineer:

Perhaps if I tell my story about lamps and whistles some professor or scientist may come to a solid conclusion about the cause of that little trouble. My first experience with that was when I was firing a Cooke engine over the Sierra Nevadas some years ago; the whistle was a very bass one—in tone—and the lamp was a common square tin gauge lamp, with glass in front and back. This whistle would put the lamp out every time that a blast of two or three seconds duration was blown in the snow sheds or in a tunnel, but out doors or in the open air it had no effect on the lamp. There was no effect at any time on the water glass lamp, no matter how long the whistle was used. Later on I was running a McQueen engine, the cab of which was not very high above the boiler head, and the whistle of which was quite coarse, or bass, in tone, the lamp was a globe lamp with a brass ventilator top and a brass shade around the globe. I had to put a block in this whistle, for whenever I used the whistle at night for a blast of more than two or three seconds duration the flame in the lamp would flare up till it was more like a torch, and as the sound ceased the flame would then die out almost entirely, until the wick was turned up again. In this case, too, the water glass lamp was unaffected; in fact, I have never seen one of these lamps that was; it has been the gauge lamp located near the top of the cab.

I ran another McQueen engine that had a shrill whistle, with a low cab and a lamp that is in common use on the Central Pacific, the globe of it is about four and one-half inches high, and there is no sort of top or ventilator to cover it, the orifice being about two inches, or a little less. In leaving town with this engine in the night time, the first time I used this whistle for a road crossing I had to be very careful, or out went the lamp, if it went out I could depend on having no more trouble with that lamp after lighting it again, but if the lamp flame recovered itself after the first use of the whistle I had to be careful for the next one or two times—after that no more trouble.

Still another. I took the place of a man on a daylight local run for a while, which, in the winter time, extended just far enough into the evening to need the lamps lit for a little while, the fireman used to watch me, and as he saw me reach for the whistle lever he would place his hand over the open top of the lamp globe, and save the flame that way, otherwise he would have to light the lamp again.

Not long since I got hold of a Baldwin engine that had a bass whistle which would put out the headlight nearly every time it was used.

Now who can explain the causes of these phenomena? PACIFIC.

Sacramento, Cal.

A Bad State of Affairs on Account of the Chain Gang System.

Editor The Locomotive Engineer:

The beauties of the pool chain gang system are being beautifully exemplified on the Georgia Division of the E. T., V. & G. Let some advocate of the system take a trip over the road, and I will venture to say that he will change his mind very quickly. Engines that six months ago could handle thirty loads are being reduced to twenty, and it is a hard matter to "get there" with them. All classes of the men are dissatisfied, consequently there is a monkey and parrot time among the men and officers. Thirty to forty-eight hours is consumed in making the trip of 158 miles. Engineers' overtime amounts to more than their mileage in many cases.

Rome, Ga. O. T.

On Spring Rigging.

Editor The Locomotive Engineer:

I would like to ask our friend, L. C. Hitchcock, to give some details on spring gear, how to arrange for proper lengths of hangers, etc. We have several sets to rearrange in the roundhouse. Would like to know the amount of compression to give (if any) before the weight of engine comes on.

Suppose an engine turned out of shop with center of main driving axle ⅛" out of square with cylinder line. Would it materially affect the setting of the valves? O. K.

Ottawa, Ont.

We referred the above questions to Mr. Hitchcock, and received the following reply:

The question has been asked, What should be the proper length of driving spring hangers to give the springs the proper tension before the weight of the engine comes on them? That depends very much on circumstances. To answer this question one should know the kind of spring to be used, its length, number and size of leaves, temper, set, etc. Then he should know the kind and weight of engine and number of springs to be used.

Most of our engines are the American eight-wheeled type total weight on drivers about 60,500 pounds, in these we use 12 leaves of $\frac{3}{8}$" x34" steel, length from center to center, 36$\frac{1}{4}$"; set, 12". These we give from 1$\frac{1}{2}$" to 2" tension before the weight of engine comes on them, and get very good results. We do not give the forward springs more tension than the back ones.

In regard to the second question, I should say that if all other parts of the engine were properly constructed you could not make each side of the engine work the same under these circumstances, but think that, if the valves were properly set, this defect would not be noticeable in the exhausts of the engine. L. C. HITCHCOCK.

Minneapolis, Minn.

Hood's Breakdown.

Editor The Locomotive Engineer:

There has been quite a discussion here between some of our old engineers, and others of the boys on the D. S. S. & A. Railway about bringing in an engine with a left back-up eccentric broken. Some of them claim that they can bring her in by connecting the blade of the left back-up eccentric that was broken to the go-ahead eccentric, with the same results that L. L. Hood gained by blocking his engine in the extreme forward notch; and some claim that it cannot be done. I do not know for certain, but think it could be done. We would deem it a favor if you would kindly give us your opinion whether it could be done or not, and, if it could be done, would it be practical to do it if you should happen to break down on the road, and not be able to handle your train on one side, that is, providing the master mechanic would allow it?

ONE WHO IS ANXIOUS TO LEARN.

Marquette, Mich.

[It would be possible if the back-up eccentric or strap were so broken, and there was lost motion enough to bolt the back-up eccentric blade to the go-ahead strap, but it would be a slow job, and would require special conditions for success. If the rod was so fastened the engine could be hooked up, but not reversed. Engineer Hood disconnected his engine the quickest and best way under the circumstances.]

Completed History of the Old Locomotive "Brookline."

Editor The Locomotive Engineer:

Just a year ago this month (April) you illustrated the old engine "Brookline," with a history of her service up to the time her name was changed to Farmingdale, and she was sold to some Eastern road.

It may be a little late, but I think perhaps the remainder of her history will be of interest to your readers.

I have run her, and was running her the very last time that steam ever turned her drivers. She was bought by the Portland & Kennebeck road, and run on the accommodation train between Augusta and Gardiner. I ran her some time when she was a drop hook. She was taken into the shop at Augusta by our master mechanic, John Ellis, and he changed her into link motion. I was running her when we had a collision, between Gardiner and Hallowell, on June 27th, 1870.

Engineer D. H. Berry was running the old "Patten" on a mixed train, Charley Merrill, conductor. In this collision Berry was killed and the fireman fatally scalded; no passengers injured.

I helped get the passengers out of the wreck, and did what I could until the arrival of Master Mechanic Ellis with a wrecking crew.

In clearing up the wreck, Mr. Ellis found the name plate "Farmingdale," and gave it to me, saying that her name belonged to me. I have it yet.

My conductor at the time of the wreck of the historic old engine was John Holmes, everybody in this part of the country knew him; he was a stage driver between Augusta and Portland before there were any railroads; he died about two years ago. I am still running a locomotive on the same road, now a part of the Maine Central.

Brunswick, Me. C. M. EVANS.

Marks is Bound to Have a Job when His Locomotive is Out of Date.

Editor The Locomotive Engineer:

Since writin' you about that job when ther locos went ter scrap I've bin lookin' round and rather think I've got hold uv sumpthin' that may pan out, even if ther railroads try ther lightnin' skeem. There is two plans I'm on ter, as ther boys say, and as there is prob'ly sum others that will be wantin' ter know how ter git ther cash fer flap-jax and such eatin', will give them a pointer.

Wun skeem is only good fer a winter job, but it's a howler while it dus last.

We hav' all run when ther tracks looked as if they was all ice, but just think uv runnin' on ice fer a steady job all winter. Wal, this is just what ther plan is, fer I've bin readin' uv a new skeem by a man named Mulrey, uv Jersey City, and shall see if I can't git a job when ther locos begin ter go ter scrap. 'Taint no slow thing nuther, fer he says it will run sixty miles an hour and not mind sech little things as lumps uv ice and when you think uv jumpin' ice chunks on ther run 'taint no slow work, don't have ter dodge 'em either.

Must be sort uv a wunderful sort uv thing, but this is an advancin' age, and such ideas as we get from ther old roads are no good any more, anyhow ther man that made ther engin says, "it's all springs and ball and socket j'ints," with cars ter match.

Jest imagin' me, ther old plug puller that used ter run ther old scrap heap, er steerin' this new kind uv go'r, all ther j'ints er givin' and twistin' and er humpin' herself over the stray cakes uv ice that may be left lyin' round loose by ther careless ice cutters. Guess 'twill seem kinder strange ter me, but I must do sumthin', and if ther j'ints only hold and don't twist too much, I'll run ther thing, if I hav ter be tied down ter ther seat, better'n runnin' wun uv them lightnin' motors anyhow, cause if yer do git "fired" off ther seat yer can find yerself again, and not hav' any uv that lightnin' playin' up and down yer spinal backbone.

I b'lieve ther new locos won't be sold, but that needn't worry any uv us runners, cause we don't often buy ther scraps they give us ter run, but I've sent in my cards after a job, and all ther men that know ther best thing ter do better follow suit if they can't trump; but recollect that I have ther first job on ther new ice line and stand reg'lar number wun.

For a summer job I've bin spottin' ther "numatic" skeem, and think it will do for a change from ther ice line, and think it will be a rest too, as ther won't be no hustlin' over the ice blocks and the like.

This skeem is sumthin' like the cable lines that run in cities, has a grip (a double-ended sort of affair) that just grabs on ter the vacuum when they want ter go, and they just fly too—ther lightnin' skeem can't touch 'em.

They just pump ther air out of the tube that lays 'tween ther rails and fire ther vacuum in, and ther piston grip just catches it, and they scoot, 'bout ther same as scrapin' ther lightnin' off ther wire in ther other skeem.

This skeem only has a few pumps along ther route that haul out ther air, so all we can do on this line is to run ther grip business.

This grip business has to push ther slides out of ther way as it passes, and then ther slides scoot back inter place so as ter keep ther vacuum from gittin' out.

Now all they hav' ter do to get speed on this thing is ter pump in more vacuum and they fly as fast as they want ter, with only a few pounds of air they will run two or three hundred miles an hour and never be behind time either, it's a great skeem.

Now when ther cars are humpin' therselves at ther rate of several hundred knots an hour, that ther slides that are floppin' back and forth must make music for ther engineer; other roads don't think that much of ther men, to give them a concert as they travel along ther road.

These slides must hustle to close in time for ther next train, and when you think that there is over ten thousand ter ther mile, and a mile a minit don't give very much time for ther operation; but that ain't troublin' me, that's their part, and as they are goin' ter give me a chance on their cars if I can sell some stock fer 'em, guess I'll work that skeem in with ther other, so as ter make sure of a job when ther locos are all cut up inter motors and ther like, fer them fellers that ain't skeered ter run ther things four or five thousand miles an hour.

Still, if you hear uv a job that wouldn't shake a feller so much as ther ice route, or be so hard on a feller that wasn't a musician as ther tunes ther slides play as they scoot by, why let er feller know, cause I want ter know ther best job ther is layin' round loose and snatch it, afore any one else gets sight of it. R. E. MARKS.

Camden, N. J.

Some Phenomena of the Road.

Editor The Locomotive Engineer:

Back in the '70s some of the drivers on the G. T. R. of Canada had their whistles blocked so that they could put out almost any lamp. Often when on top, near the engine, I have tried to shield my lamp from the whistle while the driver whistled for the station. One engine driver used to have fun with a cranky agent by making pretense of calling for brakes or off brakes when engine was opposite the lamp on the order board, and extinguishing it. Those whistles would often make the fire fly in sparks out of my red mustache on a dark night in rainy weather.

There were not many injectors then. The pumps had "pet cocks" which the driver opened occasionally to see if she was taking water, and which would throw a stream outside of the right of way when engine was running fast. When the sun or moon was shining, and you were running in the right direction, a "rainbow" would appear on this water from the "pet cock." By moonlight the colors would be very pale. Several phenomena that used to interest us "old-timers" seem not to be observed by the trainmen who came up these later years. CONDUCTOR.

Fargo, N. D.

On the C., B. & Q., instead of the usual signal bell in the cab, or the whistle air signal, they use a small whistle located on top of the cab and blown by steam or air. A heavy coil spring holds the valve closed, the bell cord being attached to the spring. It is just as hard to operate from the rear of a long train as the old bell, and is fully as uncertain—but it's different.

New Form of Flexible Wheel Base Tramway Locomotive.

The peculiar locomotive shown on page 89 was designed for a special purpose, and is, to say the least, a very ingenious piece of work. The inventor and builder, Mr. E. P. Cowles, of New Decatur, Ala., has built several of them, and they are running successfully. He describes them as follows:

This engine is especially designed for use in lumbering, quarrying, etc., where the roads are built temporary by reason of requiring frequent removals, and are as a consequence very rough and uneven, with many heavy grades and sharp curves.

It follows from the nature of this service that the engines are mostly used in sections remote from repair shops. It is therefore desirable that they should be so constructed that they can be kept in order and repaired by such mechanics and with such materials and tools as may be at hand. In this respect should be on the same grade as the ordinary stationary engine.

The object sought and attained in this engine is to produce, at a reasonably low cost, a thoroughly reliable and serviceable locomotive, having the greatest possible tractive power, by utilizing the entire weight, including fuel and water, for this purpose, combined with a degree of flexibility never before attained in a locomotive without the use of gear wheels, slip and toggle joints, so objectionable as a source of breakage, lost motion, noise and unsteady action.

The entire weight of this engine is carried on two independent freely oscillating driving trucks, swiveled to the engine frame like ordinary car trucks. They are perfectly free to turn and follow curves, or twist to conform to an uneven track, without in the least interfering with the transmission of the power from the engines, which are direct-acting, like any locomotive.

One axle *a a* in each truck is tubular, through it passes the engine crank shaft *b b*.

They are coupled together in the center by a universal joint *c c*.

The truck is swiveled to the engine at this point by hangers depending therefrom. The bore of this tubular axle is larger than the shaft.

On each end of the shaft, just outside of the wheels, is a double crank *d d d d*, to which the main rods *e e e e* of the engines are coupled. These cranks have journals outside, with bearings *f f f f*, sliding vertically in hangers depending from the engine frame. The hangers maintain the crank-shaft always at right angles to the longitudinal axis of the engine, while they are maintained parallel to the plane of the frame by rock shafts with arms connected to the bearings *f*.

The wheels of the tubular axle have ring-like crank-pins *g g g g*, coupled to the other wheels of the trucks. The wrists of the double cranks pass through these rings.

They have the same play in them that the shaft has in the tubular axles. It is obvious that while the crank-shaft is maintained in the same position with reference to the engine frame, the trucks are free to oscillate in every direction to the extent of the play of tubular axle on crank-shaft, and at the same time the rotary motion is transmitted to all the wheels as rigidly as if the main rods were coupled directly to them.

The engine frame forms a platform on which the boiler, cab, fuel-box, tank, etc., are placed. It is made with two heavy, strong sills, lying directly over the cylinders, and performs much the same office as the bed-plate of a stationary engine.

Besides maintaining the engines in line, they also take all the working strain, relieving the trucks entirely of the thrust of the engines.

This permits of a perfectly strong, durable truck frame being made of a combination of wood and iron, like those of a passenger coach. As far as possible, iron is bolted to wood, reducing the liability to breakage to a minimum.

The wheels have chilled cast rims that can be removed easily. Two men can remove the worn out tires and put on new ones in six hours, or replace them with those of a shape suitable for wood rails.

Besides the usual truck springs and equalizers there are bearing springs between the trucks and engine frame. On a very rough, uneven track, the engine runs as smoothly as a passenger coach.

The cylinders are placed midway between the trucks, with piston rods extending through each head, one connected to the rear, and one to the front truck. To compensate for the varying length of the main rods, owing to their angularity, as the cranks approach the upper and lower points in this revolution, the piston heads are made double, one *h h* annular connected to one piston rod by a perforated disk, the one connected to the other rod solid *i i* fitting steam tight inside the first, and having a longitudinal play equal to the variation to be provided for. Their areas are equal, and obviously steam acts on each with the same force. At the same time they are free to draw out to accommodate any variation in the length of the connections. They are provided with steam cushions, which prevent concussion in case the wheels of either truck slip.

The engine illustrated weighs eight tons, which is equally distributed on eight driving wheels 28 inches in diameter, width of gauge, 42 inches, length of truck wheel base, 42 inches, total wheel base, 16 feet. It will turn curves of 50 feet radius and twist 10 inches in the length of its wheel base, cylinders are 10 inches diameter by 12 inches stroke. They have balance valves and can be reversed under full pressure of steam, slipping the wheels either way. The trucks are provided with steam brakes, which are also arranged to be worked by hand. Sand-boxes are provided at each end. It will run and haul equally well either way. The boiler is of the upright type. The tank is of strongest and simplest form possible. A plane cylinder placed horizontally in front of the boiler. The cab is roomy and neat, making it easy and agreeable to fire and run.

This engine has hauled four empty cars of 4,000 pounds each up a grade of 600 feet per mile, turning curves of 50 feet radius, having a grade of 450 feet per mile, at the rate of 12 miles per hour. It has run on a reasonably straight track at the rate of 25 miles per hour, and this on 16-pound rail.

The engine is covered by three patents, with others pending.

A New Ten-wheeler for the B. & O.

The B. & O. shops at Mt. Clare, Md., have recently turned out a new pattern of heavy ten wheeler that is destined to become their standard freight engine.

These engines have cylinders 21x26, straight radial stay boilers 64 diameter, and a 60 wheel. The two forward driving tires are bald.

A very neat steel cab is used, and wrought-iron doors of a very heavy pattern are swung from each side of the tank, and take the place of coal boards. The main rod is fluted or is of I section. The fire-door is the double sliding door of English pattern. The Pennsylvania style of double bar guide is used. Cast-iron rockers of heavy pattern are employed.

In the cab they have devised a rather clumsy steam box, from which most of the valves radiate like quills upon the fretful porcupine.

This engine is fitted with Sellers re-starting injectors, air brakes and steam heat. The use of the latter is not stated for a freight engine, but this first one, it is said, will pull heavy excursions during the season, and so has passenger equipment. Just what use steam heat will be in July and August is not stated.

The engine, on the whole, is a very good and handy one, and is a big improvement over the present freight engines of the road.

Examinations of Enginemen.

For years there was little or no examination of enginemen, especially of firemen about to be promoted, but within the last few years there has been considerable agitation on the subject, and now there is liable to be a lot of examinations formulated that are as absurdly too great as the old method was too small.

It is of great importance that the engineers of this country be well selected, well posted and able men; it is of just as much importance to the engineers as to anybody else, but it is also of great importance that the examination be of such a nature as to prove the engineman's knowledge of *operating* locomotives, not of *building* them or designing them.

The future engineer should be molded, acquiring certain knowledge at a certain time, and gradually rounding out his education and experience until he becomes a master of his business. Incompetents and drones should be kept out of the way of earnest workers, and the latter given all the chance in the world.

The present method of making engineers is as crude and as illogical as it would be to send a child, entirely uneducated, into a high schoolroom; pay no attention to it, never give it a lesson to learn, never call it to a class or hear it recite, and at the end of four years call the child up, critically examine it in the higher branches, and make it principal of the school, at the same time telling it that it was not well posted, and you would not be surprised to hear of its failure.

To the end that future examinations may be fair to both sides, logical, require knowledge that is necessary, and not require knowledge that is not necessary, and to insure a well-selected and well-posted class of locomotive engineers, the editor of this paper offers a plan for progressive examinations of locomotive enginemen in another column, only hoping that in some measure it may be a means to the desired end.

The writer is thoroughly convinced that it does very little good to put green firemen on switch engines in order to fit them for road service. The work is so entirely different that it does little real good. The only advantage is that it employs some of them near by where they are available when wanted. Two trips on a road engine at the start, when applicant is anxious to learn, is worth six months' yard work.

We believe that any master mechanic who will try the following plan will appreciate its advantages.

Keep applicants on extra laborer's or wiper's list, and keep in the shop or roundhouse, on running repairs, one or two old firemen who have passed their final examination; they are where you can reach them on short notice, and can be used either as extra firemen or engineers; they are experienced, and can be had as firemen on the most important trains in an emergency—you feel safer knowing that a capable fireman is out on the fast run. If a freight engineer don't show up, you have a man within call that you can use.

Cost of Being "Odd."

A look through any locomotive shop will at once convince an observant mechanic that there is no more attempt at uniformity or standard patterns now than there ever was, probably there is less.

If everybody tried to build alike, probably little progress or improvement would be made, yet many of the so called road standards are peculiar, to say the least.

Several large orders for equipment have lately been given, that will involve a large expense for special patterns and special tools to do the work, that will in no way add to the earning capacity or facilities for repairs. Does it pay?

The president of one of the largest roads in this country recently visited a locomotive works to protest against the delay in delivery of an order of upward of fifty locomotives of two or three classes. When told that the delay was caused by the necessity of making new, or altering old patterns, in constructing special hammer dies, odd thread taps and double-barreled reamers before work could be commenced at all, he became interested.

When shown that the stock patterns of the works, the standard screw threads of the country, and reamers of established taper that could be purchased in the market, would have been just as good, if not better, he said he thought it too bad to go to so much trouble.

When told that the following of the specifications to the letter would delay delivery about four months, he was out of patience, but when told that the same number of locomotives of the same size, capacity and efficiency of the standard pattern of the works could have been furnished for nearly two thousand dollars less for each one, he was downright mad.

To be sure, many of our master mechanics are not responsible for the mechanical devices they are in charge of, they are a legacy from some predecessor; but it is a question whether or not the head of a mechanical department is justified in virtually bringing into the world a large family of feeble-minded children, just to match those of his wife's by her first husband.

Wouldn't it be better to start new and let the old die off?

This, of course, is a matter that each must decide for himself, according to the particular circumstances in which he finds he is placed.

Certain it is that motive power on many of our roads is costing from five to twenty per cent. extra on account of little eccentricities of design.

Dampers—Need of a More Perfect and Simpler One.

In the days of wood burners it was not so difficult to keep ash-pan dampers tight as it is now with coal, and all know that, with comparatively air-tight dampers, properly manipulated, a great deal of blowing off of steam was avoided.

In Scotland and several other European countries it is not uncommon practice to make ash-pans of cast-iron with the damper joints milled, so that the pans are water-tight; when these dampers are closed, after steam is shut off combustion is checked, and little or no waste occurs.

In America the damper has fallen sadly into disuse; this has been caused by the great difficulty in making or keeping pans tight in the very large class of American locomotives whose fire-boxes are located above the frames, and especially so where there are one or more pair of wheels under the fire-box.

Hard coal engines are, as a rule, of this class, and it is a treat to see a hard coal ash pan not warped out of shape by heat.

On the continent of Europe it is not uncommon to see locomotives with netting air spaces in the ash-pans, like many American engines, and no ash-pan dampers, but a damper on or in the smoke-stack.

This damper answers every purpose of ash-pan dampers, as far as checking the draught is concerned is but a fraction of the weight of the old dampers, is not distorted by heat, is away from the track, costs far less than any ash-pan form of damper, and is always easily operated.

The general form is in the shape of a disk of iron that is so arranged as to be easily turned to cover or uncover the top of the stack; this disk usually has a small hole through it, just enough to let the gas escape.

It is the plan on the Lehigh Valley and other hard coal roads to lay a piece of tank iron on top of the stacks of engines standing in the roundhouse with fires banked. This is the stack damper, to all intents and purposes. It seems as though, with one of these dampers on our straight stacks, with a handy lever in the cab within the reach of engineer or fireman, that this howling of the pops on long down grades, around yards and stations, and in roundhouses, could be considerably checked, and a lot of alleged dampers, that look more like propeller blades, together with their deck handles, rods and bell cranks, could be dispensed with.

Our cousins across the big salt lick beat us a little on fuel consumption, and we credit their firemen with knowing more about their business than ours do; but suppose you educate a fireman up to understand that steam wasted at the pop is wasting fuel, and that he could save it if he checked the draught, and then provide no means of checking it, what good does his education do? If these stack dampers answered no useful purpose, those Germans and Italians and Frenchmen would not go on building them year after year.

Isn't there a field for this simple device here?

A Move in the Right Direction.

The adoption of a six foot and a half wheel by the B. & O. for their new fast express engines was a step in the right direction toward higher speed for light trains, the next will be the introduction of a similar engine with a single pair of drivers, no side rods, a four-foot trailing wheel under the fire-box, and a fire-box fifteen inches deeper and eight inches wider, made possible by this construction

As this paper goes to press, the editor turns toward the golden West to see if there is not something of interest to write about on the Pacific slope. The next issue of the paper may be better or worse for our absence, and we hope our readers will excuse us in the one case, and the paper in the other. There are no subscriptions owing, but we may as well remind those who think they owe the editor anything in the shape of chastisement, that May is the month in which to call and settle.

Don't worry because you are not a brilliant man. Brilliant men don't accomplish as much in the long run as the one who does a little every day. Keeping everlastingly at it is what accomplishes results. You are all right so long as you accomplish an object, make a point, or advance a step each day. You will move slower per hour, but faster per year. Your brilliant men make magnificent jumps, and look pretty while in the air—but they often light on their stomachs.

Correspondents who have a personal grievance against some road should air their grievances to their committees or organs of labor orders. This paper must stick pretty closely to mechanics, and not go far out of its way to discuss abuses of operating officers on the Reading—or any other road.

The best smoke preventer is an intelligent fireman who has been carefully trained in his business—it also helps matters to have the engineer know a thing or two.

Communications written on both sides of the paper go to the scrap heap without reading—life is too short.

Book Review.

BOILER MAKING FOR BOILER MAKERS. By W. H. Ford, M. E. John Wiley & Sons, New York. Price, $2.

This little book of 225 pages is a practical treatise on work in the boiler shop, and is written in such language as boiler makers understand. It shows the approved methods of riveting, staying, bracing, punching, drilling, smithing, and shows the economical points of boiler shop management. The author of this work was a mechanical draftsman, whose work drifted into designing and laying out material for boilers. He saw the need of a practical work on boilers, and tried to buy one, but did not run across the ideal one in mind; he commenced keeping a note-book and to gather data, and this work is the result. The work is not a brand new thing, but has reached its second edition.

A great many engravings are employed, and the work abounds in kinks, tools and appliance ideas, any one of which is worth $2 to a boiler maker.

ASKED & ANSWERED.

(37) G. H. M., Eagle Grove, Ia., asks:

What would be the cause of an engine not cutting off the same at both ends of the cylinder, after having been squared up in the corner, and found to be all right? A.—If the valves are square in the corner for both forward and backward stroke, the probable cause of their being out when hooked up is that the point of suspension or the tumbling shaft are not correctly placed.

Progressive Examination of Locomotive Engineers and Firemen.

QUESTIONS AND ANSWERS.

By JOHN A. HILL

EXPLANATORY.

So much of the examination of firemen for promotion to the responsible position of locomotive engineer is unsatisfactory on account of there being no proper system of training, and there is withal so much uncertainty as to what a man really knows, even after he has passed an examination, that the author of this plan has been encouraged to propose it. He claims no originality in the questions or answers, but has selected the simplest and best from every available source. The only original proposition is in using a series of progressive examinations to insure good material to start with, and aid and assist the fireman to learn the proper things first and provide a screen to prevent the advancement of incompetents.

Every child is taught to creep before it walks; the primer comes before the fifth reader; kilts before pantaloons, and youth before manhood. The boy in the shop is put at some laboring or helping job, where he has an opportunity to observe, see others work, learn how, and why, and what; he becomes a mechanic step by step—not at one stride—he is not put on a drill press for three years and expected to become a mechanic.

Mankind, profiting by the experience of past and passing generations, and learning first the rudiments, then the elements, finally reaches proficiency in such calling as each individual elects to follow

A young man who has attended a soda water apparatus, sold pain killer and swept out a drug store for four years, is not made prescription clerk ahead of the youth who has studied chemistry and has been employed three years as assistant to the prescription clerk—knowledge is necessary before assuming responsibility.

Locomotive engine running is a responsibility, than which there is no greater, and the most painstaking care is none too efficient in selecting and training men for this more than responsible position.

The way to secure a good class of engineers is,

First. Select good, clean material, inspect for culls, and have some quick and fairly accurate method of testing for such defects as would prevent the candidate from ultimately becoming a first-class passenger engineer

Second: Provide the opportunity and means, or point out the way, to the student to learn the rudiments of his business first—teach him how to fire, before he goes head-over-heels into valve motion.

Third: Provide an incentive to the learning of the right part first, and establish a point at which no progress or any other defect in the candidate for advancement will call for a termination of the apprenticeship.

By the method here proposed, responsible officers can provide a system of *periodical* examination of firemen, advance them step by step until they become thoroughly proficient enginemen, and abandon the usual rule, of putting a conglomerate gang of men upon locomotives, letting them fire a term of years, and select the oldest for examination, only to find that he knows little about his business, that he is color blind, illiterate, or intemperate—all of which should have been discovered before he was given a job at all.

The Progressive Plan provides in the preliminary examination for the establishment of a gauge for candidates, one that proves that he is possessed of a common school education, is not afflicted with defective vision, personally desires employment in this line of work, and is prepared to stand its hardships, with the hope of promotion; is of proper age, and points out to the candidate what he is expected to learn and how best to learn it.

The first examination occurs after one year's actual service. The record of the candidate for advancement is looked up, and he is examined in the rudiments of his business, the questions being of an elementary order, to see that the subject is getting the proper groundwork of his trade. Especial attention is paid to his understanding of all signals in use by the road, as even the youngest fireman is responsible for the proper transmission of signals to his engineer, this point is especially important on single track roads.

The second examination takes up the subject of fuel, combustion, boilers, and the duties of firemen. It insures his understanding something about the care of fires, draught appliances and economy of fuel, while he can still put in practice some of the lessons learned.

The third examination occurs after the third year of service, and is a thorough one on the mechanism of the engine, brakes, etc. The examiner requires a remedy or a cure for every conceivable break-down liable to occur on the road; and this examination should be complete enough to warrant the superintendent of machinery in promoting the successful firemen as needed, upon their presenting him with a certificate of examination on train rules and time card from the proper officers of the transportation department.

If the candidate fails to pass satisfactorily at this examination, he is to be apprised in detail where he is weak, and given a chance to post himself and try again when his term for promotion comes—for with progressive examinations there can be no objection to "the oldest man" coming first.

The early examinations are mainly to secure the proper material and then put the young fireman in the way of himself getting hold of the right kind of information, advise him, guide him, and get him in the way of *thinking* and reasoning out things for himself

He is led to study certain important phases of railroading at a time when he needs information on these subjects most, and those who are inclined to put off and lag in interest are kept moving by the thought of the next examination

Some objectors will say at once, "Oh, they will learn those rules by heart and repeat them off like clock-work." Even so, this will do good rather than harm—and is far more than the majority of men learn before promotion now.

These questions and answers are intended principally as a guide to the kind of questions that will be asked, in actual examinations—fewer questions will be used, but on these subjects.

It treats only of such parts of mechanism and such conditions as are common to all locomotives and to all railroads, and it is expected that the officers of each road will add to it important subjects of a local nature—such as the water scoop on the Pennsylvania, the smoke-jet on the New York Central, and the water-brake on the Rocky Mountain roads

PENALTIES

First Examination. Discharge for proven charges of drunkenness, insubordination, or chronic quarrelsomeness. If more than half the questions asked are missed, applicant to go back on the list six months and again come up in his new turn. Demand perfection in examination on signals. On second trial, if applicant shows no capacity to grasp the subjects, and a disposition to be lazy or indifferent, dismiss him. He will make the same kind of an engineer that he does a fireman, and—you don't want that kind.

Second Examination: Same as the first.

Third Examination. If applicant for advancement has passed former examinations all right, and seems from his answers to understand the subject generally, but is unable to give the correct answers to specific questions, it would be well to correct him or give him a few days to get the matter straight. If, on the other hand, he gives evidence of not understanding the subjects treated, and would not, in your estimation, be a safe man to trust with a locomotive, he should be sent back to firing for six months, taking his turn behind the men hired the six months after he was. Failure on the second trial should at least call for taking candidate out of road service.

TO THE EXAMINER

Bear in mind the experience of the man being examined. Do not think for a moment that your mission is to humble him, to "catch" him, to impress upon his mind how densely ignorant he is and what a store of railroad knowledge you possess. Your real mission, especially in the examination after the first and second years of service, is to find out the progress made in certain lines and guide the appren tice in the right direction, showing him what it is especially necessary for him to know, and giving him advice how to gain the desired information. Be impartial, patient and just, and, above all, avoid making yourself a bugbear to those to whom you are supposed to be a leader and guide.

In final examination, if possible, go with applicant to a locomotive under steam and propose your breakdown problems rather than have him come to your office—the man will feel more at home and give more intelligent answers.

If an answer is given that is manifestly the result of inquiry, but is wrong, ask the man's engineer the question; if he answers it the same, do not blame the applicant.

TO APPLICANT FOR EXAMINATION.

Suppose you have passed your preliminary examination, been given a book of rules and examination book, and have fired a year. Be sure before you go to examining officer that you know what you are going for, and are at least thoroughly conversant with all signals in use on the road, and know something about combustion. Be orderly and cleanly, and go to examination fearlessly—the examiner can't hang you. If there is any subject that you cannot settle on the true solution of, ask those above you, even to the examiner. Remember that the exact questions here shown will not be asked, so that it will do no particular good to commit answers. What you want is a fair, practical knowledge of the subject, then you can answer any reasonable question upon it. Don't try to "post up" for examination day—get posted and keep so. Remember not only your life, but the lives of others depend upon your knowledge of your business, especially about signals and train rights. Work on a locomotive in either place is a serious business and worthy of your earnest thought and attention.

PRELIMINARY EXAMINATION.

NECESSARY QUALIFICATIONS OF APPLICANT.

Applicants for the position of Locomotive Firemen on the . . . . Railway.

Must be more than 18 and less than 30 years of age, unless applicant has had previous experience on a locomotive; if under the age of 21, consent in writing from parents or guardian must be submitted; those between the ages of 21 and 25 preferred.

Applicant must have a common school education, at least equal to the grammar grades of the public schools of the State—graduates of regular high schools given preference.

Must be strictly temperate, of good moral habits, and physically strong enough for the arduous work of firing.

Applicant must be able to distinguish the color of flags or lamp signals—such as actually used on the road—across a space provided, not more than one-fourth of a mile, through the open air; must prove to the satisfaction of the examining officer that he is not defective in vision or hearing.

Possessing these qualifications, and the road being desirous of employing men, he is permitted to make out an application in writing, in presence of the examiner.

FORM OF APPLICATION.

. 189

To the chief officer of the Motive Power department of the . R. R.

Being extremely desirous of securing service on this line in the capacity of locomotive fireman, with a view to future promotion, if found proficient, I make the following statement:

My full name is . . . . . . I was born at . . . . . on the . day of 18. . and am . . . . years . . . months and days of age. I desire permission to ride for a few round trips over one division on regular freight to learn my duties, the location of tanks, signals, etc., and will assist the regular fireman all I can in order to the better understand the work (can be omitted where fireman has had other road experience, but is desirable). Should I still desire to secure a position as fireman, after seeing the actual service, I will come and so report to you.

I am (single or married) . I have been employed by this company before as . . . Former occupation . . . . Experience on other railroads . . . . I can be found at . . . . but sincerely hope you can find a place for me in the wiping force or at some other work where I can be instantly available as an extra man in any emergency that may occur.

. . . .

[Record of former experience will be investigated.]

It is important that the applicant be given permission to ride for a round trip or two on the class of engines he will have to fire, be obliged to remain on the engines as long as the crew does, and perform as much of the fireman's work as he can; if he persists in being an engineer after this he is in earnest, and his time so put in should be paid for at regular fireman's wages—it is a good investment.

QUESTIONS AND ANSWERS.

Examiner. If freight train No. 10 ran from A to B, six miles and a half, at the rate of 15 miles per hour, how long would it take?

A. Twenty-six minutes.

Q. How long does it take a passenger train traveling 30 miles per hour to make a mile?

A. Two minutes.

Q. If this road has 350 engines, each making 100 miles per day, how many miles do they all make per day?

A. Thirty-five thousand miles.

Q. Suppose each fireman wasted half a cent's worth of coal a mile by letting steam blow off at the pops too much, or by throwing away coal, how much would that amount to a day to the road?

A. One hundred and seventy-five dollars.

Q. What do you read?

A. . . . . .

Give the applicant time, and do not try to hurry or "rattle" him, but upon his correct and more or less prompt answers to questions in simple arithmetic like these, you get at his understanding of figures and give him something to think about.

Advice something on the following line would be timely:

You have, no doubt, thought over the matter seriously, and understand something of the duties of the road and its dangers. It is doubly dangerous where any faculty is dormant while on duty; train yourself to avoid sleep or drowsiness on a locomotive; it is a habit that grows, and ofttimes kills. You will have many duties to perform, and it is desirable, and necessary, that you learn to do them not only well, but cheerfully. Cultivate the faculty of getting along well with the men with whom you are at work, and avoid dissensions. Try and please your engineer; remember he has years of experience, you have none. He can teach you much that you need to know; he may appear taciturn, cranky, or close-mouthed, but the meanest engineer on earth will learn to like and help a loyal fireman, who has nothing to say against him or the engine, who tries hard to keep steam and keep the engine reasonably clean, and who is always willing to help him with his work—especially in case of an accident.

Establish now, while you are young, the habit of taking rest as soon as you are in; do extra work, loafing or visiting afterward—you may have to go out before you expect.

Don't forget that it is not the *last* drink that hurts a good man's reputation—it is the *first*. Be temperate. The officers of this road have no right to say to you, "You shall not drink intoxicating liquors," but they have the right to say "We will not employ a man in any capacity that drinks"—and that is what they do say.

Beside keeping the engine "hot" for the engineer, you owe the company a duty in trying to be economical in the use of all supplies, and especially of fuel; remember that when the pops are blowing, they are blowing away *coal*.

On the road, get into the habit of looking at the orders and keeping track of trains running against you; if you are in doubt, ask the engineer; if he refuses to show you the orders, come to me and so report.

Every fireman can afford a little money each year for reading matter, and you should make a study of your business. Take at least one railroad paper, one treating of locomotives and rolling stock preferred, say the . . . . or the . . . . You need Forney's Catechism of the Locomotive at once; you will find it most useful to you now and as long as you remain on a locomotive; Sinclair's Locomotive Running and Management should come next, it is especially valuable because it treats more of firing and running; Alexander's Ready Reference is also a good book, and cheaper than either. Use your books to verify, prove and make clear the problems you encounter in practice.

Your work and habits in the future will be carefully noted, and no habit or fault will be tolerated in you that could not be overlooked in the engineer of the most important train on the road; you must not consider yourself a mere coal shoveler, but as a student earning his way and in training for a most responsible position—we can hire mere coal passers for smaller wages.

Remember that in a year from now you will be required to pass an examination on your business, to ascertain how you are profiting by experience and study. While I shall not confine myself to the exact questions here printed, I give you the questions so that you will the better understand what line of study is best for you. Hunt your Catechism over industriously and you will find pretty nearly everything you want to know in it. Form a habit of thinking of the *why*, and ask questions, of your engineer, the roundhouse foreman, the traveling engineer, or of the Superintendent of M. P.—find out what you want to know.

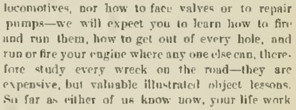
We will not expect you to know how to build locomotives, nor how to face valves or to repair pumps—we will expect you to learn how to fire and run them, how to get out of every hole, and run or fire your engine where any one else can, therefore study every wreck on the road—they are expensive, but valuable illustrated object lessons. So far as either of us know now, your life work will be *operating* locomotives, and your success depends on how thoroughly you learn the business. Be particular to learn all you can about the rules of the road, orders, local conditions, etc. Bear in mind that you may be set back or dismissed the service if you do not keep up with the majority, give evidence year by year that you are going to make a first-class locomotive engineer. I hope to hear good reports of your service.

(First Examination Questions next month.)

An Ingenious Track Gauge and Curve Elevation Level.

Iron track gauges, with three gauging points, are now in common use. They insure the gauge being radial to curves of any degree, and are lighter and stronger than the older forms.

To get the elevation of curves, a notched level is used. The gauge of tracks at curves should be widened an eighth of an inch for each degree of curvature.



A very simple and efficient device to measure all of these requirements has been devised by Mr. William M. Chalk, of Spivey, Kan., an employe of the Santa Fe road.

To the usual iron gauge he adds a spirit level and his invention, which makes the device do the work of three tools. The engraving shows his device. The sliding gauge notch on the end, when at its highest point, leaves the tool simply a track gauge, for use on tangent track. By lowering the slide so that the mark on the scale is the same as the curve of the track in degrees, the device answers the purposes of the old level, and at the same time widens the gauge the proper amount. This is accomplished by inclining the sliding scale, as shown.

The device can be made in sections for easy packing in a case, for convenience in carrying, where used by roadmaster as a test gauge. The inventor wishes to have it put on the market by some firm of makers.

The Engine that was Lost in the Quicksand—The Truth About a Lie.

For the past three months the following item has been going the rounds of the press, sometimes getting itself into a railroad paper as gospel truth. Not one of the editors seems to have thought it worth while to even wonder how they sounded through sand for 100 feet, much less to have gotten hoisting tackle down to take hold of the lost sheep through 100 feet of quicksand. Then the idea of wet quicksand preventing rust by keeping out the air is novel, to say the least, but for the lie:

"Says a locomotive engineer: 'I once had an interesting experience with a quicksand. My engine ran off a low bridge near River Bend, about 100 miles east of Denver, and fell into a small creek filled with quicksands. A wrecking train came up in a few hours, but the engine had entirely disappeared. The railroad officials ordered it to be raised, but it could not be found. We sounded with rods to a depth of over 60 feet, but not a trace did we discover of the engine, which had vanished as completely as if it had never existed. Four years afterward it was found at a depth of over 100 feet and was raised. We then ascertained that there was scarcely a bit of rust on it, the breaks were few, and after a little tinkering it was put upon the road again. The sand had kept out the air and prevented the iron from oxidizing.'"

In a private letter to the editor, Joseph T. Markham, of Denver, Col., now an engineer on the Denver & Rio Grande road, says of this accident:

* * * "The engine referred to here was the '51,' on the Kansas Pacific, now known as the Kansas division of the U. P. She ran into the bed of Kiowa Creek, about one-fourth of a mile east of Bennett station, then known as Kiowa station, which is 31 miles east of Denver, and in Colorado. The accident happened at 12.15 A. M., May 22, 1877. Engineer Johnny Bacon, and Fireman Frank Seldon, and a cook going out to the Hugo section house, were all killed.

"The engine disappeared in the sand by morning, and two other men and myself were sent to search for her. We were furnished with round rods of half-inch iron, from fifteen to twenty-five feet long, and spent four or five days in the search. I am just as sure as a man can be that we found the engine, for we found a solid body about the size of a boiler. It lay about fifteen feet below the center of the track, and twenty feet deep in the sand. Twenty feet further down stream we found the tank, and near it were other pieces. We also found several pairs of car wheels.

"The fireman's body was found the day after the accident, half a mile below the wreck, the cook's body was found the second or third day, one and a half miles below, and the body of the engineer not till the fourth or fifth day, and about four miles away. All of them were on top of the sand.

"The engine was a Baldwin, eight-wheeler, 16x24, numbered 51. I had been firing her just before, but had quit and gone into the bridge and building department.

"It is only about thirty feet to bed rock at this point, so the engine could scarcely go the hundred claimed.

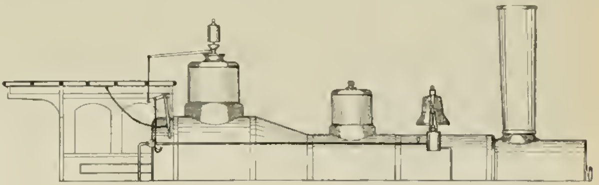
"When we told the man in charge of our department that we had found the engine, and where, he said he didn't want the bother of getting her out, and I do not think anything looking to that end has been tried since. She was certainly still in the sand when I left in '82, and the old timers tell me she is there yet."

In this case the truth is far more interesting than the lie.

What promises to become a very valuable publication has just issued its Vol. 1, No. 1, at Detroit, Mich. It will appear under the name of *The Quarterly Register of Current History*. It is the intention of the publishers to make this quarterly a concise and intelligent review of all current events for the time it is published, as selected from the newspapers of the country. All newspapers are too bulky to preserve, and if they were, a few years of files would furnish the proverbial hay-stack for the preserver to hunt in for the needle of information he remembers he dropped there some time since. The new review aims to present an interesting narrative account of current events that shall be thoroughly indexed and become a useful reference for the library. The subscription is $1 per year.

A New Bell Ringer.

The illustrations herewith show the details of construction of a new bell ringer of very simple design. In Fig. 1 there will be seen two openings for pipes, the one to the left being the steam or air pipe, the one to the right being the exhaust, steam is admitted through upper opening opposite an annular groove in valve 18, through



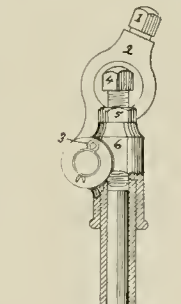


Fig. 1.

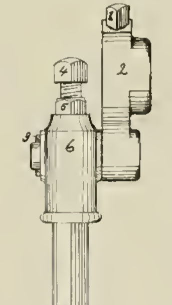

Fig. 2.

which four holes are drilled, admitting the pressure under the single action piston 10, this causes piston 10 to rise forcing the bell to swing. Piston 10 has a stroke of $1\frac{1}{4}$" when at its extreme travel, crank 2 has a stroke of 4. The connecting rod is in two sections, 6 and 7, which allows the crank 2 to make a complete revolution without causing piston 10 to move. When the ringer is started to work, the piston 10 will be driven upward, causing the bell to swing, and valve stem 17 will raise the valve 18, closing steam port, and use pressure expansively by traveling the length of the lap before it will open the exhaust port. The bell having received an impulse, will continue its motion after the piston 10 has reached the upper end of its stroke, the crank box 8 sliding on rod 7.

The impetus which the bell receives being expended, it will fall, the set-bolt 4 will strike the end of rod 7, the piston 10 will be forced downward, coming in direct contact with valve 18, closing exhaust port and opening steam port, after cushioning on the pressure, remaining under piston 10 after exhaust is closed. It will be seen that the valve 18 is only operated at the terminations of the piston, 10 stroke.

Packing rings 15 on piston and main valve are packing rings D 6, No. 8, Westinghouse Air-brake Co.'s Catalogue, 1890. This is the only bell ringer that can be adjusted to use pressure in proportion to the power required. This is accomplished by means of valve stem 17, which is secured in its adjusted position by jam nut 16. No change in length of connecting rod is required in making this adjustment. These bell ringers are in use that cut off pressure after piston has moved ½ on its stroke. This arrangement makes it so economical in use of pressure that air is always used in preference to steam, and it has never caused any trouble with train brakes.

With the use of the automatic starter shown in upper cut, the bell is always ringing when it ought to, and is not forgotten or neglected by the engineer or fireman after sounding the whistle for station or highway. This bell ringer has been adopted by the Chicago & Northwestern Railway and is in use on many other western railways. They are sold at a uniform price of $12 each.

Both the ringer proper and the automatic starting feature are patented, the device is manufactured by the Gollmar Bell Ringer Co., of Baraboo, Wis.

Wound Up.

When the Webb compound locomotive came to this country she excited a great deal of interest. The fact that one pair of drivers could slip with the other pair standing still was a great mystery to those who did not know that the high-pressure engines ran one pair and the low-pressure engine the other, no side rods being used. A few days after her arrival a crowd of shop hands were watching her start a train. The back drivers spun around for a minute or two, but the big piston was on the center and nothing "went away." One shop hand says to another: "Why don't she start?" The other was posted and replied: "He ain't ready yet, he's just winding her up, he'll start her in a minute."

We have a note from a Western engineer, who says that, "Chain-ganging a hog over two divisions is nothing more nor less than a complicated, heterogeneous conglomeration of confused ideas." If it's as bad as all that the practice should be abandoned.

A Peculiar Brake.

Thomas Inglis and William Schiermann, of Tyler, Texas, have recently brought out a peculiar form of chain brake, cuts of which are shown herewith, and the inventors, one of whom is foreman of the Cotton Belt Shops, describe their device as follows:

"This invention was intended to secure an apparatus for cars, to diminish their velocity when running, if desired, or act automatically in case of accident, and not to subject the action of the so-called brake to the accidents of leaking joints, playing out of fine mechanical devices and bad management of brake operators, but to furnish a power brake, and an automatic one, that was simple in construction and did not require skilled mechanical labor to maintain and operate, and in consequence, diminishing the danger of derailment and decreasing the wear of the wheels; through the peculiar construction of our machine, doing away altogether with the brake beams, which cause two-thirds of all the derailments.

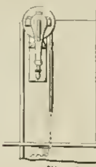

Fig. 3.

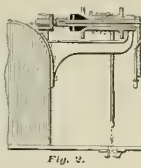

Fig. 2.

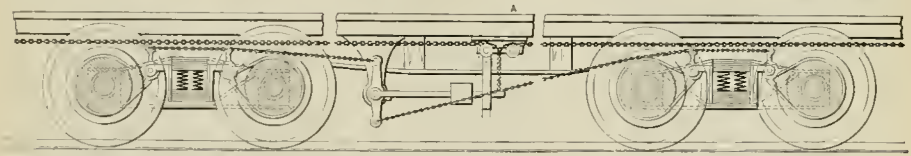


"As seen in drawing, we put a brake disk, formed in the shape of a pulley, on the axle of the truck wheels. Around this brake disk is a brake band made out of band steel, that fits close to the brake disk about two-thirds around, and may be lined with vulcanized paper to prevent too fast wearing. Each end of this brake band is fastened to corresponding arms of a three-armed lever, which is fastened and turns on a bolt in an iron bracket which is fastened to the truck bolsters. The third arm of this lever mentioned stands straight up, and through its moving around its fulcrum, the brake band is operated.

"As brake power we employ a weight on a long lever; same weight can be moved back and forwards on this lever, and adjusted to any place to increase or decrease the power with which the brakes are applied. This long lever works around the same pin as the equalizing lever, both levers working side by side, one acting on the other by means of a lug, cast on the side of the equalizing lever. This is an important feature of our construction of this machine, because it makes the brake independent of the movement of the long power lever, on which the weight is fastened, when this lever moves upward. The only effect on the brake is when it is lowered below the horizontal position. By this we overcome the slack between the cars, the lever can travel upwards under the car and down to horizontal position, setting the brake only when brake chain is loose; the brake can be operated by a common brake staff, now in use, by connecting with the main chain; only the work will be reverse from what it is now. You have got to wind the chain around the brake staff to release the brake, and let the chain off to set the brake.

"On a standard car the main chain has a travel of twelve inches to set the brake full.

"One engraving shows the apparatus on the locomotive; a windlass winding a wire rope on a drum takes up the slack in the brake chain. There is a friction clutch behind the drum that can be released to any amount necessary for service stop, by use of a trigger lever shown in the handle."

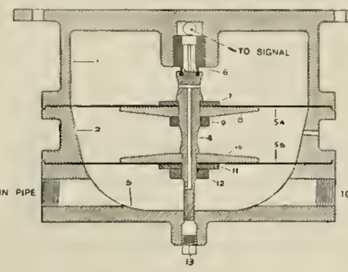
The enthusiastic inventors write us that they are about to try this device on a train, but we fear they will find that the slack of their long chain will be a serious trouble, and that with, say, fifty cars, the well windlass on the engine will have some strain to bear, and the operator some work to do.

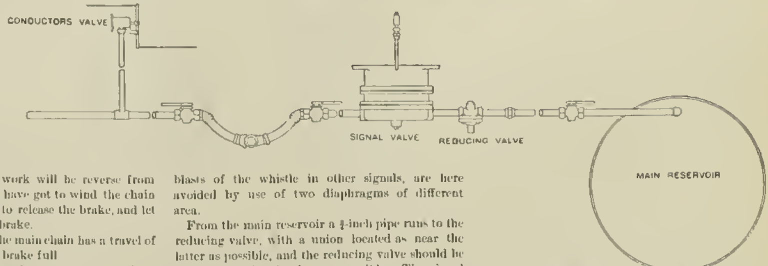
The Boyden Train Signal.

The Boyden Air-brake Co., of Baltimore, have recently put out a new train signal operated by compressed air, like the Westinghouse signal, and interchangeable with it.

The upper engraving shows a section of the engine apparatus, and the lower cut the complete device.

The advantages of this device are: No auxiliary reservoir is required, hence economy of space and construction. A self-adjustability is provided the various moving parts, by which a certainty of action is assured. Simplicity of construction and easy accessibility to all parts. It gives a short, quick blast. No greater discharge of air is necessary to operate the whistle from the rear cars of a long train than from the forward cars. The diaphragms are not subject to deterioration, as they are made of brass; and the vibrations, which cause double blasts of the whistle in other signals, are here avoided by use of two diaphragms of different area.





From the main reservoir a ⅜-inch pipe runs to the reducing valve, with a union located as near the latter as possible, and the reducing valve should be as near the signal valve as possible. The signal valve should be secured to the running board just under the cab. The ⅜ inch pipe from the reducing valve to the signal valve can enter either of the ⅜-inch pipe connections therein, and the whistle pipe should extend into the cab, with the whistle located conveniently to the usual position of the engineer. From the signal valve a ¾-inch pipe extends back to the tender and train in the usual manner.

The operation is as follows: The reducing valve is set to allow about 35 pounds of air pressure to pass from the main reservoir to the signal valve, and from thence to the train pipe; at the same time, this air presses the small diaphragm 5 B, and thereby seats the whistle valve 6, and prevents the whistle from blowing while the train pipe is being charged with air; the air passes through the passage in the stem 4, and charges the upper chamber above the large diaphragm 5 A, and thereby equalizes the pressure on opposite sides of the two diaphragms. The chamber between the two diaphragms is open or exposed to the atmosphere.

When it is desired to give a signal, the conductor's valve on any car is opened and closed as many times as desired; for instance, three times in quick succession, which will produce three discharges and cause three reductions of pressure in the train pipe, and in the signal valve under the smaller diaphragm 5 B, as in the action of the device; the pressure in the valve chamber above the larger diaphragm 5 A will not be reduced by these discharges; the greater pressure there, caused by the first discharge, will move both diaphragms and unseat the valve 6, and air will pass from the upper chamber to the whistle and produce a blast, this will instantly reduce the pressure in the upper chamber below that in the lower chamber, and thereupon the valve 6 will be closed; by this time, the effect of the second discharge of air from the conductor's valve will cause the valve 6 to again open, and the whistle will make a second blast; this will be repeated by the third blast, and so on—all without confusion of signals.

The highest place in the world regularly inhabited is stated to be the Buddhist monastery, Halne, in Thibet, which is about 16,000 feet above sea level. The next highest is Galera, a railway station in Peru, which is located at a height of 15,635 feet. Near it, at the same level, a railway tunnel, 3,847 feet in length, is being driven through the mountains. The elevation of the city of Potosi, in Bolivia, is 13,330 feet; Cuzco, Peru, 11,380 feet; La Paz, Bolivia, 10,883 feet, and Leadville, Col., 10,025 feet.

Physical Tests of Materials.

The following is the standard test of materials that enter into the construction of a locomotive required and given by the Baldwin Locomotive Works, where the buyer has no pet test of his own.

All materials used in the construction of the locomotive shall be of the best quality of their respective kinds, carefully inspected, and subjected to the following tests. Notwithstanding these tests, should any defects be developed in working, the corresponding part will be rejected

All boiler-iron will be specified C. H No 1 flange quality, and must be made from the best charcoal blooms.

A careful examination will be made of every sheet, and none will be accepted that show mechanical defects.

A test piece to be furnished from each sheet, to be tested. Such test strips must show an ultimate tensile strength with the grain of not less than 50,000 pounds, an ultimate tensile strength across the grain of not less than 45,000 pounds, and must show a ductility, measured by elongation, of not less than 20 per cent. Should any of the test pieces fail to fulfill the above requirements, the corresponding sheet will be rejected

Should any plates develop defects in working, they will be rejected.

Each plate must be stamped with the maker's name and the guaranteed tensile strength and elongation as above.

A careful examination will be made of every sheet, and none will be accepted that show mechanical defects.

Test strips taken lengthwise from each sheet and without annealing should have a tensile strength of 55,000 pounds per square inch, and an elongation of 30 per cent., in section originally two inches long.

Sheets will not be accepted if the test shows a tensile strength less than 50,000 pounds, or greater than 65,000 pounds per square inch, nor if the elongation falls below 25 per cent.

Should any sheets develop defects in working, they will be rejected.

Copper plates for fire boxes must be rolled from best quality Lake Superior ingots; they must have a tensile strength of not less than 30,000 pounds per square inch, and an elongation of from 20 to 25 per cent., in section originally two inches long. Test strips must be furnished with each fire-box for testing.

Iron or steel for stay-bolts and braces must have an ultimate tensile strength of not more than 60,000 pounds nor less than 50,000 pounds per square inch, with an elongation of not less than 30 per cent., nor undergo a reduction of area of fractured section of more than 35 per cent.

Copper stay-bolts must be manufactured from the best Lake Superior ingots, they must have an ultimate tensile strength of not less than 30,000 pounds per square inch, and an elongation of from 20 to 25 per cent., in section originally two inches long.

All boiler tubes must be carefully inspected and be free from pit-holes or other imperfections. Each tube must be subjected to an internal hydraulic pressure of not less than 500 pounds per square inch by the manufacturers before delivery. They must be rolled accurately to the gauge furnished by the Baldwin Locomotive Works, filling the gauge to a plump fit. They must be expanded in the boiler without crack or flaw.

When tested, iron or steel tubes must show a tensile strength of not less than 55,000 pounds per square inch, and a ductility of not less than 15 per cent.

Tubes of brass or copper to be of uniform circumferential thickness and solid drawn; to be perfectly round, and to resist an internal hydraulic pressure of 800 pounds per square inch. From the tubes under test, a piece four inches long will be cut, annealed, sawn lengthwise, and doubled inside out without showing sign of cracks.

When annealed they must withstand flanging cold a flange ⅜ of an inch broad for 2 inch tubes without cracking. Copper tubes must withstand flanging hot as well as cold. Tubes other sizes than 2 inches diameter must flange to a width proportional to their diameter.

A piece 30 inches long, annealed and filled with rosin, must withstand being doubled until the extremities touch each other without showing defects.

A piece 30 inches long, not annealed, filled with rosin, and placed on supports 20 inches apart, must withstand bending to a deflection of 3 inches without showing defects.

Bar iron should have a tensile strength of 50,000 pounds per square inch, and an elongation of 20 per cent., in section originally two inches long. Iron will not be accepted if tensile strength falls below 48,000 pounds, nor if elongation is less than 15 per cent., nor if it shows a granular fracture.

Of approved make, and of following guaranteed mileage. For 28" wheels, 40,000 miles. For 30" wheels, 45,000 miles. For 33" wheels, 50,000 miles. Other sizes in proportion.

(Adopted by Joint Committee of Master Car Builders Association, American Railway Master Mechanics Association, and Association of Manufacturers of Chilled Car Wheels, November 21, 1889.)

Deficient mileage will be adjusted upon return of the defective wheel, or that part of same containing the defect causing withdrawal from service. Or, if preferred, wheels will be furnished subject to approved specification and drop test, without mileage guarantee.

The locomotives for the Chignecto Ship Railway are being supplied by the Canadian Locomotive and Engine Company. They are to have eight wheels coupled, and will be without bogies. The cylinders are 22 inches in diameter by 26-inch stroke. The boilers are to be 59 inches in diameter, with 250 two-inch tubes, having a heating surface of 1,741 square feet. The steam pressure is 175 pounds. The wheels are to be 47 inches in diameter, and the grate area 29 square feet. The tanks will have a capacity of 3,620 gallons, and with this on board the total weight of the engine will be 180,000 pounds, all of which will be available for adhesion. Two of these locomotives are to haul a vessel in a cradle over the distance of 17 miles, which separates the termini of the line, at a speed of 10 miles an hour. The cradle is to be carried on 120 four-wheel trucks, and the maximum total weight hauled will be 2,500 tons.—*Ex.*

The number of compound locomotives in use or in process of construction has increased between Nov 1, 1889, and Nov 1, 1890, from 580 to 1,034, according to a statement by Herr von Borries in the *Engineer*. The total number is divided as follows Germany, 430; England, including those built for South America and India, 523, Italy, 2, Russia, 32, Switzerland, 11; North America, 8; street railways, 28.—*Ex.*

Numerous answers to questions on air pump breakdowns, and other subjects, are received after the answer has been published. These, of course, are not used, though many are interesting, and often correct.

Railroad Ventilated Pails

are the best pails ever made for use of railroad men

Thousands in Use. For Sale Everywhere

REARDON & ENNIS,
MANUFACTURERS,
TROY, N. Y.

On receipt of P. O. Order for $1 50 we will send one of these pails by Express.

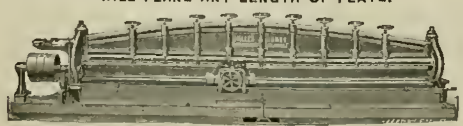
TOOLS FOR LOCOMOTIVE BOILER WORK.

THE CUT BELOW SHOWS OUR

BOILER PLATE PLANER.

WILL PLANE ANY LENGTH OF PLATE.



Tools cut both ways and have independent adjustment. Table acts as a gauge for setting the Plate. Driven by a Steel Screw, which is supported its entire length so that it cannot be bent or sprung. Seven sizes.

THE HILLES & JONES CO., Mfrs., Wilmington, Del.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formula patented by Mr. G. W. Lord. For decree of court, etc., address G. W. LORD, 320 Union Street, Philadelphia, Pa

Modern Heavy Switcher.

One of the best designed and most symmetrical switching engines to be found anywhere in this country is depicted in our engraving

This engine was designed and built by the Pittsburgh Locomotive Works for the Cincinnati, New Orleans & Texas Pacific R. R., and bears the initials of one of the leased lines. The general dimensions are as follows:

Cylinders, 18x24 inches.

Driving wheels, 50 inches diameter.

Wheel base, 10 feet 8 inches.

Weight in working order, 93,800 pounds.

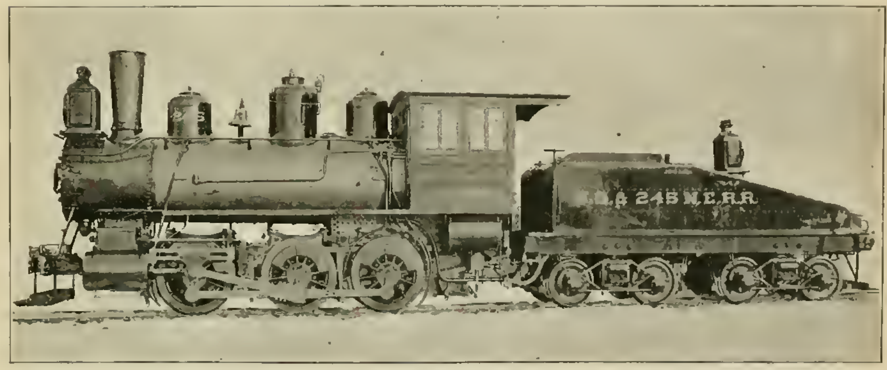
Diameter of boiler, 54 inches.

Number of flues 180; length, 9 feet 10 inches; diameter, 2 inches.

Fire-box, 90x34½ inches.

Tank, sloping, capacity 2,400 gallons.

For so heavy a six-wheeled switcher, there is the least overhang of weight at the ends, and the drivers are so arranged as to carry the load equally on each. The engine has an extended front, air-brakes, double sand-boxes and headlights, Laird guides and solid-ended rods. Every wheel under the engine and tender has a brake shoe on it.



MODERN HEAVY SWITCHER.

A Pair of Promotions.

E. M. Roberts, who has been our subscriber from the first issue of the paper, and who was formerly in charge of the Ashland Coal and Iron Company's railroad at Ashland, Ky., but has been more recently connected with the East Tennessee, Virginia & Georgia R R. at Atlanta, Ga., has taken charge of the machinery department of the South Carolina Railway, as superintendent of motive power, with headquarters at Charleston. Another of our early subscribers, W. J. Wilcox, has been promoted from his position as general foreman on the South Carolina Railway, to be master mechanic of the Charleston, Cincinnati & Chicago Railroad, with headquarters at Blacksburgh, S. C.

Mr. McNaughton, of the Wisconsin Central, has a very neat kink for showing the wear of eccentrics. He has a groove turned in the center of the face of eccentric, this groove is about an eighth of an inch wide, and half as deep. When the eccentric wears out of round—and they all do that—the depth of the groove shows plainly just where the wear has taken place.

High Speed on English Roads.

The railway companies running north by the West Coast lines have announced their intention to run the train leaving Euston at 8 P. M. for the north in twelve hours and five minutes to Aberdeen, instead of twelve hours fifty minutes. Just a year ago, the time of that train, which was then the fastest night train from London to the north, was fourteen hours from Euston to Aberdeen. In July, 1890, it was reduced to the time at which it now stands, hereafter it will, therefore, be only five minutes short of two hours less time from London to Aberdeen than it was only a year ago. Only a very few years ago twelve hours from London to Perth, 452 miles, by the West Coast route, was reckoned wonderful speed; but now 542 miles are to be covered within the twelve hours.

A Flying Trip Over the Northern Pacific.

(Editorial Correspondence.)

Nearly two years ago I wrote some notes on the Brainerd, Fargo and Mandan shops of the N P. road, but as my trip at that time only extended to the western boundary of North Dakota, the notes covered the eastern end of the great system for only 560 miles of the 4,160 operated.

The present trip has taken me across the continent to the tide-water of the great Pacific Ocean, and these notes are written at Portland, Oregon, instead of at New York.

As I have described the main shops of the system at Brainerd, and the next two division shops, we will skip them in the notes, just as I did in this trip, and commence where we left off eighteen months ago, at Dickinson, North Dakota.

I stopped at Dickinson, but knew beforehand that there were no shops there, but Dickinson is the headquarters of the superintendent of the Missouri division of the road, and I wanted to have a quiet chat with the man who sits in the superintendent's chair, not so much because I am stuck on superintendents, as a rule—I have seen the time when I avoided them—but because I want to keep track of the bright and progressive enginemen who get into such positions by sheer force of character, persistence and work.

J. E. Phelan commenced on this road as a fireman; he shoveled coal seven years, some of the time on the Lake Shore, then ran an engine for several years, was appointed traveling engineer, then master mechanic, and finally superintendent. He made himself conspicuously useful as an engineer, and attracted the attention of his superior officers, and made his name known the world over by his articles in THE LOCOMOTIVE ENGINEER on Air-brake Practice, afterward published in book form, reaching a third edition in a year, having been sold in every country where air-brakes are in use.

Mr. Phelan is not yet thirty-five years of age, and is undoubtedly one of the coming railroad men. He is sopping up experience in his present trying position, making few mistakes, and learning invaluable lessons for all made. There have been too many operative officers made of men totally without practical experience, and I am greatly interested in helping and encouraging every man who gets off a locomotive to assume an official position. I have before now called the attention of engineers to this matter, and asked them to go out of their way to encourage more of this kind of promotion by making these men successful; it helps engineers as a class, puts them in the line of promotion, and makes life less a burden.

The N. P. road from St. Paul to Brainerd runs northwest for 138 miles through a good agricultural country, then turns west, running across northern Minnesota and into North Dakota. Here the timber thins out, and the green opens and prairies give way to desolate looking stretches of land, good soil, but arid in a measure, and a land that has lured thousands to itself by grand promises of great yields, but has been prone to mock their patient labors about two years out of three. This spring, however, the Dakotas are verdant and prospects bright, but, well—wait till after harvest.

Western North Dakota lies higher, is more arid, and sage brush and bunch grass proclaim the northern fringe of Uncle Sam's great shawl—the plains. From Dickinson for a hundred miles or so west, the road traverses the "bad lands," named by the Indians. These lands are all their name implies, they support little vegetation, less water, game or domestic animals. Much of the territory is occupied by fantastically shaped mounds or hills, of rock and shale of a reddish or dirty yellow color, that has all the appearance of, and doubtless is, mud, hardened by the heat of the sun. Geologists tell us that all this vast territory was once the ground floor of some great sea that has been tideless and waveless, lo, these many years.

One of the first things a railroad man will notice on a trans-continental trip over the N. P. is the excessively heavy trains, the good condition of the splendid power and rolling stock, the steady grades, and the comparatively slow speed between stations; but if he is a thinker, he will think out a lesson on speed right here. The stations are far apart, and stops seldom made, so that by constantly pegging away, the great twelve car trains soon wear out the distance between St. Paul and Portland, 2,055 miles. It is getting away from stations that makes time.

There are but two through trains each way per day, but these are heavy enough to require double-headers, even on the prairies, when the wind blows.

The trains consist of three first-class vestibuled sleepers, one dining car, one colonist sleeper, two Pullman "tourist" sleepers, three coaches, and three mail and express cars. The sleepers and diner run through over the entire line, more than 2,000 miles. The tourist sleepers are something new, and must be a source of great comfort at little cost to people of moderate means. These cars, as operated by the Pullman Company, are fitted up complete with mattresses, pillows, blankets, clean bed linen, curtains, and carpet in the aisles. The toilet-rooms are fitted with wash stands, towels, soap, combs, brushes, etc., requiring nothing to be furnished by the passenger. A uniformed colored porter, with each Pullman car, is charged with the sole duty of looking after the comfort of patrons using these accommodations. A double berth in these cars will accommodate two persons comfortably. You can use one of these cars from St. Paul to Portland for $3. The colonist sleepers have upper and lower berths of ash, the berths or seats are not upholstered, and bedding is furnished by the passengers. A large range is provided, and a fire kept for the benefit of those who wish to cook on the car.

No stops are made for meals, but a ten minute stop is made at all division terminals, where the cars are inspected and the tanks filled. While such stops are made, a blue signal is displayed at the station, and it's "agin' the law" to move the train until the blue signal is removed and a bell rung. This insures safety to trainmen inspecting brakes and wheels.

On some of the comparatively level divisions, standard 8 wheelers pulled the train, but most of the way, 19x24 10-wheelers do the work. These engines are splendid machines, and are in good condition as a rule; they are comparatively new, however. Radial stay, wagon top or Sample boilers are used, and give splendid results. They carry bad water well, and are easy to keep clean; they have extension fronts and straight stacks. Over the Rocky and Cascade Mountains the trains are helped by 22x28 "hogs." I went to sleep somewhere in the bad lands of Eastern Montana, and when I awoke with the sun of another day shining behind the buttes of desert, the train was running through a beautiful valley, the grass green, the hills covered with timber, cattle and sheep grazing far and near, the Yellowstone River winding about the foot of the hills, and in the west, the bald, white peaks of the dear, grand old Rockies lifted their snowy crests above the clouds.

In a few minutes the train stopped at Livingston, where the largest shops on the road, except Brainerd shops, are located. I spent 24 hours there, and picked up a good many pointers that I shall give to the readers of THE LOCOMOTIVE ENGINEER when I can get some sketches made, and do the ingenious mechanics I found there full justice.

I will skip the shop notes, and merely outline the trip.

Livingston is the diverging point of the branch that runs down to the Yellowstone National Park, but this is not open for the season yet.

Leaving Livingston the grade is heavy, and a double-header is required until the summit is reached in Bozeman tunnel. The country is rough, but green in this section. At Logan, 1,056 miles west of St. Paul, a branch runs to the great mining town of Butte, fifty miles south of the main line. This branch runs on through Butte, and joins the main line again at Garrison, 134 miles further west. Half of the regular passenger trains run over this line, and the other half go over the northern track, via Helena. Helena and Butte are the first cities with move to them you find, they are prosperous mining centers. West of Helena a "hog" again leads the 10 wheeler up a 22-mile grade to the tunnel on Mullan Pass; then there are 100 miles of down grade to Missoula.

Timber becomes heavier as we go west, and vegetation is perceptibly heavier on the Pacific slope. The Rocky Mountains are not so high nor so rough in the north of the Union as they are in the south. Up in British America they lose much of their mountainous appearance, and are simply great tracts of elevated land. They get bolder and rougher as one goes south, until in Mexico they become volcanic. This can be seen in the difference in elevations reached by the different lines of road.

The highest point reached by the N. P. is 5,873 feet. This is but a little above the altitude of Denver, and the D. & R. G. reaches an elevation of more than 11,000 feet above the sea.

Skirting the northern base of the Bitter Root Mountains, the road traverses an interesting country, containing scenery of great beauty, but daylight struck on our train along here, and when I came to myself again we had crossed Northern Idaho and passed Spokane Falls, a hustling city of the new State of Washington, with half a dozen branches and lines of road of her own, and a couple of dozen on paper.

There are about one hundred miles of country in Eastern Washington that is pretty desolate and barren. There are some towns and some mines, and a few farms, but I think if I was in the business of making country I should have made this different.

At Pasco the road crosses the Columbia River on a long and high bridge, and at Ellensburg the road is in a grassy valley only 1,510 feet above the sea, and 1,784 miles west of St. Paul. From here the road commences to ascend the Cascade Mountains. The scenery is grand, water and waterfalls plentiful, vegetation growing rank, pines and fir trees upward of 200 feet high growing thickly all over the mountain sides.

The great train merely crawls up here, with its two big engines digging their toe nails in for all they are worth, but finally the great tunnel under Stampede Pass is reached. This tunnel was opened and timbered, and is now being arched with stone. It is nearly two miles long, being the second longest in North America, the Hoosac tunnel being the longest; it is lighted from end to end by incandescent electric lamps. This great hole pierces the range 2,885 feet above the sea, and has 1,105 feet of rock above it.

It is only 78 miles from this tunnel to the tide-water of Puget Sound, which the road reaches at Tacoma.

Here is a live, hustling city of 40,000 people, who are building up a metropolis of better structures, taking them on an average, than any eastern city. The road has a line running north to Seattle, Sedro and Anacortes, and to the extreme northwest point in the United States.

From Tacoma south for 147 miles, the road runs through a heavily timbered country, in which there are some signs of agricultural pursuits, and at last reaches its final western terminus at Portland, Oregon, the largest and finest coast city north of San Francisco.

There are enough people in Oregon and Washington to secure their admission into the Union as States, yet the country is so vast and the resources so boundless, that those who are here seem to make little impression on the country. The lumber business is one of the greatest industries, and the immense firs seem to invite the lumberman, and grow as rank and close together as weeds.

President Harrison visited Tacoma and Seattle a few days before I did, and the thrifty people killed two birds with one stone, by leaving up the arches built for him, and making them do service to welcome me. One of these was a timber arch, the side posts being two firs left with the bark on for about four feet from the ground, and then sawed square for ten feet. They were 36 inches square, not a knot to be seen, and the grain as straight as the saw cut.

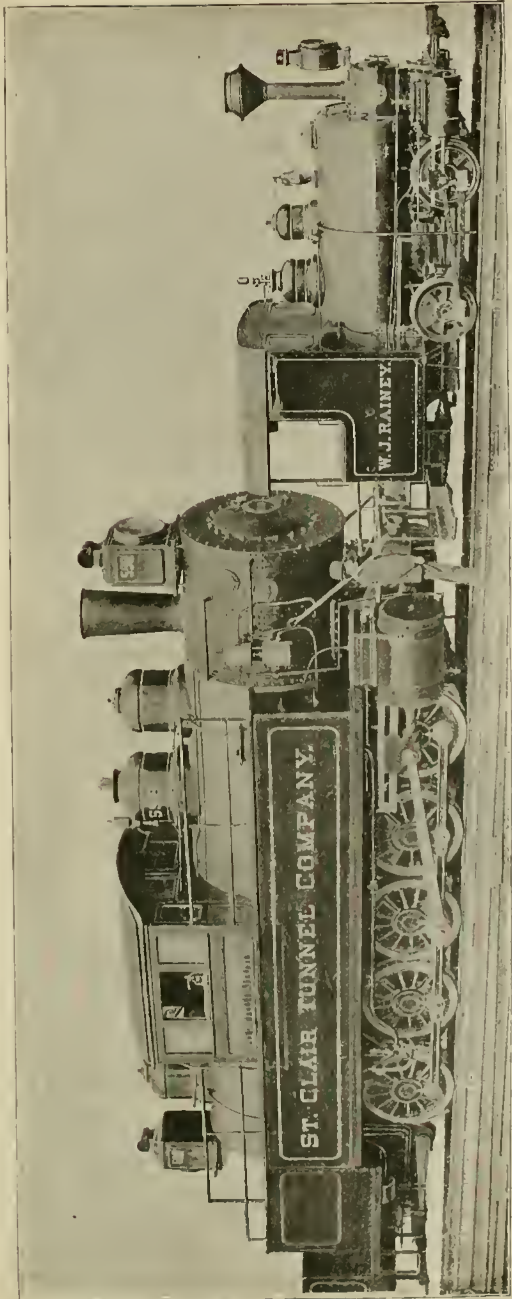
Another arch was composed of coal and coke. The coal is a fine quality of lignite, free from sulphur, and found inside of thirty miles from the city. On one of the floats of the parade was a single block of coal, weighing 16,800 pounds, without a seam in it. They made nearly 2,000,000 pounds of coke here last year. Wood is burned for most purposes; it is fat, and burns like rosin; it can be bought at retail for $2.50 per cord, and one of the local iron works pay $1.85 per cord in 1,000 cord contracts.

This is not an advertisement for Washington. If it was, I would go on, and tell you of its mining and agricultural advantages, but I will simply state that it is claimed, and it looks reasonable, that either Oregon or Washington has every resource that Pennsylvania has, and ten times as much of it.

One of the arches was composed of iron. An immense pile of ore, on either side of the street, made the foundation, and from this a ten-foot pillar of pig-iron was piled up, loghouse fashion, the ore came from the native hills only a few miles away, but the pig iron was imported from Scotland. Seattle is a larger town than Tacoma, has magnificent buildings, and a beautiful harbor and water front. Past her door or to it, come the ships of the Pacific ocean. Both of these cities are interlaced from center to circumference, by rapid transit lines of electric, cable or steam motor cars; these are fast, neat, and well patronized. I venture to say that one could go five miles in either town, while he went one in Philadelphia, or, barring the elevated road, in New York.

On the Columbia River the great industry is catching and canning salmon. The trains are ferried over this stream at Kalama, and enter Portland west of the river, ocean ships coming up the stream to the Portland docks.

The Northern Pacific road was, from the start, a stupendous undertaking. It cost millions of dollars to lay its iron way from the Mississippi to the Pacific for more than two thousand miles across arid plains, deserts, and over mountain passes; to



THE HEAVIEST LOCOMOTIVE IN THE WORLD.

aid the undertaking Congress gave them vast tracts of land, every other section on both sides of the track, I believe, and now there are many who want to cut down this grant, and take back the land.

By the building of this great road, a country before almost inaccessible, has been opened, and made habitable, and, if the consideration was to be land, they got little enough. The undertaking was stupendous, the expense enormous, and the traffic had to be created, for none existed before the road was built. For such service to the country a consideration something in proportion to the good done should be rendered.

This northwest coast country is a country of magnificent distances. A thousand miles, or so, is not far in Washington, Oregon or Northern California. This was impressed upon me this morning as I thoughtlessly stepped into the ticket office of the Southern Pacific Company to secure a sleeper ticket to Sacramento, and found that the capital of the golden State was only one thousand and ninety-four miles south, and San Francisco is ninety miles further. Yet people here talk of "taking a run down to 'Frisco," just as a New Yorker talks of going to Washington, or a Londoner of going up to Liverpool. J. A. H.

The Heaviest Locomotive in the World.

The large engraving shown herewith was made from a photograph, and represents one of four engines recently built by the Baldwin Works for the St Clair tunnel. The general dimensions are as follows:

Cylinders.... 22 in diam x 28 in stroke
Driving wheels .... 50 in diam
Driving wheel centers (cast iron) 44 in.
Tires (standard Otis steel). 3 in. thick
Tires, first, second, fourth and fifth pairs, flanged, 5½ in. wide; third pair, plain, 6 in. wide.
Tires secured by Mansell retaining rings
Tires, first and fifth pairs, 1 in play between rails, second and fourth, ¾ in play.
Boiler of ⅝ in. steel .. .. 74 in. diam.
Rivets . . 1 in diam, 2¾ and 3½ in. centers.
Laps—all longitudinal seams have double riveted butt joints, with double covering strips.
Steam pressure . . . . 160 lbs. per sq. in.
Tubes, 281, iron. .... . 2¼ in diam 13 ft 6 in. long.
Fire-box .... 132⅛ in long x 42⅛ in wide.
Water spaces . . 3 in. wide at sides, 4 in. at back
Firebrick arch supported by top bolts
Side screw stays, ⅞ in diam; crown screw stays, 1 in diam., riveted over at top and bottom
Grates .... Water tubes with drop bars.
Fuel Anthracite coal.
Crossheads of cast steel, with phosphor bronze bearings
Steam chest valves .. . . Balanced
Cylinder lubricators . Seibert sight feed
Injectors Two Friedman No 10 W F
Brakes—Westinghouse American, operated by air, on fronts of all wheels, with Ross-Meehan shoes.
Tank capacity, 1,600 galls (277 cu. in.) of water and 3 tons of coal
Wheel base total . . 18 ft 3 in.
Gauge of track 4 ft 8½ in
Weight on drivers in working order 195,000 lbs.
Steam bell ringer
Fuel, anthracite coal

These engines were designed to haul heavy freight trains through the new tunnel under the St. Clair River, between Sarnia, Ont, with Port Huron, Mich. The tunnel is 6,000 feet long, and the approaches are 1,950 and 2,500 respectively, the grade of the approaches being 105 feet per mile. For the work they have to do we consider them extraordinarily well designed. All weight is available for adhesion; there are no trucks and no need of any, as the engine will be employed on straight track most of the time. All the tires except the main ones are flanged.

The arrangement of the cab, in the center of the boiler and up where a man can see, is right, and this, with the side tank, should be the pattern for all heavy switchers, with perhaps a roof over the fireman's deck where soft coal is employed. This engine burns hard coal, so constant firing is not necessary.

The intention is that the engines shall not be turned around, as they will run equally well in either direction, two headlights and two sand-boxes are provided.

The boiler is the huge part of the machine, being 6 feet and 2 inches at the smallest ring. The engine backed up in front of the monster was one built on the same stall, and happened to be finished at the same time the 598 was. It shows the comparative size of the pusher to good advantage, and serves to show something of the diversity of design built at the Baldwin Works. Every wheel of this engine has a brake shoe on it, operated by air. The rails through the St. Clair tunnel weigh 100 pounds to the yard. These engines are capable of exerting a pull upon their draw bars of over 58,000 pounds, and were guaranteed to haul 760 long tons (2,240 pounds) up a two per cent. grade.

Butler's Rod Brass.

Master Mechanic L. M Butler, of the N. Y., P & B., had some trouble with broken bushings in solid-ended rods, and noticed that they always broke through the large hole for the set-screw, so he devised a new way of holding the bush.

He cuts a keyway in the strongest part of the stub end, as shown in the engraving A rib on the bushing fitting into this prevents its turning, and makes it necessary to cut only a small hole through it for oil.

The outside of the bush is cast as near the right size as is possible, and is then forced through a steel die that trims it off to the proper shape, a second die being used to perfect the fit.

This is as cheap as turning, and makes a first-class job of solid ends.

Wants Us To Have a Sure Thing.

In our April issue, under the above heading, we published a brief communication from a Wisconsin correspondent, who enclosed money to pay for 33 bound volumes of THE LOCOMOTIVE ENGINEER, and added the following pleasant suggestion:

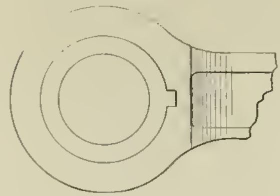
I think if the managers of our railroads would subscribe for your paper and furnish each engine crew with a copy, and have them receipt for them, same as the time card, it would be like bread cast upon the waters—it would return to them tenfold at the end of the year in net earnings for the company. If they would scatter them through the shops and roundhouses, and read them themselves, it would do some of them good. I send you eleven names, including myself, for three bound volumes each, for '88, '89, and '90. We all like it here.

The hint has certainly been taken by one railroad manager, for a few days ago we received from Gen. Supt. F. S. Gannon, of the Staten Island Rapid Transit Co., a list of 40 names of enginemen on his road to be placed on our mailing list as subscribers, the papers to go to their individual addresses, and the bill to the company.

While we hope no railroad man will go slow about subscribing because he hopes the company will save him the trouble of sending in his name, we shall place no fatal obstacles in the pathway of any other railroad managers who want to adopt Mr. Gannon's plan, when it will be recognized that increasing the efficiency of the men employed in the practical departments of a railroad is the surest path to dividends.

A Headlight Would Have Told the Tale.

In his report to the English Board of Trade on the collision which occurred on January 3d, at 12.19 P. M., at St. John's Wood-road station, Metropolitan Railway, Major-General Hutchinson says, "This very extraordinary collision was caused by an engine and brake van running backwards for at least 600 yards, down a steep incline of 1 in 60, in the tunnel between St. John's Wood road and Marlborough road stations, the driver, fireman, and guard being all under the impression that they were running forwards until they had again reached the mouth of the tunnel which they had entered about four minutes previously—too late to prevent the van from coming into collision, at a speed of five or six miles an hour, with the engine of a passenger train which was pulling up at St. John's Wood road station rather short of its regular stopping-place, the driver having noticed through the fog the brake van running back towards his engine. Charlton and the fireman were then both intently looking out for the home signal, 231 yards beyond the distant signal, Charlton giving the engine sufficient steam to keep it, as he thought, in forward motion, the reversing lever being in the second forward notch from mid-gear. Instead, however, of seeing the home signal, the engine must have first stopped and then gone backwards without either of them being in the least aware of it, and they were quite unconscious of what had taken place until the daylight at the St. John's Wood road end of the tunnel made them realize what had really happened. Charlton gave his evidence in a very truthful manner, and, extraordinary as it seems that he should not have noticed the stoppage of his engine before it began to go back, there is no good reason to disbelieve his statement or that of his fireman, which is much to the same effect as his own. The brakeman in the van had felt the engine stop, but had then thought that they had again gone forward, and was only aware of the retrograde motion when his brake van came to the St. John's Wood road end of the tunnel, too late for him to apply his brake." That the train should have run back down an incline for 600 yards, and that the driver, fireman and guard, all careful men, should have all been under the impression that it was running forward seems almost incredible; but there is every reason to believe the truthfulness of their evidence. Some means will have to be adopted to prevent similar accidents in future; a powerful lamp, throwing a strong light on the near wall of the tunnel, would, we think,



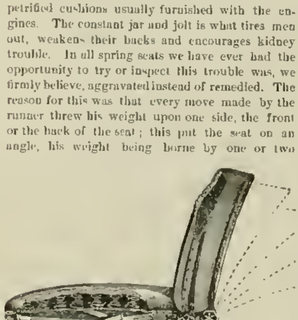
BUTLER'S ROD BRASS.

answer the purpose, and would have the recommendation of not being expensive.—*Railway Herald* (London)

Perhaps these men who honestly thought that they were going ahead when they were going backward, furnishes a clue to the reason some men think that their engine is slipping ahead when she is really slipping back or holding her wheels still.

A Platform Spring Cab Seat.

The contrivances that men rig up for themselves to take some of the jar off their backs on hard riding engines are a little better than the solid boxes and petrified cushions usually furnished with the engines. The constant jar and jolt is what tires men out, weakens their backs and encourages kidney trouble. In all spring seats we have ever had the opportunity to try or inspect this trouble was, we firmly believe, aggravated instead of remedied. The reason for this was that every move made by the runner threw his weight upon one side, the front or the back of the seat; this put the seat on an angle, his weight being borne by one or two



A PLATFORM SPRING CAB SEAT.

springs, and to maintain the position the muscles of the back were severely strained. Great care had to be taken to get "balanced," and more care to keep so. They were ungainly, especially in a drop seat form, and were made very uncomfortable by the breaking of one spring.

The seat here illustrated is the invention of a practical engineer, and has advantages over anything of the kind we have yet seen.

There is but one main spring, the cushion is full of small springs to make the seat soft, but the weight of the seat and the occupant is taken by the large central spring; the equalizing levers are hung from the seat corners to the base, being hung at the centers to the top of spring as shown, making a perfect platform spring seat. The entire weight can be placed on one corner or out of the center, yet the seat goes down level, and level only.

There is no forward and backward jerk, that is so tiring. The platform system of springs takes up all the side thrusts as well as the jumping motion.

The back is adjustable to any angle or can be instantly let down level with the seat where used on a "drop" seat. This back being fast to the seat, moves with it, and does not come and go like the old-fashioned back cushion that is fast to the cab with a spring seat under it.

The makers of this seat, Stannard & White, Appleton, Wis., are both engineers. They have named it the "Brotherhood" seat, and have been selling them for some time; they are extra well made and upholstered in leather; this is durable, and does not burn, or hold moisture or dust, as plush does.

The Railroad Side of the Question of Locomotive Standards.

It has been stated quite recently that, instead of working toward uniformity of locomotive design, the railroad master mechanics of the country appear to be demanding increased diversity of patterns. It is claimed that the reason for this lies in the fact that there is so much desire to impress the stamp of individuality upon the locomotives that few railroads follow the practice of accepting the builder's standard engine. It is quite possible that there is a greater diversity of design now than there was a few years ago, but we doubt if the true reason for this condition of affairs is the one referred to above. There is no doubt a desire among some master mechanics to do their own designing simply for the glory of it, and not because they have thought of a number of important features which are not to be found incorporated in designs already available; but, on the other hand, many of the designs made during the last few years have been the outcome of an attempt of each road to adopt standards for itself, with the idea of reducing the expenses of maintenance and repairs, and having the engines specially adapted to its own work

This policy of the railroads will doubtless become more marked as they consolidate into large systems, and their mechanical departments are managed with the greater efficiency which generally comes with the enlargement of the interests controlled by one management. This is a move in the proper direction, and is just exactly what a mechanical department should do, providing it has the good sense to adopt each feature of every design which becomes its standard simply because it is meritorious, and not because the idea originated with it.

Take any large system on which the entire mechanical department works as a unit, whose standards are adopted only after very careful consideration and discussion at meetings of its master mechanics, in which each man is free to express his opinion and tell his experience; should not they adhere to the standards so determined upon, even though it appears to the builder of locomotives as if they were causing him unnecessary labor by so doing? They will find it easier to maintain the engines than if every bidder had his own way and the road was finally equipped with a heterogeneous lot of locomotives. Providing a railroad has chosen its standard wisely, the question of conformity to, or variation from, its standard, when buying a lot of engines, may be stated thus: Will we have our own standard, so as to keep all our engines of this class alike, and thus facilitate repairs, etc., or will we accept the standard of the builders? If we do the latter it will be easier for the builder, but he constructs the engine in a few weeks or months, and we have it on hand from five to twenty years; will the slight reduction in first cost, which will come from accepting the builder's standard, pay us for the increased cost of maintenance?

So far as locomotive design and operation is concerned, each railroad is far more independent of others than is the case with its cars, and there is no call for its adopting other people's standards, except so far as they have been demonstrated to be better than its own. Of course it should never neglect to profit by the experience obtained by others, and in so far every mechanical department pervaded with the right spirit will look to others to see what they are doing. In this respect there can be no doubt but that some fail to improve their opportunities, and either remain ignorant of certain facts or learn by their own experience, when the knowledge could be gained from the experience of others.

We hear from time to time more or less about railroads making standards in locomotive work which shall be general, but something can be said on the other side. Do locomotive builders, for instance, take any steps toward achieving uniformity in their designs? Are not the locomotives turned out by the various builders in this country as their standards well known by special features which characterize their construction? We suspect that if an attempt were made to reduce the standard of the builders to a uniformity, they would be found to be just as slow in a move of this kind as the railroad men have been in the past. Without a great pressure is brought to bear, neither railroads nor builders will make their locomotive standards uniform, and where designs have been carefully considered before acceptance as standards there seems to be no reason why they should change them — *Railway Review.*

Locomotive Running Repairs.

By L. C. Hitchcock

SHOES AND WEDGES.

The subject of shoes and wedges in a general way might, perchance, come more properly under the head of general repairs, or back shop repairs, as it is quite frequently expressed.

However, it often occurs that work comes into the roundhouse which makes it necessary that the man who does the work should have a thorough knowledge of a correct way to line and fit up shoes and wedges, as practiced in the machine shop where engines go for general repairs. Right here let me say that I consider it a mistaken idea to suppose that most any kind of a workman is good enough for the roundhouse, as the class of workmen seen in some roundhouses would seem to indicate, for there is scarcely a day passes which does not bring to the roundhouses work which, if done quickly and in a proper manner, requires the brightest and best mechanics obtainable.

We will suppose that an engine with a broken driving brass comes into the roundhouse for repairs, and after the drivers are removed it may be found that the shoes, wedges and boxes are cut so badly as to necessitate facing. In a case of this kind it certainly would not pay to put in the driving brass and not repair the shoes and wedges. After having removed the boxes, and gotten the work started on the brasses, the attention should be directed to the shoes and wedges. There is a diversity of opinion in regard to the best way of lining these up, some claiming that they should be lined square with lines placed through the centers of the cylinders. Others say that it is better to work from the male engine truck center casting. I have observed that better results follow working in the last mentioned manner, provided that the male center casting is in an exact central position between the engine frames. The reason for this belief I will explain further on.

The first thing to be considered when starting to line up a set of shoes and wedges is the condition of the pedestal braces, and should these braces be bolted to the jaws as are those of the Baldwin and several other builds of engines, they should be bolted to place after the removal of the driving boxes, and care be taken that the slots in the braces closely fit the pedestals, or ends of the jaws. In case they do not fit they should be heated and the slots closed sufficiently to allow fitting with a coarse file. I consider it good policy to leave about $\frac{1}{32}$" space between the pedestals and bottoms of slots in brace after the brace has been drawn tight. This will allow the brace to again be drawn tight in case there is any wear on the sides of the slots in the braces. After the braces are fitted remove the driving springs and saddles, have the engine frames nicely cleaned, and give the face of each jaw a general bearing to a true surface plate. Now see that the center casting is centrally located between the engine frames. Should the shoes and wedges have liners in them they should be removed, and each shoe and wedge be placed in its proper position on the jaws, leaving the bottom of each wedge stand away from the pedestal brace about $\frac{1}{4}$", and block firmly each shoe and wedge to the face of the jaw. Now take two blocks of wood each about 3"x4" (*A*, Fig. 1), and of such length that, when they are placed in an upright position, one on each forward pedestal brace, their upper ends will be about on a level with the bottom of the center casting. On top of these blocks place flatwise a true wooden straight edge *B*, and block its edge firmly against the faces of the shoes with stick *C*. On the upper surface of straight edge get the exact central point between the engine frames, and using this point as a center, lay off the diameter of the center casting *D*, and notch the back edge of straight edge where these lines come. Then clean off the bottom part of the center casting and pass a fine line around it, and carry the ends back to the straight edge, tie a light weight to each end, and drop the lines into the notches mentioned. (See Fig. 2). Now see if the straight edge is square with each line. If it is not square with the lines, shims should be placed between one end of the straight edge and face of shoe until it comes square.

When shoes and wedges are squared from lines running through the centers of the cylinders the straight edge is used as just described. The difficulty which arises is that the cylinders are very seldom exactly in line with the engine frames, and where they are not it is impossible to get the straight edge square with both lines, and where an effort is made to do so, and the shoes and wedges are lined from the straight edge in this position, the drivers are not square with the engine frames and center casting. This will cause flange wear to driving and engine truck wheels. Then the latter method requires more labor, for it necessitates the removal of both pistons.

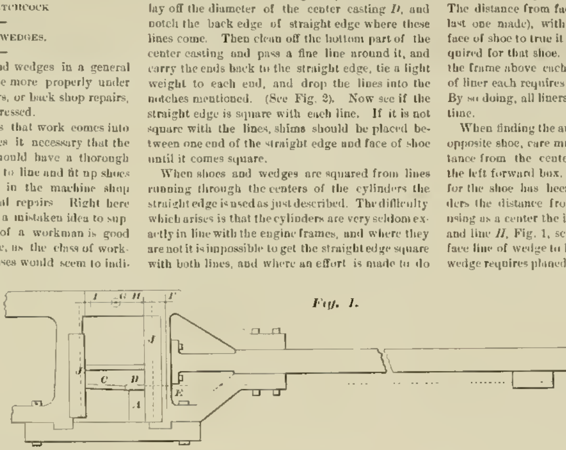


Fig. 1.

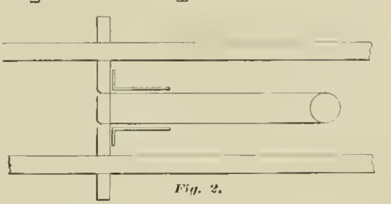

Fig. 2.

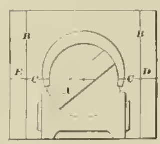

Fig. 3.

Now to return to our line around the center casting. When the straight edge is perfectly square with both lines make a prick-punch mark *E*, Fig. 1, on the outside of the forward jaw on each side of the engine, an equal distance from the face of straight edge and top of the frames, and with a pair of trams transfer these punch marks to the same points on the back jaws. Now through the first punch marks made scribe a line to, and square with the top of frames. Then scribe the face line of each shoe and wedge to the top of the frames, and at an equal distance from the top of each frame get the central point between the face lines and see if these central points are equally distant from the lines first scribed to top of frames. That is, see if the distances from lines *F* to points *G*, Fig. 1, are the same on each side of the engine. In case they are not equal, change the central points until they are equal.

After these central points on the forward jaws are placed exactly in line with the straight edge as described, and the central points between the face lines of the back shoes and wedges have been made, tram from the forward to back points on each side; the back points may have to be slightly changed to make these distances equal. The boxes should now be fitted to the journals, after which place a piece of wood *A*, Fig. 3, firmly between the brass and cellar, flush with the sides which bear against the wheel hubs when the boxes are in place. On these pieces of wood get the centers of the brasses, and transfer the shoe and wedge bearing faces of each box to the outside faces by scribing lines *B B*. Now scribe line *C* squarely across the last two lines, and passing through the center mark on the piece of wood. Fig. 3 represents the outside face of the right forward box. With a pair of dividers now space the distance from the center mark to punch mark *D*, and scribe this on the frame towards point *F*, using point *G* as a center. The distance from face line of shoe to line *H* (the last one made), with what is needed planed from face of shoe to true it up, is the amount of liner required for that shoe. It is a good plan to write on the frame above each shoe and wedge the amount of liner each requires as each amount is ascertained. By so doing, all liners may be cut out at the same time.

When finding the amount of liner required for the opposite shoe, care must be taken to space the distance from the center mark to punch mark *E* on the left forward box. After the amount of liner for the shoe has been found, space with the dividers the distance from punch marks *D* to *E*, and using as a center the intersection of horizontal line and line *H*, Fig. 1, scribe line *I*; the distance from face line of wedge to line *I*, together with what the wedge requires planed from face to true it up, is the amount of liner needed for that wedge.

After finding the amount of liner required for each shoe and wedge, take them down, cut out and fit each liner where it belongs; now replace the shoes and wedges on the jaws with the liners in them but not riveted, and place the straight edge in its former position; be very sure now that the distance from mark *E* to the straight edge is equal on each side, then scribe the lines *J J* down the frame and outside flange of each shoe and wedge, square with the top of frame. This mark should be made near enough to the face of each shoe and wedge to insure it being seen by the planer hand should he hold them in a chuck on the planer. Now with a pair of morphrodite calipers get the distance from the straight edge to lines *J* on the shoes, and scribe it from the straight edge on the inside flange of each shoe, then set the points of a pair of dividers to the lines *J J*, and taking the lines on the inside flange of the shoes for centers, scribe a line on the inside flange of each wedge, remove the straight edge now from the forward jaws, and block it to the shoes on the back jaws, and see that the distance is the same on each side from the straight edge to the marks which were transferred from the forward to the back jaws. Then from the straight edge lay off the inside of each back shoe, and wedge in exactly the same manner as just described for the forward ones. Now if each shoe and wedge is chucked on the planer to mark *J*, and mark on inside flange when finished, and then put in their places on the jaws, their faces will be square with the top of frames and the lines from the center casting. To insure that no more be planed from the faces than necessary, the distance should be given the planer hand from line *H* to *J* for each shoe, and from *I* to *J* for each wedge, and after the planing is done, lines *J* remain as proof lines, and will show whether the planing has been properly done or otherwise. After each shoe and wedge is planed, replace the liners in each just as they were when they were laid off, and rivet them there, using but two rivets near the top of each; liners riveted in this manner will not buckle as they will when more rivets are used.

After the liners are all riveted in, place each shoe and wedge in its proper position on the jaws, and block them firmly to face of jaws, and try if their faces are flush with lines *H* and *I*, are square with the top of frames, and parallel with each other; if so, give each a general bearing with a file to a true face-plate (use no scraper), after which true the shoe and wedge bearing faces of each box, using as a face-plate each shoe and wedge where it belongs in the box, they are then ready for service. If the directions as given are closely followed it will not be necessary to try the boxes in the jaws previous to wheeling the engine, and the wedges can be adjusted after the wheels are in place.

The Rock Island's latest passenger engines have crossheads, rockers and tumbling shaft of cast steel. The tumbling shaft and arms are all in one piece, require no machine work, but facing of bosses and pin-holes on arms and bearings turned. They are slightly heavier than wrought-iron, but do not look at all heavy. They were made by the Eureka Cast Steel Co., of Chester, Pa This class of work is destined to become very popular, as far better and cheaper parts can be had with less work, and running repairs cheapened.

The Latest in Composite Photography.

Angus Sinclair recently took a brand new Kodak camera on a trip through the South. He religiously "took a shot" at almost everything he saw. Angus knew enough to take off the cap, but he read the legend, "You press the button, we do the rest," and translated it literally He "pressed the button" some seventy-five times, but did not turn the key that moves the film along. The result is that the photo is of a combination order—sort of scrambled view—with a frog-pond from behind Knoxville lying on the side of one of the seven hills of Richmond, an East Tennessee compound going up a Chattanooga church spire, a magnolia tree growing out of the back of an Atlanta razor-backed hog, and a four-year-old pickaninny calmly holding Lookout Mountain in his hand.

The new sleepers on the Erie's limited trains between New York and Chicago have many improvements over the old standard Pullman. The smoking room is large and the wash-basins are located in it, leaving the end of the car, and the passage way clear, making it much pleasanter to go through, to and from the diner, as ladies do not have to go through a crowd of half-dressed men. The hand pump and marble slab basin are gone, and the basins and slab are of metal brightly nickeled, a simple lever turns on hot or cold water at will, the water for the car being delivered by air pressure. The cars are finished in mahogany, and plush to match, the usual curtain railing on each side of the car is absent, the rails and brackets folding back into the upper berth, giving the car a much more roomy appearance. The means of ventilation have been increased and improved; vestibules have made it harder to properly ventilate cars. The trains are lighted by the compressed gas system.

It is estimated that 60,000,000 ties, equivalent to more than 365,000,000 cubic feet of raw material, are used annually in railway repairs. From 13,000,000 to 20,000,000 are supposed to be used annually in new railway construction, making in the neighborhood of 80,000,000 ties consumed each year, at a cost of $30,000,000 to $35,000,000 The amount of money invested in railway ties under the 210,000 miles of main lines and sidings in this country would equal more capital than the combined capital of some of the largest industries extant, and it is estimated that more than 6,000,000 acres of forest lands would have to be cut to supply the necessary timber to furnish these ties. Oak is preferred over all other kinds of wood for ties, and it is claimed that about three-fourths of all in use are made from this hardy timber The remainder is divided mostly into pine, then into red, white and California cedar, chestnut, tamarack, hemlock, cypress and redwood.—*Ex.*

The Maryland Central road contemplate changing their gauge from three feet to standard. They operate eleven locomotives on eighty five miles of track

Correspondence

Not Happy Yet.

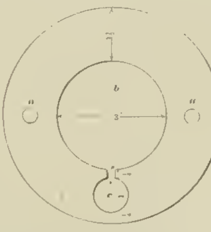
Editor The Locomotive Engineer:

Your answer to Question No. 32, in April issue, does not suit me. An engine is pulling twenty-five loads. She breaks off five and runs ahead with them. The throttle or lever not being touched, yet the exhaust is easier and lighter. You say the exhausts take place closer together. Why should they take place closer together when valve has same travel as it did before train broke? You say that after the engine has gained speed there is not the time for the cylinders to fill with steam that there is when moving slowly and cutting off so late in the stroke.

Remember that the steam is being cut off at the same point of stroke; it is not earlier or later. Cylinders getting half of the boiler pressure, and ports having the same opening, I thought that steam was quick enough to fill the cylinders.

Pine Bluff, Ark. WALTER HAMBLIN.

[The point of cut-off has nothing to do with the exhausts taking place closer together—it is the speed that fixes that. There are four exhausts to every revolution, and the engine may make one or one hundred revolutions in a minute. In this case she commences to increase speed the moment she breaks away from her train. Steam is quick enough to enter the ports at almost any speed, but at higher speed cannot fill them with so much pressure, because it does not have time]



Another Cause for Leaky Triples.

Editor The Locomotive Engineer:

The leak referred to in letter from A H. Tucker, in your April number, is not always caused by the emergency valve spring, as we have found from experience on the equipment at this place. A large number of the first quick-action triple valves had leather seats on the emergency valves, but they now make them of rubber, as the leather would not remain air-tight for any length of time. The leak caused by this gasket will blow continuously through the exhaust port of pressure-retaining valve.

If the trouble is not caused by this seat, I think E. Taylor (also letter in April number) will find the trouble in the large gasket between the triple valve and the auxiliary reservoir, where the "special" freight cylinder, reservoir and triple valve are used, same as plate *D* 34, catalogue 1890. In these there is a one inch passage from triple valve through the auxiliary reservoir to the brake cylinder, which leaves but a small portion of the gasket above the one-inch hole cut, to admit air to brake cylinder when brake is applied. This part of the gasket blows out frequently, and lets the air escape through the exhaust port of triple valve to the pressure-retaining valves, and there it will blow until the gasket is renewed Too much oil in the triple valve and brake cylinders helps to soften the rubber until it blows through; in cases of this kind the trainmen sometimes close the pressure-retaining valve to stop the leak, which, of course, keeps the brake set on that car. I enclose a sketch of gasket showing where it gives out, *a a* represents bolt holes, *b* to auxiliary reservoir, *c* one-inch air passage to cylinder, *x x* where gasket blows out. J. R. M.,

East Buffalo, N Y. Gen. Foreman.

Hot-air Pipes and Other Air-brake Pointers.

Editor Locomotive Engineer:

I cannot resist putting in a word about hot-air pipes in answer to F. B. A.

I have had this trouble with 6" pumps and believe it is due: First, to latent heat escaping from compressed air. For instance, at each stroke of the pump there is about 350 cubic inches of air reduced to twenty-eight or thirty inches. Now this air space contained so many units of heat, and after compression the heat escaped from the reduced space until its temperature was the same as its surroundings This heat had to go somewhere, and if it was not conducted away rapidly enough it would get the pipe hot next the pump, as that is the thinnest place, and would show heat sooner if the air outside was a bad conductor, as it is on a warm, dull, cloudy evening. To satisfy any one, let them feel a stream of escaping compressed air, and see how it will take the heat back again from whatever it touches until it reoccupies its original space. Second, in 6" pumps the passages were more liable to get stopped with gum causing heat by friction. Third, as the air got hot it expanded more, and the pump had so much more work to do in compressing thinner air or air with more resistance, on account of heat expansion, that it had to use more power to keep up pressure, and if the heat burned the gum out of the pipe, air would get out faster, and pump would cool if not too dry.

In the quick action triple valve with emergency stop it takes more pressure to release the brakes, as they have ten pounds more air on top of piston in triple valve, and the slide valve has the friction of ten pounds more pressure to resist the piston, and usually less air in train pipe to start them with than the plate D. 20 triple.

Another wrong theory, in my opinion, is that water will leak into pump from steam cylinder It will have to flow down a smooth piston rod at atmospheric pressure through packing that will hold one hundred pounds of air or more, and I do not believe that is possible. I think that the water deposits from the air under pressure, and then only under certain conditions, and not necessarily on damp or wet days; but when air is taking up water or drying things it will deposit faster, and when it is giving water up, the pipes will be comparatively dry, so when my tobacco is dry I watch the drain cocks closer.

Another bad thing, in my opinion, is the term "excess pressure" When I get on an engine to instruct an engineer I try to find if he calls it "excess." If so I generally find him carrying his brake handle in release. If he calls it reserve he uses the running position. As an illustration: If the engineer had one hundred dollars laid by, it might be an excess to his employer, as may be the reservoir pressure to the man who doesn't run, but the engineer relies on the money as a reserve, and should not be misled to such an extent as he usually is in the other case by the term "excess pressure."

I have found it to be of great advantage to me to keep a small test gauge and thermometer, and believe that it would help explain many things that, without them, are apparent contradictions to correct air-brake practice

Would be very much pleased to learn what conclusions others have arrived at in these matters.

Roanoke, Va. GEORGE HOLMES.

Traveling Cranes in Locomotive Repair Shops.

Editor The Locomotive Engineer:

I wish to take up your editorial in the April LOCOMOTIVE ENGINEER, arguing against the use of traveling cranes in locomotive repair shops, and correct some statements which you make there.

We have, in our shop here, an electric traveling crane, made by the Shaw Electric Crane Company, Milwaukee, Wis., which has a capacity of 50 tons, and has been tested to 60 tons.

This crane travels over all the pits, from end to end of the machine shop, and it is run from a dynamo placed in our engine-room, which is belted to a pulley run by a clutch, fastened to the main line shafting, so that we do not run the dynamo, except when we want to use the crane. This answers your argument—that traveling cranes require power at all times, whether in use or not.

We have an electrician who takes charge of our five dynamos, keeps in repair all of our electric lights, and both of our electric transfer tables and runs these and our electric crane, when necessary, and his services would be required for the lights and electric transfer tables if we did not have the crane, therefore it cannot be said that the crane requires a man in attendance all the time.

The amount of repairs which this crane has required in the past nine months would not amount to $10 altogether, and the amount of oil used is very small indeed.

Our crane occupies no floor room whatever, and is not in the way of any belting or machinery, and I will guarantee that we can take an engine off its wheels, or put one on its wheels, in one-twentieth the time that the same work can be done on the drop tables. For example, we regularly remove the wheels from our heavy ten-wheel engines (weighing 63 tons in running order), in ten minutes, and less, from the time the engine is ready to raise until it is resting on the blocking, and can do it, on a wager, in five minutes. To do this same work with a drop table, and get the engine back into place on the pit, on which it is stripped, cannot be done in much less than two hours, as I know by experience.

If you take a trip this way we shall be more than pleased to prove to you the above statements, and show you the fine plant we have here, which, for its size, is not surpassed in the United States.

M. K. BARNUM,
Superintendent of Shops, Union Pacific R. R.
Cheyenne, Wyo.

The Whistle and Lamp Business—Water-brakes.

Editor The Locomotive Engineer:

Some of the boys seem to be much worried over the whistle and lamp business, or why the whistle blows out the gauge lamp.

Sound is produced by the vibration of air. Flames, under certain conditions, are very sensitive to these vibrations, and when the small lamp flame is exposed to the sound from steam whistle, it is simply "shook out." Every tone of sound, from bass to shrill, gives a different vibration, or, in other words, produces a "sound wave" of different length. When the flame of certain length or breadth is struck, as it were, by a certain sound that vibrates it, if the flame is sensitive to that particular sound it won't stand that shaking up, as it were, and will go out.

The only way to keep the lamp lighted is to change burner to get a different size flame, or change whistle to get different tone. Another way might do to change position, or protect lamp flame, so that the sound waves won't strike it so hard. Many remarkable effects are produced on thin and delicate flames by different sounds, as scientific experiments have shown.

The action of whistle on cab lights is simply mechanical, and done through the air. There is no hoodoo about it.

Concerning the water-brake, it becomes interesting when our friend talks about how "she shoots water out of her exhaust nozzles into the front end with the cylinder cocks closed." This sounds like the engine that wouldn't suck her ashes. There will be trouble on the Deadwood Central if they don't open their cylinder cocks and quit letting in so much water. The water gets into front end because too much is admitted to exhaust passage, and at the moment the valve closes, it "back acts" out the nozzle. No more water should be admitted than will destroy the vacuum in cylinder, caused by the reverse action, without "sucking ashes" from smoke-box, lubricating the moving parts, besides doing its main duty, that of creating back pressure on pistons, and holding the engine back, making it a valuable aid to other braking appliances.

We use the water-brake constantly on descending certain grades, consolidated engines having made nearly half their mileage in the past four years with water-brake applied, and there is no indication of unusual wear on cylinders or valves, neither has any accident or breakage occurred from its use. Our cylinder cocks are of a pattern as large as an inch globe valve nearly, and kick up considerable dirt along the road, which is about all the trouble we have. Cocks are always open when water-brakes are applied.

Would be very glad to hear of any experience in regard to it.

DOC.

Dunsmuir, Cal.

Coal Burning.

Editor The Locomotive Engineer:

My friend "Doc," met me the other day, and turned a few ideas loose on coal burning, which you may wish to hear. We got to talking of the time back in '70 and '71 ("Doc" always likes to talk about old times), when we both fired wood; very naturally the talk worked around onto coal for fuel. He said: "When you and I got a dollar and a half for a day's work firing wood, and put in as much more time scouring the brass, washing the cab, and keeping things neat and clean, as we spent on the road, we were regular kings. Why, my engine had as much brass on her, outside her cab, as there is on fifty engines to-day. If a fellow run across a brass acorn in a junk shop or pile of scrap brass, he gobbled onto it and hunted for a bolt to screw it on, where it could be polished up and shine. Those days are gone now, and I ain't sorry. To-day there ain't a bit of brass in sight on my engine, even the bell is painted black. My fire boy has put some kind of stuff on the brass in the cab—I guess it is sulphur—that turned it black as jet, and he keeps it wiped off, so it shines like a black bottle. In the old days they did not pay any attention to how much fuel you burned. If a big pile was used up every trip, that was your bad luck, they never seemed to think of the cost, it was *git there* and *pull cars*. *Now* they have found out that coal costs money, and if the engines will do the work on less coal, there is so much less to be paid out for it. I believe it is a good sign, for the next thing they find out will be that it costs the company more to burn poor, dirty coal at a low price than to pay a fair price for good coal. It costs just as much to haul a car of poor coal 300 miles as a car of good, and handling it from the mine to the tender is the big end of the expense. I could fix my engine so she would burn a quarter less coal if we got good all the time, but about once in ten days—sometimes as long as a month—I get a tender full of fine dirt coal, so the nozzle and extension front have got to be fixed to make steam with that stuff. The rest of the time she chaws up good coal like sin; our square fire-boxes are too small to do a good job on poor material.

"Some of the firemen make you tired, too; they load her up with about six or eight scoops of coal just as it comes, some of it chunks as big as your head, then they climb up on their perch, and think they are 'getting there.' The other day I had one of them black smoke fellows. The conductor came ahead with orders once, and said: 'Doc, when you shut off we can't see in the coaches for smoke.' The boy says to me—that shows how much he knows—'You can't fire an engine without making smoke; if the smoke quits coming out of the stack she won't steam.'

"It is a blessing that he is the only one of the kind we have got on the road. I shook him at the end of the trip, and he is on a yard engine now, where he can't do much hurt. My regular fireman will keep her hot all day, and she never makes any smoke to hurt—just a little each fire that he puts in. I see to keeping a good arch in her, and he attends to the rest. He puts in one to three scoops at a time, and don't fire any oftener than the fellow that puts in twice as much at a time. When he first came on with me he used to spend about half of his time cracking coal, and would not put a chunk bigger than your fist into her. I asked him why he did it, he said the engine would not keep hot on coarse feed. She used to burn eight ton on the round trip, and never was what you could call a good steamer, now she takes five and a half to six ton, and is a daisy. I have made up more time on the fast run since I got him than anybody else, he ought to have the credit of it. She is always within about five pounds of blowing off, and stays right there, so I can hook her up in six inches, and whale the stuffing out of four cars, or nine inches with night express, which has nine cars mostly, when ever we are late, which seems to happen every day; some of the fellers on the other division don't seem to care about getting in on time.

"But that boy of mine is a dandy. I begin to believe what you told me last fall—that knowledge always helps out muscle. He hain't got much muscle, but he is way up on knowledge. Our traveling engineer is always asking the boys hard questions. I guess he don't know how hard it is to answer some of them. I told him so a while ago; he laughed, and said it didn't hurt anybody to have to rustle around and learn about his trade. Well, as I was saying, when they run up against a hard question they come over to my boy, and he gets out his books and talks about combustion, leverage, expansion, lap and lead, till you can't rest. I never knew but one other fellow just like him. He is master mechanic of a big road now, and I am a common plug puller. It is curious how some men take an interest in such things, and get good soft jobs out of it."

"Doc" is about right about some of his ideas. There is a closer watch kept of the fuel account now than ten years ago. The engines are expected to draw larger trains at faster speed than they used to; lots of them do not burn any more fuel in doing more work, while a good many engines haul a train of 60,000 pound cars, and use less coal than we did fifteen years ago with the same number of small cars. It pays to keep a close watch of the coal pile, it is the heaviest bill, next to wages, in the expense account of locomotives. He don't say so, but he seems to think that the fireman is responsible for all the coal that is wasted. He is way off there. If the engine is not worked evenly, pumped evenly, and a regular speed kept up between stations where the grades will admit of it, the close fireman wastes his skill. No amount of skill on the part of the fireman will avail, if the engine is worked hard out of one station with the injector full on, and easy out of the next one, and water level getting lower every mile. It takes coal to make up time; if lost time is all made up in a few miles, instead of spreading it out all the way to next meeting point, the coal pile will suffer. Both men on an engine have to do their best on a poor steamer to get over the road on time. What helps a poor steamer will make a good one better, and cut down her coal bill considerably, let alone the comfort you have working her. But you will hear it said, "You don't have to be particular about that engine, she will steam—just throw it into her any way." Maybe so.

CLINTON B. CONGER.

Grand Rapids, Mich.

"Please Note my Exceptions."

Editor The Locomotive Engineer:

In writing on the question of "Better Engineers," your correspondent makes use of some statements and insinuations that, in my judgment, need correcting, if not plainly rebuking. He says, "The great mistake has been in not recognizing the fireman as the future engineer." This statement is a mistake, to call it by its mildest appellation. A very large per cent. of the engineers on the "Milwaukee" road have been promoted from firemen. That they entered the service with the expectation of becoming engineers, and that the company intended, when they employed them as firemen, to so promote them, provided they could stand the most exacting of all tests—practical experience—no one familiar with the practice of this company will deny. What is true in this regard, of the "Milwaukee," is true of a majority of the roads in this country. The engineers themselves have always "recognized the fireman as the future engineer," as can be very conclusively proven. The fact is that the fireman has been so recognized by every one intimately connected with the railway service since a very early date in its development. And if he had not been so recognized Mr. "Sense" would have seen a very different class of men in the service as firemen, either now or ten years ago. Now, after men had entered the service under the operation of this custom, it would be manifestly unjust at a later day to "*weed them out*," because they might not be able to pass an examination that the company may have seen fit to adopt.

After a man has rendered faithful, careful, safe and acceptable service from three to thirty years, according to the capacity in which he is employed, it is not strange that men who are in every way competent to judge, and who have known him all through the trying ordeal, should refuse to accept anybody's statement that the man is incompetent.

The insinuation that either of the Brotherhoods is a repository for incompetents, or a veil behind which they hide, is a libel, the animus of which some one in the vicinity of Jamestown, S. D., may understand, but which I am unable to surmise. It's not to be wondered at that the author of such an imputation should hide behind a *nom de plume*, and have the concentrated "gall" to sign himself "Common Sense."

I can't say that I exactly like the tone of this communication for a mechanical journal, but if you allow one writer a dig at the Brotherhoods, you certainly can't refuse to let a Brotherhood man resent it. A. H. TUCKER.

Chillicothe, Mo.

The Air-brake as She is Writ About.

Editor The Locomotive Engineer:

I notice a great deal of discussion going on in your valuable paper relative to air-brakes, and it is a mystery to me how correspondents take upon themselves such weighty subjects without knowing the first principles of the subject on which they write. For a long time I thought I knew just a little bit about air, but after reading the enclosed article, cut from a magazine, I find that I do not understand the first principles. This may be a "chestnut" to a great many, but it is the first time I have seen it, and thinking perhaps it might be the means of setting your correspondents right, I send it to you. Wishing success in your endeavor to supply a good readable paper chuck full of desirable information,

I am yours truly,

C. T. McELVANEY,

Ass't Master Mechanic M., K. & T. R'y.

Denison, Tex.

The article referred to by our correspondent is entitled, "How Air-brakes Work," and reads as follows:

"Some of our older readers can remember the time when the 'brakemen' had something more to do than help women off and on the cars and mangle the names of stations. In those early days the stopping of the train was attended with shrill whistling, frantic twisting and straining at the brake-wheels, and a squeaking of the slowly acting apparatus beneath the cars. Now the train glides at almost full speed to the station and suddenly and smoothly stops within its own length.

"What makes the difference? 'Oh, we have air-brakes nowadays,' you say. True enough, and it is about these very air-brakes that we want to have a chat, for we half suspect that you, dear reader, have a general, not to say hazy, idea of the way in which these brakes are worked.

"The first air-brake was called the 'vacuum' brake. Under each car was placed a cylinder with flexible rubber sides. It looked like an accordion, and was connected with the locomotive, which operated an air-pump.

"In order to stop the train air was pumped into the cylinders, which were expanded, and by means of iron rods and levers pressed the brakes against the edges of the wheels. When the air was released the brakes were withdrawn.

"The 'Westinghouse air-brake,' now in general use in this country, England and the continent, acts on just the opposite principle. The flexible accordions are replaced by heavy iron cylinders, in the ends of which are pistons. The rods of the piston are connected with the brake beams. By means of very strong steel springs the brakes are drawn tightly against the wheels, so that unless they are pulled back the brakes are constantly 'on.' The pulling back is accomplished by pumping the air out of the iron cylinders; this draws the end pistons in and pulls the brake beams away from the wheels. It will be readily seen that this brake is greatly superior to the other form. The first is always 'off' unless forced 'on,' the second always 'on' unless forced 'off.' So in case the train is broken in two the rubber connection is at once broken, the air rushes into the cylinders, down go the brakes, and the cars stop.

"There are levers and cords in every car by which a little child can put on brakes the whole length of the train, simply by letting air into the vacuums of the cylinders.

"The air-pump is on the side of the locomotive, and looks like two large collar boxes with a piston working in and out between them. The pump is always at work while the train stands at the station, pumping the air out of the cylinders, and drawing back the brakes ready for the start. Next time you have a chance, look over the air-brake apparatus and fix these every-day facts in your mind. There are many interesting things connected with very familiar objects, and the more we know about them the better."

Darkening Headlights for Signals.

Editor The Locomotive Engineer:

It has been said that on some roads, at all meeting points for trains, the head and all train lights must be darkened on the trains in side track; curtains have been invented to shroud headlights on engines while standing on side track. What is the advantage of this system?

In the writer's experience, when making a meet, on the last minute, and not wanting to stop, to *see the headlight* of the other engine on the side track, and to know they are in out of the way, is a great deal more satisfactory than to go feeling your way through the yard on an uncertainty, and more particularly if the meeting place is on a curve; if they are not there the place is dark; if they are there, and all lights shrouded, the place is dark and everything uncertain. Headlights go out sometimes; suppose you are making a meet with a man who is always on time, it is dark and stormy, your headlight has gone out by virtue of a bird flying against the glass and breaking it, or any similar cause. As everything is dark at the station, you take it for granted they are on the side track, and pull through; but they got laid out and did not make it; your watch is two or three minutes fast from some unexplained reason, and you meet on that curve in the cut—you know the rest. If your headlight had not gone out, there is a possibility you would have known to a certainty that they were not in the side track; if they had been there, and all lights burning, everything would have been safe. Brethren, let us have light. W. DE SANNO.

Corry, Pa.

Locomotive Engineers—Present and Future.

Editor The Locomotive Engineer:

I have noticed for some time past that it is quite the thing—not only in your paper, but in other R. R. publications—for correspondents to criticise in very strong language ignorance in engineers.

I do not know why this is done, or what object they have in view by pursuing this course. Would they have the public believe that the ranks are filled with ignorant, and, consequently, incompetent men? That officials, high in authority, would countenance such dense ignorance as is portrayed by some of these writers? That they would trust not only valuable property, but human lives, in the hands of men who have no idea of how it should be managed?

To create such an impression would not only lower the engineers in the estimation of the public, but it would have a tendency to reflect against the management of a corporation that would place a premium on ignorance by advancing such men to positions of trust. Through all the tirade of abuse that has been heaped upon them, I am unable to recall one instance where it has been resented. Perhaps it is because the "mud throwers" hid behind an *incognito*—as they always do—or possibly they may have thought it unworthy of their notice and treated it with silent contempt. Be that as it may, I thought I would like to say something in their defense.

I am brought in personal contact with many engineers, and, as far as I am capable of judging, they are the superior in intelligence to any class of skilled labor I know of.

We do not, nor do we expect to find many of them who are scientists, mathematicians or graduates of the higher institutions of learning; but we do find men of good common sense, sound judgment, quick perception and excellent reasoning faculties—men who are perhaps able to give points to writers who are afraid to be known in print.

I remember of hearing a superintendent of motive power of one of our largest R. R. systems in the West say that he owed much of his success—as far as operating locomotives was concerned—to knowledge obtained by conversing with engineers. Now, how could or how can any of the so-called densely ignorant engineers diffuse light or knowledge of any kind whatever?

We cannot deny there are some who have missed their calling; were promoted, not because of their peculiar fitness for the position, or that they merited it in any way, but by reason of seniority, a pull with the powers that be, or various other reasons. Thus it is that there are some incompetent engineers. No doubt some roads do, even in this advanced age, employ men as firemen who scarcely have the rudiments of an education. They learn intuitively how to perform their various duties, and in time how to start and stop a locomotive, how to regulate the water feed, and how to "tie up" in case of a breakdown. They have never given the matter any special thought or study, because they have not the mental ability to grasp it. They could enlighten themselves on many subjects if they would devote a small portion of their leisure time to reading suitable books; but to these men reading is distasteful and irksome. They have no use for book knowledge; they feel their weakness, but cannot apply the remedy. Invariably, in every case, they can be blamed for their ignorance, but can you blame them for being engineers? I should say not.

There is one very dangerous shoal for the young engineer to pass. To illustrate: A young man is graduated from college as a physician or lawyer, and receives his sheepskin; but, if he would succeed in his chosen profession he must not rely wholly upon his college record, he must keep up with the times, and still devote much time to study and research.

A young man is graduated from a technical school and writes three or four letters after his name, but if he stops here he will get left. He must keep abreast with our nineteenth century hustlers or be relegated to the rear of the procession with the drones.

Again: A young man has been firing a number of years, has an excellent record, is bright, intelligent, and quick to "catch on." He at last reaches the height of his ambition, through merit, and becomes an engineer. As a fireman he was of an investigating turn of mind, would ask to be enlightened on subjects that he did not understand, but now that he is an engineer he is above asking questions, because an engineer should know almost everything. This young man has ceased to be progressive. "Got there," as it were, and now he is going to take things easy.

He has lapsed into sort of a comatose state, and, if he does not awaken, some one will pass him, and in a few years he will find himself in the rear rank.

Every trade and profession is burdened with weak material, and there is always room at the top for those who desire to get there, and are willing to work and sacrifice something for it.

I believe the time is not far distant when mechanical officers of railroad companies will realize the necessity of abolishing the rights of seniority, and adopting a system of written examinations, whereby they can determine qualifications and fitness for so responsible a position. Until some such course is pursued, there will certainly some creep in who will not raise the standard of intelligence among our engineers. Nevertheless, I do not perceive the benefit to be derived from constantly hammering at them, and holding them up for ridicule before the whole railroad world. The corporations that have poor engineers must endure them, and the only solution of the problem that I see is for them to be careful who they promote in the future.

Albany, N. Y. T. B. PURVES, JR.

Varnishing Car Sashes and Blinds.

The great puzzle is to keep blinds in proper condition when it is a necessity to revarnish the exterior of a car once a year, and not a necessity to revarnish the interior oftener than once in three years, and the blinds stand right in the gap between these two extremities. Really, the outside of a blind, especially the lower half, needs varnishing as often as the outside of the car does, but you cannot well do one side of a blind without doing the other, as the varnish runs through, and if you should do the blind all over as often as that it would become overloaded, and the inside would crack up like a turtle shell. The only conclusion is, then, to revarnish the interior of the cars as often as good judgment would seem to dictate, taking into thought the durability of the blinds—say once in three years—and then all can be done together, blinds and all, unless the blinds are dispensed with and curtains used, which, to our mind, is the best solution of the whole trouble.

Another thing as to sash: The glass should be thoroughly bedded with good putty into the sash, and the beaded side put on the inside of the car. This is important to keep the rain from running down on the glass between the bead and the glass, and soaking into the wood and driving off the varnish. You will notice that varnish is the first to leave the sash when the water gets in.—C. E COPP, in *Painters' Magazine.*

The Mason Regulator Co., of Boston, have acquired the exclusive right to manufacture and sell the piston throw indicator for air-brakes, patented by Mr. Frank Robinson, of Bangor Mr. Robinson is the master mechanic of the Maine Central R R., and this device was invented by him for use on railroad cars. It is perfectly simple, and indicates at any time to a car inspector the condition of the piston of the air-brakes. The Mason Co. will soon have description and catalogues ready for distribution.

We are always glad to change the address of any subscriber, no matter how often he moves; but it would save us a lot of trouble if, when writing for a change, you state whose club, if any, you were in. THE LOCOMOTIVE ENGINEER has by far the largest club list of the railroad papers, and the larger it gets, the harder to find a single name if classified in among the clubs.

In putting in new flues let the fire-box end project through the sheet a distance equal to two and a half times the thickness of the tube; this will be just right for beading down. If it is less than twice the thickness of tube, take it out; it will cause trouble.

The Austrian railway companies have been requested by the government not to engage any more foreigners for service on the railways, particularly in the administrative departments. Foreigners who are at present employed will be compelled to become Austrians or Hungarians within one year, if they desire to remain in the service This action of the government is based upon military reasons.

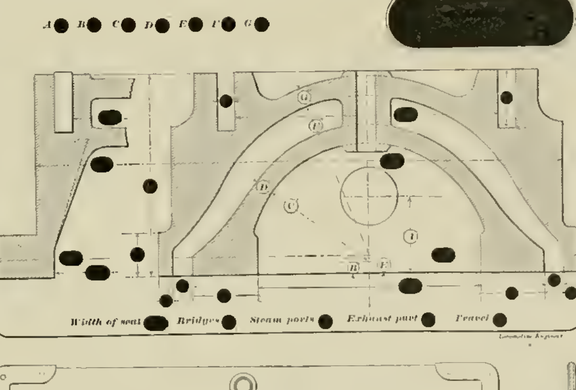
The Dixon Crucible Company, of Jersey City, have received a letter from Master Mechanic David Brown, of the D., L. & W., at Scranton, Pa, in which he says:

I can now give you an answer in regard to your pipe joint grease I consider it an excellent grease for mud plugs in locomotive boilers. The plugs come out easily, and when taken out are clean. We will order some on our next requisition, and use it hereafter.

New System of Shop Card Drawings.

At the shops of the estate of F. W. Richardson, Troy, N. Y., they make hundreds of locomotive valves every month; both the Richardson balanced valve and the Allen-Richardson. There are hardly two roads in the country that use valves of exactly the same dimensions, and it has been the practice in this shop to make a complete drawing for each order. This took time and cost money.

Superintendent W. S. Rogers has devised a scheme to avoid making drawings, and at the same time preserve a complete file of orders filled with drawings for use in case of a duplicate order. He has a holder to preserve the drawing from mutilation, which is shown in Figs. 1 and 2, and is described as follows:



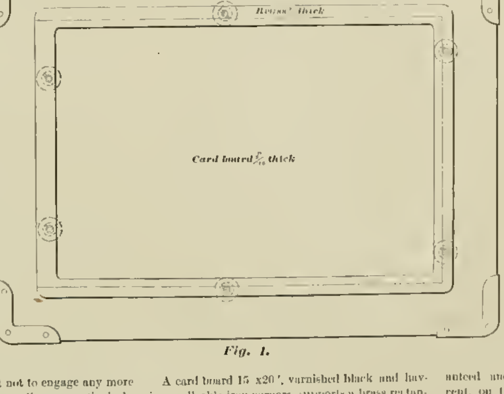


Fig. 1.

Fig. 2.

A card board 15 x20", varnished black and having malleable iron corners, supports a brass rectangular frame 11¼" wide by 16¼ long over all, and ⅛" thick by ⅞" wide. This frame is held to the card board by six screws, carrying washers at suitable distances apart, the frame being tapped for that purpose A grommet is put in top edge of card, that it may be hung up instead of lying on the bench on machine or getting on the floor.

Blue prints on cloth of the Richardson and Allen-Richardson balanced slide valves, with dimensions left blank as shown in cut, are kept in stock, the prints being cut to a standard size, as shown by the dash and dot line in Fig 1.

When an order comes in the office the dimensions are filled in on blue print, all dimensions for shop use being in heavy black ink—all other data being recorded in its proper place in red ink. The print is then slipped under the brass frame on the card and sent into the shop. After the order is filled the print is removed and filed away in alphabetical order in Shannon letter files especially made for this purpose, to be brought out again when duplicates are ordered. This system does away with the cumbersome varnished drawing card methods for each and every job.

This plan is, of course, of especial use in a manufacturing plant where many things of the same general form are used, but the plan can be adopted in railroad shops for a great deal of work, and much time and expense saved

Two of the Great Railroads of the World.

The Pennsylvania Company's system of railroads is composed of no less than 120 corporations, certainly a colossal aggregation to be under the management of one head. President Roberts, in his last annual report, says that, with few exceptions, all these corporations are in good financial condition, and are earning fair returns on the capital invested. They represent 7,915 miles of railroad and canal, and have a share and bonded capital of over $700,000,000 They earned in 1890 more than $133,000,000 gross, and moved over 137,000,000 tons of freight and 84,000,000 passengers. In thirty years, on the lines east of Pittsburgh & Erie, the increase in gross earnings was over 800 per cent., and in net was more than 200 per cent. The cost of the securities of other corporations now held by the Pennsylvania was $113,183,734, and the direct revenue from them last year was $4,-439,404, which is in excess of the total funded debt of the Pennsylvania Railroad In connection with the above figures, the report of the London & Northwestern for 1890 is interesting. Its authorized capital is £110,-077,934, or, figuring the pound at $4 85, $533,-877,979. On this the gross receipts from traffic were $29,651,339, and the net amounted to $16,199,117 Dividends at the rate of 4 per cent. were paid on the guaranteed and preference stocks, and of 7⅛ per cent. on the consolidated stock The amount of these stocks is £77,107,238 The mileage of the system was 1,916 4 miles. It will be seen that although the mileage of the Pennsylvania system is 7,915 miles, which is just about 6,000 miles more than the London & Northwestern, the capitalization of the two companies is by no means so far apart, that of the English corporation being $533,-877,979, against $700,000,000 of the Pennsylvania These facts should not be forgotten when the results achieved in both countries are under discussion.—*Railway Age.*

Mr. Robert Quayle, division master mechanic of the Chicago & Northwestern, at Clinton, Iowa, has been appointed master mechanic of the Milwaukee, Lake Shore & Western.

CONTENTS

A Railroad Abuse that Should be Remedied.

One of the most vexatious problems that manufacturers of railway appliances and supplies have to deal with, and which, in its net results, is not without a bearing upon the welfare of railroad men and the status of important railroad interests, has its root in the action of certain classes of railway officers, and constitutes a flagrant abuse which should be remedied.

We refer to the manner of issuing the numberless advertising pamphlets and dodgers of all sorts that railway passenger and traffic agents or other officials are all the time getting out, in the supposed interest of the road, and for which "advertisements" are solicited from manufacturers of railway appliances who are doing business or hope to do business with the road. Doubtless most of these so-called "advertisements" are solicited with an eye to economy in the cost of advertising the railroad. In many instances there is room for suspicion that the profits derived from their appearance in railroad pamphlets are in the nature of a private "spec.," in which, possibly, the relative or favorite who does the "soliciting" is concerned. In either case, not very much study of the subject is required to show that the railroad pamphlets so issued are by it given such an advertising look and bulk, that the public which might be willing to read them, if issued on their own merits, give them very little attention, and, of course, this tends to defeat the object nominally aimed at.

As a matter of fact, with very few exceptions, the manufacturers of railway appliances and supplies, from whom these so-called "advertisements" are solicited, regard all such solicitation as made under cover of an implied threat of business disadvantage, in case of their refusal to comply. The veiled request is really a demand in the eyes of the manufacturer, with which he complies unwillingly, and is a form of tribute or levy, to which he frequently, in the privacy of his ledger, applies a much stronger epithet.

The reason is plain. A pamphlet is gotten out, containing bird's-eye views, and eulogistic descriptions of the boarding houses, scenery and other attractions along the line of the Bungtown, Bugleford & Bang-up R. R., to be gratuitously distributed among grocers, lawyers, doctors and other non-railroading classes in the community. No matter with what motives advertisements of railway appliances are solicited for such a pamphlet, they cannot possibly do the manufacturer any good, because grocers, lawyers, doctors, etc., do not buy railway supplies themselves, and cannot in the least degree influence their selection, purchase or use.

Now, if this sort of thing involved a tax only occasionally extorted, manufacturers could stand it and still be happy, but the trouble is, that the snap has proven too soft, and the number of railroads practicing or permitting it has come to be legion. Instances are not wanting, in which manufacturers find their bills for this kind of bogus advertising running into thousands of dollars yearly, and some find them so onerous, that they acquire misleading ideas with reference to the whole subject of railroad advertising, perhaps finding themselves able to reserve little or no money to spend for real advertising. Of course this tends to hinder the introduction of new appliances on railroads, no matter how meritorious, and, equally of course, this effect is to the disadvantage of the railroads.

But there is another way in which these bogus advertising schemes operate to the detriment of railroads, and that is by the handicap necessarily put upon the progress of legitimate railroad newspapers, through the diversion of advertising patronage to which their facilities for supplying useful information to railroad men should entitle them. Whatever tends to increase the efficiency of railroad men, benefits the road with which they are connected, whether they are employed in the cab, the roundhouse, the repair shop or the places of higher authority. In like manner, anything which lessens their opportunities for acquiring such increased efficiency, involves injury to the railroads. The tax in question becomes, therefore, a tax on knowledge, detrimental to every legitimate interest connected with railroads. We are glad to say that probably THE LOCOMOTIVE ENGINEER is affected by this cause to a relatively less degree than most railroad papers, because expecting to derive so large a proportion of its total revenue from circulation—the regular edition called for to supply the wants of readers being now 16,000 copies every month—but the fact remains, that the railroads responsible for the perpetration of such an abuse are placing obstacles in the way of their own development and prosperity.

The remedy, if remedy there be, will have to come from one or both of two sources. Manufacturers will have to more generally make up their minds that the implied threat is as devoid of weight as the alleged benefit. A prominent manufacturer has hit upon the plan of requesting the solicitor in such cases to bring him a letter from the general manager of the road, asking him to recognize the publication in question. Forty-nine times out of fifty this letter never comes, and no indication appears anywhere, that his refusal involves any disfavor with the practical or the buying departments of the roads concerned. Another manufacturer asks for a letter from the purchasing agent, and with equally happy results.

The other part of the remedy will have to come from the railroad officials. Passenger and freight agents, and other subordinate officers who have been getting out such publications in good faith, may in time, perhaps, realize that the method they have been following tends to defeat the object aimed at. Those who have practiced it for other reasons, should be promptly set right, by prohibitory orders issued by the general manager.

Old Boilers.

Some years ago, when 50,000 and 60,000-pound cars were first introduced, some enterprising roads painted up some of their old stock, and increased the capacity—with a stencil. Just now there is a fad for high steam pressure, and a master mechanic is almost afraid to have his new boilers built for 140 pounds pressure, for fear of being considered behind the age. There has been no little amount of risk taken in increasing the pressure, on the stencil plan, by screwing down the pop valves. There have already been several disastrous boiler explosions this year, and there will be more. Have you got a boiler in charge that is more than twenty years old, and if your family were going to live over that boiler, and you had your way about it, you would not reduce the pressure by half?

Lithium is the lightest metal in the world, and iridium is the heaviest. The former is worth $6,880 per pound, and the latter $1,070. There are a dozen metals more precious than gold.

Car Coupler Facts.

The action of the officials of the Vanderbilt roads, in deciding to adhere to and hurry the application of the master car builders' standard coupler, known as the Janney hook, will no doubt have a great deal of weight in preventing a reopening of the question by the association. We have little doubt that the coupler has come to stay, and, if it has, the sooner its adoption is universal the better. It is not a perfect thing, however, and has faults that cannot be remedied, if the present lines are adhered to.

To begin with, it is not a mechanical device, no mechanic would think of making a part of a machine to stand buffing and pulling strains in the shape of a bell crank, if he could help it. The "lines" having been established, no improvement can be made, it will be impossible to increase the sizes of parts for any service, the wear of one hundred miles of hard service destroys the contour lines, and a limit for wear of knuckles will soon have to be established that will cost nearly, if not quite as much to keep up as does the present breakage of links and pins. It is altogether likely that, if even the poorest of the link and pin couplers had been adopted universally, a score of years ago, there would not have been the harvest of death that finally made the adoption of one standard kind of coupler imperative. It has been the meeting of different kinds and sizes of couplers that has caused half the deaths of our trainmen, but a very large percentage have lost their lives or limbs simply from the fact that they have been obliged to be on the tops of trains in all kinds of weather, and on all kinds, sizes and shapes of cars.

The universal adoption of the automatic air brake will do far more to protect the lives of trainmen than will the coupler, but both can do much that has been neglected for far too many years

---

On the Connecticut River road they have excellent water, and a leaky boiler is almost unknown. One engine, the "J. Mulligan," named for the president, himself an old engineer, has been in constant service since 1857, thirty-four long years, and has only had one new fire-box; she is a Schenectady eight-wheeler with 16x22 cylinders. There is another engine in the service that has made over 140 miles per day for eighteen years, and the extent of repairs to her boiler has been limited to the removal of a dozen flues to clean out the scale—the original fire-box and flues are still used without a sign of giving out.

Followed Instructions.

Once upon a time there was a road where the officers considered that the conductors were not making a fair divide, and kicked One of them thought he was going to improve matters by eliminating money from the question between the conductors and the treasurer He put up a notice that conductors would not turn in cash, but must buy tickets with money collected and turn the tickets in. One conductor seemed to return about the usual number of tickets as before the change, while the others' returns had increased. After some weeks he was called up.

"We know you have received cash for fares, but your returns do not show it Do you understand the instructions in this matter?"

"Yes, certainly; buy tickets, punch them, and turn 'em in."

"Well, why don't you turn 'em in, then?"

"Haven't got 'em all punched yet."

"What tickets are they?"

"Meal tickets, of course!"

Countersunk rivets are to be avoided where possible. Countersinking weakens the sheet, and countersunk rivets are no stronger than beaded rivets. Countersunk holes should be reamed with a 60° reamer, but the taper should never be deeper than three-quarters of the thickness of the sheet.

One of the greatest blessings secured to the traveling public by the use of vestibuled trains is the drowning of the noise of the moving train To properly appreciate the extent of this, it is only necessary to open the side doors of the vestibules, and listen for a moment to the roar.

ASKED & ANSWERED.

(88) E. A Rox, Zanesville, O., writes.

Suppose a back up eccentric slips, could it be set by putting reverse lever in forward notch, and make a mark on valve stem close up to the gland, then put reverse lever in backward notch, and turn eccentric until mark on valve stem comes to gland, then fasten eccentric; what position would engine have to stand? 2d. Is the go-ahead eccentric always coupled to top of link? *A*—Yes, if you put the engine on either dead center, move the loose eccentric around the axle in the direction it runs when moving the engine 2d Yes; almost universally where the shifting link is used

(89) R. O E., Mt. Savage, Md., asks

Is there a mixture of acids called "bright dip" that will polish rough brass without file or lathe? If there is, please publish the formula *A*—The dip referred to is a solution of potash that cuts off grease, paint and gum from brass immersed in it when hot, and afterward dried in sawdust. It is only used where there is a need of this work in large quantities, such as a general car shop.

(40) J. C., Sherbrooke, Can., asks.

Kindly state reasons in your next issue "why a locomotive with a 17x24" cylinder is superior in starting and handling train to one with 16x20" cylinder" *A*—Because there is more pressure exerted on the larger cylinder, for the same reason that you can lift more with a seventeen foot lever than you can with one only sixteen feet long

Progressive Examination of Locomotive Engineers and Firemen.

By JOHN A HILL

FIRST EXAMINATION.

[*After One Year's Service*]

Q What engine have you been firing?

A. ——.

Q What engineers have you fired for?

A. ——.

Q Has there been anything to hinder or prevent you from picking up desired information for this examination?

A ——

Q Have you been left during the year?

A. ——.

Q. Have you been suspended during that time—if so, what for?

A.——.

Q Have you acquired the habit of comparing your time with the clock or the watches of engineer or conductor daily?

A. ——.

Q. Do you thoroughly understand all the signals in use on the road—yes or no?

A. ——.

Q. What signal devices are provided and in use on your engine?

A. ——.

Q. When used as a fixed signal, and not on a train or engine, what does red signify?

A. *Red signifies *danger*, and is the signal to stop.

Q. Green signal?

A *Caution;* go slow

Q White?

A. *Safety;* go on.

Q What is a green and white combined signal for?

A. To stop trains at flag stations for passengers or freight.

Q Blue?

A To be used by car inspectors. Cars so marked should not be moved.

Q. What is a torpedo used for?

A. Torpedoes are additional signals, and are so placed as to call attention to the regular signals

Q. Then if one is struck you merely watch for the signal?

A No, *One* means stop; *two* is to slow down and go ahead cautiously, looking out for danger signal

Q. What is a *fuzee* used for?

A Danger signal, generally dropped by heavy trains to warn following trains of their presence. They burn ten minutes, and must not be passed while burning.

Q Beside any you have mentioned, what else would you consider a danger signal that would call for a stop?

A Any light swung across the track, or a hat or handkerchief waved, or any violent signal given by any person.

Q. How should the rear of trains be marked?

A Each train, when running, must display two green flags by day and two green lights at night, one on each side of rear of train, as markers to indicate the rear of train. Yard engines will not carry markers.

Q. Then if you were following a train you would be on the lookout for green lights?

A. No, sir. Green lights, as markers, are *toward the front*, so that the engineer can see them, not back, except when the train gets out of the way on a siding, when the green lights must be taken down and red ones put up

Q. What lights must be displayed on the end of trains then?

A. Either a headlight or two or more *red* lights, except yard engines. They must have a headlight on each end, or where but one is used, two green lights must be displayed on the end in place of red.

Q. What is this for?

A To distinguish yard engines from regular road engines.

Q. What is the rule about bell-cords?

A Every car in a passenger train must be in communication with the engine by bell-cord, or its equivalent in the shape of the air signal or electric wire. It must be connected to the bell or whistle of the engine, and through and so connected to the rear car that in event of the train parting it will signal the engineer

Q. What do green flags or lights carried on an engine mean?

A. That the train carrying them is followed by another train running on the same schedule and having the same train rights and no more.

Q Suppose the engine carries white signals?

A Denote that the train is an extra, having no time-card rights. Yard engines never carry white signals.

Q. Suppose you stop at a small place with a single siding. You have a car to set out, and there is one in the siding with a blue flag on it; what do you do?

A Always notify the car inspector or repairer, that he may move his flag to protect himself.

WHISTLE SIGNALS.

Q What does one *long* (——) blast of the whistle denote?

A A station, railroad crossing or junction.

Q. A *short* one (—)?

A Stop; set brakes

Q. How would you ask to have brakes released?

A. By two *long* blasts of the whistle (—— ——).

Q. What do two *short* blasts mean?

A It is the answer to any signal given the engineer, except the one signal "train parted" It means "I understand."

Q. Suppose your train broke in two; how do you notify crew by whistle?

A. By three *long* (—— —— ——) blasts of whistle, repeated until answered.

Q. What do *three* short (— — —) blasts mean?

A. It is the signal for backing, and must be repeated until a signal is received from the rear of the train.

Q What are four *long* (—— —— —— ——) blasts for?

A. To call in a flagman from the west or south.

Q. How would you call in one stationed to the north or east of you?

A. By four *long* and one *short* (—— —— —— —— —) blasts

Q. Why this difference?

A. To avoid making mistakes and withdrawing proper protection from the train

Q. What is the use of four *short* (— — — —) blasts?

A Call for attention to watchmen, bridge or switch-tenders, train crew, or any one.

Q. What do five short (— — — — —) blasts mean?

A. Protect the rear of train by flag.

Q What use is made of one *long* and two *short* (—— — —) blasts?

A It is a call for attention to signals carried by an engine (single track only), and is given to all engines of the same or inferior class trains. It means, "Do you see my signals?"

Q If you were left in charge of the engine on a siding, and a train passed you carrying green flags and gave this signal, what would you do?

A Answer "I understand," by two *short* (— —) blasts.

Q. Well, suppose you were left on a freight engine, and you had green signals up, and a regular passenger train came along, would you call up your signals?

A No.

Q. Why not?

A Because the first-class train would have a superior right to the second section of my train, and would not have to observe signals on freight trains The freights must protect themselves against the passenger.

Q. What is the road-crossing signal?

A. Two *long* followed by two *short* (—— —— — —) blasts.

Q. The cattle signal?

A. A succession of *short* blasts

BELL-CORD SIGNALS.

Q. What does *one* tap of the signal bell mean, suppose you were standing?

*Special rules in use to be added These are the signals provided by the standard code

A. Go ahead, or start.

Q. *Two* taps?

A. If running, stop at once; if standing, call in the flagman.

Q. Three taps?

A. If running, stop at next station; if standing, back up.

Q. Four taps?

A. Reduce speed

Q. If running, and you heard one tap of bell, what would you expect?

A. That the train had parted.

Q. Suppose you found it had, what would you do?

A. Notify the engineer.

Q. What should he do?

A. Give three long blasts of the whistle, and keep the forward part of train going until he was sure that the rear was stopped.

LAMP SIGNALS.

Q. What does a lamp swung across the track mean?

A. Stop.

Q. Raised and lowered vertically?

A. Go ahead.

Q. Swung vertically in a circle across the track when the train is standing?

A. Back up.

Q. Swung the same, at arm's length, when train is in motion?

A. Train parted.

Q. Suppose the same signals were given with a flag or by the hand?

A. They mean the same.

Q. What is a fixed signal?

A. A station board, crossing signal, or any point signal that is not moved.

Q. Suppose you find a signal missing or imperfectly displayed, where one is usually provided, what should be done?

A. The imperfect or absent signal must be regarded as a danger signal and its condition reported.

Q. What use is made of the engine bell?

A. It must always be rung before moving any engine or train, through all tunnels, over crossings, and through streets, and at least a quarter of a mile before and until past all road crossings.

Q. What do you understand by steam pressure as registered by the gauge?

A. Steam pressure of so many pounds per square inch above the atmosphere.

Q. Why do you say above the atmosphere?

A. Because the atmosphere has a pressure, at sea level, of 14.7 pounds per square inch, and the steam gauge registers nothing when there is no steam on it.

Q. In a locomotive boiler is there any part that has more pressure to bear than another?

A. Yes. Steam pressure is elastic, and exerts itself evenly in all directions; but there is more pressure at the bottom, because that part has to support the weight of the water besides the steam pressure.

Q. What object is there in having exhaust steam go through the stack?

A. To increase the draught on the fire.

Q. How does the exhaust steam create a draught on the fire?

A. By creating a current of the gases through the stack, ejecting them and the air in the front end, and forming a partial vacuum in the front and stack.

Q. How does that affect the fire?

A. The pressure of the atmosphere forces air through the grates and the fuel, supplying the flame with needed oxygen, and causing it to burn fiercely.

Q. Then you think a large quantity of air is necessary to make a fierce fire and raise steam rapidly.

A. Yes.

Q. Then why is it that if you have a thin fire, and a hole is made in it, steam will fall at once?

A. The air is cold and goes direct through the flues, cooling them off. In order to have the air do any good it must be thoroughly mixed with the gases given off by the incandescent fuel.

Q. What is black smoke?

A. A mixture of various gases, watery vapor, air and carbon. The carbon is the black part.

Q. Will it burn?

A. Not after it is formed. It can be partly prevented by intelligent firing.

Q. How can it be prevented?

A. The carbon of the coal is released when a fresh fire is put in, and if at the moment of release it can be mixed with the proper quantity of air and kept at high enough temperature, it will ignite and burn. The fuel is cold when first supplied to the fire, and keeps the temperature below the igniting point. The best preventive is to fire "light," that is, supply a small quantity of fuel at a time.

Q. Is black smoke wasteful?

A. Yes, but not as wasteful as generally supposed and claimed. It is very disagreeable to the public, and costs the road a great deal to keep cars and other property clean.

Q. What effect would a very small nozzle have on your fire?

A. It would cause a very fierce draught and tear holes in a thin fire.

Q. What do you have to do then?

A. Carry a heavier fire.

Q. Is there any objection to this?

A. Yes. It is harder to get air through it to keep up combustion.

Q. When the fuel burns most in the front of the fire-box what does it denote?

A. That there is more draught through the lower than through the upper flues.

Q. When it burns most under the door?

A. That there is too much draught through the upper flues.

Q. How can this be remedied?

A. By changing the diaphragm or draught pipe.

Q. What do you do to prevent black smoke from rolling when engine is shut off?

A. Try to put in a slightly heavier fire long enough before shutting off so that the fuel will begin to burn, and not give off black smoke when supply of air is checked. If engine is shut off unexpectedly at any place where it is desired to prevent smoke, opening the fire-door, or slightly starting the blower, will generally prevent it.

Q. What good effect does it have to open the fire-door when the engine is at work?

A. When fire is heavy it sometimes aids combustion by furnishing needed air; generally prevents waste of steam at the safety valve.

Q. What bad effect does it have?

A. Cools the tubes and is liable to cause them to leak.

Q. What are a fireman's first duties on arriving at his engine before leaving time?

A. To see that the engine is ready for the road, that all oil-cans are filled, and all signal lamps ready for use, that the full set of firing tools are in their places, that the flues and ash-pan are clean, and the fire in the proper condition for service.

Q. What effect does wetting the coal have?

A. Serves to keep down the dust and make less dirt, but is a detriment to the fire.

Q. Why?

A. Because all the water taken up by the fuel must be evaporated in the fire before the fuel can be burned.

Q. What should be the condition of your fire on arriving at a station where a stop is made?

A. Avoid putting in a green fire just before a stop.

Q. What should be the condition of your fire when you pitch over the summit of a long grade?

A. The same as for a station stop.

Q. If the engineer keeps using the injector, or pump, after pitching over, how should you maintain your fire?

A. Use the blower and fuel to keep it bright.

Q. Are you making much progress in the study of combustion, and can I explain anything to you, or tell you where to get the desired information?

A. ———.

Q. What do you consider of the first and greatest importance to an engine or train out on the road?

A. Protection, to be certain that the train rules, telegraphic orders, or signals entitled the engine or train to occupy the track where it is, and did or did not authorize it to move to other points; and in case of accident, or the disuse or misuse of the general forms of protection, for the train or engine crew to protect themselves by flags.

Q. Do you assist your engineer when anything is to be done to the engine?

A. ———.

Q. How much coal does your engine generally burn a trip?

A. ———.

Q. Is this more or less than the general average?

A. ———.

Q. How do you account for the difference?

A. ———.

Q. Are you satisfied with the business, and are you fully determined to master it and become an engineer?

A. ———.

LECTURE.

This has been your first year's service, and in consequence the examination has been an easy one. Next year I shall expect that you know all about the signals, and have forgotten no part of this examination. I shall expect you to know the object of every piece in a locomotive boiler, what it is for and how it works. I shall expect you to be pretty well posted on combustion. To this end study your books, and try and get a good general idea of the laws of combustion. I shall not expect you to know all the gases by name, perhaps, but such a knowledge will not hurt you. I shall, however, expect you to be able to tell me what results are obtained by certain combinations of fuel and air in locomotive fire-boxes. I shall expect you to know what effect a fresh supply of coal has on heat-producing flame, where loss occurs and where gain. You will be expected to understand all the draught appliances in use on this road, and tell how to adjust them to overcome certain defects found in the burning of the fire.

You will be expected to know how much coal your engine has burned per mile during the past year (take this from the monthly bulletin, or get it at the fuel agent's office), and how this compares with the consumption of other engines of her class, and give a reason for the difference. You will be expected to explain how steam is generated, tell what constitutes the different kinds of steam, and trace it from the moment it is generated until it passes away from the locomotive and is lost.

I shall expect you to tell the trouble to be expected from low water, heavy firing, holes in the fire, dirty coal, clinkers, etc., and how to avoid this trouble. You will be expected to know what kind of firing has a tendency to cause leaky flues, and what kind prevents leaking.

To know what the brick arch is for, what it does, and under what circumstances it cannot be used.

To know the forms of the different kinds of boilers, and the peculiarities, advantages and disadvantages of each type.

Devote some thought and study during the next year to boilers, their use and abuse, to the combustion of fuel, and the duties of a fireman, for on your proper understanding of this subject your advancement in the service depends.

A New Cab Signal.

One of the engineers on the elevated road in this city had a little breakdown experience recently that he is not liable to repeat.

The bell in the cab gave out, and he tied the bell cord to his leg, so as to be able to properly interpret the signals, and leave his hands free to handle the engine.

It appears that this engineer was accredited among the men as being a crank, and they proceeded to "get even." Three or four of them went back in the train and "doubled up" on the cord, giving a long pull, a strong pull, and a pull altogether, elevating the crank to the roof of the cab twice as a signal to go ahead. The next time the bell gets out of order he will tie the cord to the boiler.

The latest wrinkle in fashionable society is giving "an engine party." A bevy of pretty girls ride in the engine of a special train which is "scheduled for fast time," and carries streamers in distinctive colors.

The Snail-shell Stack.

The engraving shows a rather new form of stack—we have seen worse ones, but not many.

It is not necessary to describe it—one look is enough.

Such a form would doubtless cost four or five times as much as a straight stack containing the same amount of material.

Those of our readers who know how quickly a draught pipe is cut out if it gets, ever so slightly, in the way of the exhaust, can imagine about how far this distillery worm would run before the exhaust would cut a skylight in the highest hump of the crook

The invention comes from Ft. Worth, Tex., and is about the ten thousandth patented smoke-stack, all of which are designed to check, baffle, retard, muffle, puzzle or paralyze the flow of the gases, and collect the dirt in them. The more changing of the currents the more cones, and deflectors, and netting, the sharper the exhaust must be to draw the air through the fire. Sharpening the exhaust means a choked nozzle and increased back pressure. What we want to do is to get more work out of the steam now made. Then we won't have to force the fire so hard to produce it. This will reduce the back pressure, prevent the throwing of sparks, do away with carrying around a ton of extension front, and the care of burned netting, cones and outlandish forms of crumbled-up sheet-iron, by common courtesy designated as a "smoke-stack."

Combustion.

The following paper was recently read in the lodge room of the Brotherhood of Locomotive Firemen, at Albany, N. Y., by a young fireman from the Boston & Albany road. As will be seen, it was written for lodge room purposes rather than for publication. Our attention was called to it by an officer of the road employing the young man, who spoke in the highest terms of praise of the effort for self-improvement. No individual or association of individuals can estimate the value they store up in themselves by taking part in this kind of work; it pays in the long run.

This fireman signs himself "W. A. B."—like all the other B. & A. men, being only modest about using his name.

The question is asked, What is combustion?

The answer given in the least number of words would be as follows:

Combustion is a rapid chemical combination of oxygen with the substances which constitute fuel.

This subject covers a great deal of ground; for when any substance has become ignited combustion has begun. Now the part which I have taken, and that which directly interests us as locomotive firemen, is combustion in locomotive fire-boxes. In order to form combustion there must be oxygen and a substance with which it may unite.

Oxygen is one of the gases of which the atmosphere is composed; the other, nitrogen—which is in the locomotive fire-box when the atmosphere or air enters it; the oxygen is separated from the nitrogen and unites with the fuel, the nitrogen passing through the flues and out the stack.

The fuel used on nearly all the principal railroads in this country is bituminous coal, but on some roads anthracite coal is used.

Bituminous coal is composed of from 50 to 80 per cent. carbon, 6 to 10 per cent. hydrogen, the remainder being sulphur, sand, iron and other substances, part of which are not consumed and go to produce ashes and clinkers, which, as we all know from experience, is one of the fireman's chief discomforts.

Anthracite coal is composed of from 70 to 90 per cent carbon, the remainder being hydrogen and foreign substances, such as are found in bituminous coal.

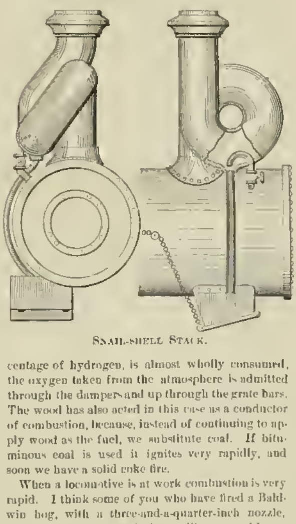
Now, we will say, here is a railroad with all the equipments, rails all laid, cars ready for transportation, locomotive standing in the roundhouse, and everything that is necessary to operate a railroad. But the locomotive stands here without a fire, consequently she has no steam, and without it she is useless. But here is the fireman, the fellow that always has a dirty face and dirty hands, and the one that will, if he sees what he thinks is a girl within half a mile, drop his shovel, get up on the seat-box, and put on one of his Sunday smiles, and if the young lady happens to look up and sees him, she says to herself, "I wonder if that fellow knows the use of soap and water."

This very important youth gets the locomotive ready for service, which by so doing the railroad is put in operation.

We will now follow the fireman as he steps on his engine, supposing the engine to be dead, that is, "without a fire," and with two gauges of water in the boiler. He first puts some oily waste on the grate bars, then he throws in wood enough to fill the fire-box about half full and shuts the door. He then goes down in the pit, and with a match, or generally a torch, he starts the waste, and in a very few minutes the wood has become ignited. He then puts in four or five shovelfuls of coal on top of the burning wood, and from time to time keeps adding more.

Soon the wood has all disappeared, and we have a coke fire, and the engine is ready to couple on the train, as far as the fire is concerned. Here we have combustion. First the waste, next the wood, and then the coal being ignited. In the first case, the waste, being saturated with oil, is very rapidly consumed. Now this oily waste has acted as a conductor of combustion, because combustion really began when the match was lighted.

The wood has become ignited, and we have combustion in the case of the wood. The wood being composed of nearly solid carbon, with a small per-



SNAIL-SHELL STACK.

centage of hydrogen, is almost wholly consumed, the oxygen taken from the atmosphere is admitted through the dampers and up through the grate bars. The wood has also acted in this case as a conductor of combustion, because, instead of continuing to apply wood as the fuel, we substitute coal. If bituminous coal is used it ignites very rapidly, and soon we have a solid coke fire.

When a locomotive is at work combustion is very rapid. I think some of you who have fired a Baldwin hog, with a three-and-a-quarter-inch nozzle, cutting off on 15 or 18 inches, will agree with me here.

In order that an engine may steam well, it is essential that the following be observed First, that the area of heating surface be in comparison with the size of boiler, and the boiler should be so constructed as to be capable of generating steam rapidly enough to supply the cylinders in doing the work laid out for the engine. As we have to employ artificial draught, it is essential that we have the grate surface as large as possible in order to make the blast orifice, or nozzle, as we call it, large enough, so that it will not create too much compression in the cylinders. Second, I will ask the question, How is artificial draught produced in the locomotive?

It is produced by a partial vacuum formed in the arch or front end.

The front end must be tight, so that the air will have no access to it except through the flues.

The exhaust from the cylinders being contracted by the nozzle is used as the means of forming the vacuum.

Third. All soft coal burners—I say soft coal burners, as I have never had any practical experience with an anthracite coal burner—should be equipped with an ash-pan with a front and back damper, capable of being closed, so that they will be perfectly tight.

Fourth. There should be some means of admitting air on top of the fire. Some of our engines have a double row of hollow stay bolts along the sides of fire-box, which I think a very good idea. Others have several holes in the furnace door, and all locomotives have a latch by which the door can be made to partly close at the will of the fireman.

We will now follow the process of combustion, taking it up as the engine starts with her train, supposing the engine to be of the standard American type, a four-wheel connected freight locomotive.

The dimensions of furnace being as follows: 6 feet long, 3 feet wide, and about 2 feet deep beneath the flues.

As I have before stated, we have a solid coke fire, probably about 1 foot thick, and all it needs is to be loosened, which is done with a bar about 8 feet long. The back damper is open, and, as the engine starts, the artificial draught produced by the exhaust steam from the cylinders begins to form a vacuum in the front end or arch.

As the exhaust leaves the top of stack it has taken the air with it, and immediately the hot gases rush through the flues to fill up the space. The next exhaust takes with it the gases now in the arch, and at the same time it forms another vacuum, and so on it continues as long as the engine is at work.

When the blower is used it acts upon the same principle What is it that forces the gases through the flues and into the arch? It is the pressure of the atmosphere underneath the grate bars continually forcing its way up through the fire, at the same time the oxygen is separated from the nitrogen, the oxygen uniting with the hydrogen and carbon of the fuel forming the hot gases, and with the nitrogen which is not used pass through the flues and out of the stack. There are a great many men, I am sorry to say, that are laboring under the impression that the exhaust draws the gases through the flues. This not being the case, as I have before stated, it is the pressure of the atmosphere underneath the grate bars, which, on a well-designed locomotive, would be several tons, provided a perfect or nearly perfect vacuum could be produced in the front end, but a difference of pressure of the air in the smoke-box and at the grates of one pound per square inch would be extra good practice. Let me illustrate this. Now, when the engine is hard at work, if you open the furnace door, and leave it open for a few minutes, the atmosphere, instead of forcing its way up through the fire, enters at the door, a much easier way, and passes over the top of the fire so rapidly that it does not have time to unite with the fuel, goes through the flues, and so on out the stack

If you observe its color as it leaves the stack, you will see that it is as clean as when it entered the door. If you look at the gauge, you will see that the pressure has fallen five or ten pounds. Why this change? Because instead of the oxygen of the atmosphere uniting with the fuel and forming the hot gases (which would be, when they leave the stack, of a dull brown color), the atmosphere passes through the flues in its natural state.

We will now return to the condition of our fire when we left it

The atmosphere enters the ash-pan through the back damper and passes up through the grate bars

The oxygen of the atmosphere unites with the hydrogen of the fuel and forms the gases or flame which is the hottest; but through bad firing and the ill construction of some locomotives this is nearly all lost, passing through the flues and out the stack in the shape of black smoke.

Combustion in the locomotive fire-box is carried on so rapidly that it is impossible to consume all the gases. But by the aid of good judgment on the part of the fireman, and some means of admitting the required amount of air on top of the fire, taking care not to get too much, a great deal that is lost in the shape of black smoke can be burned, which, of course, is a saving on fuel.

Again, as the atmosphere forces its way up through the fire, the oxygen unites with the carbon of the fuel and forms coke. This is entirely consumed in the furnace, except that which is carried out the stack in the shape of sparks, providing the fireman understands his business.

After the engine has run we will say about thirty miles, the engine being worked to her full capacity, as they usually are on a freight train—of course we will take into consideration the quality of the coal used—we will begin to experience some trouble with the ashes and clinkers that are beginning to accumulate on the grate bars.

Now where do these ashes and clinkers come from, if the hydrogen and carbon are either consumed or expelled from the furnace?

In all coal, as I have before stated, there is a certain amount of foreign matter, such as sulphur, sand, iron, etc., which are not all consumed during the process of combustion, and these remaining substances go to produce the ashes and clinkers. The grate should be so constructed that by turning them over once or twice, or shaking them when arranged to shake, the dirt can be dropped in the ash-pan.

Now the ash-pan being partly full of ashes, there is not a sufficient amount of air admitted through the back damper, and by opening the forward damper the required amount is obtained, and you go on as before, until the fire requires cleaning a second time. You then proceed as before, and, when you have done so, the ash-pan will probably have to be cleaned out to admit the required amount of air and also to insure the safety of the grates. If you then have a clean fire the front damper may again be closed, and your fire is in as good shape as when you started on the trip.

I have heard a great many firemen say, this engine should be fired with a heavy fire, and that engine should be fired with a light fire.

Now such talk don't amount to a row of pins.

I say that no soft coal burner should ever carry more than from twelve to fifteen inches of fire, and I prefer to fire generally with from eight to ten inches. Understand this must be all fire, and not a pile of green coal and clinkers.

Another thing that is very important in an engine's making steam, and that is, not to allow the flues to become stopped up.

Nearly all of our Baldwin hogs have a brick arch in the front end of fire box.

Now the theory of the brick arch is all very well, and it is a coal-saving device, providing the brick is in the proper shape.

What I mean is, that it shall be put in in the proper manner, be all there, and the flues all clean behind it.

But when engines are run as those engines are, it is more of a nuisance than anything else. The engine does very well for maybe two weeks after the arch has been put in, then the flues begin to get stopped up, and maybe the front brick falls down, and woe be unto the poor unfortunate that has to pull it out.

He gets the hook red hot, bends it in the shape of a grape vine, burns his hands, says bad words, and just as he has got about half of it out he breaks the end off the hook; then he is in a fix. But finally he puts all his wits together and comes to the conclusion that he will bend it over to within about six or eight inches from the end, and he calls the engineer to help him and between the two, and an unlimited amount of bad language, the job is finally completed.

But then there is about half the pieces of the brick yet to be gotten out, and the poor stoker, with the help of the engineer and head brakeman, manage after awhile to either get them out or pull them back so as to make room for a little fire in front, and little it is, for when you get started it would take a steam shovel to keep anything like a fire up in front.

Then the flues begin to stop up very rapidly and no way to clean them out, for if you attempt to punch them out from the front end, you have first got to take the diaphragm rigging out, which takes about half a day, then you cannot get behind the steam and exhaust pipes, and, after you are all through, you want a watchmaker to put it together again.

There is yet another thing which I must mention, and that is, the front ends or arches.

On nearly all modern locomotives, especially those built within the last three years, will be found the extension arch. But we will first take up the old-style arch with the diamond stack and petticoat pipe. In the first place, the arch must be perfectly tight, so that air cannot reach it except through the flues. Next, there should be a netting and cone in top of stack, taking care that the netting shall not be too coarse, for, if this precaution is not observed, the engineer is apt to receive a letter from the super. asking if he celebrated the Declaration of Independence all the year round.

The nozzle or exhaust tip should not be either too large or too small, for one produces as bad an effect as the other.

If the nozzle is too large, the blast will not have sufficient force to form a proper amount of vacuum in the arch, and if too small, the vacuum will be formed so rapidly that the fuel is forced through the flues and out the stack before it has had time to become ignited.

The last, but not the least important, is the petticoat pipe. There can be no rule given for the dimensions and adjustment of this indispensable article. It should be made so that it will reach within about eight or ten inches of the base of stack, and be fitted with a movable sleeve at the top and a flare at the bottom, and, when placed in position, the center of pipe should be directly under the center of stack.

Experience will determine the distance it should be placed from the bottom of arch and the space intervening between it and the base of stack.

If set too low at the bottom, the lower flues will become stopped up very easily, and if set too high, the draught through the lower flues, which will act on the forward part of the fire, will be too strong. If the top of sleeve be too high, or too near the base of stack, the upper flues will likewise stop up easily, and if too low, the draught through the upper flues, which will act on the back part of fire, will be too strong. It should be adjusted so that the draught will be equal in all parts of the fire-box.

It will be found, with careful firing, the flues will keep themselves clean, and the engine will make plenty of steam with eight or ten inches of fire.

The extended front end, which is now being put on nearly all new engines, is a little different in its construction, the exhaust pipes extending to within twelve or fifteen inches of the top of arch, the tips being placed above a wire netting which extends all across the top of arch.

Back of the exhaust pipes is a deflector or diaphragm plate, which, raising or lowering, regulates the draught, performing the same duties as the petticoat pipe in the old-style arch.

There is a slight difference in the construction of the arches in different makes of engines.

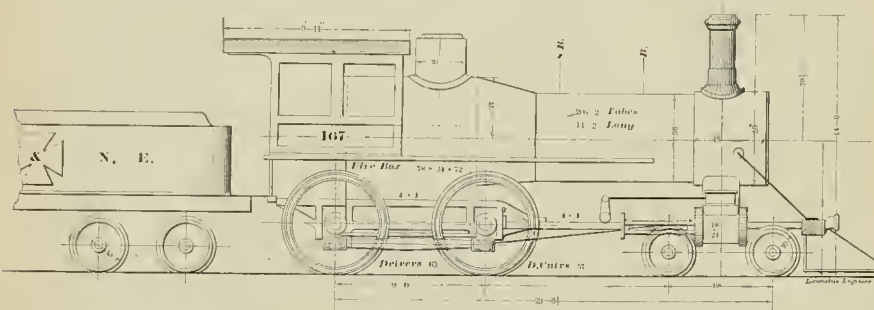
The New England "White Wings" Train.

By L. R. Pomeroy.

Through the courtesy of Mr. Albert Griggs, supt. motive power, the writer was afforded an opportunity of a ride on the locomotive which draws this peerless train.

CONDITIONS.

85.8 miles without a stop; schedule time, 135 minutes; a line with scarcely two consecutive miles of straight track; a succession of heavy grades for seventy-five miles, some of which are long and trying, for example, one grade of 14 miles 40 to 60 feet to the mile, and another of 22 miles varying in amount. Train composed of seven heavy cars, as follows:



THE "WHITE WINGS" TRAIN LOCOMOTIVE.

6 cars at 35 tons each	210 tons
1 diner	41 "
Engine	54 "
Total weight	305 "

Track in excellent condition, displaying great care and watchfulness on the part of the "Department of Maintenance of Way." All dark places well protected by efficient signaling.

HOW THESE CONDITIONS WERE FULFILLED.

The locomotive was designed by the supt. motive power, Mr. Albert Griggs, especially for these conditions, and the advantage in having the drivers 63 inches is apparent, when the physical conditions of the line are taken into account; and the great teacher, experience, has borne testimony to the wisdom of this design, making possible a more uniform speed for the entire distance.

The following outline will show the general features of the engine:

Total weight, 109,000 pounds, on drivers, 62,000 pounds, boiler material, ½" Carnegie's steel; steam pressure, 160 pounds per square inch. Heating surface, fire-box, 138 square feet; tubes, 1,205 square feet, total, 1,343 square feet, wrist-pins, 8½ x 3½"; crank-pins, 3¾"x4"; valve travel, 5½"; bridges, 1¾" thick, exhaust port, 2¾"x17"; lap O. S. ⅞"; lead, 1/16"; eccentric throw, 5"; valves, line and line inside, single nozzle, 4¾" opening, radius of link, 57"; distance between eccentric rod pins, 11"; offset of link saddle pin, ¼; eccentric rod pins, 1¾" back of center of link; lower rocker arm, 9½", upper, 10¼"; center of lifting shaft, 18" back of center of rock shaft; center of rock shaft, $6\frac{3}{4}''$ above top of frame; center of rocker, 3" above top of frame, length of lifting arm, 18; link hanger, 15"; points of cut-off according to notches in sector (forward gear).

1st	notch,	$4\frac{1}{8}''$.
2d	"	$8\frac{13}{16}''$.
3d	"	$13\frac{1}{4}''$.
4th	"	$16\frac{1}{4}''$.
5th	"	18
6th	"	$19\frac{1}{4}$
7th	"	$20\frac{1}{4}$.
8th	"	$21\frac{1}{4}$

The train and service leave nothing to be desired, and is beginning to be appreciated by the traveling public The number of passengers increased 17 per cent. the first ten days

THE RUN.

The train pulled out exactly on the minute, *i. e.*, 3 P. M., and No. 167 lifted the train into speed without a slip or groan, first crossing drawbridge, then running a sharp curve at South Boston. The first mile (through the crowded yard) consumed three minutes, the next 2.7 miles consumed nine minutes; the next 13 3 miles consumed sixteen minutes (49.8 miles per hour), at which point the train was up to schedule. The fortieth mile-post was passed in just one hour from the start, and the balance of the distance, 45.8 miles, consumed 75 minutes to stop, being the end of the run. Three reductions of speed were made—one slow up for a crossing, one for water (by scoop), and one for a junction.

Going west, the running time is made with comparative ease, but going east the New Haven road very frequently delivers the train to the New England considerably behind time, necessitating sharp work on the part of No. 167, and some notable runs on this account have been recorded; one in particular, the writer recalls, of 48 miles in 51 minutes, on an average of 56.47 miles per hour.

It is readily seen that it is necessary to design an engine for this service with ample reserve power, and No. 167 fulfills these conditions admirably.

At Willimantic the train is turned over to the New Haven road, and from this point to New York the run was comparatively uneventful.

A person making this run from Boston to Willimantic cannot help being impressed with the great uniformity of speed and steadiness of the run, and with all the absolute absence of black smoke, and these respective conditions are fully accounted for

First—The comparative small wheel admits of the engine gaining and maintaining such a speed on the ascending grades that it is not necessary to make spurts on the descending grades, and on tangents, as heretofore with engines in this service with larger wheels.

Second—No more competent engineer can be found than Mr. E. E. Potter, who guides this train, and the writer was greatly impressed by the skill and watchful care displayed, together with the keen eye after the economics manifested.

Third—The careful and intelligent firing of Mr. C. E Robins contributed in a large degree towards the results accomplished

The best work was done with the lever in the second notch cutting off at $8\frac{13}{16}''$; when hooked back to the first notch, cutting off at $4\frac{1}{8}''$ the engine labored and seriously objected, and at no time was the throttle stem out more than three quarters of an inch, showing the wide margin of reserve power.

The Best Form of Boiler.

Mr. John Hickey, Superintendent M P. of the N. P. Railroad, recently spoke on locomotive boiler construction before the Western Railroad Club Mr. Hickey favors the form of boiler now widely known as the Sample boiler, having a wagon top extending ahead of the fire-box in order to carry the dome and admit of the use of radial stays

The speaker favored a brick arch supported on tubes running lengthwise of the boiler, heads braced by straight rods fore and aft, rather than diagonal braces from the shell to the heads, a double-riveted mud ring and an arched crown made in one piece with the side sheets, the outside shell sheet being also in one piece; tubes arranged in vertical rows and cross-pieces of plate above the crown, to prevent surging of the water

Among other sensible things Mr Hickey has this to say on the subject of domes:

It is the opinion of many that the dome is a means of supplying dry steam to the cylinders. Now, while this may be a fact when the domes are located only a short distance from the heating surface, it is not true when the domes, as in the case of many boilers, are located some distance therefrom. The fact is that a high dome, situated some distance from the heating plates, instead of furnishing dry steam to the cylinders, as is usually expected, delivers steam of a moist character, particularly so, if it is not perfectly and fully covered with non-conducting material to protect it from the surrounding atmosphere. Sufficient steam room between the surface of the water and the shell is a far more desirable place in which to store steam. Domes, of course, afford a convenient means for throttle valves and other attachments, but they should be no higher than is absolutely required

On the care of the boiler after it is put in service he says:

The care and management of a boiler is of as fully great importance as to have it properly designed and constructed. It is at best subject to destroying forces which may reduce its factor of safety from the first day. The principal causes leading to this end are sudden and unequal expansion and contraction of the boiler, as a whole or in part. This evil is created in its worst degree by washing out with cold water while the fire-box or other parts of the boiler are at a high temperature, thus contracting the lower sheets, while those on top are in a high state of expansion, thereby placing the boiler to a stress greater, perhaps, than any ordinary working pressure it may be called upon to bear Impeded circulation of water within the boiler, caused by accumulated incrustation, or restricted waterways, when these conditions exist in connection with the surfaces exposed to the fire, are influences which rapidly lead to fatigue of the metal. Permitting the entrance of cold air to a fire box, immediately following the dumping of fire from the grate bars, and the extravagant use of the blower when trying to raise steam hurriedly in a fresh-fired boiler, thus heating and expanding the tubes, result in distortion of tubes and tube sheet, brought about by the hasty heating of these parts, while the shell of the boiler is comparatively cool. Low water, when sufficiently low to permit overheating of the plates, results in permanent reduction of their strength

Economy in Use of 60,000-pound Cars.

At a recent meeting of the Central Railroad Club at Buffalo the above subject was discussed after hearing a report of the club's committee on the subject.

The report of the committee on "Whether results have shown economy in the use of freight cars of 60,000 pounds capacity for merchandise," consisting of E D Bronner, A. C. Robson and A. Vail, was presented by Mr. Bronner. It stated that ten replies were received in response to letters of inquiry sent out Five roads stated that they had used cars of this class extensively, that the carrying capacity is utilized to its utmost limit, that the cost of maintenance is no greater than that of smaller cars, and conclusions based upon practical experience were that they are economical, both from mechanical and operating standpoints The other five roads owned no cars of the capacity named, and of these, two did not favor them From statistics furnished by large manufacturing car builders, the following average prices and weights for 20 and 30-ton cars were derived

	Total Capacity	Total Weight	Total Cost
3 20 ton cars .	120,000	72,000	$1,575
2 30 ton cars	120,000	60 000	1,300

The comparison shows a saving in dead weight on every 60 tons carrying capacity of 12,000 pounds as well as $275 in the cost of the cars. In the opinion of the committee the expense in repairs would show a decrease in favor of the 30 ton car; *i e.*, the three cars required to carry 60 tons will cost more to maintain than the two cars of larger capacity It might be argued that the larger weights will be more destructive in their effect on the 30-ton cars, but this is not the experience of the roads that have adopted them, as in a well-designed wooden car the parts are increased in proportion to the increased strains. The committee was of the opinion that all the arguments brought to bear in favor of the 20 over the 10 ton car will apply in this case, provided it is admitted that the 20 ton car is not the maximum practical limit, and the report closed with an affirmative answer to the question with which it dealt.

Pedrick & Ayer, of Philadelphia, have issued a large and very handsome catalogue of all the tools they build It not only shows the tools themselves, but illustrates many attachments, and shows many applications of these tools to different kinds of work. As usual with this firm, the book is a work of art. Harry Ayer's fine Bohemian hand is visible from A to Izzard.

Train wrecking costs the wrecker his neck in California now—if he is found out.

Bound Volumes and Back Numbers

OF

THE LOCOMOTIVE ENGINEER,

Vols. 1, 2 and 3.

Bound Volumes for 1890 are now ready for delivery. Price $2.00, postage prepaid. Bound Volumes for 1888 and 1889 still on hand, at same price.

Unbound Volumes of each year now ready, and mailed to any address in the United States, Canada and Mexico, at regular subscription rate of $1.00 a year. Single Copies, 10 cents each.

Address,

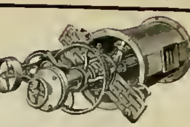
THE LOCOMOTIVE ENGINEER,
96 Fulton St., New York.

CYLINDER BORING and FACING MACHINE.

Made any size required. Will bore cylinder and face off the ends at same time. Built strong and powerful, has variable feed that feeds either way.

PORTABLE CYLINDER BORING MACHINE.

For boring IN THEIR PRESENT POSITIONS all makes and sizes of Steam Engine Cylinders, Pumps, Steam Hammers, Air Compressors, Mining and Hoisting Engines, Heavy Housings, Large Wheels, etc. Machines made any size required.



Pedrick & Ayer, Philadelphia, Pa.

BORING BAR FOR LATHE.

HAS HARDENED STEEL CENTRES, CONSTANT FEED OF CUT GEARS, STEEL FEED SCREW AND NUT. ALL BARS ACCURATELY GROUND, AND ARE FIRST-CLASS. ALL SIZES MADE.

Greenwood's Universal Planer Chuck.

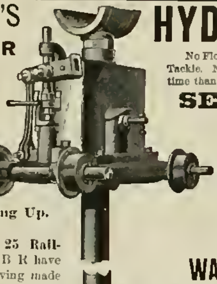
For Straight, Curved (Concave or Convex), or Angle Work. Used on any Planer with Cross-Feed for Links, Wedges, Keys, etc. Indispensable for Locomotive Builders and Master Mechanics.

STEEL

OPEN-HEARTH-CASTINGS. STANDARD STEEL CASTING CO., THURLOW, PA.

HYDRAULIC TOOLS FOR RAILROAD WORK

VREELAND'S TRANSFER JACK Will Remove and Replace Drivers or Trucks without Jacking Up.

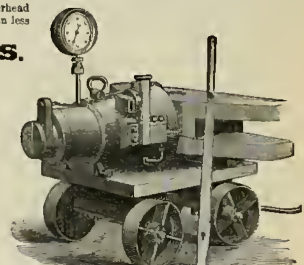


In use on over 25 Railroads. The B & O R R have now four in use, having made three distinct orders during the past year.

No Floor Space required for the Vreeland Transfer Jack. No Overhead Tackle. No Blocking. No Danger. Drivers and Trucks taken out in less time than it takes to jack Engine up.

SEND FOR CIRCULARS.

Hydraulic Press for forcing pins into Locomotive Drivers, either under the engine or out. Also useful about Railroad Shops, for forcing on and off Balance Wheels, Cranks, Gears, Pulleys, etc. Inclosed Piston. Cannot Clog. Valves are large and fall to their seats, no rush of water being required to seat them. Parts easily examined or repaired. Pump is independent of cylinder casting. Movement of ram, 12 inches. 60 to 150 tons pressure.



WATSON & STILLMAN, Mfrs.,
204, 206, 208 & 210 E. 43d St., New York.

EUREKA CAST STEEL COMPANY

OFFICE AND WORKS: CHESTER, PA.
CRUCIBLE, WROUGHT IRON, AND STEEL CASTINGS.
RAILROAD AND MACHINE CASTINGS, LOCOMOTIVE CROSS HEADS, AND GEARING A SPECIALTY.
GUARANTEED KNUCKLES FOR M. C. B. COUPLERS.

"Here is a valve just as good as the Genuine Jenkins Bros., and costs you less money." This is the war cry of the imitators and their friends. In answer to this cry we will drag out our old hundred ton gun—which never fails to clear the field—and here is the SHOT.

A FAIR OFFER.

If you will put a Jenkins Bros. Valve on the WORST PLACE YOU CAN FIND, where you cannot keep other valves tight, and if it is not Perfectly Tight, or does not hold Steam, Oils, Acids, Water, or Other Fluids Longer Than Any Other Valve, you may return it and your money will be refunded.

JENKINS BROS., New York, Philadelphia, Boston and Chicago.

SELDEN'S PATENT PACKING.

With Rubber Core for Steam.
With Canvas Core for Water.

If you are not using it, give it a trial, and satisfy yourself of its merits.

RANDOLPH BRANDT, SOLE MANUFACTURER, 38 Cortlandt Street, New York.

STEEL CASTINGS

FROM 1-4 to 15,000 LBS. WEIGHT.

True to pattern, sound, solid, free from blow-holes and of unequaled strength.
Stronger and more durable than iron forgings in any position or for any service whatever.
60,000 CRANK SHAFTS and 50,000 GEAR WHEELS of this steel now running prove this.
Crossheads, Rockers, Piston-Heads, etc., for Locomotives.
STEEL CASTINGS of every description.
Send for Circulars and prices to

CHESTER STEEL CASTINGS CO.,

TOOLS FOR LOCOMOTIVE BOILER WORK.

In connection with our line of Tools for above purpose, the Cut herewith shows our

DOUBLE ANGLE SHEAR,

FOR BRIDGE BUILDING, SHIP BUILDING, OR ANY KIND OF RAILROAD WORK.

This is *the* Machine for Shop Work, as the Knives can be changed to cut Round, Flat and Square Iron. Has many advantages over any other style made. Being double, it will cut either right or left. Its knives are of a proper height for convenience of working. It will cut a bar square off or on a bevel. Being supplied with a clutch, it can be stopped instantly.

The HILLES & JONES CO., Mfrs., Wilmington, Del.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formula patented by Mr G. W. Lord. For decree of court, etc., address G. W. LORD, 320 Union Street, Philadelphia, Pa.

The Locomotive Engineer.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. IV, NO. 7. NEW YORK, JULY, 1891. $1.00 per Year or 10c. a copy.

Taking Desperate Chances.

On one of the fastest runs the country has heard of in some time, there was a little side incident that, had it been known back in the coaches, would have caused a stampede for the bell rope.

Shortly after starting, the engineer discovered that the bolt that holds the inside pair of guides to the cylinder head was loose, he watched anxiously, knowing that a stop and a disconnect meant a bad reputation for him as a flyer, he came to the conclusion that the outside pair of guides would hold the crosshead, and that the bolt was simply jarring loose It grew steadily worse, and finally dropped out, the top guide swung in toward the frame, but the engineer kept up his speed, and kept his eye on the guide. The gibs flew off the crosshead, and the guides soon left the yoke to help ballast the track and the engine ran in this condition in the neighborhood of one hundred miles, reaching a speed far in excess of 60 miles per hour.

The engineer was not censured by the officers—because he was successful. Suppose the other guide had let go? There might have been a —— "

W H. Hudson has been appointed M M of the E. T, V & G at Atlanta

A Mechanical Feed-water Purifier for Locomotives.

The device here shown is an attempt to take from the water used in locomotive boilers some of the impurities by mechanical means. The designers do not claim to handle all kinds of bad water, or to get all the impurities out of any water, but have proven in practice that they can take out enough mud and lime to double the life of flues and extend the period between washing out four or five times as long as for plain boilers.

There have been so many cure-alls offered for bad water that railroad men as a rule are prone to avoid the subject—it has been worn out

This purifier works on a different principle from any we have seen, and has some advantages over any of the others

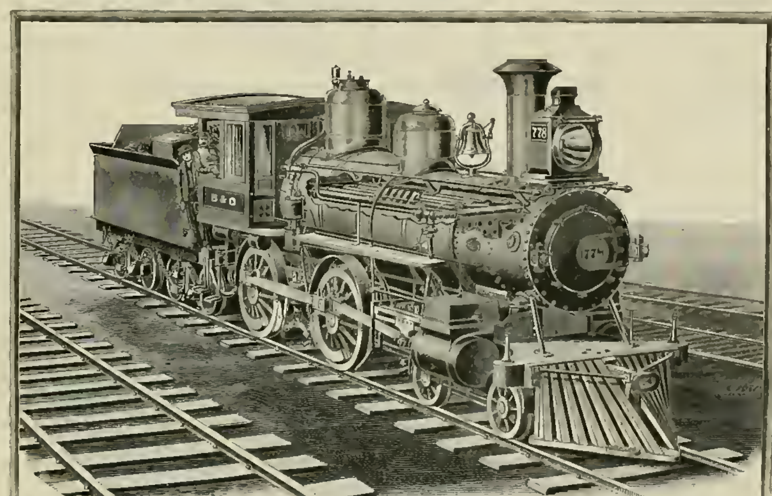
The principal objection to feed-water purifiers, located inside the boiler, has been that they were so made as to require the removal of the boiler-head to get them in, they were located in the steam space, and scale baked upon them, soon filling them up, their frequent blowing off lost a great deal of water, and anything that prevented the prompt closing of the blow-off cock would allow the water to be blown down to a dangerous point

This device can be put into the boiler in sections through the dry pipe hole in front tube sheet; it is located below the water line, and scale-forming matter is deposited on the interior surfaces in a moist form, and not baked on, the flow of feed-water being very sluggish and the delivery being above the water line, in blowing off, only the water in the purifier is lost, dry steam forces the mud and scale out, and it is impossible to endanger the crown sheet if the blow-off cock sticks open

The engraving on this page was made from a photograph of a B. & O engine now running with the purifier, and shows how it is hung in the boiler, it is only necessary to make two holes in the shell just above the flues near the forward tube sheet, and these holes are protected by brass flanges to which the cross-piece is fastened. Both injectors are connected to this cross-piece, as is also the blow-out plug

The engravings on page 122 show the plan of the tubes as well as the details of the interior sheet metal surfaces, for deposits, and the series of dams to retain the mud.

The purifier is made of 4 or 5 inch pipe, according to size of boiler, and is six times as long as the tubes, this large area of pipe causes a sluggish flow of water, which becomes heated above the boiling point by the time it reaches the middle of the purifier, and is then increased to about 300°



FIELD FEED-WATER PURIFIER

before reaching the large outlets into the steam space of the boiler. Heat precipitates impurities depositing the scale-forming matter upon the interior surfaces of the device or sending it to the bottom in the shape of mud; here it is retarded and kept back by dams, where it can be blown back through the large blow-off cock provided.

The interior tubes are made of sheet steel easily removed, if necessary, when heater is out.

The writer recently inspected one of these heaters that had been in use for some fifteen months in an engine of the Wisconsin Central, then in the Waukesha shop for general repairs. They have bad water there, and experience much trouble from mud and scale, but this device was found to be in good condition, not filled up, and the engine had only been washed out twice in five months, instead of every two weeks, as is the rule.

The B. & O. engine shown herewith has also done remarkable work with the purifier; it is also in use on the Great Northern & Southern Pacific.

This device seems to be constructed on common sense lines, to work in practice, to cost little, require no repairs, and be of little trouble to the engine men, and is worth investigation by any master mechanic who has the care of boilers using bad water. It is made by the Field Feed-water Purifier Company, of Chicago.

A Useful Memento.

The annual convention of the American Society of Civil Engineers was held on Lookout Mountain, Tenn., on May 20th.

The Queen & Crescent gave them a special from Cincinnati to Chattanooga, and the engineering department of the road got out the neatest and most interesting pamphlet, describing the points of interest along the line, that we have ever seen.

There is a margin index that gives the miles, geological formation, and altitude; then the points of interest are named and briefly explained just as a person who knew the country would, if seated by you in the cars.

History of places is outlined, battle fields pointed out, principal industries mentioned, natural formation of the country explained, sizes, cost and length of principal bridges and tunnels given, and, in fact, all the prominent or interesting things along the line are mentioned in an entertaining way. If the passenger departments of our railroads would get out little books on this line, entertainingly written, they would be more than appreciated by the traveling public, and would be kept by many, to aid the memory in recalling journeys for business or pleasure.

Some petty division superintendent on the Chicago & Eastern Illinois has issued an order that train and enginemen must not stop to eat at the only place on a division of over a hundred miles. The men are often obliged to double, and are as often delayed three or four hours on the run—this obliges them to eat from three to five meals out of a lunch pail, with no chance for a warm bite, or go hungry. For our part we don't see why this little two-for-a-cent straw-boss don't make them leave their dinner pails at home—or charge them for carrying them. Railroad men who want to eat every day are "trying to run the business of the company," and ought to be shot down—send for Pinkerton's. They will want to sleep next.

"A Man's a Man for a' That."

We have before us a photograph of about as handsome a testimonial as we have ever looked at. It was presented by the employes of the motive power department to W. T. Small, late Superintendent of M. P., Northern Pacific Railway, on his leaving the service. The scroll is signed by every master mechanic on the whole system, and ought to be, as it no doubt is, highly prized by its owner, coming, as it does, not only from the hands, but the hearts of the men who have been long associated with Mr. Small in his work. It reads as follows:

W. T. SMALL, *Supt. Motive Power, Machinery and Rolling Stock, Northern Pacific Railroad—Machinery Department Employes:*

DEAR SIR—We learn with profound regret that you are about to sever your connection with the great corporation you have so long, faithfully and efficiently served. This regret is shared by all who have worked under your directions, and as you are about to leave us, it is fitting that we give expression to our esteem and affection for one who has been not only our superior officer, but our friend and ready helper.

The manifold duties and great care which devolve upon the occupants of high official positions, are such as to almost inevitably separate them, so far as personal regard and sympathy are concerned, from their subordinates. Very often to the organizer and superintendents of large and important enterprises, the men who are necessary to carry out the details, lose their individuality, and are looked upon simply as parts of the great machine. In the discharge of the great duties and responsibilities that have devolved upon you, however, you have never lost sight of the individuality of your subordinates. In all your business relations with us you have treated us kindly and considerately. You have sympathized with us, appreciated our work, and whatever our station has been, your actions have shown that you fully endorse the sentiment of the poet Burns—

"Rank is but the guinea's stamp,
A man's a man for a' that."

To a skill and knowledge which have rendered you familiar with the smallest details of your great department, you have added an executive ability of the most remarkable scope and power. Skilled in your profession, we esteem you as a master among mechanics. Able in your administration, we confide in you as an executor. Blameless in your life, we honor you as a citizen, just and true in your rulings, we admire you as a man, thoughtful and considerate in your bearing, and in all your relations to those under your directions, we love you as a friend.

In whatever field of activity the future may find you, we feel assured it will add fresh laurels to your name, and enhance an already brilliant record. However great the distance between us, our heartfelt wishes for unqualified success will always attend your life's journey. We realize that the universal satisfaction felt under your administration here will follow you in your future field of duty, and the benefits we have received and learned to appreciate from your influence will be enjoyed by those under your supervision. While bidding you a sorrowful farewell, we bid you a hearty God-speed.

Signed on behalf of the employes

They also presented Mr. Small with a purse of $2,000. We do not approve of these big presents from men drawing small pay to one drawing a larger check, but the boys wanted Mr. Small to know how they appreciated him. The testimonial is enough, and the best of the two.

In putting hose fitting into air hose some shops use soft soap, some oil, and some white lead; but the D. & R. G. have found that sperm gives good results, does not rot the hose, or cause the rubber to stick to old fittings, causing trouble to get them out of ruptured hose. The sperm is kept melted, and the fitting dipped into it for about half an inch. This becomes thick before the fitting enters the hose, but stays and lubricates all the way. It fills up rough spots, and prevents tearing the lining of the hose.

Machine for Attaching Air-hose Fittings.

The machine illustrated herewith was designed and built at the Oakland, Cal., shops of the Southern Pacific, and is the best and most complete of anything of the kind that we have seen.

As will be seen, the fittings are forced into the hose by air operating the piston of a common freight-brake cylinder.

to cross-piece, bolts passing through guide bars and tapped into top plate (2). Block *C*, 3" thick, fitted with sliding plate (3), which projects 4" beyond inner edge, and is bolted through block with C. S. hd bolts tapped into top plate (4). These blocks are grooved, as shown, 1½" diameter, the inner edge 2" diameter and 2¼ deep for expansion of hose, the inner edge covered with ¼" iron plate (5).

The guide bars (6), ¾ x1½ x23", let down flush and projecting up to bottom of grooves in blocks. Stop plate (8), ¾ x8 4¾", let down flush in side frame between the guide bars. Oil-pan (9), 4 x6" x 15, as shown. Cylinder *D*, ordinary freight-car cylinder-bolted, as shown, placed 15¾" from inner edge of blocks to cylinder head, center line 1⅝" above frame. Cylinder *L* 4" diameter fitted through leg and bolted as shown. For cylinder release *k* and *n* use "Bassett's" air-brake valve; the cocks

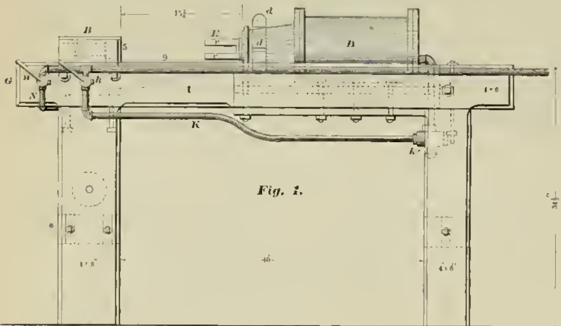

Fig. 1.

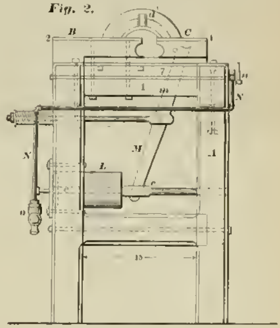

Fig. 2.

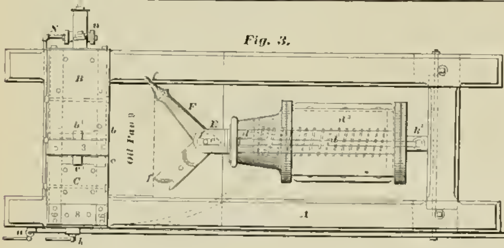

Fig. 3.

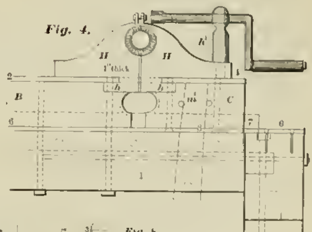

Fig. 4.

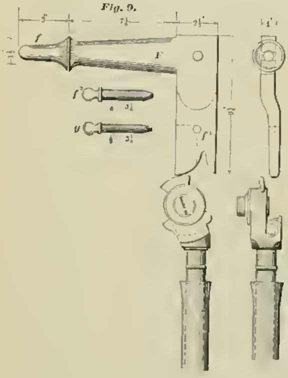

Fig. 9.

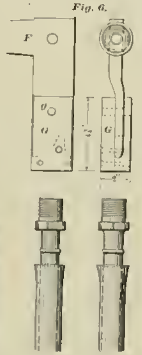

Fig. 6.

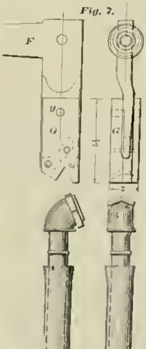

Fig. 7.

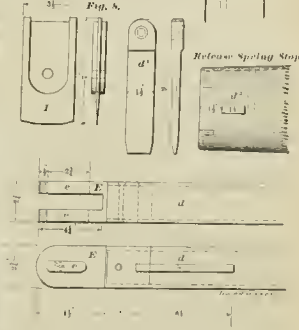

Fig. 8.

Fig. 1 is a side elevation, showing the position of cylinder and arrangement of operating levers. Fig. 2 is an end view, showing the hose holding vise and the small cylinder and levers that operate the jaw. Fig. 3 is a plan. Fig. 4 shows the hose clamp attachment, and Fig. 5 the knife used in cutting up hose from fifty-foot lengths. The other figures represent details on a larger scale.

The frame *A* is of wood, and the following additional specifications are given when duplicate machines are to be made.

Front cross-piece (1) framed to set down ¾ below top of side pieces. Block *B*, 3¾" thick, rabbeted on bottom to fit on cross-piece (1), and for guide bars (5) and slide (3) of block *C*, and firmly bolted

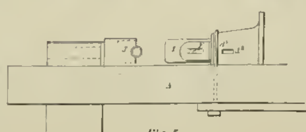

Fig. 5.

in side frame and on to cross-piece, the outer bar placed ½ from edge. Outside plate (7), ½ x2½ x 16", let into cross piece, bolted through as shown.

k and *n* are ordinary ⅜" pressure valves top removed and body turned down to fit pipe coupling.

The hose vise is long and has an enlargement in the slot at the end, to admit of the expansion of the hose when fittings are forced home; this vise will hold the hose under any end thrust without the use of a mandrel or filling piece.

The hose is laid into the slot in the vise flush with the front of jaw, the operator touching cock *n* admitting air to the small cylinder and firmly clamping the hose in position. The taper arm of ram *F* is introduced if the hose is hard and heavy, and a movement of the cock *K* forces it into the hose, enlarging it, if a coupling is to be attached, the end of it is dipped in oil, held in a pan directly under the vise as shown in plan, the end is placed against the hose and the forked fitting of *F* pulled up against the piece, this is made possible by the slot in the end of the piston rod, and prevents cramping or catching of the piece.

If a pipe fitting, either straight or angled, is to be attached, other forms of forks are used, as shown in Figs. 6 and 7.

All fittings are forced into the hose before clamps are applied and then all done at one time. A pair of steel jaws, as shown at *H H*, in Fig. 4, are fastened to the jaws of the vise—the hose clamps having been slipped over the hose before the last fitting was put in—the hose with clamp is placed against the stationary jaw of the attachment, and air is admitted to small cylinder. The points of the jaws engage the projections on the clamp, and leave the bolt lugs standing up clear; the bolt is introduced by hand, and the little socket wrench sliding in the standard *K* runs the nut up quickly, and is always in place for the next one; the nuts need only be screwed up to touch, as the vise has the hose clamp forced into the rubber.

The S. P. Company buy hose in fifty-foot rolls and cut it themselves. When this is done the bell crank fitting *F* is removed from the piston, and the knife *I*, Figs. 8 and 5, put on; a block of hard wood is fastened in front of the vise jaws to serve as a cutting block, and the long hose is introduced from the side of the machine, through a piece of pipe about two feet long, that serves as a guide and prevents the hose from laying out of the groove in cutter block; the hose extends past the knife to the proper length, where it strikes a gauge. A movement of the cock *K* moves the piston ahead and cuts the hose straight and clean.

The piston rod of the large cylinder is slotted, and a large key *d'* prevents the rod from turning around and disarranging the sockets or knife, when the latter is used the piston is turned around one-quarter of a turn, to bring the knife at right angles to the hose.

The boy who operates this machine does the work surprisingly fast and well, and with no hard labor. One of these machines on any road using air brakes or steam heat will pay for itself almost every time it is used.

The man formerly doing the hose work at the Oakland shop, and whose name we have mislaid, worked out the details of this machine, as he needed them in doing the work, and has applied for a patent on the combination.

There is probably no road in the country where as much attention is paid to the wishes of the patrons as on the Erie; this is especially true of the commuter patrons. No suggestion, request or complaint is ever ignored; a courteous letter is written to each correspondent, and if a request is refused, the reasons are given, all complaints are investigated, and the action taken communicated to the complainant, suggestions are accepted with thanks, adopted, if good and feasible, and if rejected, the reason for such action is given. General Passenger Agent Rinearson has an assistant in the shape of Mr. G. E. Allen, who is a professor of courtesy, and upon whom falls the lot of making people happy and contented. This policy has very largely increased the suburban business of the road, and bids fair to make the Erie the largest commuter carrying road out of New York, and is strangely in contrast with that of another well-known road, whose president told a committee of citizens who asked for a slight but necessary change in the running of trains, that he didn't care for the commuters—they were a d——n nuisance, except to burn coal that the company had to sell.

The Master Car Builders and Master Mechanics did very little about the M. C. B form of coupler this year. The M. M.'s simply resolved that it was a step in the right direction. It is now altogether likely that the link and pin will be left off of new cars on most roads, and the vertical hook substituted. No doubt more stringent laws will now be enacted to force the roads to use automatic couplers, but there is ten times as much damage done and lives lost because trains are not equipped with automatic brakes. Laws should reach for this point.

Micrometer Attachment for Calipers and Measuring Rods.

The illustration herewith shows a very handy little device, the invention of Mr. C. B. King, foreman of the Northern Pacific machine shop at Livingston, Mont.

The cut is full size. One end is slotted and a round hole bored into it, and a set-screw serves to make it fast to the end of a rod or the leg of a caliper.

The end screws on and off on a forty-thread

screw, and there are twenty-five divisions on the index, making each division one-thousandth of an inch.

Any mechanic can see where this little attachment could be used to advantage in measuring cylinders, etc., with rods. It is especially useful in tire or other work where shrinking fits are to be made and careful measurements necessary. It can be used on outside or inside calipers, on rods, or in almost any measuring device, where no provision is made for fine adjustment. It would pay some manufacturer of tools to put this little device on the market.

Locomotive Running Repairs.

By L. C. Hitchcock.

DRIVING-BOXES.

When an engine is undergoing general repairs, special attention should be given to the driving-boxes and driving-brasses, to see that they are fitted up in first class order. If any part of the work

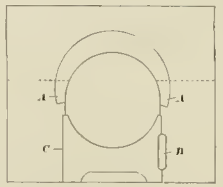

Fig. 1.

is slighted do not let these parts come in for their share, for nothing is more discouraging to a good engineer than to have his engine pound in the driving-boxes and brasses, and a renewal is the only remedy where the brass is too large for the journal, and if the box closes, or the wedge is not the proper taper, the play of the box between the shoe and wedge cannot be taken up by setting up the wedge. These evils can be overcome only by removing the box, which necessitates trouble and expense.

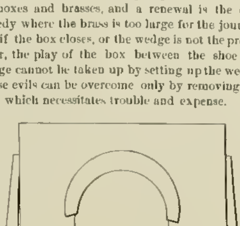

Fig. 2.

Some engineers, and foremen too, for that matter, in cases of this kind advocate planing the wedge until it has the proper taper to overcome the play of the box between the shoe and wedge. This I consider poor policy, for reasons which I will hereafter give. When an engine comes into the machine shop for general repairs, after having been in service for two or three years, the driving boxes, shoes and wedges are in a majority of cases very much in need of repairs; the shoes and wedges need lining and facing, the boxes will need planing, and the brasses will generally require renewing, or in case they are heavy enough they will be too large for the journals, or be loose in the box. When there is plenty of material in the brasses, and they are too large for the journals and loose in the boxes, it sometimes pays (when everything else is equal) to shim the brasses tight in the boxes, this will also close them to the journals, but in most cases this shimming does not pay. I think that the better plan is to put in new brasses while the opportunity is offered. Where the brasses to be renewed are of the solid pattern, in the form of a half circle, the box should first be planed out to a true circle, leaving the distances from the crown to the points *A A*, Fig 1, about $\frac{1}{16}$ inch greater on the side which is to go next to the hub of the driver; this will prevent the brass from working out of the box, should it become slightly loose, and this distance should be great enough to allow that part of the brass which rests in the points *A A* to be from $\frac{3}{4}$ inch to 1 inch below the center after the brass is bored to the required size. The outside of the brass should now be either planed in the slotter, or turned to the size that the box was finished, then the brass may be fitted to the box by planing from the edges which are to bear in the points *A A* a sufficient amount to allow the brass to go into the box the last inch at about twenty tons pressure; this will generally spread the bottom part of the box about $\frac{1}{16}$ inch. Now, at about the point represented by the dotted lines, and centrally between the flanges, bore a one-inch hole through box and brass on each side, and into these holes put brass plugs, making a good driving fit. The brasses should now be bored out to fit the journals before the cellars are fitted into the boxes. Boring the brasses generally allows the bottom of the boxes to close about $\frac{1}{32}$ inch, if the brass is put in under the pressure mentioned, and this leaves the top of box $\frac{1}{32}$ inch narrower than the bottom part; this causes the part which contains the cellar to be a trifle wider at the bottom than at the top, provided that the sides of this opening were originally planed parallel; this makes the removal of the cellar easy after it is started, even if it is very tight when up to place.

Some builders cast the boxes with a slot across the sides of the openings which contain the cellars, and in some cases these slots are also cast in the cellars. When the cellars are in place this leaves openings from side to side of the boxes, as shown at *B*, Fig. 1, and a rib at top and bottom of both box and cellars. I do not like this plan, for in replacing a cellar the top will strike against the bottom of the top rib on the box, if the cellar tips in the least. A good way to overcome this evil is to plane out about $1\frac{1}{4}$ inch wide from each end of each rib on cellars and boxes, liners can then be riveted on, of the required thickness to make the cellars tight in the boxes, and both sides of the cellars and boxes will appear as shown at *C*, and the cellars will be sure to go straight to their places, if entered properly. Now, fit the brasses to the journals, being careful to make that part which comes below the center of the journal, when the box is in place, exactly the size that the journal is in diameter.

After the brass has been brought to a general bearing on the journal, I think it a good practice to file from the crown a place about $1\frac{1}{2}$ inch wide and $\frac{1}{32}$ inch deep; this insures a good bearing on the sides to start with; after the brasses fit the cellars, and they being $\frac{1}{32}$ inch taper will go nearly up to their places before becoming tight, they should be fitted tight enough so that when they are up to their places the box cannot close a particle, and still not be tight enough to spread the box. Now, with the cellars in place, plane the shoe, and wedge bearing faces of the boxes, leaving each side an equal distance from the center of the brass, and perfectly parallel with each other.

Now, a word in regard to not being able to take up the lost motion of boxes between the shoes and wedges by setting the wedges up. As previously mentioned, the cause of this trouble is that either the shoes and wedges have not been planed parallel, or that the shoe and wedge bearing faces of the box are not parallel, the latter is generally the case. Now, if a brass is pressed into a box at twenty tons pressure, and the shoe and wedge bearing faces are planed before the brass is bored out, or the cellars fitted, when the brass is bored out the bottom of the box will close; this throws the planed faces out of parallel, and the box is in the condition represented in an exaggerated manner by Fig. 2, and, if the wedge has been planed square with the top of frame it will stand in the position shown at *A*, and any attempt to set it up will cause it to strike between the box and frame at the top, leaving the bottom loose, and, if the top is planed off to fit the box, it will be as shown at *B*, and the box cannot work freely between the shoe and wedge. Should a driving spring become weak, and let the frame down a little, the box will pound between the shoe and wedge, and should any unevenness in the track cause the box to lower, it will stick. But boxes sometimes get into the condition just described when the shoe and wedge bearing faces were parallel when the engine was first turned out of the shop, and this is owing to the cellar not having been fitted in the proper manner at the start, or having been filed smaller by some roundhouse man the first time the box was packed after going into service. I have heard of men reducing the cellars after the engine came out of the machine shop, so that they would not have so much trouble while packing them. This I consider very poor policy, for this reason: As the brass wears, the tendency of the box is to close in at the bottom, if it has been put in under sufficient pressure to hold it tight in the box, and when the cellar is loose the box closes to it, and the evils described are produced.

Allowing a driving-brass to run hot is a more serious thing than some engineers appear to realize, for it is sometimes, and where it becomes very hot it is in a majority of cases, followed by evils which can only be remedied by the removal of the box. The trouble referred to is the journal boring out the brass, and is produced as follows: The first things to become heated are the journal and brass. When heated, they expand; the box, being cold, does not expand, and is held tightly between the shoe and wedge, if properly fitted up, and does not give as the journal expands; the consequence is that the journal cuts its way in the brass until it has become free. Most engineers will remember that in most instances of hot driving-boxes small particles of brass will be seen, which have worked out from between the box and wheel hub. When the journal cools off it will resume its original size; the brass is then too large, and the journal will pound from side to side when the engine is working hard; but some one may say, "When a driving-brass heats and expands, the box will stick between the shoe and wedge, and a good engineer will at once pull the wedge down a little, to allow the box to work freely." True, he may do this, but this does not prevent the journal and brass expanding faster than the box, in which case the journal is sure to cut its way in the brass.

In some shops they take up the lateral motion caused by the faces of the boxes against the wheel hubs by planing from the inside flange of each shoe and wedge where it bears on the jaw, and putting a liner on the outside flange; this crowds the box towards the hub face, and takes up the lateral motion, but at the same time the size of the shoe and wedge has been thrown out of standard, and the spring saddle will not stand an equal distance from the inside and outside of the frame. I think that care should at all times be taken to keep all parts to a standard size, for where this is not done it causes much trouble where many engines are to be kept in repair. A better way to do in the case cited would be to measure the distance between the driver hubs, and from outside to outside of engine frames, and find whether the wear was from the face of the box or from the driver hubs. The liner should then be put where needed to keep all parts to standard dimensions. This is best, I think, even if the face of the box has to be planed off, or that of the wheel hub turned to allow for a liner of sufficient thickness to warrant it remaining in place.

While speaking of liners for this purpose, I will say that I have seen very good results follow facing the hubs of engine truck and driving-wheels, and also the faces of the driving-boxes with babbitt metal, and the difference in labor would, I think, make the use of this metal cheaper than turning and riveting on brass plates.

Baldwins are building twenty compound locomotives for South America.

Progressive Examination of Locomotive Engineers and Firemen.

By JOHN A. HILL.

SECOND EXAMINATION.

[*After Two Years' Service*]

Q. Are you sure you know all the signals in use on the road?

A. ——.

Q. Have there been any new ones introduced during the year, or any changes in old ones?

A. ——.

Q. What have you been firing?

A. ——.

Q. What is the general form of a locomotive boiler?

A. Generally a cylindrical boiler, having a fire-box of square section, surrounded by water, with tubes from it through the cylindrical part to a smoke-box on the front end.

Q. Why is the fire surrounded by water?

A. So as to present a large amount of water to the direct action of the fire, thus absorbing the heat.

Q. Tell me just what parts go to make up the fire-box.

A. The two side sheets, the crown sheet, the back sheet with furnace door set in it, and the forward or flue sheet, set full of tubes running to the smoke arch.

Q. What strains must the fire-box be constructed to withstand?

A. A crushing strain. The pressure is between it and the outside shell of the boiler, and tends to force the box in.

Q. How are the sheets of the box supported?

A. By stay bolts screwed into the outside sheet of the boiler, and through the fire-box, and riveted down.

Q. Is the crown sheet supported in the same way that the side sheets are?

A. In some classes of boilers they are.

Q. What classes?

A. In those with the outside shell of round section, the stays are spaced farther apart on the outside shell than on the crown sheet of the fire-box. They are on a radial line from the center of the boiler, and are called radial stayed boilers. Another form of boiler has a square fire-box, and the back end of boiler shell is also square. The direct stays in this boiler are straight. It is known as the Belpaire fire-box.

Q. What other form of staying is used on crown sheets?

A. Crown bars. These are heavy bars, generally set across the fire-box. They have points, or feet, at each end, bent down and resting upon the seam of the side sheet, keeping the bar above the crown a few inches. The bars are double, and a thimble is placed between them and the sheet, and a bolt goes through the sheet, the thimble and the bar, and is secured by a nut on the inside. The bars are then attached by stays to the shell of the boiler; these support the sheet.

Q. What are the objections to this form of construction?

A. It is hard to keep clean, is heavy and costly, and the bars occupy a great deal of the water space.

Q. What are the principal objections to the direct stay boiler?

A. It is a little more difficult to replace broken stays.

Q. What are its advantages?

A. It is cheaper to make, and gives a much better chance to wash out the mud and scale, and to inspect.

Q. How is the bottom of the fire box fixed?

A. The outside sheets and the fire-box sheets are riveted on the outside and inside of a heavy ring the shape of the fire-box, known as the foundation ring, or, more commonly the mud ring.

Q. What is below this?

A. There are iron grates across the bottom, with openings between them for the admission of air, and an ash-pan below them to catch fire and ashes that drop through.

Q. Has the ash-pan any other function?

A. Yes; it is usually fitted tight to leg of boiler, and has two more doors, or dampers, for the regulation of the amount of air admitted to the fire.

Q. Of what use is the cylindrical part of the boiler?

A. It carries the largest part of the water to be heated, and the tubes go through it, allowing much of the heat passing through them to be absorbed by the water.

Q. What is a wagon-top boiler?

A. One having the fire-box end larger than the cylindrical part, and connected to it by a cone or inclined sheets.

Q. What is the dome for?

A. The dome is a receptacle of steam, placed on the highest part of the boiler to insure dry steam, and is a convenient place to place the throttle valve, safety valves and other fittings.

Q. Is the dome necessary to the use of a locomotive boiler?

A. No; many locomotives are in use without domes.

Q. What must be the condition of the boiler to give good results?

A. It must be clean, its heating surfaces clear of scale or other foreign matter, and the circulation of the water must be good.

Q. What do you mean by circulation?

A. The movement of water in the boiler in such a way as to come in contact with the heated sheets, a fresh supply of water taking the place of that evaporated.

Q. What would be the result if there was no circulation in a certain portion of the boiler—say on one whole side of the fire-box?

A. The water in that place would be evaporated into steam, leaving the sheets bare, and they would become overheated.

Q. Suppose it did become overheated, what then?

A. If it became hot enough, and there was pressure enough on it, it would be forced off the stays and an explosion would occur.

Q. Suppose a crown sheet becomes bare and red-hot, do you think it would be more or less liable to come down if water were to suddenly be put upon it?

A. Less liable unless an excessive pressure were suddenly created to help force it down. It is the softening of the sheet by heat, and the pressure, that forces them down. Water cools and hardens the metal.

Q. What is the result if many of your flues stop up?

A. The boiler is robbed of that much heating surface, the draught is impaired, and the result is poor steaming.

Q. Why are the checks so far ahead on boilers?

A. So as to introduce the cold feed water the farthest from the fire, and allow it to become more or less heated before it comes in contact with the hot sheets of the fire-box.

Q. What hurt would it do to feed directly against the fire-box?

A. When the feed was off, the sheet would become as hot as the others around it, and when the feed was on, it would be cooled and contract, causing leaks, and perhaps cracks.

Q. Trace the flow of steam from start to finish when the engine is at work.

A. It is generated at or near some part of the heating surface, rises to the top of the boiler, enters the dome, and from there goes into the dry pipe through the throttle valve, into the steam pipes in the front end, and through the steam passage in the cylinder to the steam chest. From these it enters the steam port, when the latter is uncovered by the valve, and enters the cylinder, there coming in contact with the piston, which is forced away from the head by it. When the valve opens the port to the exhaust, the steam goes out of the same port which it entered, escaping under the valve to exhaust cavity in cylinder saddle, and thence out of the nozzle and the smoke stack.

Q. How many engines the same size as yours are doing the same work yours is?

A. ——.

Q. Which one has burned the most coal per mile the last year?

A. ——.

Q. Which one the last month?

A. ——.

Q. How much has yours burned?

A. ———.

Q. Is this any better than you have been doing?

A ———

Q. What sized nozzle has your engine got?

A ———

Q. Have you read Forney on the amount of water evaporated to a pound of coal, and the amount of fuel that should be burned per square foot of grate surface, and tried to compare your own engine's performance with it?

A ———.

Q. What is the brick arch used for?

A To aid combustion, thus preventing black smoke; it also prevents cold air from the furnace door from going directly into the flues, causing them to leak.

Q What is the extension arch for?

A To catch and carry sparks.

Q How is the draught regulated in an extension front?

A Usually by an apron, or diaphragm, extending from the front tube sheet, above the tubes, to a point about half way to the bottom of the arch. This is adjustable.

Q. How is the draught usually regulated in short-front engines?

A. Short fronts are usually fitted with diamond stacks, and these have a cone and nettings to break up and prevent the throwing of cinders. The draught is usually regulated by a lift-pipe, or petticoat pipe, placed between the nozzles and the stack. It is larger than the nozzles and smaller than the stack. Raising and lowering this pipe regulates the draught.

Q What is a safety valve for, and how does it work?

A A safety valve is a valve opening outwardly from the boiler, and loaded either by a weight or a spring, in locomotives usually a spring. This load is so regulated that when a certain amount of pressure is reached the valve and load are lifted and the pressure relieved.

Q Why are two usually provided?

A. For safety, in case one sticks or becomes inoperative.

Q. Tell me what a blower is for, and when it is a good and when a bad time to use it.

A The blower directs a jet of live steam up the stack, creating a partial vacuum in the front end and causing an extra draught on the fire. It is useful when a green fire is being urged into life. It draws away the dust and ashes when cleaning the fire, and prevents black smoke. It is a bad time to use it strong when fire is knocked out of box, or is partly dead, as it draws cold air into the tubes and may cause leaks.

Q Suppose your fire is old and somewhat dirty, and you notice, on opening the door, that the fire is dull red or of a bluish tint, but at once becomes lighter, often with slight crackling noise, what does that mean to you?

A I think that the bottom of the fire having become fouled by clinkers or ashes, prevents the admission of the proper amount of air for the fire, and the open fire-door supplies it. By leaving the door on the latch temporarily, the fire will burn better, but the clinker or ashes should at once be hooked or shaken out, so that air may enter through the grates.

Q. If the fire gets all the air it can use, isn't that enough? Why not leave the fire-door partly open?

A. The air must be thoroughly mixed with the gases given off by the coal, and this is best done through the grates and the fuel, as the jets of air are then broken up and thoroughly mixed. In opening the fire-door a large body of air enters and passes directly through the gases, only the outside mixing with them. This cools off the boiler.

Q How can you prove that mixing theory of yours?

A. By turning my scoop upside down in the fire-door, and on an angle toward the grates, the air is forced in a wide sheet down upon the fire and more thoroughly mixed, as is proven by the brightness with which the fire burns, it being possible to see all the grates in this way.

Q. What is the result if a hole gets in the fire?

A. Engine will lose steam, air enters in a large body, and goes through the tubes cold and unconsumed.

Q Why is it necessary to carry a thicker fire in one engine than another?

A. The harder an engine works her fire, the heavier it must be, to prevent tearing holes in it. Engines with small nozzles are more apt to pull the fire than those with larger ones.

Q. What is the best way to regulate the steaming of a locomotive?

A. By the fire.

Q. How?

A. By using as light a fire as can be made to stay on the grates comfortably, and breaking the coal in proportion to the depth of the fire.

Q Explain that point.

A If the fire is very thin, it is necessary to break the coal pretty small in order to insure combustion, and to break up and more thoroughly mix the air entering through the fuel. If the fire is thick, it must be coarser, or it would shut out the air altogether.

Q Is it possible to admit too much air?

A. Yes. All air admitted above that necessary for combustion cools the gases and helps keep them below the igniting point.

Q. How much air should be admitted then?

A. That depends upon the amount of coal that it is necessary to burn. If the train is light, and little coal is burned per square foot of grate per hour, it will sometimes be better to close one damper; but if the fire is being forced hard, and a large quantity of fuel burned, air must be admitted in proportion to the fuel used.

Q. What would be ideal firing?

A A constant supply of fuel and air.

Q Why is this impossible?

A. Because fuel is fed by hand, and the supply is intermittent, and because enough fuel must be kept on the grates to prevent tearing of the fire. If the fire door is opened, and a large quantity of fuel put on, it cools the gases below the igniting point, and gives off little effective heat until the mass becomes heated. On the other hand, if a very constant firing is kept up, the air admitted at the door will do the same thing, so that the fireman must stand between the two extremes. The only thing to do is to keep fire enough to prevent pulling, and then regulate the supply of air as will give the best results.

Q. Taking a hard-working soft-coal engine, do you think it practically possible in road service to admit too much air through the fire?

A No. It will be almost impossible to get enough, and if some air is admitted above the fire it will produce more perfect combustion, provided it is broken up and mixed with the gases. Perforated doors and hollow stays do good in cases of this kind.

Q What is the difference between hard and soft coal for use on a locomotive?

A. Hard coal is almost entirely composed of carbon, giving off very little gas, and its use is simpler; it is not so necessary to admit air over the fire; the flame is short and intensely hot; a long fire-box is necessary in order to burn a large quantity at a time; as it gives off little gas, there is no smoke to speak of.

Q Are you on good terms with your engineer? Do you talk about the engine or the work, and do you see the orders, and know what trains you should meet or pass?

A ———.

LECTURE.

I recognize the fact that the past year has been one of hard work for you, and one that has not given you much time for study. But if you read a little each week or month, and then compare the theories laid down by good authorities with your daily work, you will soon have a very large fund of practical information based on proven ground.

I have directed your thoughts upon boilers and combustion, because it is of the greatest importance to the company and to you. If you are reasonably careful, you can save many dollars by so firing as to prevent wasting steam at the pops.

Next year I will examine you upon the mechanism of the locomotive, and ask you what you would do under every circumstance of breakdown that I can think of. There is no occasion for you to learn a lot of answers to a lot of set questions relating to breakdowns. What you want to do is to understand the general plan and principles of a locomotive, to know what each individual piece does, and what part of the complete machine it is, remembering that a locomotive is *two* steam engines connected by the axles and steam pipes only. If you understand the principle of the thing you cannot be "stuck" on a question if you stop to think—and I shall not hurry you.

I want you to remember that the business of the road is to transport freight and passengers with the least expense and delay, and that the engineer is the brains of one great engine. It is not to the interest of the company for an engineer to spend hours and cause long delays to show his skill or ingenuity in patching up a broken engine, when he could have been towed in in half the time. At some time, and under some circumstances, it might be best, under others worse; the end must justify the means.

Good judgment is the most essential thing in a successful engineer. I shall ask you many questions about maintaining your engine, but I shall expect you to know only as much as concerns you as a runner—you are not a builder. But if you say you would key rods or set up wedges with the engine in a certain position, I shall certainly want to know *why* you do so. Study the *why*.

Keep up your reading of current literature on locomotives. You will find something each month that you did not know before or had forgotten. Should you pass the next examination satisfactorily, you will be given a note to the superintendent for examination on time-card and rules. Passing that, your name will be entered, in its turn, on the list of extra engineers, and I trust that in time you will be in charge of a locomotive.

(Final examination questions next month.)

The Cheapest Fare in America.

The Southern Pacific Company doubtless run some trains on which the least fare is collected in this country.

The main station at Oakland is on "the mole," a long fill extending some two miles into the bay. Passengers reach it from San Francisco by a four-mile ferry. There are several stations in Oakland and suburbs, and a great many suburban trains are run in several directions. The trains run right through the business streets, and by some agreement made in securing the original franchise, the company is debarred from collecting fare in Oakland. People who come over in the boats pay 25 cents for a round trip, and can get off at any station in Oakland.

It is a regular thing for people of all classes to crowd upon the trains going and coming, and use them just as they would free street cars. Nurse girls, with three or four children, and young people, out for fun, ride back and forth over several miles of track, and no fare is asked.

The road also runs a number of "laborers' trains" between Sacramento and San Francisco, 135 miles, the fare being very low—$1 50, we believe. This is also one of the original promises that the company would like to get rid of, and therefore accommodations are rather meager. The seats are all plain pine boards, in the oldest and poorest coaches, and the seat backs are boards only about ten inches high.

It is cheaper for a tramp to have a state-room on this train than to ride on a truck.

Didn't Believe in Wear and Tear.

"I distinctly remember the first summer this road started," said a D. B. G. foreman to the writer as we stopped where some men were loading links and pins—"I distinctly remember that Superintendent Borst sent up a writen order for two dozen links—that wa'n't many—but old Uncle Johnnie Greenwood, the master mechanic, shook his head, and asked me if those twenty new flat cars didn't have links come with them, and when I said they did, he said: 'Let 'em take care of them then; we won't make any.' Now we use two car loads a month, and everything else about the road has grown in proportion."

Correspondence

Early Lake Compounds.

Editor The Locomotive Engineer:

I beg to correct you in regard to the first marine compound used in this country. In October, 1845, I was a passenger on the side-wheel steamer "America," from Chicago to Buffalo, that had a compound engine. It was horizontal, and from recollection, the cylinders about two and four feet diameter, and eight to ten feet stroke, what might be called a steeple compound laying down; it had no condenser, as I recollect. The engineer claimed it saved nearly half the fuel. It made the run to Buffalo in less than four days, which, at that time, was considered very smart. I remember we raced with the larger steamer "Wisconsin," and passed her easily. The "America" was a new boat; this was her first or second trip.

The steamers at that time were nearly all side-wheelers. ALLEN WOOD,

General Manager St. A. & S. B. Ry.

Dip for Cleaning Rough Brass.

Editor The Locomotive Engineer:

In your June issue I noticed the following in the Question column:

"Is there a mixture of acids called bright dip, that will polish rough brass without file or lathe? If there is, please publish the formula."

The following receipt gives good results. It does not polish rough brass, but it gives it a very neat appearance, and answers for many purposes as well as if it were polished.

Sulphuric acid, 12 pounds, nitric acid, 1 pint, niter, 4 pounds; soot, 2 handfuls, brimstone, 2 ounces; pulverize the brimstone and soak it in water one hour. Add the nitric acid last.

For cleaning injectors, checks, pump governors, reducing valves, etc., we use the following.

Strong nitric acid in sufficient quantity; dip the brass in the liquid for an instant, withdraw, and immediately immerse it, first in cold water, then in boiling water, for a short time only in each bath, then allow it to dry. Repeat the process, if necessary. T. B. PURVES, JR.

Getting Things Right.

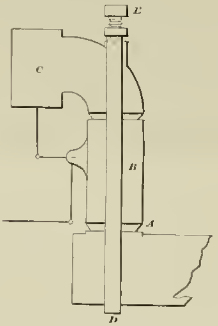
Editor The Locomotive Engineer:

The thought has often occurred to the writer that if some of the men who design locomotives had to do the running repairs they would get things into a different shape from what they do. Of course, construction is sometimes complicated, necessarily, but there are times when the location of parts could be better arranged and made easier to get at.

Take injectors as an example. How often are they stuck down in the corner of the cab in a dark, hard-to-get-at place? It is not much of a trick to put them there when new, with the proper wrenches and other tools at hand, and all nuts easy to turn, but when it comes to doing repairs, it is another thing, every nut is tight and immovable, no proper wrenches to work with, and ninety-nine times out of a hundred the injector is hot, and it is generally managed to have the overflow pipe where nothing but cuss words and a hammer and chisel will do any good. I once saw an injector placed back of air-pump, when injector required packing, had to take down air-pump to do it.

The greatest evil of them all is to locate the air-drum under the footboard. If there is anything that will start a man to swearing it is to have to work under an engine setting up wedges, packing cellars, etc., and butt his head against the drum, it is an imposition, backed up by indifference, and in some cases ignorance, on the part of the man who will put an air-drum under the footboard. They are bad enough under the boiler, forward of the links, but that is not the place for them. Put them in the coal pit of tender, or on top or back end of tender, anywhere but about the engine. Why not put them on the top of boiler in place of sand-box, and put sand in wheel cover? The late A. J. Stevens, of the Central Pacific, combined his air-drum and sand-box in one, on top of boiler of his local engines running in Oakland, Cal., and they were all right.

Some builders should be ashamed of the way



the dry pipe connections are made in boilers. A dry and stand pipe, properly made, will have a ball joint on its top side A at back end, with the stand pipe B ground in to make the joint; with the throttle case C ground on the stand pipe, and with the stirrup D passing around the dry pipe and up around the stand pipe, and with a single set-screw E, the joints are both made at the same time, and the set-screw is get-at-able. This may not be new, but it is much better than standing on one's head in the dome trying to knock out split keys or unscrew nuts to get the thing apart.

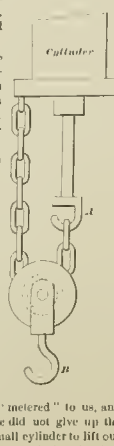
Corry, Pa. W. DE SANNO.

[It may be more convenient about doing work under an engine to have the air-drum on the tank or top of boiler, but that is a bad place for it, just the same. The drum should be the lowest point in the air-brake system, so as to trap all the moisture where it can be drained off. With the drum high, the hose between engine and tender become traps for water and oil that it entrained, and causes trouble from freezing and rotting out hose.]

Increasing the Power of a Lift by Reducing the Speed.

Editor The Locomotive Engineer:

As in many other locomotive repair shops, we are obliged to use our driving wheel press for tender and truck wheel work. A chain block did very well for handling them, but it took three men to do it, and not make very good time either.



After the city water was connected with our shop system we abandoned the chain block, and replaced it with an 8-inch cylinder of sufficient length to elevate a pair of our smallest wheels. Our city pressure is about 60 pounds per square inch, and with a cylinder of this size we could manage our largest and heaviest tender wheels with ease, but could not lift a pair of driving wheels.

If we had increased the diameter of our cylinder to accommodate the driving wheels, it would have required as much water to lift a light load as a heavy one, and as we handle fifty trucks to one pair of driving wheels, we concluded the small cylinder would be the most economical, as our water is "metered" to us, and paid for by the gallon. We did not give up the idea, however, of using the small cylinder to lift our heaviest drivers into the press, and the sketch I send you illustrates how we did it.

Some of the boys were positively sure that no greater weight could be lifted by hook B than by hook A, and watched with much interest when B lifted driving wheels as easily as A lifted the truck wheels, the speed, of course, being reduced.

When not being used for driving wheel work the chain is disengaged from cylinder and hook A, and hung over upper bar of press.

There is nothing new in this, of course, but I thought it might interest some of your readers, as it illustrates a mechanical law.

The same principle was applied to get a heavy teaming truck out of a mud hole in which it was stuck.

The driver worked and urged his team for all they were worth, but no go, they could not budge the load. There were many suggestions from the crowd that had gathered on the street, and one young fellow was willing to back his suggestion—that he could pull the load out with one horse—with a five-dollar bill. The attention of the owner of the team was called to it, and he offered to give the young man five dollars if he was successful.

This is the way he did it: Detached both horses from the truck, and around the hub of each forward wheel took as many turns with a ⅝-inch rope as the length of the hub would admit, and to the other end of the ropes he hitched the traces of one horse. Betting was very lively as to whether the horse would pull it out or not, but at the first word he started, and out came the load with scarcely an effort, and he did not stop until the rope had unwound from the hub.

The owner gave up the V, but considered it worth five dollars to learn the kink.

East Albany, N. Y. T. B. PURVES, JR.

Another Pump Problem—A Bent Piston Rod.

Editor The Locomotive Engineer:

A short time ago one of my 8" pumps got to groaning very bad, and all the swearing and valve oil the engineer used would not stop the groaning. So I concluded that a wing of one of the air valves had broken off and got under the air piston and bent the rod. Well, I took off the bottom head, then removed the air piston, but found nothing. I then examined the air valves and found them all right. I then took off the top head to examine reversing valve plate bolts, and found them all right. I then took out the piston and rod to see if it really was bent, and it was. The piston rod was perfectly true when it was put in the pump. Now will some one tell me what bent that piston rod close to the steam piston head? I discovered what it was that bent the rod, but not until I had done lots of thinking. W. F. RELYEA.

Syracuse, N. Y.

By the Way.

Editor The Locomotive Engineer:

If I were asked for a definition of a valuable correspondent to your paper, I would answer, he whose article some other correspondent takes exception to. I often wish, while reading, that I could meet some of your live correspondents, see what kind of men they are.

Would go a hundred miles to see John Alexander, heard a mother say last evening, "If I only knew his address I would write and thank him for the good his letters have done Ed," (her son), but nobody takes exceptions to what he says.

It is different with some others, a few days ago I was at Houston, Texas, started out to get acquainted with Mr. Campbell, whose articles on Traveling Engineers and Valve Setting have been numerously criticized, if not answered.

At the office I met a pleasant-appearing gentleman of perhaps 48 or 50 years, who during a twenty-years' residence in the Sunny South has lost none of the git-up-and-git that has taken to the front so many other Ohio men.

I started to get on the good side of him by asking if he needed the services of a traveling engineer, with a snap that a pop valve would envy, he answered "No sir, no sir, I don't want a traveling engineer."

I next told him that I had experience in setting valves; this seemed to interest him, as he asked me how long it would take me to set the valves on an engine. I told him that I had done it in nine minutes and thirty seconds, beating by half a minute the best time recorded in THE LOCOMOTIVE ENGINEER.

He asked me where I was from, and when I said Colorado that settled it. With a pleasant smile he grasped my hand and said that some time past he had sent the road's champion liar out to Colorado to see some kinks he had heard of, but that he had only staid a day, and on coming back he reported that a champion liar from Texas was only an amateur in Colorado, assured me of the pleasure he had in meeting me, and that his time was at my service. I gladly availed myself of his offer, and was repaid by being shown, not the largest, but the neatest shop that I have seen in Texas; and let me say that the railroad shops of Texas are models of neatness within, and many surrounded with beautiful gardens of flowers.

After an hour spent pleasantly I left and *sized* him up as a man who is proud of his business, takes a live personal interest in his men, expects and exacts faithful services, and when rendered does not fail to let them know that it is *appreciated*.

Denver, Col. A RAMBLER AFTER KINKS

Injector Puzzles.

Editor The Locomotive Engineer:

Considerable information has been gained by the pump problems published in your paper, and I have been expecting some one to commence propounding questions on injectors; and as the rest appear backward, I will submit one or two—just for a starter.

Take the Sellers of '76. Suppose you can prime, the water raises readily to overflow, but the injector "flies off" or breaks—what is wrong?

Suppose you prime as before, but when you pull out spindle to force the water to boiler, the injector "breaks." There are three causes for this action, and all easy enough—what are they?

Wilmington, Del. EDWARD GIBSON.

The Master Mechanics Association.

The regular June meeting of the American Railway Master Mechanics Association was held the third week in the month at the Stockton Hotel at Cape May, N. J., and was the largest gathering the association has yet held, and the twenty-fourth in number.

The week preceding, the Master Car Builders held their meeting at the same place. Their meetings are not so interesting as the master mechanics', but are of as much or more importance to the railroads, on account of the interchange of cars.

The standards of this association have saved the railroads hundreds of thousands of dollars and the public lots of delays and loss, still, it is more than likely that it will, sooner or later, be merged into the master mechanics', for the simple reason that, within the past decade, car building as a separate department has lost its standing, and the office of car builders has been merged with that of master mechanic; this may be, and probably is, all wrong; the responsible car builder should have credit for his work and be the head of his department, but it's too late now—in ten years there will be no car builders, pure and simple.

The convention opened this year by a speech from a local politician who was chock full of welcome, but not much of a speaker; then President John Mackenzie got in his fine work, making his speech short and all point. The roll call shows a membership of 458, ninety five having been added during the year.

The first paper read was on Exhaust Pipes and Nozzles.

The committee report actual experiments with single nozzles exclusively. We quote from the report:

"We hold that the aim of the designers should be:

"1st. To choose such size and shape as to secure free steaming.

"2d. The exit of the steam should be as free as possible, to avoid injurious back pressure.

"3d. The discharge should be as nearly central with stack as can be, so as to produce maximum effect.

"4th. Exhaust from one cylinder should not blow over into the other.

"5th. The exhaust pipe should terminate at such distance from base of stack as to insure its being completely filled at each discharge.

"In designing single pipes we hold that the most vital point is the relative areas at tip and at combining point. Where the last-mentioned point is largely in excess of the other, it will inevitably result in blowing over the bridge, raising the back pressure line into the well-known hump.

"On the other hand, where the area at tip is the larger, it will be found that the velocity given to the steam at the bridge will, provided the form is easy, carry it past the tip without any tendency to blow over. Not only is this so, but the contrary effect will be at times observed—*i. e.*, there will be a partial rarefaction in opposite cylinder, as will be shown in indicator cards.

"It has been clearly shown that the height of the bridge cuts no figure in effecting back pressure, but that lowering the bridge affords the designer a chance to straighten the discharge before it leaves the pipe.

"We suggest that the distance be made from three to four and one-half times diameter of tip. Also that sudden changes in form be as far as possible avoided, both from the increased resistance to free exit, and also because the eddy caused by sudden enlargement or contraction causes deposit of gas carbon from cylinder oil at those points.

"We do not think that the pipe should be regarded as a reservoir, because such treatment so prolongs the discharge of the steam that the pressure is not relieved when the piston begins return stroke.

"We consider that the pre-release affords ample time to discharge the steam. The height of the pipe should be such as to insure that the base of stack shall be completely filled at narrowest part. If, however, it be more than filled, an injurious eddy is formed.

"We think that the general practice is to put the pipe too high. Where care is not taken to insure straight discharge, part of it impinges against side of stack with injurious results to steaming. Raising the pipe, of course, obviates this trouble in a measure."

The subject of Testing Laboratories was next subject of report, and a very exhaustive report it was. It gave the cost for a testing department complete, and gave figures from several roads, showing a large percentage of material condemned by the inspectors.

The relative value of steel and iron axles then came up, and a great diversity of practice was shown by the discussion.

The committee on the subject of Feed-water Purification gave the replies of many to their circular, and tell of a dozen of things tried for this purpose, most of which are condemned. They end their report as follows:

"To sum up the information, your committee gleans the fact that up to the present writing the efforts to purify the foul water, and soften the hard waters, especially for locomotive boilers, have proved unavailing, and there is still much room for experiments in this direction. The sentiment of those who have expressed themselves is in favor of a mechanical device, as against the use of chemicals or compounds. Your committee has not the information at hand that would warrant the recommendation of any device, but directs attention to the Barnes Mechanical Device, which, from a mechanical standpoint and the evidence before us, warrants us in taking this action.

"The evidence is preponderant and almost unanimous against the use of chemicals or compounds, while with the use of oils there is ever danger unless the greatest of care is exercised in placing it in boilers, as it cannot be surmised what mischief it is working by adhering to crown sheet or other parts coming in contact with the fire. Your committee is skeptical on this point, having personal knowledge of the damage arising from such practices."

For all of this we are inclined to think that railroad master mechanics have been giving their boilers medicine without knowing just what was the matter with them. They have tried pretty nearly everything that came along. To know how to get impurities out of water it is first necessary to know what is there to get out; no compound or no mechanical device will work well in all waters, any more than one sized hat will fit all men. It would be folly to use a compound in some waters that a purifier might help greatly, and *vice versa*.

The old question of the Standard Car Coupler then came up, but there was less discussion than was expected, and a resolution was finally adopted stating that the coupler was a step in the right direction—practically an indorsement, but done half-heartedly, as if they were a little ticklish on the subject—which, no doubt, many of them were.

The committee on the Examination of Engineers and Firemen made an exhaustive report. Early in the year they sent out a circular to the heads of the motive power departments of our roads, asking the following questions:

No. 1. Do you examine engineers employed from other roads on anything except time card rules? If so, what plan do you pursue, and of what does the examination consist?

No. 2. Do you examine firemen candidates for promotion? If so, what line of examination is followed?

No. 3. In hiring men for firemen, what age do you consider the limit past the age of 21 years?

No. 4. Do you advise the first year in service, as fireman, be on switch engine?

No. 5. What do you consider the shortest time a firemen should serve in that branch of service before he is allowed examination for promotion to engineer? If fireman fails in examination, how do you deal with him?

To these some fifty replies were sent, and from the average replies the following deductions were made:

Q. 1. (a) When possible, such as old roads, trunk lines, etc., it is not considered best to hire engineers, as such, from other roads, but to make or educate their own engineers from the ranks, and by so doing have men that are better adapted to the requirements of the particular service required; a better opportunity is afforded for more intimate and satisfactory knowledge as to the character of the men, and does not place any hindrance to the best incentives and inducements for men in the ranks who are looking and working toward the higher positions.

(b) But when, such as new roads and isolated systems, it is not possible to educate or make all their own engineers, it is deemed best to give applicant same examination as to firemen candidates for promotion; in addition to this have to furnish satisfactory evidence of character and disposition from the roads where the applicant has been employed.

Q. 2. Except in a very few cases, many general replies have been given to this question, stating that applicants for promotion were questioned and carefully examined, but not stating any particular form, merely citing questions that would illustrate the general form or method used. Several elaborate plans of examination were here mentioned.

Q. 3. The majority favor as a limit past the age of twenty-one years, not over twenty-eight years.

Q. 4. Twenty-five out of forty-seven favor first year's service as fireman to be on a switch engine.

Q. 5. The almost unanimous opinion is that three years is the shortest time a fireman should serve before being allowed examination for promotion as engineer, and it is quite the general opinion that applicant should be given one or even two additional opportunities, being set back on the list if he fails to pass examination for promotion, and are all quite agreed that if he fails on these he should be dropped from this branch of the service entirely.

We quote from the report:

"A great deal has been said against having fixed sets of questions for use in examination of applicants; that the men would learn the answers to the questions, etc., and thereby defeat the object or purpose of the examiner. Now, it seems to your committee that this objection is more apparent than real, for the examiner is not compelled to rigidly adhere to the set questions, but is at liberty to vary them as the circumstances demand; and as to the applicant committing the answers to the questions, or getting helped by the others, etc., is this an objection? The bare fact of the applicant so applying himself as to commit the answers is in itself a great point gained, and the examiner can readily determine whether the applicant has an intelligent conception of the matter involved in those questions or answers.

"A great many of the forms of questions furnished from time to time are so elaborate or intricate that an expert mechanical engineer, or even master mechanic, would make sorry work with them. The idea of the questions is not to puzzle or trip the applicant, but to determine if he has sufficient knowledge of the machine he is to have in his care to satisfy the requirements of service

"The idea of progressive examinations, as advanced by Mr. John A. Hill, associate member, is so *apropos*, and withal based on such practical and common-sense grounds, that your committee cannot refrain from presenting a brief synopsis of same in connection with this report."

Here follows a complete outline of the plan of progressive examinations as proposed in this paper, the report ending as follows:

"The plan covers the whole field from the preliminary to the final examination for promotion, advancing step by step, and is well worthy of careful study."

This report was received without discussion.

The subject of Operating Locomotives with Different Crews was then taken up. The committee thus state the advantages and disadvantages of using more than one crew on an engine.

"The advantages of operating locomotives with more than one crew are that it saves a large investment of capital in power, decreases the amount of fuel wasted in housing, banking fires and restarting them, and saves roundhouse room and fuel and plant for warming them in severe weather, where there are an unequal number of trains in opposite directions, the pool system gives the men exactly equal hours of rest and equal work By the double-crew system almost as much service can be secured as by the pool system, but not as even chances for the men.

"The greatest disadvantages of the pool or chain-gang system is that it relieves the engineers of the sense of responsibility; they lose all interest in the care and maintenance of the engines, and in consequence less miles are made between overhaulings than where the men try to maintain the power It is almost impossible with any double-crewing system now in vogue to fix the responsibility for the results of misuse or carelessness, such as cut journals, valves, etc It is difficult for the firemen to learn the peculiarities of steaming of the different engines. The engines are not properly cleaned, and no incentive is offered to the men to be economical in the use of fuel or supplies. The inspection and cleaning usually attended to by regular crews is in pooling an extra expense.

"The double-crew plan leaves the care of the engine between two crews, and the entire sense of responsibility is not lost, but it is a very difficult matter to arrange the runs, especially on freight, so that the division of hours of labor and rest are equal among the men. And the details of arranging and changing runs are very annoying and unsatisfactory."

We quote further

"The tendency of modern operating is turned toward doing the most business with the least investment for power possible, and it is more than likely that none of the large lines will own engines enough to man each with a single crew and do the work.

"Your committee is led to believe that pooling can only meet with success where particular attention is paid to the inspection and repairs; in fact, where they make special provision to care for the engines, as they do on the P. R. R. No road can hope even for comparative success, handling the work as they would where engines had their regular crews.

"In passenger service your committee believe that the double crew plan is better than the pool system; the runs can be more evenly distributed, and the double crews do not lose their sense of responsibility or relax their care of fuel or stores.

"In freight service it is a very difficult matter to arrange the runs for double-crewing, and where many 'extras' are run, and the seniority of engineers call for the best runs, it is well nigh impossible.

"Where pooling is found necessary, even temporarily, your committee are of the opinion that better results will be secured if extra wipers and cleaners are put on to clean all engines fairly well in a few minutes while the fire is being cleaned, the tank and sand box filled and the engineers oiling around. Hostlers should be provided at terminals and engine taken to a track where all this work can be done at once; at the same time the hostler and his helper should take off the oil and clothes-boxes of the crew that brought the engine in, and put on the private boxes of the men who are to take her out, boxes specially designed for handling should be provided. The oil and supplies should be charged to the *crew*, and not to the *engine*; this provides a check for wastefulness and is an incentive to be reasonably economical.

"Blank reports should be furnished and each engineer be required to turn over one to an inspector on arrival; this, in addition to reporting the work necessary, should contain a few questions, that could be answered by 'yes' or 'no,' that will show the general condition of the engine, how she steams, condition of brakes, and whether or not the engineer considers her in condition for further service without repairs.

"Inspectors should be provided at all changing points, these men should be selected from the most experienced and careful engineers, and no work should be done on an engine without the approval of the inspector"

The question of the Best Form of Heavy Engines for fast service came up, and a long report was submitted. The discussion was principally whether the ten-wheeler or the Mogul was the best form. The discussion brought out the fact that there was almost unlimited faith in the safety of the pony truck. The report ends as follows:

"As a summary we would say, from all information furnished, we gather that the preference is for the ten-wheeled engine as against the Mogul, on account of its being practically the same as an eight-wheel, the forward drivers being simply burden bearers, and leaving wheel bases actually the same. Next because the distribution of weight is such that, while gaining sufficient adhesion to utilize all the power, there is not an excessive weight on either wheel. For example, an engine properly proportioned for 20x24-inch cylinders at high speed will weigh about 130,000 lbs. On a ten-wheeler this would give 32,000 on truck and 98,000 on drivers, while with a Mogul we would scarcely put more than 20,000 on pony, leaving 110,000 or, perhaps deducting 2,000 for difference in construction, 108,000 to divide on six drivers. While this weight would not perhaps be destructive to track, it is more so than the 16,333, besides being useless. Again the majority claim greater safety on crooked roads for ten-wheel engines

"In conclusion, the committee would say that the relative economy of these engines in fast service, as against eight-wheel, could better be answered in the future than at present, with the limited actual experience we now have.

The committee on Standards of the Association made a very sensible report, from which we condense the following:

"The principal business of the members of the association is connected with the construction, repairs and operation of locomotives, and this work is confined to a system of roads operated by one company, or to a single, independent road The locomotives in their care not being interchangeable with other roads, and its operation and the care of it being confined to the road which owns it, we regard it as highly important that each road should adopt standards of locomotive construction best adapted to the service required, and the geographical position in which they are located, but we do not regard it as essential that the standards of all roads should be the same."

They believe nothing should be adopted as a standard until all are agreed that no improvement can be made; as the adoption of imperfect standards by this association would have the tendency to prevent the investigations which it is our object to encourage

They recommend the following:

"United States Screw Threads, Micrometer Gauge for Sheet Metal, Limit Gauges for Bar Iron, and Gauges for Driving-wheel Centers and Tire These standards and others of a like nature which may be added are important in our dealing with manufacturers, and the general adoption of these will be in the interests of economy, and your committee would recommend that they be maintained and reaffirmed as standards of this association. But the axles for light and heavy tenders and the tests and specifications for cast-iron wheels should not be standard, but should have the indorsement and recommendation of the association, to be adopted by the members as they may see it to the interests of the road they serve. Of the Journal Bearing, Journal Box and Pedestal, these standards were adopted by a joint committee appointed by the Master Car Builders and this association, and your committee are of opinion that it was proper to approve the recommendation of that committee, but that it should not be regarded as a standard of this association. The only other standard which has been adopted by this association is that of making 6 miles per hour the standard mileage for engines in switching service. The committee think this is the general practice, and should have the recommendation of the association, but it is not of sufficient importance to be placed on the list of standards."

The committee on Air-brake Standards and Care of Air-brake report in favor of publishing a book of rules on the subject, said rules to be printed by the Car Builders and Master Mechanics Associations to insure absolute uniformity This subject was left over for one year, as the rules submitted covered only the Westinghouse appliances, and it is designed to make it cover all.

The association owns something over $8,000 in bonds, known as the "Boston Fund," from the fact that it was started in that city, they have no use for the money, and it has long been a white elephant on their hands The association have now agreed to buy four scholarships in the Stevens Institute of Technology, and give them to the sons of members or widows of members who can pass the best examinations before the public shool officers. In event of more applying than there are scholarships, those passing the best will be given the scholarships. This will dispose of the fund, do some good, and ought to make four living monuments to the association, and will be, no doubt, an honor not a little coveted

The noon hour discussion brought out a great many points on the compound locomotive, and developed quite a debate on the relative advantages and disadvantages of the four-cylinder and two-cylinder types. It was shown that there were upward of seventy compounds built in the U S in the past eighteen months.

Mr. Forney stirred up quite a discussion by saying that he never knew of a case where the application of an indicator had done any good to a locomotive. Those who know Forney best say that is his way of awakening interest—it is not a bad one

There was also much interest taken in the discussion on the proper heat for flanging steel, some specimens of boiler steel were shown by Mr. Blackwell, that were bent double and hammered down cold at one end without a flaw, while the other end was badly cracked at a dull red heat It was the unanimous opinion that boiler steel should be flanged and bent only at a bright red heat.

The next meeting of the association will probably be at Saratoga.

Steam Heat Suggestions.

The Master Car Builders' Committee on Steam Heat recommend that:

1. That all pipe as far as possible should be located inside the car

2. That a uniform location should be adopted for the ends of the pipe between cars

3 That a standard pipe union or corresponding device should be adopted for connecting the rubber hose with the train pipes.

4. That means for heating cars independently should be retained.

A Chicago paper says that the Duluth, South Shore & Atlantic Railroad has a scheme on foot which includes a new line of steamers. The plan is to connect Lake Superior with the Atlantic Ocean, the terminal cities being Duluth and Norfolk, Va. One of the connecting links of railroad, the Columbus, Lima & Milwaukee, has just been bought.

The Trouble with Manufacturing in a Repair Shop.

It used to be an easy matter in years gone by for those in charge of the machinery departments of railroads to build locomotives, machine tools or what-not, charging the bulk of the expense to running repairs, and thus make a showing of cheap work.

Many a man has been permitted to build engines of his own peculiar kind by making the claim that they were cheaper than those on the market.

Now there is a different system of doing business. Directors and stockholders want to know how much it costs per mile to run their engines, cards showing the results are exchanged by the larger roads and comparisons made.

The average manager, stockholder or operating head seldom looks farther than the pay-roll—that must be kept down

The man who makes his own locomotives, machine tools and what-not, has a big pay-roll and has to be cut down, while the one who buys everything he can, keeping only men enough in the shop to keep up running repairs, gets along the best, has the better reputation—and, usually, better rolling stock

No master mechanic can afford to do much manufacturing; it may be a satisfaction to him, but it is sure to be expensive, and put a load upon his department that he will get no credit for, and indeed he is lucky if he is not condemned as "a good man, but too expensive."

You may know that you are saving the company money, but remember that the average stockholder and director are blind except as to the size of the pay-roll—keep your eye on that

The Value of Failures.

There are some kinds of mistakes that human nature insists on making in each individual case, and no amount of experience of others will prevent constant repetitions It is useless for a father to tell his sons that he has been all through the list of indulgences in the shape of dances, horse-racing and the circus, and seen the folly of them—the boys want to see the folly of them for themselves. No mother ever prevented a daughter from marrying by pointing out her own cares and responsibilities.

But it seems as if railroad men ought to be willing to show up some of their mistakes, just to keep others out of the same pit, and for the general information of the craft We recently visited a shop in company with a man who for long years was a M M, the general foreman showed us a device he had half completed for turning up crank-pins. When we got out on the street again the old M M. said, "That pin turner won't work, I was all through that ten years ago"; then he gave a very good reason why it failed, and showed where the design was at fault.

When asked why he didn't put the foreman "on," he said, that he learned by experience, and that the foreman might do the same, and that he could just see where he would stop, subsequent inquiry proved that he was right. It would seem as though a little knowledge of his failure would have saved one man a lot of work, and one road a lot of expense, and, perhaps, a dozen others.

We can only find out whether or not a device or a process will work by trying it, and we find out whether they will not work in the same way When a man gets up a thing that works we hear about it and use his idea, and usually pay him for it, but when he gets up a thing that won't work he keeps mighty still, and hunts for some fellow who is working on the same line, then, looking wise, he explains to his friends where the man is "off," thus keeping up his reputation for being a smart mechanic. One of the greatest of American inventors said that his greatest achievement was the magnificent return from twenty one failures. Railroad men are too much afraid to tell about their failures.

The committee appointed last year by the American Railway Master Mechanics Association on the examination of engineers and firemen, consisting of W H Thomas, superintendent M P. of the E. T V & G.; John Player, of the Santa Fe; F. D. Casanove, of the P., Ft W. & C.; J. W Luttrell, of the N N. & Miss. Valley; and L. R Pomeroy, of the N. Y. Suburban Rapid Transit, did us the honor of recommending to the association our plan for progressive examinations, the report being received by the association without discussion or a dissenting voice. This is, to us, no ordinary honor, and one of which we feel very proud—it's a mighty poor specimen that can't feel proud once in a great while.

Two years ago, when the Webb compound locomotive came here from England, this paper made a wood engraving of her, the first one shown on this side of the water, the cut has since been used by several papers, giving THE LOCOMOTIVE ENGINEER credit for it. Last month the *Journal of Railway Appliances* borrowed the engraving, cut off the imprint on it, and rehashed something about the engine, without telling where they borrowed the engraving The "*Appliances*" seems to be just about as far behind the times in journalistic courtesy as they were in the illustration of this engine.

Book Review.

CALKINS' STEAM ENGINE INDICATOR E & F. N Spon, publishers, New York. Price, $1.50

This work is a very neat and complete one of more than a hundred pages, originally issued by the makers of the Calkins indicator and other instruments as a trade catalogue It is an advertisement and direction for use of their goods only, and as such is a very creditable piece of work, but it is not such a work as we can recommend our readers to purchase for information on the general subject of steam engine indicating, and it is altogether likely that the people who originally issued it would be glad to furnish it free to those who use, or are thinking of using their instruments.

ASKED & ANSWERED.

(41) H. W C, Newcastle, asks:

If a boiler 42 inches in diameter, ¼-inch plate, will stand 100 pounds pressure, what pressure will a boiler 60 inches in diameter, ⅜-inch plate stand? *A.*—84.33 pounds per square inch

(42) C. W H, New Brunswick, asks:

With a broken wheel or tire, what is the best way and easiest to get wheel raised off the rail to put block under box or axle? *A.* Run the wheel up on wedges, block under the box, and repeat until load is relieved. Jacks are sure, but slow

(43) H. W C., Newcastle, N. B, asks:

Is the pressure in auxiliary reservoir and main reservoir, and train pipe, equal when the automatic brake is not applied? *A.*—If engineer's valve is at "full release," yes, if in "running position," there will be about twenty pounds more pressure in main drum than in train pipe and auxiliaries.

(44) J E H, National City, Cal, asks

Please explain as clearly as possible how the point of suspension of the link, length of hangers, and position of lifting shaft affects the distribution of steam in the cylinders. *A.*—Read Elementary Lessons in First Principles, in October, November and December, 1889, issues. The subject is too long for this column.

(45) G. E R, Westown, Pa., asks:

Does the pressure on the crank-pin of a locomotive have the same leverage to move the engine when the crank is on the upper side of wheel as on the lower? The fulcrum appears to change from the axle to the top of rail, and it appears to have more power when the crank is moving toward the cylinder? *A.*—There is no difference in the leverage when pin is above or below the axle, and the fulcrum does not change

(46) J. H. C., Jersey City, writes

Will you please answer the following questions, to settle a dispute between several locomotive enginemen on the New York division, P R R., and oblige: 1. At what point in a locomotive boiler can be found the greatest pressure? Some say the steam dome is under the greatest strain; others say not I claim that if two pressure gauges be placed, one at top of dome, the other at leg of fire-box, the lower one will show the greatest pressure, owing to the height of water *A.*—At the bottom, on account of weight of water. 2 Why are check valves placed below the water line? *A.*—Because it is generally considered best to feed below the water line Some locomotives are fed above 3. Will an injector work with compressed air in place of steam? *A.*—No.

(47) M. C. G., Durham, N. C., writes:

To settle an argument between some brother engineers and myself, please say if a locomotive's drive wheels slip in rounding a curve. And if they do slip, please explain how, and oblige. *A.*—The outside rail on a curve is longer than the inside one, and in going around it, one of the wheels in a pair must slip on one rail or the other unless the face of the wheels are coned enough to compensate for the difference in length of rail.

(48) Helpless, Charleston, S. C., asks:

1. What is a locomotive? *A.*—Anything capable of moving from place to place, but now universally considered as a wheeled machine, driven by a boiler and one or more steam engines. Look in your dictionary. 2. What is lead given a locomotive for? *A.*—To fill the ports early and reduce the shock of the engine in passing the centers. 3. What is the wheel base of a locomotive? *A.*—The distance from the front to rear wheel on locomotive is the *total* wheel base, and that from the forward to rear driving wheel the *rigid wheel base*. 4. What is the wheel center? *A.*—As usually spoken of, it means the diameter of driving wheel center—not counting the tire.

(49) Reading Fireman, Philadelphia, writes:

Am on a saddle tank switcher, equipped with the latest improved Sellers injectors. The one on the right side will prime all right, but won't throw water into the boiler with steam above 115 pounds per square inch. The left one will throw water with steam at any pressure. What is the matter with the right injector, and what should we do if the left one played out? *A.*—To all appearances the cause of non-work in the right instrument is that it does not get water enough to condense the high-pressure steam; perhaps the strainer or some part of the supply pipe is partially stopped up. The only thing to do in case your left instrument plays out before you get the right one repaired, is to reduce the pressure, as quickly as possible, to a point where the right-hand instrument will go to work, change injectors, and if the right one will work on the left side look to the connections for the trouble; if it acts the same there something is wrong in the instrument, which should be repaired.

Official Changes on the Chicago, Rock Island & Pacific.

Mr. Geo. F. Wilson, heretofore General Master Mechanic, has been appointed Superintendent of Motive Power and Equipment, the position of Master Car Builder having been abolished after the death of Mr. Verbryck.

Mr. H. Monkhouse, heretofore Assistant General Master Mechanic and Assistant General Master Car Builder of the C., R. I. & P., has been appointed Assistant Superintendent of Motive Power and Equipment, with headquarters at Horton, Kansas.

Mr. John Black, Jr., heretofore General Foreman of Machinery, at Chicago shops, has been appointed Division Master Mechanic, in charge of the Illinois Division, with headquarters at Chicago.

It has now become customary for trainmen to apply the air-brakes to test them by opening the train pipe cock at the rear of the train; if they release on doing it, their being coupled up clear back is proven. In some places a hose coupling, with a pipe bent into the shape of a hook, and terminating in a cock, is coupled to rear end of train, and the hook hung over hand rail; this allows switchman who rides the rear end to stop the train just where he wants it. At the Union Depot in Denver the men have added to the pipe a small whistle with a separate cock to blow it; this uses so little air that it will not set the brake by too heavy a reduction of the train pipe pressure, and is very useful in giving signals to the enginemen, and to warn persons who may get in the way of the backing train.

Master Mechanic B. Haskell, of the Rocky Mountain Division of the Northern Pacific road, uses the surface blow off cock to clean out ash-pans. Their ten-wheelers are very hard to get under, and the firemen appreciate the "steam ash hoe." He pipes from the cock down to a cross-pipe, fastened to the frame across the front of the ash-pan. This cross-piece has several flattened nipples that point back on a level with the bottom of the pan. A small amount of water will clean out the pan, either running or standing, and insures the death of all live coals.

The Baldwin Locomotive Works are building some pushers for the Erie that will have the distinction of being the largest on earth. They will be decapods with cylinders 24x28 and a boiler 76" in diameter at the smallest ring.

Caught a Tartar.

Cyrus Warman, the energetic, poetic and phonetic editor of the *Western Railway* at Denver, which is in the State of Colorado, has got himself into bad form with some people for advancing the democratic and heretical doctrine that kings, demigods, queen bees, be-tumble bugs and professional labor-trouble quacks are not born to rule by the grace of God, etc., etc.

Cyrus rose up, and buckling on his steel pen and his trusty nerve, he attacked some ex-railroaders who always represent some of the labor orders on committees to adjust grief before railroad officials. Cyrus even went so far as to give names and dates, etc., etc., he called upon officials to meet committees of their employes who actually shoveled coal, boiled water or handled air on the road, and to refuse to do business with princes of jawsmithery who were assuming to furnish brains for the poor, ignorant car hands.

The jawsmiths took up the case of heresy, and condemned Cyrus to be hanged eleven days on a gibbet of outraged labor three hundred and nine feet high, to be drawn, quartered and fed to the dogs in the dirtiest alley in poverty flats. They proceeded to have him read out of a labor order in which he had long been a staunch, knotty old post, with the bark on. This was only the starter to carry out the dire sentence of the dread tribunal, but it appears that the hereinbefore mentioned tribunal had not asked one all-important question in a case of this kind, viz., "What will he be doing, all this time?" Cyrus had dipped his pen in gall, now he changed its bath to vitriol, brimstone, sulphuric acid and *truth*—ah, *truth*, that's the stuff that makes 'em squirm.

He proved all the charges he had made, and made harder ones; he justified his position, won the friendship of the best class of railroad men, showed his own loyalty to real, honest labor, and demanded reinstatement in his old order.

Cy. Warman was right, he attacked a form of abuse that is making half our necessary committees useless, and an expense upon labor, and bringing the orders of laboring men into disrepute. Being right, Cy. will come out of the fight with all his prerogatives restored, his honesty of purpose unimpeached, and the labor armor of the jawsmiths whom he attacked so full of stab holes that they won't hold cord wood.

Brothers, when you send a committee up to see the "old man," pick out the best men on the whole road, men who have good records of service to the company, and whom you are sure the officers respect and will listen to; don't pick out men noted for talk or bluster, and whom you know are obnoxious to the officials, who, by their very manner, will offend most men and put them on the defensive. Send gentlemen to meet gentlemen, and business men to do business, send them to *argue* your case, make offers, open negotiation, and make contracts as any other business men do, not to bluff and bluster, and threat and browbeat to secure that which reason could obtain. The best engineers and firemen on the road are none too good to meet the officers of the road in a test of argument.

There is a crisis in the Supreme Council of the federated railway employes. There is a fight between the switchmen and trainmen on the C. & N. W., the trainmen having filled the places of some 400 switchmen discharged at one swoop. The result will probably be that a new law will be adopted, making the majority rule. Now one can block the wheels of the combined orders. If the trainmen's order follow up the work commenced on the Northwestern, of course they will have to get out of the council, and we will have, for the first time in our history, an organization of scabs—any other word fails to describe the Northwestern fellows who made an agreement with the officers of the company that they would fill the places of the switchmen if they were discharged. The switchmen caused the trouble by striking prematurely in the first place, but this does not excuse the trainmen—two wrongs never made a right.

W. A. Stone has been appointed M. M. of the Alabama division of the E. T., V. & G. C. L. Petrikin has resigned, to go into other business.

Some Notes of the Southern Pacific and Central Pacific Shops.

When one speaks of the Central Pacific, the Southern Pacific, or almost any road in California, he speaks of something that was. All these roads exist, but they are not doing business in their own names—everything is owned or controlled by the Southern Pacific Company.

This great corporation was organized in 1885. It had unlimited capital, and inside of two years had control of the Central Pacific road, 1,354.64 miles; the little Sacramento & Placerville, 5.64 miles, and all the Sacramento River steamers, the California Pacific had 115.44 miles; the Northern Railway, 300.48; the Oregon & California, 474.80, the South Pacific Coast Narrow Gauge, 104 miles, and the Southern Pacific Railroad and branches that had 1,799.81 miles of track. All of this they combined and called it their Pacific System, in all 4,244.81 miles of track.

Then they got control of the Galveston, Harrisburg & San Antonio's 936.90 miles, the Texas & New Orleans' 207.73, the Louisiana Western's 112.03, Morgan's Louisiana & Texas' 283.50, the Gulf, Western Texas & Pacific's 55 miles, and the 92 miles of track owned by the New York, Texas & Mexican. This line, of 1,687.16 miles, they call their Atlantic System.

There are 5,931.97 miles of track, reaching from New Orleans west through Louisiana, Texas, New Mexico and Arizona, and traversing the entire length of California, and extending north across the State of Oregon to Portland, and east from San Francisco across California, Nevada, and to the junction with the other great lines at Ogden, Utah.

This great network of tracks serve a far larger territory than any other in this country, for at New Orleans they send their freights to New York by their own ocean steamers, and at San Francisco their boats run north to Alaska.

ISOLATED.

The Central Pacific road was commenced early in the 60's, and built by the assistance of the United States government. It was for a long time isolated from other roads, and was made to depend upon the resources of the Pacific coast for its supplies. It was then, and is now, a long and expensive haul from the East to California.

For this reason the main shops of the old C. P., at Sacramento, are different from almost anything else in the country. It is more in the nature of a manufacturing plant than are most railroad shops.

SHOPS.

The shops are large, rather old-fashioned, and comprise, beside the usual machine, car, blacksmith and other shops, a very large foundry and an extensive rolling-mill.

They do not roll their own rails, but do make their fish plates, track bolts and all other forms of wrought iron. They cut their own nails, make their own spikes, mold their own car wheels, and have built most of their own cars and locomotives. On all wrought iron they save from one to two cents per pound over eastern goods delivered. It costs $1,000 freight to bring a locomotive from the East to the Pacific coast, so that they have that much the advantage in building their own.

There are in operation on this system locomotives of almost every build, but many of them were built in the Sacramento shops. Most of them are wood-burners.

A GENIUS.

Mr. A. J. Stevens, who was for years at the head of the motive power department of the C. P., was, without doubt, an ingenious man. On every hand are evidences of his inventive genius and originality, but by his work it is perfectly plain to a mechanic that he was not a systematic man, and one so anxious for improvement that he could never come to a standard for anything.

STEVENS' VALVE MOTION.

There are some sixty locomotives now running there with his valve motion on them in one form or another. This is a radial gear, driven from a return crank on the main pin, something like the Walschaert motion, but having two separate valves and valve stems. One of the stems is hollow, the second one going through it. This rod is packed by a small metallic packing, very hard to get at and to maintain. Most of the engines having this gear have 30-inch stroke, making a very long cylinder casting, but the steam chest is longer than the cylinder. In some cases two chests are used. The port is short and direct.

On some of these engines the cylinders are placed under the front of an extension arch, and a very long main rod employed, but as they come into the shop Mr. Small is setting the flue sheet ahead.

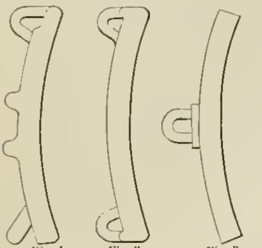

Fig. 1. *Fig. 2.* *Fig. 3.*

These engines show a slight saving of fuel over the common link-motion engines, but it costs more to keep up the gear.

CRANES.

All over the shops are hydraulic cranes of all sizes, and used for all purposes—all home made. They are very efficient, and some of them very large, especially those in the foundry

FORGE AND ROLLING-MILL.

Many of the machines in the rolling-mill were built in the shop. It is but natural that men, thrown upon their own resources, will devise ways and means to accomplish ends, and I was particularly interested in some of the inventions of Mr. Stephen Uren, who has charge of the rolling and forging work.

WROUGHT BRAKE SHOES.

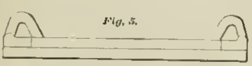
The road uses wrought-iron brake shoes of one or the other of the three forms shown in Figs 1, 2 and 3, generally 1 or 2, and they forge up these shoes from punched or sheared pieces at one blow of the hammer.

The blanks are built up, as shown in Figs 4, 5 and 6, of pieces. The loops are bent and cut off from the bar cold, and for the other pieces a cheap grade of iron is rolled the exact size, and sheared up to proper lengths by the cheapest labor

Figs 7, 8 and 9 show the way it is piled up. These completed piles are placed upon a "peel," a flat, shovel like instrument, and by it placed in a large furnace; there is a guide piece across the peel, and a rod running back to the handle that enables

Fig. 4.

Fig. 5.



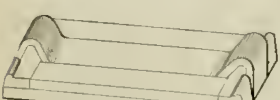


Fig. 6.

the operator to push the pile of iron off without disturbing the relative position of the pieces.

When a welding heat is obtained, the blank is picked up and placed on the lower die of a steam hammer that is properly formed, and one blow welds the pieces together, curves the shoe, and leaves the loops for the hanger bolts intact.

In Sketch 10 is shown a gauge, against which the hot blank is placed. This gauge is knocked out of the way by the upper head, but the spring automatically returns it to place when the head is raised. These heads, or dies, are easily made of cast-iron, and are held on the anvil and hammer-head by the usual dovetail. The advantage of wrought shoes made in this way, is that, after the face is worn away, a new piece of flat bar can be sheared off, placed on the old, worn shoe, heated and welded up again in this die, the loops and lugs on the back remaining intact. Wrought shoes wear several times as long as cast ones, and can be made cheaper for service rendered. Mr. Small has recently conducted some experiments, however, that led him to believe that they are not as good for steel tired wheels as are cast-iron shoes. Steel-tired wheels are expensive things to wear out.

LINK FORGING.

Another ingenious hammer die is his device for forging links. This device has been in use here for some years, but there is a dearth of information of hammer work, and "how and why" explanations are always interesting.

Links are cut from the bar, scarfed, bent and welded up by five blows of a steam hammer, using one die for all the processes. Fig. 1, page 133, is a view of the face of the upper die, and Fig. 2 of the lower one. Fig. 3 shows the right-hand end of both dies, upper one raised, and Fig 4 is a back view of the dies when closed. Fig. 5 is a view of the left end of both dies, and six is a front view.

Into the face of the lower die, and shown at *f*, is a steel knife let into a slot in the die, and on each side of this knife are oblong projections, as shown at *e*. Now, in the first step, the heated bar is pushed across this knife from *d* until it strikes

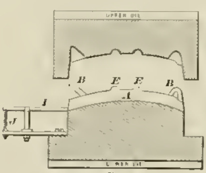

Fig. 10. *Fig. 12.*

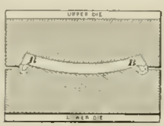

Fig. 11. *Fig. 13.*

the gauge *g*, and as the hammer descends, the knife cuts off a piece the proper length for a link, and at the same time the projections around the knife scarf the ends out. The heated piece is then picked up, and each end placed in the slot on the left end of the anvil, and against the gauge, as shown in Fig. 5. This bends the ends, leaving the piece as shown in the dotted lines in Fig 3. It is next placed across the rollers and against the gauge *m*, as shown, and the upper die descending, the lug *o*, passing between the rollers, bends the link into the shape shown in Fig. 7. It is then brought to a welding heat, and placed in the curved slot *r*, Figs. 1, 2 and 4, where it is welded up. Of course these processes are carried on in such a way that the delivery of finished links is regular.

LARGE NUTS OF SCRAP.

Very large bridge nuts are forged up from scrap boiler plate, and many other forgings can be made in the same way. This is accomplished by punching out blanks of old boiler plate, piling them up, heating, and forging them in a suitable die.

This device consists of a large die-box *A*, Fig. 1, set over a block set in a cavity in the anvil block, said block being removable, so as to discharge the forged piece through the die.

The hole in the die-box is square, and has removable cheek pieces, so that any form can be made by cutting out the cheek blocks, as shown in Figs. 2, 3 and 4. When I was there they were forging bridge nuts, $2\frac{3}{4}$ inches square, and were using a die like Fig. 2.

The large lever that handled the foundation block *D* is shown in Fig. 5.

On top of this block there is placed a bottom piece of steel, with a depression for centering the center plug *E*, Fig 7. Around this plug as many blanks—first heated white hot—are placed as desired. The hammer descends and welds the whole into a single piece. The lever swings out the foundation piece, and a tap of the hammer drives the bottom plug and finished piece out through the die. Bridge nuts, weighing as much as fourteen pounds, are forged in this way, and turned over to the store department for $3\frac{1}{2}$ cents per pound.

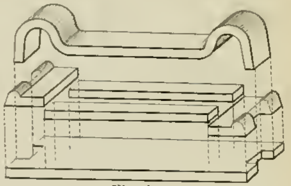

Fig. 9.

Mr. Uren's improvements on spike making and bolt heading machines are illustrated on another page.

PUNCHING.

A great deal of punching is done in this shop Most of the holes usually drilled in engine frames are punched here. Some of the heaviest punching I have ever seen done under an ordinary steam hammer was being done on some heavy equalizers, as shown in the sketch. After heating, the forging was placed in a very heavy yoke, made in two pieces, as shown, that completely enclosed the center of the lever, and prevented its expanding in any direction. In the bottom of the yoke there was a loose steel die the size of hole to be punched, and through the top binder a similar slot acted as guide for the steel punch that was driven through the work by a steam hammer. This makes a clean, clear cut, and does it very cheaply.

BIG WORK.

One hammer in this shop is turning out 40 axles per day.

The rolling mill turned out 12,000 tons of iron last year.

The foundry is a large one, but the work is done by contract.

VALUABLE EXPERIMENTS.

Out of all the diversity of equipment found here, Mr. Small is expected to find the best, adopt it and discard the poor, and to this end he is making a series of experiments that will be of great value to all other roads as well as to the S P.

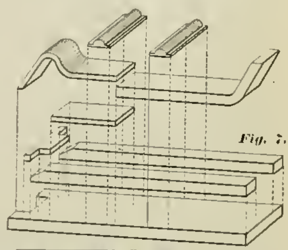

Fig. 7.

Fig. 8.

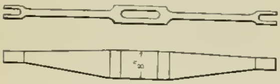
RIGID *vs.* SWING TRUCKS.

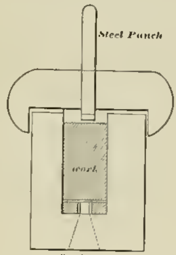
For instance, the question of the relative values of rigid or swing trucks, for freight cars, has so many advocates on each side that it is hard to come to a decision. Mr. Small took ten cars, each with rigid and swing trucks, and took them to a crooked and hilly section of the road, and experimented with them, light and loaded, under every conceivable condition, and proved by the dynamometer that rigid trucks not only curved easier, and wore their flanges least, but pulled easier than swing trucks.

He proved that the main trouble from rigid trucks come from neglect of the side bearings. Rigid trucks can be built for a third less than swing trucks. The repairs are much less, and the truck is far stronger and safer, but many railroad officers think they can't be used safely on crooked track. All their new cars will have rigid trucks.

TESTING WHEELS.

Another interesting and valuable experiment was one to find the cause of so many broken wheels caused by heating. An elaborate machine was con-





structed for this purpose, that imposed upon a pair of wheels all the conditions of actual service, and provided means for weighing the loads applied, etc. Not only all patterns of wheels made by themselves, but those made by twenty-eight manufacturers, have been tested to a failure in this machine, a careful record of load and time being kept for each. This test has been very carefully made, and extended over a long time. The result is that a form of wheel has

Fig. 1.

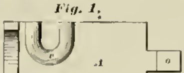


Fig. 3.

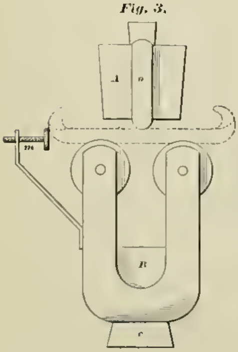

been designed and tested that has double the value of the wheels formerly used.

FUEL.

They have also made extensive fuel tests, and can tell you the relative value of all the coal used. Coal is very dear in this part of the country. They are paying $6.50 for it now, and have paid as high as $14. The Stevens motion was designed to save coal. Numerous stacks, etc., were used for the same purpose, and they are now trying a compound.

Mr. G. H. Baker, the author of a work on combustion, and formerly traveling engineer on the C., B. & Q., has recently been appointed fuel agent, and will labor with the men. We have little doubt that, if the men became interested, and got a

Fig. 2.

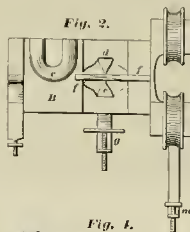

Fig. 4.

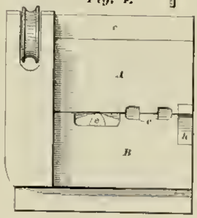

Fig. 7.

percentage of the saving, that they could make a better showing than compound locomotives or anything else. Much of the fuel here comes from Australia and from Wales. Vessels coming for wheat bring it as ballast.

EXPENSIVE COAL CHUTES.

While we are talking about coal I might as well say that the S. P. has about the worst and most expensive means of handling it. All over the road coal is put on engines by little iron cranes, mounted on four-wheeled push cars, and operated by steam, a small boiler being fast to the mast. They lift the coal in iron buckets, usually from the ground or from cars. They must have a great many of these

Fig. 5.

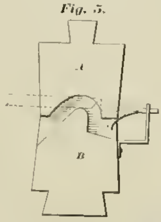

Fig. 6.

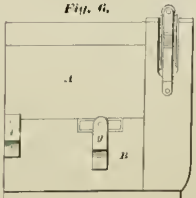

expensive little crabs, for they seem to be standard. Right at Oakland is a fair sample of coal handling. Coal is shoveled out of the ships into buckets and loaded on cars. These are hauled to Oakland yard and the coal is shoveled out upon the ground, and from there shoveled into buckets that are finally lifted upon the tenders by the little cranes.

A good coal chute at each division station would pay for itself in a very short time.

There are no new engines being built now, the works being pretty busy when they keep up the repairs. They are building 500 new box cars of 60,000 pounds capacity, and 25 narrow-gauge cars. They are breaking up a whole series of 30,000-pound cars that have reached the age for retirement, and will get rid of thirty or forty old locomotives in the same way.

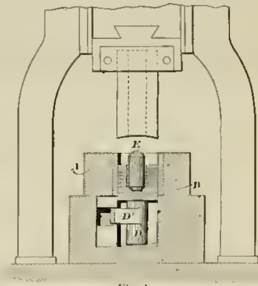

Fig. 1.

BUILDINGS.

The shop buildings are large, and in pretty good condition, but the work is more or less scattered, the offices of different departments separated, and there are several drawing-rooms in different parts of the works.

The car and paint shops are always full. One shop here is devoted to Pullman car repairs. There were thirteen sleepers in the shop, the road having over eighty in its Pacific system assignment.

Between the car shops there is a very large transfer table, operated by a chain, while a fine Norman horse pulls cars on and off it.

The table at the back shop is operated by steam, put in recently.

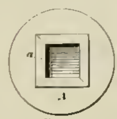

Fig. 2.

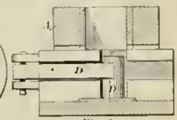

Fig. 5.

Fig. 3.

Fig. 6.

Fig. 7.

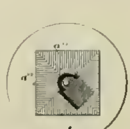

Fig. 4.

Mr. Small has made a great improvement in the appearance of the old passenger cars by extending the ends of the monitor roof to the end of the car.

AIR-BRAKE ATTACHMENT.

All engines employed on heavy grades have the Sweeney air-brake attachment, which is simply a pipe from the steam chests to the air drum, with a suitable cock in it. It is used in case the air-pump gives out, or the pressure becomes reduced from repeated recharging of the auxiliaries. By reversing the engine the pistons become air-pumps, that instantly recharge the drum. The device is cheap, requires no repairs, and is certainly an extra safeguard. I noticed that on all heavy grades, even when two locomotives were attached to the trains, that the water-brake was used. Driver-brakes are not employed, but it would seem that by their use it would be unnecessary to use the water brake.

MANY MEN OF MANY MINDS—MANY MILLS OF MANY KINDS.

The great diversity in sizes and styles of locomotives makes the details of repairs something very hard to understand. All the old lines mentioned at the beginning of this article are only leased. Each has its complement of rolling stock, and all is kept separate, and the initials of the different lines used. Most of the locomotives used in the northern country are wood burners, with the old-fashioned balloon stacks, containing about a half acre of eight to the inch netting.

GOOD ENGINES

Mr. Small has recently rebuilt a lot of 17x24 engines, putting on new boilers the same size as those sent out by builders on 18x24 engines of the same class. He has in these engines some of the best power I have seen. They always have abundance of steam, have great adhesion, and are more economical than larger engines in the same service.

In all the boilers built in these shops they flange the holes for wash out plugs out, and tap the flange. This makes a strong job, and gives about an inch of good thread for the plug

HEAVY WORK

This shop build and repair the steamer engines for the river boats, transfers and ferries some of which are very heavy They make 18-ton forgings in the hammer shop.

NEW USE FOR OLD RAIL

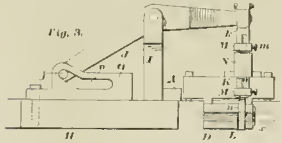
Great piles of scrap are kept on hand to be worked up in the mill, but no good use had been found for old steel rail, and there was, practically, no market for it. Mr. Small recently conceived the idea of rolling the rail head out thin, leaving the bottom intact, and using the very strong T thus formed for brake beams. To test the matter, a few beams were made by drawing out the rail head under a hammer. The beams proved, under test, far stronger than necessary, light, and very cheap A form of brake head has been made that goes on over the end of the beam, and a special forging forms the fulcrum.

They had the beam on a number of coaches when I was there, some of them having six-wheeled trucks with a shoe on each wheel, and they are certainly a neat-looking device. Mr. Small has also devised an equalizing device for six-wheel brakes, that is simpler and neater than any heretofore brought to my notice

Around and between these shops many Australian gum trees grow. In front of one of the offices there are immense palms, dates, figs and other trees, and a profusion of lilies and roses But everywhere are evidences that it is a hot old place when it is hot. J. A. H.

Some Improved Attachments for Bolt-heading and Spike Machines.

The use of pine ties in the West has created a demand for a better spike than that usually sold in the market, and many substitutes for the common spike have been devised and tried, but experiments have proven that, taking all things into consideration, the spike was the best, even in soft wood, if it could be prevented from breaking up the fiber of the wood around it The ordinary spike, with a



rolled point, will break the wood around it for an inch in all directions, while one with a ground point would scarcely break it at all.

Mr Stephen Uren, general foreman of the forge and rolling mill of the S. P. road at Sacramento, Cal., has recently perfected an attachment to a spike machine, or, more properly, a bolt-heading machine, by which he is enabled to form a knife edge on every spike in one operation with the heading process.

Fig 1 shows the outlines of an ordinary bolt or spike header. The hot bar is fed in from the front, and clamped by the side dies that hold it firmly while the ram block *H*, driven by the eccentric, forces the head into shape, and a cam roller forms the point

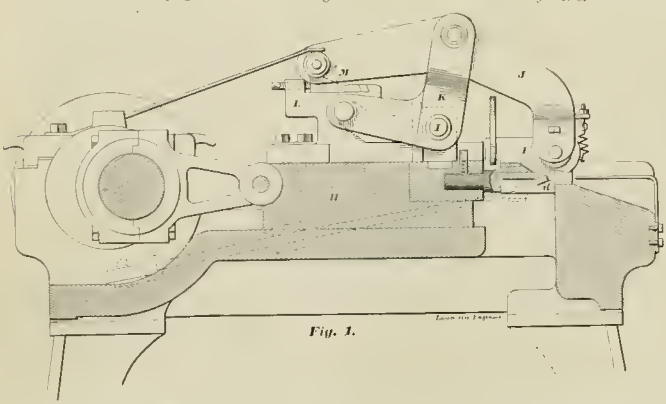


Fig. 1.

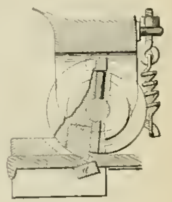

Fig. 2.

Fig. 5.

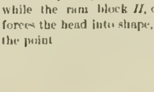

Fig. 4.

Mr. Uren's invention consists in arranging the levers as shown, the lever *J* carrying the point-forming roller. His lever is supported at the center by a bell crank *K* from a lug on the machine at *I*. On the moving die block there is fastened a cam block *L*, on top of which there is an adjustable incline block *M*, that forces down the roller upon the point of the spike. A cam slot in the block carries a roller on the end of the bell crank *K*, and an incline in this slot gives the lever a forward, rolling motion, rolling the end of the spike against the die block *d* and forming the point

Instead of allowing the roller to pass clear over the point of the spike, forcing it down to what may be termed a forged edge, the inventor provides a stop in the roller, as shown in Fig 2 This prevents the roller from turning on its work just before the steel cutter edge, on its face, reaches the point of the spike, and before the ram has reached its forward motion. The result is that the levers proceed in their journey, forcing the roller ahead past the point of the spike, and shearing the point off instead of rolling it.

The writer stood by one of these machines not long since, and saw it turning out spikes with points sharp enough to cut the fingers if handled carelessly

Another ingenious device of the same inventor is here used for punching keyways in bolts while being headed. He puts keyways into all sizes of bolts from half inch up. He uses a lever on top of the machine, much the same as in the spike machine, Fig. 3, showing the general arrangement, the bolt being held in the side clamp firmly while the head is being formed. The lever is so arranged as to punch the keyway at the same time The most ingenious part of the machine is the punch holder, shown in Fig 4 This holder is large and strong, for attachment to the standard, but will hold a very delicate punch. These are simply strips of tool steel, of the proper size, ground across the end only. They are cheap, require no forging, and a broken one can be replaced in a few seconds.

They are using one of these machines large enough to punch the keyways in draft bolts for freight couplers, and it must be saving ten times its cost every month.

Both of these devices, as well as those of the same inventor, described elsewhere in this number, have been patented by Mr. Uren and adopted by the S P road

---

That awful fast run with Jay Gould on the Northwestern was lively—seventy-six miles per hour having been maintained for some time. The daily papers had the train flying at the rate of 102 miles per hour, but there's an awful gap of difference between 76 and 102

We have received from Geo. E. Ferris, of Nashua, N H., a photograph of a Boston & Maine engine, that is accused of slipping ahead when shut off, and running down hill, the same one that our correspondent Jas. Nute wrote about We will give a beaver overcoat to the man who will give us a ride on an engine that will do this trick in our presence.

John Wiley & Sons, of this city, have issued the eighteenth edition of Angus Sinclair's book on Locomotive Running and Management It is enlarged by forty-five pages of new matter, containing several plates of locomotives, spring gear, equalizer systems and truck arrangements, as well as sections of a locomotive cylinder and steam chest, etc. The price has not been increased.

How About the Enginemen?

General Meigs wants the tenders of locomotives pulling postal cars made sloping in the back end, so that in case of collision the postal car will slide up the back of the tender and escape being crushed. In an interview with a reporter General Meigs expatiated at great length on this subject. He held that the end of a tender, as at present constructed, acted like a ram on the car next to it in case of accident. We must differ from the views of this big military man, and humbly express our conviction that the present form of tender is weaker in a concussion than the ends of most postal cars, and that a sloped tender would make a wedged weapon of offense that would be much more effective in crushing through a car than the present shape.—*National Car and Locomotive Builder*

And it might be added with justice that, even if neither car or tender would be crushed, as the General apparently believes, that such a proposition shows an entire disregard for the safety of the enginemen. Possibly the General would consider it quite entertaining, when sitting in a locomotive cab, to have a postal or baggage car occasionally slide up on top of him.—*Railway Review*.

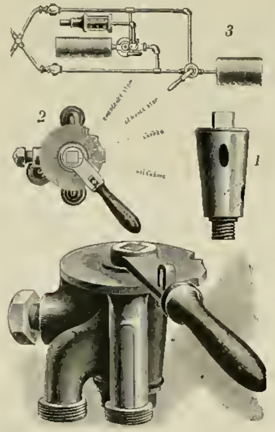
The Leeman-Jones Brake Valve.

We present on this page a cut of the latest attempt to solve the old problem—how to recharge the auxiliaries without releasing the brake.

This device was invented by C. E. Leeman, air-brake instructor, and A. W. Jones, Div. M. M. of the D. & R. G. road.

This idea of re-charging and still hold the brake on has taken a great hold of many engineers, and not a little ingenuity has been wasted to accomplish the desired results.

Every plan thus far advanced calls for a second line of hose, and an extra train pipe; this is bad enough, but we are unable to see why the recharging feature would not be dangerous with the present form of triple valves. The valve is now operated by the difference in pressure on the opposite sides of the triple's piston; when the train pipe pressure is reduced the brake is set in proportion to the reduction, and the air from the auxiliary is expanded into the cylinder, a further reduction of pressure in the train pipe will set the brake more, and we fail to see where the difference is if we



leave the train pipe pressure alone, and increase that in the auxiliary; for this will force the piston of the triple down, and apply the brakes harder—just what you don't want.

This valve is a simple one, something on the style of the Boyden valve; it is shown in the recharging position, all the other stops are the same as in the Westinghouse valve. It is a good and simple way to re-charge while the brake is on, if that is desirable—which we very much doubt.

Magnitude of Car Repair and Interchange Business in Chicago.

The business of the Chicago Belt road is, principally, transferring freight cars from one road to another in the city. Peter H. Peck, Master Mechanic of the Belt road, was present at a discussion of the interchange rules before the Western Railway Club in Chicago in April, and gave the following interesting figures

"Knowing that the interchange rules and the interchange of cars were to be discussed to-day, I have taken the pains to ascertain some facts as to the extent of interchange of cars at Chicago, and I have some figures that will be of interest to the club members, especially to the heads of the car departments.

First, I addressed letters to all the general freight agents in the city (21 roads), asking the number of cars brought into the city by their lines during the month of November, 1890. Also the number transferred to other lines. I have received enough replies to make a fair estimate. I find there were delivered into the city 261,811 cars during that month, a daily average of 10,069 cars. There were transferred to other lines 146,212 cars, or a daily average of 5,623 cars.

Averaging the length of the cars, from end to end of drawbar, at 32 feet per car, the daily average brought into the city is a fraction over 61 miles of cars. There were over 34 miles of cars transferred during the same time. Calculating the day at 24 hours long, there were 419 cars brought into the city and 234 transferred during every hour of the day.

I have also addressed letters to the heads of car departments or those having charge of the departments in the city, asking them for the number of car inspectors and car repairers employed on freight cars. I have replies from all of those addressed, which showed that there were 256 inspectors, 1,463 car repairers, and 27,970 cars repaired during November, 1890. Deducting the Belt, C. & C. Terminal and stock yard inspectors, we have left 210 men to inspect daily 10,069 cars, or about one man to 48 cars. Estimating the pay of the men at $50 per month, the cost is shown to be four cents per car for inspection alone, which sum, I think, is too much.

The daily average of cars repaired is 1,076, or 107 per hour, or 1¾ cars in every minute.

I asked for the number of drawbars broken, but most of the roads did not keep this record in 1890.

[*Continued on page 136.*]

The Belt broke one drawbar to every 278 cars handled (though this year, so far, we are breaking less), but taking that as a basis for calculating this, there are 36½ drawbars broken daily in our interchange.

The above figures do not include the repairs of cars actually broken in the city, as many of the car shops are located elsewhere.

In the same month, November, 1890, over 50 per cent. of the cars transferred by the Belt road were more or less defective. I have the reports of the number of cars that the Belt road has records against. The lowest per cent. received in defective condition is 20, the highest is $82\frac{6}{10}$ per cent., and if M. C. B. cards had been given for all defects in the month of November there would have been 2,888 cards issued daily. I think it would have been impossible to issue this number, especially under the present system of inspection. Cars would be detained too long, and we would have extra switching and double inspection. This work could be done, however, under a system of joint inspection, controlled by one chief located in the city, the same as the car service association is worked at present. There would be some trouble and attention from the heads of car departments to get such an inspection system into shape, but I think it is well worthy of a trial at least."

Charles L. Haskins, an engineer on the Jacksonville, Tampa & Key West, called at this office last month. Charlie and ye editor railroaded together in the Rockies some years back, and while there Haskins had the worst fall a man ever had and live. He was running a mixed train on the Silver Cliff branch of the D. & R. G. with a narrow gauge consolidation engine; the track was very crooked, and the grade in the neighborhood of two hundred feet per mile. In rounding one point of rocks above Grape Creek the road bed was supported on a wall of rocks laid up almost perpendicular for 66 feet, and resting on a step in steep rock at that. This wall gave way, and the engine and tender fell out from the cliff, turned over in mid-air and struck on solid rocks 94 feet below. Haskins was found 104 feet from the track, he was injured principally about the head, and was unconscious. In the half-filled coal space of the tender stood Charles Davenport, the fireman; he was buried in the fine coal as the tank struck bottom up, and left there, the tank breaking loose from the engine and rolling over and over into the creek—some eighty feet further down the precipice than the engine. Davenport was seriously bruised, and suffered for some time from an injury to his back, but is now running on the road. Haskins was unconscious for twelve days, when he did come to himself his wounds had all healed, and he knew less about the wreck than most of the men on the road. The axles of these engines are five inches in diameter and less than thirty inches between the wheels; but this one bent some of her axles badly, and was hauled in on a flat car. Haskins runs on a road now where there isn't a stone along the right of way big enough to throw at a bird—he's been to all the rock he wants.

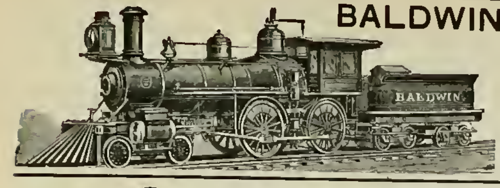
John Shanley, engineer on the D. & R. G., took a new 20x24 "hog" two years ago, one of a lot of thirty, and has since run her more than 100,000 miles without general repairs. All the others have been overhauled, but John's mill appears to be good for 30,000 or 40,000 miles yet, the tire being in fair shape. The total cost for repairs to this engine for this service has been a trifle over $500. The officers of the road have agreed to make Shanley a present for this service—a cool hundred dollar bill would be about the proper thing. There isn't a road in the country that would not be glad to sign an agreement with its engineers to give each one twice that amount for the same service.

"Some of the Functions of a Locomotive" is the title of a little pamphlet recently issued by H. A. Luttgens, assistant superintendent of the Rogers Locomotive Works. It is interesting, but especially devoted to advertising his patent stack damper—a very good device. Mailed free on request.

On the Canadian Pacific a train recently ran from Vancouver to Montreal in 92½ hours, including three hours' detention from a mud slide. From Smith's Falls to Montreal, 128.3 miles, the running time was 2h. 5m., or at the rate of 61.6 miles per hour.—*Ex.*

From some of the discussion on steel axles one would be led to believe that some roads were using crucible steel, they have so many snap off short at the hub. Probably square shoulders has something to do with the trouble.

On the Madras Railroad, in India, they shake the grates by means of gearing, and a cam wheel on the rear axle; this shaker can be brought into use by depressing a capped rod in the foot-plate.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

ANNUAL CAPACITY 1,000

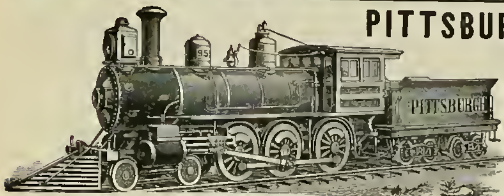
LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable.

COMPOUND LOCOMOTIVES.

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, etc.

BURNHAM, WILLIAMS & CO., Proprietors, PHILADELPHIA, PA.



PITTSBURGH LOCOMOTIVE WORKS,

PITTSBURGH, PA.

Manufacturers of

LOCOMOTIVE ENGINES

For Broad or Narrow Gauge Roads.

From standard designs, or according to specifications, to suit purchasers.

TANKS, LOCOMOTIVE OR STATIONARY BOILERS

Furnished at Short Notice.

WILSON MILLER, Pres. and Treas. D. A. WIGHTMAN, Supt.

J. & J. B. MILHOLLAND, 240 FIFTH AVE., PITTSBURGH, PA.

BUILDERS OF

NARROW GAUGE LOCOMOTIVES.

WITH or WITHOUT LINKS.

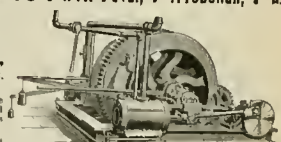
Very simple in construction, and adapted to STAND HARD WEAR and TEAR, and especially in the dirt and dust of Coal Mines.

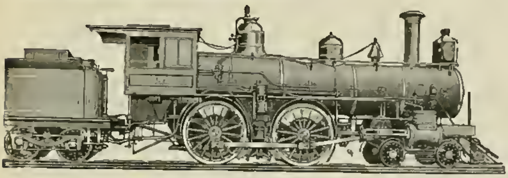
WIRE ROPE HAULAGES,

For COAL MINES and TRAMWAYS.

Over 75 complete Wire Rope Haulage Plants in successful operation. Plans and Estimates Given on Application.

Inclined Plane Railway Plants a Specialty.





DICKSON MANUFACTURING CO.,

SCRANTON, PENN.

Locomotives of every style and size, Standard and Narrow Gauge, made to Standard Gauges and Templets. Also for Plantations, Mines and Logging.

SPECIFICATIONS ON APPLICATION.

JAS. P. DICKSON, Pres. WM. H. PERKINS, Sec. & Treas.
E. W. WESTON, V. Pres. JOHN DEVINE, Supt.

RICHMOND LOCOMOTIVE & MACHINE WORKS, RICHMOND, VA.

BUILDERS OF

LOCOMOTIVES

FOR EVERY VARIETY OF SERVICE

MOTORS

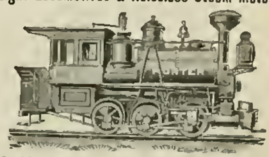
for Street Railways, Tram Roads and Mines

Also manufacturers for the Polo Road Locomotive Company of their efficient logging engines and cars

H. K. PORTER & CO., Pittsburgh Pa

BUILDERS OF

Light Locomotives & Noiseless Steam Motors.



Send for New Illustrated Catalogue, containing information useful to every Locomotive Engineer or Railroad Man. Mention this Paper.

RICHARDSON & ALLEN-RICHARDSON

BALANCED SLIDE VALVES.

New Patent, April, 1891.

6,000 LOCOMOTIVES EQUIPPED. IN USE ON 175 RAILROADS.

Manufactured only by

M. C. HAMMETT,

Successor to Estate of F. W. RICHARDSON, Troy, N. Y.

Ross Regulator Valve

FOR CAR HEATING.

Low in price and always reliable. No complicated parts. Easily understood. Durable. Has no equal.

ROSS VALVE CO.,

TROY, N. Y.

Railroad Ventilated Pails

are the best pails ever made for use of railroad men

Thousands in Use. For Sale Everywhere

REARDON & ENNIS,

MANUFACTURERS,

TROY, N. Y.

On receipt of P. O. Order for $1.50 we will send one of these pails by Express.

Gould's Steam and Water Packing,

(PATENTED JUNE 1, 1880.)

Especially Adapted for LOCOMOTIVES and STEAM PUMPS and HIGH SPEED ENGINES.

(The Original Ring Packing.)

Self-lubricating, steam and water-tight, less friction than any other known packing. None genuine without this trade-mark.

THE GOULD PACKING CO.,

A. CHIPMAN, Treas. East Cambridge, Mass.

CORRUGATED COPPER GASKETS

For all Pipe Fittings and Unions, whether for Steam, Water or Air. Can be used wherever any gasket can be applied, with better satisfaction and greater durability than any other. **Will not leak, rust, stick, burn or melt.** All sizes and shapes, ⅛ to 42 inches. In use on N. Y. & N. E. R. R. and others. *Write for particulars.*

U. S. MINERAL WOOL CO., 2 CORTLANDT ST., NEW YORK.

WINTERTON METAL POLISH.

BEST POLISH AND QUICKEST CLEANER KNOWN.

Class A, for Hot Brass, Copper, Nickel, etc. Class AA, for Cold Brass, Copper, Nickel, etc. Class B, for Finished Iron and Steel.

Send 10 cts. for Samples. Try it.

Specially adapted for Locomotive Work.

W. W. CALLERY & CO., 36th & Butler St., PITTSBURGH, PA.

Patent Adjustable Shrinkage Gauge.

Pedrick & Ayer,
1001 & 1003
Hamilton Street,
PHILADELPHIA,
Pa.

Special Tools
FOR
Railway Repair
Shops.

By the use of this Gauge, the boring of Locomotive Tires can be accurately done and with proper shrinkage to any desired allowance. It is so arranged that wear on the points is entirely overcome, there is no wear on the measuring pieces, they being hardened and ground to micrometer measurements. It is made to conform to the Master Mechanics' Standard of Sizes and Shrinkages as adopted by them in June, 1886.

STEEL OPEN • HEARTH • CASTINGS.

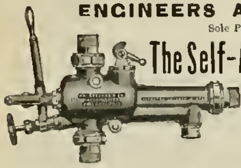
STANDARD STEEL CASTING CO.,
THURLOW, PA.

WM. SELLERS & CO., INCORPORATED.

PHILADELPHIA, PA.

ENGINEERS AND MACHINISTS,

Sole Patentees and Manufacturers of



The Self-Acting Injector of 1887.

Range of Capacity over 60 per cent., and can be regulated, therefore, to work continuously for light or heavy trains. Never fails to promptly lift hot or cold water.

No service on a locomotive sufficiently severe to permanently stop its working.

IT WILL RE-START ITSELF

should the Jet break from interruption of the steam or water supply, as soon as the supply is resumed.

ADJUSTS ITSELF

to varying steam pressures without waste of water. Increases quantity of water with increase of steam and vice versa. Very easily operated—Started by pulling out the lever, and stopped by pushing the lever in. Descriptive Circular and Price List sent on application to Office and Works.

WATSON & STILLMAN,

204, 206, 208 and 210 East 43d Street, New York.

MANUFACTURERS OF

HYDRAULIC TOOLS FOR RAILROAD WORK

Vreeland's Transfer Jack

Will remove and replace Drivers or Trucks without Jacking Up.

Bouncing a Deadhead.

"Speakin' of train robbers," said the old-timer, leisurely crossing his lean shanks, "I never had to do with real, live robbers, but when we were buildin' the U. P., I seen more Injuns than a few.

"I jimmed a shifter around the yard at Omaha when I first struck the country, and used to hear the boys tell about the redskins ditching trains, stealing telegraph wire, and 'casionally shooting at an engin', to say nothin' of riding around free, and being mighty over-pompious to everybody.

"But as long as I wer'n't in the immedgat' Injun belt, I didn't worry much.

"One day I got a new Roger, and started for the front—then all the Injun stories I ever heerd come back, multiplied four hundred per cent

"All day I was on the lookout for red and green blankets; every bush looked like it might have a Crow or a Wyandotte behind it, but the sun went down without a sign of reds.

"Well, I had a train of material for the front, and would jest about get there for breakfast, if I bustled—so I hustled.

"About eleven o'clock I stopped at a little temporary water tank to liquidate and lubricate, feelin' rather sleepy for my long hours. While the fire boy was taking water I did the grease act, going around to the left side.

"As I climbed up in the gangway, and sucked in my breath to blow out the torch, my heart hit the roof of my mouth, for there, in the right gangway, stood a big, fat, greasy Injun; he had on a yellow blanket, carried a rifle, and greeted me with a grunt.

"'Wher' goin'?' sais I, gruff like.

"'Um Yum,' sais he.

"'Git off,' sais I.

"'No git,' sais he.

"Here my visitor made a move to get up on the fireman's seat, and, I don't know what popped it into my head, but I took the long oiler by the snoot, and made a lick at the gauge glass that was then almost in his face.

"Afore you could say Gee-whiz, that cab was full of steam, hot water and muffled whoops, I pulled out the plug to let the old girl make her escape, and about the second turn of her drivers I heard a heavy body hit the sod on my side with a thud, and a sound floated up to us that reminded me of a scar't hog—kinder' like 'Wough!'

"Bill and I lay low in the tank for fear of being shot, until we were outside of the range of a Krupp cannon. I often wonder now which was scar't the worst, me or the Injun."

On the Santa Fe they are having the best of results from using a cast-iron ring in place of brass for ball joints of steam pipes.

Letter ballots are out for the adoption or rejection of the standards agreed upon at the last convention of the Master Car Builders.

HISTORICAL LOCOMOTIVES.

Development of the American Eight-wheeler.

The American eight-wheeler is so well known a form of locomotive as to need little explanation, but few of our readers know just how that magnificent machine was evolved from the general chaos of styles, and went at once to the front as the best form of locomotive for our conditions.

Up to the year 1836, all the engines built in this country either had all the wheels under them connected, or had a truck of one, two or three pair of wheels in front, with a single pair of drivers, the general difference being in the location of this pair of driving wheels. Baldwin placed them behind the fire box, while Norris placed them ahead.

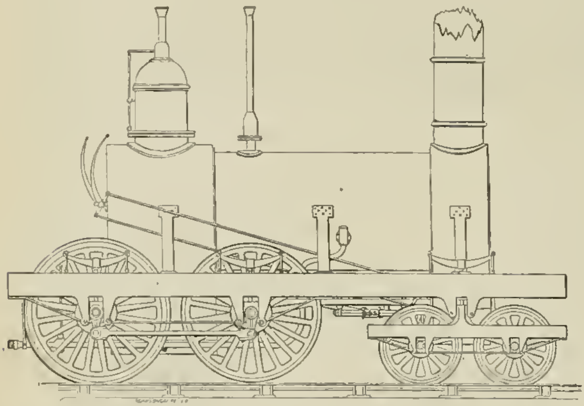
The swiveling truck early became a favorite, but the greatest trouble was to distribute the weight of the engine on the very light rails of the day, and where more than one pair of wheels were used to maintain the machinery, racked as it was by

Historical Locomotive Mercury

being rigid; this kept the single connected engines popular.

In 1836 Henry R Campbell, of Philadelphia, patented the 8-wheeler, "in order to better distribute the weight"; he built an engine after his patent, and tried it on the old Philadelphia & Germantown Road; it did fairly well, but was very rigid and hard riding.

Late in 1836, the firm of Garrett & Eastwick, of Philadelphia, built an 8-wheeler, called the "Hercules," for the Beaver Meadow Road (now the Lehigh Valley) in which an attempt was made to make the engine more flexible. Mr. Eastwick devised a separate frame with pedestals, in which the



THE FIRST EIGHT-WHEELER.

two pair of wheels were placed; this frame vibrated upon a center bearing, and could move as a truck does, except that it could not turn. This allowed it to adjust itself to uneven track, provided the unevenness was alike on both sides, otherwise it racked the framing; this frame was underneath, and separated from the main frame by side bearing springs. This was better than the old rigid plan of Campbell's, but not very much. This engine "Hercules" was the first one to have bolted straps and half-boxes on the side rods, instead of a gib and key; the rods had no keys.

This engine weighed fifteen tons, and was to run on a crooked road having strap rails only five-eighth of an inch thick, and two and a half inches wide; they were laid on stringers with "mud-sills" or ties underneath.

This engine was so flexible that she could accomplish more work than the others in use, and more like her were ordered. But in the meantime, the firm took in as a partner a young mechanic, Joseph Harrison, Jr., who set about simplifying the flexible engine, and the result was the invention of the modern equalizer, now universally used in this country and most foreign countries.

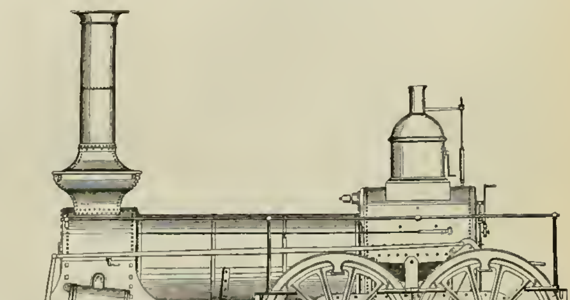
Harrison's first equalizers were made of cast-iron, very heavy and clumsy, and were hung above the frame just as they are now in 8-wheelers, the ends bearing on round pins that went down and rested on top of the box; this can be seen very plainly in our illustration on the first page. Mr. Harrison's patent covered all the combinations of equalizers now known, and also provided one for the truck. This device made it possible to use any number of driving wheels on the roughest track, and was, up to that time, the most useful improvement made in the engines of Stephenson.

The other builders condemned the use of more than one pair of driving wheels, and did not credit the equalizer with any virtue for some time. M. W. Baldwin said he could not see how they would curve without slipping some of the drivers, and he thought it impossible to maintain four wheels all exactly the same size, and thought them complicated, but their good points were forced upon him by their service, and in 1845 he bought the patent on the 8-wheeler of Mr Campbell, and that of the equalizer of Eastwick & Harrison, and at once turned out his first-class "C," and afterward said she was the best engine he had then turned out.

In 1839, Eastwick & Harrison got an order from the Reading Road for a then "big engine"; she was to weigh all of *eleven* tons, not less than *nine* tons to be on four drivers, and must burn anthracite coal in a horizontal boiler. This engine, when built and in service, made the fortunes of her builders.

In order to properly distribute the weight, the rear axle was placed *under* the fire-box, just as they are now in mogul and consolidation engines; the boiler was a "dome" or "Bury" boiler, and the fire-box was five feet long—at that time something gigantic. Two-inch tubes were used, placed close together, and nearly filling the cylindrical part of the boiler, but were only five feet long.

The cylinders were 12½x18. There was no cut-off used. The wheels were 42 inches in diameter. The exhaust was a box filled with numerous small jets, known as the Gurney exhaust, and the com-



EIGHT-WHEELER BUILT IN RUSSIA.

mon blower was here used for the first time. When finished, this engine was named the "Gowan & Marx," after a London firm of bankers.

This engine interested the whole railroad world by her great tractive power. On her trial, Feb 20, 1840, she drew from Reading to Philadelphia one hundred and four, four-wheeled cars of coal at the rate of 9.82 miles per hour—the road had a falling gradient of nearly four feet per mile, 27 miles of dead level, 9 miles of it in one place, and only one ascending grade of 26.4 feet per mile for 2,100 feet. This train weighed 423 tons, and, including weight of the tender, equaled *forty times* the weight of the engine. That was the best ever done then, and is pretty hard to beat now.

This remarkable work attracted no little attention at home and abroad, and among others who came to see and be convinced, were two colonels sent out by the Emperor of Russia to report on the best machinery and appliances for a road then projected between St. Petersburg and Moscow—the first in the empire. These officers reported in favor of engines built upon the general plan of the "Gowan & Marx," and in due course of time the Emperor Nicholas asked Eastwick & Harrison to visit St. Petersburg, with a view to contracting extensively for his government.

In 1843 Mr Harrison went to Russia, and formed the firm of Harrison, Winans & Eastwick, taking into the firm Mr. Thos. Winans, of Baltimore, and entered into a contract for building 162 locomotives and iron trucks for 2,500 freight cars.

In 1844 they closed their place in Philadelphia, taking their tools and instruments to Russia, and established the Alexandroffsky Head Mechanical Works, where they completed their fat contracts.

When the first engine was being built, Mr. Harrison designed and built a machine for accurately boring the holes for crank pins exactly at right angles to each other—this is believed to have been the first quartering machine—a rude application of the principle had been used by him in Philadelphia in 1838. This contract was finished in 1851, but a new contract was entered into for repairing the rolling stock that kept the firm busy up to 1862, when they came home to America full of honors—and shekels.

Eastwick & Harrison's 8-wheelers made their great reputation as freight engines, but before they left for Russia, or in 1842, they built for the Baltimore & Ohio two fast passenger engines, one of which, the "Mercury," is shown on the first page; in 1844 this engine ran 37,000 miles, the highest record made up to that time.

This engine had a front truck with no other side frames than the springs, to the ends of which the axle-boxes were fitted, from the top of the spring bands across the truck a heavy iron axle or shaft was so fitted as to support the front of the engine, and allow the wheels to move vertically with the least friction.

The main rod was connected to the back pair of wheels, but next the wheel center; the cylinders being set high enough for the main rod to clear the front pin. Harrison's equalizing lever is plainly shown between the wheels.

This engine had a reversible valve gear containing fewer parts than any other ever built. There was but one eccentric on a side; these were on the rear axle, and connected directly to the rocker on the back of the frame, and the valve rod ran direct to the valve, there being no way to disconnect or change it in the least. The valve worked upon a movable seat called the "reverse block", this block was connected to a stem of its own that is shown extending back under the valve stem, and is connected by the rocker shaft across the frame as shown, the lever on the deck being employed to move it.

When the motion was set to run the engine ahead, the reverse block acted simply as a false seat, the ports through it were direct, and just as they are on any engine, but when the reverse block was set to back the engine, the direct ports were moved over the valve seat end and bridges, and a new set of ports presented to the valve; in this set the ports were crooked and passed each other; the steam entering the front port was conducted to the back end of the cylinder, while that let into the port at the back of the cylinder went through the block to the front of the cylinder.

This ingenious scheme was the invention of Mr Eastwick. Its advantages were simplicity and certainty of action, but it had disadvantages, the clearance was increased the thickness of the block when in forward gear, and four or five times as much for backward gear, and it was not possible to use a valve with very much lap, any lead given the valve in forward motion caused a corresponding delay in backward motion.

The very first engine built by the firm of Garrett, Eastwick & Co., in 1835, had this reverse gear. She was built for the Beaver Meadow Road, and named the "Samuel D. Ingham," after the president, and had a roof on posts to protect the engineer and fireman—the first cab.

Thus it is seen that for the many little things that go to make up the complete modern locomotive, to Mr Joseph Harrison, Jr., or his associates, must be given the credit of several important contributions, namely. The cab, the bolted stub end rod, the equalizer and the blower, to say nothing of the equally important quartering machine.

Truly all these have done much good toward perfecting the American locomotive, and are a far better monument to the memory of Joseph Harrison, Jr., than any shaft of marble or tablet of brass ever can be.

Locomotive Running Repairs.

By L. C. HITCHCOCK.

WASHING BOILERS.

One of the most important parts of roundhouse work is the regular and thorough washing of locomotive boilers. There is no part of a locomotive which should have more care and attention, but at the same time there is no part of an engine which is so liable to be overlooked and injured as the boiler. To insure the boilers being regularly washed, some means should be taken by which a correct record can be kept of each time a boiler is washed. A very good way to do this is to give the boiler washer a book in which to put the date each boiler is washed. At the end of each week he can present his book to the roundhouse foreman, who may from it make a weekly report to the master mechanic, giving the number of each engine, and date the boiler was washed. These reports could be placed on file for reference. By referring to a book kept in this manner the boiler washer could wash each boiler after a lapse of any specified time, and if an engine came in which did not run regularly into the roundhouse where he worked, he could wash it, and keep a record of it, for boilers are more liable to be neglected than washed too often. The length of time a boiler should be allowed to run before washing depends materially upon the locality in which the engine runs. Those running in localities where the water contains but little sulphate and carbonate of lime need not be washed but about once in two weeks, but where the water used contains ingredients which produce hard scale, the boiler should not be allowed to go longer than one week without washing; and I have seen water used which produced scale so rapidly that it was very necessary to wash the boiler after each trip. To obtain the best results, hot water should be used while washing a boiler, for the reasons that hot water will more readily remove scale, and it is not so injurious to the boiler as cold water. Cold water thrown into a hot boiler produces sudden contraction, and consequent strain upon all parts. In cases where steam cannot be had for heating the water, and the time for washing is limited, a good way to proceed is to blow the steam off, and run in cold water until the boiler is completely full, then open the blow-off cock and allow the hot water to run out but little faster than the cold water is forced in; in this way the boiler can be cooled quite rapidly, and sudden contraction be avoided. After the boiler is comparatively cool, wash with not less than 100 pounds pressure. A good way to provide hot water for washing purposes is to run a permanent steam pipe through the roundhouse from the pumping or stationary boiler, if the house is heated with steam this pipe may lay in the pit with the heater pipes, but a better way is to place it at a sufficient height from the floor to clear the engine's stacks, for by this means less trouble will occur from condensation. Branch steam pipes should be put in from this main pipe to each hydrant, connect as shown by Fig. 1. Take a gas pipe tee, one end and the side opening of which is the size that the water stand pipe calls for; the other end should be the size desired for the branch steam pipe, and this pipe should be one size smaller than the main pipe from the boiler Now take a piece of pipe the size of the smaller end of the tee, and swedge down one end as represented by Fig 2; the diameter of the openings in the ends of this pipe should be in about the proportion of ⅜" to 1¼", cut thread enough on the larger end to take a check nut and elbow after it is

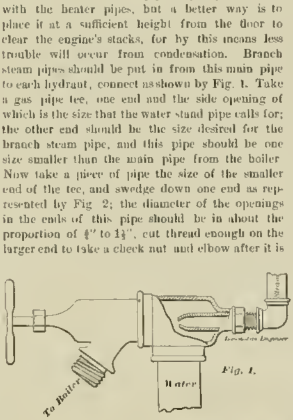


Fig. 1.

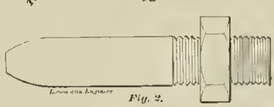

Fig. 2.

screwed through the smaller end of the tee from the inside. When in position the small end of this nozzle should be in line with the center of the water pipe, as shown in Fig. 1. Attach the tee to the hydrant pipe at the side opening, and put the hydrant cock in the opposite end from the steam nozzle. A globe valve should be put in the water pipe below the tee, by means of which the water supply can be regulated. With this arrangement good results may be obtained with from 80 pounds to 90 pounds steam pressure, and after the washing is completed the boiler can be filled with hot water, which will facilitate matters where the engine is wanted for immediate use

When washing a boiler not provided with a mud drum or hand hole in the bottom of front sheet of shell, the washout plugs should always be removed from the front flue sheet, but where the boiler is equipped with the appliances mentioned the removal of the flue sheet plugs is not so essential. All other plugs and hand hole plates should be removed each time the boiler is washed, and I consider it a good plan to remove the steam dome cap, also, for by thus doing incrustation can be loosened from the crown sheet, bars, and braces; the stream of water can be thrown directly on top of the crown sheet, this will wash the scale into the boiler legs, from whence it can be removed through the hand holes.

When the washing is completed it is a good plan to ignite a piece of greasy waste, fastened to the end of a rod of sufficient length that the burning waste can be passed through the hand holes in the corners of fire-box, and every part of the side, back, and flue sheets be examined to be sure that every particle of deposit is removed from them and the mud ring. A torch of this kind should also be passed through the plug holes in the boiler head, the top of crown sheet and space between the crown bars can thus be examined

When preparing a boiler for service, after having been washed, care should be taken to keep a bright hot fire until steam is generated, this produces rapid circulation, and scale will not form so rapidly under these circumstances as when the water is heated slowly. I have seen boilers filled with cold water, and then charged with steam from another engine by the use of a steam hose, so that the blower could be used. This is a very bad practice, for the reason that, under these circumstances, the upper part of the boiler is hot, while the lower part is cool; this produces unequal expansion, and strains the seams and stay bolts.

When a roundhouse is equipped with the appliance for heating the water as described, and the time for washing and preparing the boiler for service is limited, the blower may be worked by using a tee connection in the blower pipe where it enters the smoke arch, and making connection between this tee and the steam pipe which connects to the hydrant. The boiler being warm and full of hot water, will not be seriously injured by the use of the blower under these circumstances, for the reason that it is not subjected to the influence of heat other than that which comes from the fire-box. About the only objection which can be given to the use of the blower as described is the rapid expansion of the tubes, but the boiler and water being warm, I do not think that this rapid expansion would be productive of serious evil, and I know that it would meet the approval of some of our "hurry up" train dispatchers.

A word here in regard to the care of boilers may not be inappropriate I would say to the roundhouse foremen, be particularly watchful of the engine dispatchers, or hostlers, as they are oftentimes called. See that they move the engines as little as possible after the fires are shaken out, for each exhaust draws cold air into the fire-box, and through the tubes, causing sudden contraction and consequent injury. Never allow cold water to be injected after the fire is removed, for by injecting cold water into a hot boiler not under fire, all parts of the boiler are subjected to chilling, and the evil results attending sudden contraction are produced.

Officials are Employes, Too.

The following circular, issued by the Lake Shore & Michigan Southern Railway Co., is a move in the right direction. In accord with prevailing methods it is now in order for the saloon keepers to boycott the road, and their patrons to strike.

CLEVELAND, OHIO, June 1, 1891

To all Employes:

The attention of all employes is called to Rule 2 of rules and regulations for the government of employes, which reads as follows:

"No person will be retained in the service of this company who is known to frequent saloons or places of low resort, or who is known to make habitual use of intoxicating liquors. Every person in charge of employes is hereby directed to dismiss from the service any who are guilty of these practices; and they will, themselves, be held personally responsible for having such men in their employ; for such are certain, sooner or later, to cause injury to lives and property."

This rule is expected to be strictly lived up to; and its rigid enforcement is required. All employes are hereby warned to comply with it.

P. P. WRIGHT,
General Superintendent.

—*Ex.*

The American Steel Wheel Company, of Boston, are now making all shapes and sizes of wheels of solid steel. They have furnished some solid steel drivers to the elevated road in this city that look as neat and light as the wrought-iron wheels used on some of their engines. The Boston, Revere Beach & Lynn road are using 28" spoked wheels of solid steel for engine trucks, and many roads are using their regular pattern of webbed wheels. Mr. W G Richards, the superintendent, has devised many details in the process of manufacture of this class of steel castings that has made all the difference between partial and complete success.

Northern Pacific Shops at Tacoma.

The old shops of the N. P at Tacoma, Wash., are located right in the city, and were built of wood. The original plant was shipped there by water, as was the first locomotives, cars, and rails, and the road built east to meet the line from St. Paul.

There are only four stalls in the old shop and there are 153 engines to look after.

Master Mechanic Warner and many of his men went there by sea thirteen years ago and have remained ever since.

In the yard there can be seen extraordinarily fine timber for car building, coal that is mined within thirty miles of the town, and coke of a superior quality burned there.

Of course these shops are totaly inadequate to keep up the repairs as they should be, and work accumulates ; still this has been greatly helped by the arrival of new engines

The repair work for the road on this coast calls for extensive shops, and the company are meeting the demand by the erection, at Edison, about two miles out of the city, of the best railroad repair shops the writer has ever seen, and we believe the best and most complete in this country. A level spot in the forest has been cleared up and the shops laid out on the most liberal plan and there is not a single makeshift or temporary feature about them.

The buildings are splendid brick structures on stone foundations, and covered with steel trussed roofs, each shop is separate from its neighbor, and each has all the room in the world for extension.

Transfer tables and tracks, cranes and trolleys will take care of the handling of material. There are magnificent storehouses and storage buildings and ample yards for material

Sewers drain the entire grounds, and the plant is supplied with water by an independent station. All pipes through the shops are in tunnels, easily accessible without digging up anything

Every tool, great and small, stands on a stone foundation that goes down to rock or hard-pan.

When we were there the tools were just being set, and great pains being taken with them ; there is not an old tool in the lay out; everything is the latest and best that money can buy. Special tools are everywhere to be seen, and there seems to be plenty of them.

In designing the shops and locating the tools especial pains seem to have been made to do the work with the least handling of material. It will be a poor manager who can't make a showing with that plant.

At the old shop we noticed that equalizers, springs, wheel covers, etc., were painted brown, making a slight and rather pleasing contrast with the regulation black

On the bulletin board there was stuck up some extracts from THE LOCOMOTIVE ENGINEER, including John Alexander's advice to young runners, and everybody, from Master Mechanic Warner to the fireman of the pony, wanted to know who John was, anyway.

Cleaning Coaches by Compressed Air.

The writer thought that he had seen compressed air used for every conceivable purpose around a railroad shop until he visited the Portland, Oregon, shops of the U. P., once the Oregon Railway & Navigation Company, and here he found Master Mechanic McLaughlin using air to the best advantage in an entirely new field—that of cleaning the interior of coaches and sleepers.

The compressing plant used was regular air-pumps with large storage tanks. Air is piped to the coachyard, and there the pipes connect with a line of small hose—ordinary garden hose ; this hose is taken into the car through an open window in about the center, so as to avoid handling so much hose. All the windows are raised and the doors opened, and the car "dusted" with the nozzle. The nozzle has a stop cock in it, and the operator can regulate the stream of air to suit the circumstances.

When we visited the yard they were cleaning one of the through sleepers, from Chicago. The nozzle man was provided with a rubber mallet, made from an old car spring. With this he gently tapped the sash and blinds, at the same time directing a stream of air up into the casing around the curtain roller and inside sash.

This is a place entirely inaccessible to feather dusters or beaters, and the air does the work perfectly, as the cloud of dust blown out attests.

Letting down an upper berth, a stream of air is directed under the mattress and around the springs, cleaning them nicely.

The air reaches every nook and corner and moves the dust.

Its nicest work is shown on the plush upholstery; the stream of air penetrates the plush to the bottom, separates the nap and cleans it without brushing it down, leaving it looking like new.

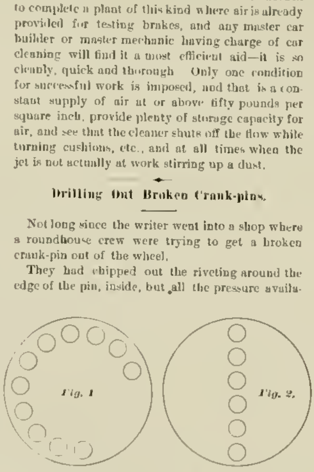
Deck sash and ventilators are easily reached, and inside blinds on coaches can hardly be cleaned in any other way.

The garden hose and nozzle is all that is needed to complete a plant of this kind where air is already provided for testing brakes, and any master car builder or master mechanic having charge of car cleaning will find it a most efficient aid—it is so cleanly, quick and thorough Only one condition for successful work is imposed, and that is a constant supply of air at or above fifty pounds per square inch, provide plenty of storage capacity for air, and see that the cleaner shuts off the flow while turning cushions, etc., and at all times when the jet is not actually at work stirring up a dust.

Drilling Out Broken Crank-pins.

Not long since the writer went into a shop where a roundhouse crew were trying to get a broken crank-pin out of the wheel.

They had chipped out the riveting around the edge of the pin, inside, but all the pressure availa-



ble failed to start the pin, and drilling was finally resorted to.

A ratchet drill was fixed up, and long hours put in drilling the pin, as shown in Fig. 1. Eleven ⅞" holes, nearly four inches deep, were drilled before the pin would start.

Had the foreman or any of his men stopped to think for a moment, they would have seen that the object of drilling is to allow the pin to shrink or become smaller, and their method of drilling all around the edge was a tedious process.

Always drill in a straight line across the pin, as shown in Fig. 2. This allows the two halves of the pin to close up, and the worst case of sticktoitiveness will have to give up to this treatment It's the logical way to go at the job, and has been used long years.

Go where you will and keep your eyes open, and you will see plenty of air-brake hose on the rear of trains hung up wrong on the dummy coupling hook. The hose head is generally hooked onto the outside hook of the dummy, and left hanging where it can swallow all the dust and dirt stirred up. The intelligent (?) passenger "gafter" does not seem to understand that the whole object of the dummy coupler is to close the end of the hose, to prevent dirt from getting into the hose and from there to the triple valves. Brakes that won't work because they are "gummed up" had never ought to surprise us—it's a wonder they work at all. It ought to be a ten-day offense to fail to protect the opening in this rear hose—unless the brakesman can prove that the coupling is so put up that it is impossible to couple the hose on. We recently asked a rear brakesman why he hung the hose as he did, and he said that he had to try the air from the rear and it saved him taking the hose down—he ought to have had a rest.

Computing Grades—The Different Ways of Expressing.

Civil engineers, in computing grades, say, so much in 100, or, such a per cent. Thus, a grade of three inches in 100 feet would be stated as "¼ in 100, or ¼ of one per cent." By the English method it would be called "one in four hundred." The American method always gives the grade per mile, which in this case would be "$13\frac{2}{10}$ feet per mile."

Where the engineer said three per cent., or three in 100, the English would say, 1 in 33⅓, which, by American practice, means $158\frac{4}{10}$ feet per mile.

To reduce grades stated in per cents or the rise in 100 feet, to feet of grade per mile, multiply by $52\frac{8}{10}$. Thus a three per cent. grade reduced to feet per mile is expressed $3 \times 52\frac{8}{10} = 158\frac{4}{10}$.

To reduce grades stated in the English method to feet per mile, divide 5,280, the feet in a mile, by the number stated, thus 1 in 25 would be expressed, $5{,}280 \div 25 = 211\frac{2}{10}$ feet per mile.

Crazy Again.

There are 30,000 locomotives in the United States, that if strung in a straight line would be 300 miles long. They cost $450,000,000 to build. The largest locomotive works is at Philadelphia, the Baldwin, and they turn out three engines a day when pushed. It takes 1,000 men a whole day to build an engine, on the average.—*Virginia Manufacturer.*

The average total wheel base of our largest locomotives with their tenders is about 58 feet; putting it at 60, and allowing that all the locomotives in this country are full length, the 30,000 would not cover 35 miles of track, and would doubtless go inside of 30 when all collected in the general round-up.

At the Master Mechanics meeting this year an associate member attempted to tell how much better a compound locomotive was than a simple engine. He is a member of the committee of science and arts of the Franklin Institute of Philadelphia, and one of the men sent out to report on the compound. He stated before the M M's that the compound went up a hill easily on the Reading road, that was so steep that it was impossible to get water into the boiler of a common engine, and when some irreverent members smiled he asked Superintendent of M. P Paxton to help him clinch his argument. Mr Paxton said the men didn't put in coal on that grade (they burn anthracite). The men probably thought the speaker was as green as grass in practical railroading, and so filled him up for fun. The idea that the mechanical heads of our American roads are called upon to sit open-mouthed and listen to such rot, strikes a man up a tree as "sorter komikal." We wonder if the cream of the Franklin Institute is represented by the committee of science and arts, and, if it is, of what use a report on a railroad subject is from men who can be induced to believe that you can't put water into a poor, common locomotive on a dizzy grade standing up on end—like a kite string—almost *thirty feet per mile*. The M Ms. ought to pass a law that associate members must know enough about practical railroad engineering so you could notice it on 'em.

July has brought her usual crop of disastrous wrecks. The excursion business is at its summer flood. More trains, more business, and green men in the train service, one or two nervous train dispatchers, and an excitable engineer, who imagines that a train of cars with windows in them calls for wild running and desperate chances, and your plan for wreck and trouble is complete. There are two reforms necessary, and necessary right now. One is something that will force brakemen to go back and flag as they ought, and the other is to force railroad companies to equip their freight trains with automatic air-brakes. Ninety per cent. of the passengers killed on our roads are killed by rear collisions, and probably ninety per cent. of these accidents could be avoided if these two safeguards were doing their duty, their whole duty and nothing but their duty.

The gauge of a road is the distance between the insides of the rail heads—not from center to center of rail, as some think.

One Sensible Judge.

"The act of God" has been one of the forms of crime against the established laws that courts could not punish for. This phrase of law has survived from medieval ages, and should be used in these times just as much as we wear breech-clouts or sandals—and no more.

At last one United States judge has been found with good sense and justice enough in him to sit down upon this worse than baby act, so often employed by our railroad lawyers to excuse gross carelessness or criminal negligence in the management.

"Not long since a train on the Virginia Midland Railroad had been derailed in a narrow cut in consequence of a landslide, which was due to a heavy fall of rain. In deciding an action for damages incurred in the accident the court remarked significantly, 'You who know so much about the law of God and the processes of nature must have foreseen that the earth hanging over that narrow, unprotected cut would be loosened by the rain and brought down upon your track by the law of gravity. Common prudence and ordinary engineering skill would have prevented such a result, and we, therefore, hold you, and not God, responsible.'"

A hundred years ago this plea would have been accepted, and any one who objected would have been called a heretic. Let us hope that it will not be another hundred years before this phrase will be unknown to our laws, and science be sufficiently advanced to provide for every purely material contingency, and reduce the business of transporting goods and passengers to an insurance.

The Difference.

From an English exchange we clip the following information on the extended use of block signaling in Great Britain:

The British Board of Trade report on interlocking and block signaling for the calendar year of 1890 has been issued. The percentage of double-track road (used for passenger traffic) that is operated on the absolute block system is 98½ in England and Wales, 100 in Scotland, and 35 in Ireland, making an average for the United Kingdom of 95 per cent. The increase from 1889 is only ½ per cent. The only roads showing a notable increase are the Manchester, Sheffield and Lincolnshire and the Manchester, South Junction and Altringham. The appendix, giving replies to the circular asking information about proposed work for 1891, which, in consequence of the recently enacted law, might be expected to be more than usually important, has very little of interest. Those roads which have the most to do to bring their practice up to the standard of the law evidently had not completed their plans when this report was made up. The Lincolnshire and Yorkshire reports that "two position blocks" have been substituted by "three position blocks" at the half dozen places named, and 16 sets of electrical apparatus to repeat the action of signal arms have been put in at various places, also 29 additional telephones in block-signaling cabins. The percentage of switches, grade crossings, etc., properly interlocked is 95 in England and Wales, 87 in Scotland, and 65 in Ireland. Ireland has increased 60 to 65, and the other countries slightly. The average for the United Kingdom is 92¼ per cent.

The average percentage of blocked track in this country is very small, indeed—certainly not five per cent. There is great need of improvement in this line.

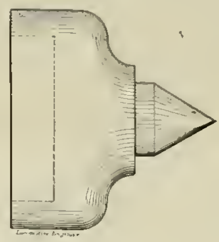
A correspondent writes that there ought to be a kick made against the practice of a reputable builder, in putting the stuffing-box for throttle stem through the boiler head from the *inside* of the sheet, with the gland stud passing through the boiler-head and having nuts on the inside end to draw the stuffing-box up to make the joint. Suppose one of these studs should break, we must take out the throttle pipe and enough crown bar stays to allow a man to get in the boiler and replace it, unless some other way of getting at it could be devised.

Last year the C., B. & Q. paid out $461,129.24 for foreign agencies and advertising.

Some Shop Kinks from the Northern Pacific.

Livingston, Mont., is a good way west of headquarters for the N. P. at St. Paul, but it has the second largest shop on the system.

Master Mechanic Angus Brown was away the day the writer devoted to his shop, but we were well taken care of by Gen'l Foreman Wm. Mallahan, Shop Foreman C. B. King and tool maker G. P. Strickland.

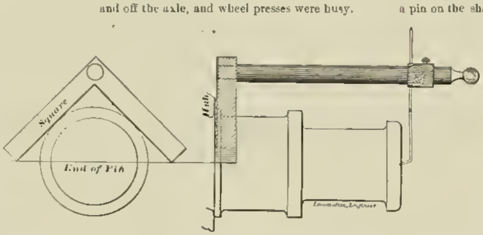


This shop is the conventional railroad shop, better than the average in having fair brick buildings, plenty of yard room and newer tools, but like them in general arrangement.

The place is kept neatly; it is not a floral conservatory, but a neat and orderly shop, where lots of hard, dirty work is done.

WHEEL WORK.

There seems to be an awful amount of car wheel work done here; the yard was full of wheels on and off the axle, and wheel presses were busy.



The writer saw a whole car load of wheels being unloaded, all but two or three pair being "slid flat." Last year, at this shop, they put on over eleven hundred new cast wheels for the Rocky Mountain district alone, mostly all "slid flat."

In making new axles, the forgings are cut off the proper length, and placed on V's between the ram and tail piece of a hydraulic wheel press, the V's being set the proper height to center the size of axle being handled.

On the ram and tail head of the press they place cast-iron blocks or caps, into which are fitted heavy hardened steel centers (see cut); one movement of the press ram forces these centers into the ends of the axle, making the center holes where wanted, and ample enough for any amount of work.

TESTING CRANK PINS.

They use here a very simple crank-pin gauge of their own make, something like the sketch shown herewith, which is from memory. The instrument is much like a surface gauge, but something heavier, the base or end is a square piece of steel formed into an angle of 45°, as shown; at the corner of this square a post is set that is at right angles to the base of the tool, and on this post are the usual sleeve and thumb nut to hold and adjust the scriber.

All crank-pin bosses are faced off, and the collar or shoulder of crank-pins next the hub receive no wear, and these two parts are taken as true points to measure from.

If the base or bottom of the square is pressed against the crank-pin boss, and the insides of the angle are brought down upon the pin collar, the post will stand perfectly parallel with the pin—if it is true—by setting the scriber to the center or to a circle drawn around the center, and the gauge be then moved around the pin, the point of the scriber will at once tell whether or no the pin is sprung. If the pin is true, the straight point of the scriber is set to the face of the bearing, and the gauge moved around the pin, to show where the greatest wear has taken place. This is an excellent tool, and one that any intelligent mechanic can easily make, and one that should be in every roundhouse outfit.

GOOD VALVE TRAM.

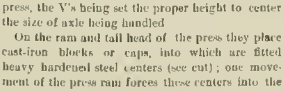
The big hogs on this road have their valve stems so close up under the running boards that it is very inconvenient to make tram marks or see them on top of the stems in valve setting, so they make a tram that will make the marks on the front of the stem; the tram has at one end the usual long point to reach the prick-punch mark on the cylinder casting back of the steam chest, and has on the other end a T, or two points, and at right angles to the point on the other end of the tram, these points make the tram a "right or left," so that one does for both sides of the engine.

FLUE HOLE CUTTER.

They make a common shank do for different sizes of flue hole cutters. The shank has a squared end for driving, the opposite end terminating in a small stem or guide to enter punch or other center holes, the shank has a collar below which the cutters are placed, and are prevented from turning by a pin on the shank that enters a right-angled slot in the cutter. The cutters are made to fit over the base of shank and up against the collar, and have four teeth or cutters about three-quarters of an inch deep; these cut on the face only, and can be sharpened by grinding on the face, which does not change the size of the hole.

TO CURE A REACH ROD WITH ST. VITUS' DANCE.

Some of the big engines on the N. P. have intermediate tumbling shafts and two reach rods, multiplying joints. Others have very long reach rods, and still others have rods with several curves in them. When length and curvature are combined, especially in big engines, the way the rod slaps and dances and jerks is appalling. Forks to prevent the rod from slapping sidewise have long been used, but it has been noticed here that most of the movement was vertical, and they have devised the plan shown in the sketch to support the center of the long rod. The usual fork is retained to prevent side motion, but below the rod, in the fork, is pivoted a roller, and the proper arc cut on lower side of reach rod to allow the roller to bear the weight of the rod in all positions it is called upon to take.



They have a good tool-room at this shop fairly stocked with good tools, including standard gauges. They have the largest sized Pedrick & Ayer miller here, but it is too big for tool making and could more than double its usefulness out in the shop.

Valve seat planers, cylinder boring machines and drilling is done by ropes from a special small shaft running across the pits in the main shop.

GOOD BLACKSMITHING.

This place is fortunate in having a foreman blacksmith who does a large variety of work with very ordinary facilities. He had just forged a long front drawhead for the pilot of a passenger engine, that would have graced the front of a fire engine, with its side hand-holds and dragon head.

Privilege has been granted to an American company, composed mostly of Boston capitalists, to construct a railroad from Carthagena, the principal port of the republic of Columbia, to the Magdalena River, together with a grant of 400,000 acres, to be selected anywhere in the country.—*Bradstreet's.*

Correspondence

Big Mileage Record.

Editor The Locomotive Engineer:

The July issue of THE LOCOMOTIVE ENGINEER gives an account of mileage made by an engine on the D. & R. G. R. R., run by Engineer John Shanley, making over 100,000 miles. There is a record here which we think will also bear publishing in THE LOCOMOTIVE ENGINEER.

Engineer H. T. Hale took Engine 56 on the Brooklyn elevated road, November 10th, 1887, which he run, without general repairs, until January 1st, 1891. This engine averaged 175 miles daily, and ran three years, one month and twenty days, and in that time did not cost the company near the amount expended on Mr. Shanley's engine. The engine was in condition for further service, but her stay bolts and flues gave out. Allowing one day a month for wash-out, the engine was in service 1,108 days, making in all 193,900 miles.

Brooklyn, N. Y. B. E. ENGINEER.

[There is a great deal of difference between running a locomotive with eight drivers and ten truck wheels, weighing, tank and all, something like 200,000 pounds, and one having four drivers and four truck wheels, weighing only 44,000 pounds. The "hog" pulls all she can, dead freight, the Brooklyn "L" engine seldom, if ever, over four cars, generally three, the "L" is up in the air, out of the dirt, the "hog" on the ground, in the sand. The record of the Brooklyn engine is good, but we find that on the N. Y. Elevated a mileage of more than 200,000 has been made repeatedly. One engine of the Second avenue ran for more than five years without being off her wheels; her mileage being nearer 300,000 than 200,000.]

Misplaced Cab Fittings and Other Abominations.

Editor The Locomotive Engineer:

I will agree with W. De Sanno that very little pains are often taken toward locating injectors, air-drums, or even gauge cocks in best places, both for the convenience of engineer, or to best serve the purposes intended. Gauge cocks are often put in back head well to side, in close proximity to reverse lever instead of closer to center of back head, where they would be less in the way, and where, when in need of grinding in, less steam would be blown in face of engineer, or in cold weather deposited on cab windows, besides a more accurate indication of the water level could be obtained. How often injectors are placed inside cab, where leaking joints, hot steam pipes, and want of room make them undesirable, to say nothing of cab windows in cold weather continually coated with moisture from overflow. Again, often when placed outside cab, injector and air pump will be so tangled up that De Sanno would surely complain about having to take them down or repair. Air drums when located on top of tender give a little trouble during cold weather. The best place for them is back of cylinder saddle, between frames when possible, or else under back end of footboard of cab on consolidation locomotives. When placed under front of engine two drums ought to be put in instead of one, so engine truck could be got at easily; besides, a cock should be put in all air-drums where it could easily be reached by engineer when necessary to drain air drum of water. We need no more contrivances on top of boiler; better to put sand-box in wheel cover, or else make it in some shape that would be low and not obstruct the view, also a better arrangement of valve, etc., for putting the sand on rail is needed.

Pittsburgh, Pa. J. J. CLAIR.

Who Invented the Balanced Throttle Valve?

Editor The Locomotive Engineer:

In your paper a few months ago you describe some English practice, and mention for one thing the flat throttle valve. Now when I was an apprentice I was told that the round double-seat throttle was an invention of Clark's, who was locomotive superintendent of the Great Northern of Scotland Railway over thirty years ago, and has been their standard since. What I would like to know is why is it called American if it is Mr. Clark's; and if it is American, I hope you will be able to tell us the inventor. The same thing has caused many debates, and no one I have met with has been able to give me information about it. Hoping, Mr. Editor, that you will give this space in your paper, and I have no doubt but some of your correspondents will enlighten us. WILLIAM PRATT.

Brainerd, Minn.

[The double-seated throttle valve has been in use in America for nearly forty years. We do not know who first used it. Perhaps some of our older readers do.]

Air-drums, Brake Failures and Pipe Connections.

Editor The Locomotive Engineer:

You seem to think that the air-drum should be the lowest point in the brake system; well, there are no objections to that, but in a great many cases the drum collects so much water from drainage that there is no room left for air.

It is possible in some accidents, when we read *the air-brakes failed*, that there was no air—it was all water—more particularly where straight air is used. If drip cups, auxiliary reservoirs and air drums are kept well drained, the danger is averted. There is the same danger in the automatic system by not having air enough to recharge with on descending grades.

There is a great deal laid to the air-brake refusing to work in emergencies that should be put on the shoulder of lazy train men, or air-brake inspectors. The air-brake is all right, and in ninety-nine times out of a hundred it will work if not handicapped by the conditions mentioned. Under the circumstances I fail to see any good reason for putting the drum under the footboard, and I think, further, that, if the man who puts it there had to monkey between the top of the drum and footboard to get the draw-bar pin out, he would vote it a nuisance.

Now a word about air drum connections, in taking down air-pipes there is great trouble in having the nipple unscrew out of the sheet, simply because the grip of the union is greater than the thread in the sheet. If the sheet is not flanged where the connection is made, a brass boss should be riveted on, to give plenty of thread for all connections. W. DE SANNO.

Corry, Pa.

[Drums that get too full of water to hold air ought to be treated for dropsy. And this is the engineer's business.]

Interesting Notes from an Engine Driver on the Government Railways of New South Wales.

Editor The Locomotive Engineer:

As an annual subscriber to your journal I undertake to offer some information on a subject referred to in your issue of April, viz. Examination of Locomotive Engineers and Firemen. I notice on page 75 that a master mechanic's committee desire information on that subject.

In New South Wales it is customary to employ youths from 14 to 21 years engine cleaning at various rates of wages from two shillings and sixpence (60c.) to seven shillings ($1 68) per day, an extra sixpence (12 cts.) per day being given for night work. They are considered to rise by biennial increases until the higher wage is reached. There is an exception to this course, however, as any fuelman, blacksmith's striker, fitter, laborer or other employe under the age of 32 years, who, having been at least two years in the service, can, when a vacancy occurs, enter as a cleaner at six shillings and sixpence ($1 60), which causes him to work at least six months in that capacity before he is entitled to promotion, and he has to undergo and pass a medical examination, and be of standard weight and height.

Men coming from, say America or India, and joining the service here with certificates of service and ability in those places, have to go through the cleaning portion before firing. When a vacancy occurs for a fireman, a cleaner is promoted who has previously been examined by an inspector as to his eyesight, knowledge of the book of rules, method of oiling, and block signal working; if he is negligent and has not posted himself up in his work, or I should say, future work, he has to stand back and allow the smarter man to go forward.

Upon being promoted he receives eight shillings ($1.92) per day of nine hours, 54 hours for a week's work; anything over that is called overtime and paid for at same rate. He receives two increases of one shilling (24c.); that is, after one year and six months he receives nine shillings ($2 16), and after a similar period 10 shillings ($2.40), and is called a first-class fireman, and after 12 months in that grade (making a total of four years' firing) he is considered fit (if capable of passing the examination) of taking charge of an engine.

He receives 11 shillings ($2.64) per day at first and a yearly rise of one shilling (24 cts.) to 14 shillings ($3 36); then serves seven years in that grade, and passes the technical examination for the highest money—15 shillings ($3 60). There is not allowed to be more than one-fourth of the total number of drivers in that grade at one time. Men very often fire for seven or nine years before promotion takes place, and rarely less than five. Where shunting (switch) engines or ballast trains are run from, the young driver or fireman has to do that work till relieved by subsequent promotions, and then go on goods and mineral trains.

It is always ascertained, upon entering the service, the knowledge you possess of reading and writing, etc. When the inspector of any district anticipates the increase of the staff of drivers, the senior firemen are called upon in rotation to present themselves at the office of the depot in which they are working, and are examined as follows: Name in full; age last birthday; length of service; present rate of pay; knowledge of rules and regulations relating to signals and the approaches to stations, whether on the up or down grade, level, etc., and the grades of the road over which you happen to have fired; block signal working and breakdowns and their remedy (the necessity of always seeing to the protection of your train being paramount in every answer); use of the eccentrics and the link motion; use of lap and lead, method of trimming those parts of engine having a rotary or oscillating motion; use and principle of injector; use and principle of lubricator (Roscoe's); principles of combustion, and method of firing different classes of engines; prevention of the omission of sparks; a complete and thorough knowledge of the Westinghouse Automatic Brake as at present in use here. Eyesight tested by inspector having a number of cards on which a number of colored circles are painted—red, yellow, green, blue, black, in various positions. There are also a lot of black dots which are just visible at the distance, about 14 feet. You have to describe the colors on each card, with the number of dots, then place one hand over the eye (say the right one) and tell the colors and dots with the other, and reverse, and occasionally the men are caught unawares and asked to tell the colors of flags that are being moved about by a man ½ or ¾ mile away.

There are several matters, especially the pump and other puzzles, that I would like to have a go at, but distance prevents. I have not always sufficient time to write a letter of any length, so do not write at all; but I may at no distant date give you a description of some of the classes of engines we have here. I consider Engineer Hood used common sense in running his engine the way he did; the result proves it. MOGUL.

New Castle, N. S. Wales, Australia.

About Examination of Firemen.

Editor The Locomotive Engineer:

The examination of firemen as they advance to the grade of engineer is all right in principle, but who is to do the examining in the locomotive department? Some of the candidates may be fortunate enough to appear before one or more of the well-chosen committee of the M. M.'s Association, but a very few of them.

Of course there are plenty of men in authority who can make these examinations, but if to hear first-class engines go limping over the road is any criterion to go by, some of those in authority had better learn something themselves.

Some men may learn to answer the questions as a parrot learns to talk; but when brought face to face with the parts of an engine they are at sea, and don't know a thing when they see it. Let me illustrate: I was working in the back shop, there was a tag with a cut of a sight-feed lubricator on it; an embryo engineer (one of the kind who are always kicking to be "set up") came along, picked up the card and asked me if it was a new kind of air-brake? Now that fellow had been using that identical lubricator right along, but when he saw a picture of it did not know what it was. John Doe can tell you what inside and outside lap is just as he has been told, but take him into the back shop where an engine is under repairs, give him a rule, show him a valve and seat, and ask for the dimensions, in five cases out of ten he cannot give them.

After a fireman has graduated as such he should put in six months roundhouse work under a good man, where he could learn how to take down rods, file brasses, and get a good insight in running repairs, and another six months working about the pits in back shop. The information gained by this course would serve him a good turn in after years, unless he was a practical mechanic to start in with. There is just this in it, the coming locomotive engineer has got to be more thorough than in times past.

Railroad companies are getting things down fine, and the boys have got to keep step.

In examining men on breakage on the road, a man may say what he would do, but when the break comes the design of his engines may force him to pursue an entirely different course, and if he is a clear, level-headed man, he will come out all right. Some engines are crippled in their designing, so far as a breakdown on the road is concerned. Take for instance that splendid engine illustrated in June issue, if she breaks a forward side pin, or strap, every side rod on her must come down; but if a rear rod, pin or strap, only the two rear sections come down.

Ask some of the young runners why and how the rods should be made to avoid taking all side rods down in case of the breakage of a forward one.

Corry, Pa. W. DE SANNO.

[Our correspondent evidently thinks the future locomotive engineer will need to know how to repair his engine as did the engineers of thirty years ago—we do not. The more they know about the way work should be done, the better, perhaps, but it is not necessary that the best locomotive runner in the world should know how to file brasses or set valves.

This fear that men will learn all about a locomotive, parrot fashion, is a fancy; no man can intelligently answer questions about breakdowns, if they are slightly varied, unless he knows something about locomotives.

Knuckle joints in side rods are the cause of disconnecting troubles spoken of, and the only cure is to make short rods reaching only from pin to pin with a brass at each end, but this costs more and is a doubtful remedy.]

Heating Air-pumps.

Editor The Locomotive Engineer:

Replying to George Holmes, of Roanoke, Va., in the June paper, on air-brakes heating and choking air passages, will say if the air valves have their proper lift, receiving valves ⅛, and discharge valves $\frac{3}{32}$ of an inch, and having perfect ground seats and good air tight rings in air cylinder, there will be no hot pipes nor corroded air passages. My theory for heating is that the pump, instead of forcing the entire quantity of air through into reservoir every stroke, as it will do when valves are perfectly seated and air is held in by discharge valve, it simply heats the air by churning it back and forth through restricted passages and through badly ground valves, burning the oil, corroding up air passages, burning packing, breaking air valves, etc. The first defect in the air cylinder is always betrayed by throwing hot air back out of the suction pipe.

I think Brother Holmes' theory as to water in air-drum and train pipes is a little wet, and needs drying, as condensation will take place whether his tobacco is wet or dry, or regardless of the condition of the weather. We all know that a warm atmosphere condenses moisture in contact with a cold surface; hence air passing through a warm cylinder into a cool pipe, thence into a colder reservoir, and kept cooling by motion of train, is the correct theory for water in reservoir and train pipes.

Mobile, Ala. D. O. SMITH.

A Cheap Hose Coupling Fitter.

Editor The Locomotive Engineer:

No doubt there are many readers of your valuable paper that have more or less experience in attaching feed, steam heat and air-hose fittings, that do not care to go to the expense of the machine for that purpose, illustrated in your July edition.

To those, I think that the accompanying sketches will furnish an idea of an inexpensive arrangement that will do the work easily, and is so simple that but little explanation is necessary. It can be used on any modern upright drill; we use it on a 24-inch Bement, the quick return lever forcing the fittings into position quite readily.

Fig. 2 illustrates the device for holding the ordinary air-hose coupling; the body is made of wood, to which a shank fitted to the drill press spindle or socket is attached with wood screws.

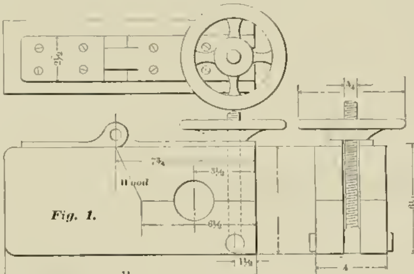


Fig. 1.

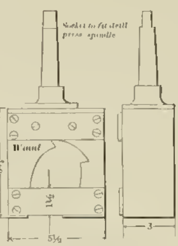

Fig. 2.

Fig. 1 illustrates the vise for holding the hose, also made of wood, with iron hinge, screw and wheel; any ordinary railroad repair shop will have plenty of these at command; if not, it is no great job to make them. the writer brought into play the following: For the hinge, a damper hinge was found to be all right, a wedge bolt was used for the screw, while a discarded spark-pot furnished the required hand-wheel.

It is operated as follows: Place the device for holding the fittings in the drill press spindle, and insert a coupling in the opening in the wood, bolt the vise firmly to the platen, having the slot for the hose just clear the edge, and also in a central position under the shank of the coupling, grip your hose firmly in the vise, allowing just the amount that the fitting will take up to extend above the vise, thoroughly grease the shank of the fitting, and it will surprise you how easy they are forced into position. The ingenuity of the average machinist will devise a way for holding all the other fittings.

This machine, with the "hose clamp holder," described in THE LOCOMOTIVE ENGINEER, Vol. II., No. XII., will make an outfit that any railroad repair shop or roundhouse can possess.

Quite an extensive machine for this same purpose was described in the *National Car and Locomotive Builder* for June, 1891, the same being used in the Topeka shops of the A. T. & S. F. In their description, they say, "and a pipe mandrel put inside (the hose) to prevent collapse," when it is gripped in the vise. This recalled a bit of experience I had when the machine described above was constructed, there was a mandrel for the same purpose that they mention, made, and possibly would be in use to-day, the same as the Topeka shop, had not the young man who had been in the habit of putting the fittings in "per force," been anxious to give the machine a trial, and did so in the absence of the writer from the room, and he knew nothing about the mandrel mentioned.

Upon my return, I found the fitting, which was to be put in a five-ply steam-heat hose, had been readily put in place without the use of the mandrel, much to my surprise. C. H. W.

Boston, Mass.

Headlight Signals.

Editor The Locomotive Engineer:

I have just been reading an article in your June paper, entitled "Darkening Headlights for Signals," and I cannot endorse the writer's views on the subject. He says, "If they are not there the place is dark; if they are there and all lights shrouded, the place is dark and everything uncertain," etc. Now here on the "Burlington" we know when we see a headlight at the station where we have a meeting point, that the opposing train is not "in to clear."

If it is in to clear, we have brakemen, whose business it is to give us signals that such is the case, even though we are unable to see the train. A common, and I think a much more satisfactory signal, is for the fireman or engineer to lift the headlight curtain twice, immediately after an opposing train has "whistled in."

If this is not possible, as in a case where a train has "headed in" on a track, and there are cars ahead, so that the headlight does not show, then, as I said before, the head brakeman will give a signal that all is right and the engineer can "let her go."

Judging from the last illustration he gives, however, one would infer that they do not have brakemen over there. He says, "It is dark and stormy, your headlight has gone out by virtue (if there is any virtue in such an occurrence) of a bird flying against the glass and breaking it. As everything is dark at the station, you take it for granted that they are on the side track, and pull through, but they got laid out and did not make it. . . You know the rest." In the first place, if your headlight glass is broken by *any* means a lantern should be fastened in it. In the second place, *you have no right to take anything for granted*, and in the third place, if you were running here and "got laid out so that you could not make" a meeting point, there would be a brakeman from your train flagging far enough ahead to stop the opposing train before a collision could occur.

McCook, Neb. T. W. BENJAMIN.

The Injector Question.

Editor The Locomotive Engineer.

To Mr. Gibson's first injector question I would say that the suction pipe was partially stopped up, or drawing air. To his second question would say that the check valve was stuck fast to seat, the combining tube was broken, there was not enough steam turned on to work the instrument, or else water was too hot to work. BEN HEAD.

Cambola, Pa.

Editor The Locomotive Engineer.

The following causes led to the trouble I experienced and spoke of last month:

First—Stuffing box nut of overflow valve was loose, allowing air to enter, preventing the formation of a vacuum. Second—A bent delivery tube will cause injector to fly off, also the combining tube not working free will cause the same, as will check valve being stuck. EDWARD GIBSON.

Wilmington, Del.

Two Waifs of the Rail—Hogskin Thompson's Mascots.

By John Alexander.

Sometime toward the close of the war there was a bright-faced boy in our Old Man's office, known then only as "Cy."; perhaps he was 12 or 14 years old, mostly all legs and freckles, as New England boys of that age are prone to be, but bright, sharp, and attentive to business; he was a boy you'd like in a minute, but he had the engine fever worse than most of 'em do, and even symptoms are bad enough.

"Cy." hounded me about getting him on to fire for two years, struck the Old Man for a chance to fire or wipe regularly twice a week, and spent all his leisure time at the roundhouse.

One morning, a little over twenty years ago, I went down to take the "Esmeralda" out, and noticed on the bulletin this legend:

"Train 12, engine '77, Engineer, Alexander, Fireman, Thompson."

"Thompson? Thompson?" said I, half to myself, "what fireman is that?"

"'Cy' Thompson, used to be call boy," said the foreman; "why, you know 'Cy' Thompson." So you see at last "Cy." started out on his career under the guidance of the greatest water boiler and train jerker on earth—myself.

"Cy" was soon changed off to a regular freight, and became one of our best firemen. We all felt a great respect for "Cy."; his father was killed at Shiloh, and he supported his widowed mother until her death, which occurred shortly after he went firing. He was cleanly, orderly, studious, and a pleasant fellow to have around.

"Cy." used to go out in society some, and when he went it was always in the best circles; first he took one girl, then another, once in a while being seen with a daughter of our general manager—but he seemed to have no regular, steady company.

As near as I can remember, it was '72 or '73 that "Cy." was promoted. He attended strictly to business, and inside of six months had the reputation of being the best freight man on the road—he was a success—the officers were pleased, his companions on the road glad, and "Cy." himself ought to have been more or less satisfied with himself, but he wa'n't.

All at once there came a great change over "Cy." I noticed it first when he commenced to run his engine into town without taking off his overclothes; then he got to loafing around the roundhouse half the time, puttering around his engine, telling stories or reading. He would come in and stay around the house hours before he would wash up, and the high-water line advanced steadily from his shoulders to his ears, and finally he only washed around his mouth, except on Sunday.

He bought cheap, ill-fitting clothes that were always ripped, or had buttons off, or wrinkled in the back.

"Cy." ate his lunch up the road one day without washing his hands, and his fireman said he was as bad as a pig, he did so again, and someone else said he was a hog, and I never knew how it all came about, but it wa'n't long before we were all calling him "Hogskin" Thompson, and I don't know but what he deserved it.

"Hogskin" Thompson never lost his reputation as a good runner; he made his engine his home and his idol; she was the cleanest and best in the service, but "Hogskin" was kept off a passenger run when his turn came, all on account of his personal habits, he saved money, but pshaw, any one can save money who gets a man's wages, and lives like a hog.

During the centennial, "Hogskin's" only sister came home from the West, bringing a little son three or four years old. "Hogskin" laid off two weeks to entertain her, washed clear down to the skin, and bought himself a decent suit of clothes, but I don't believe he took his sister any place; he devoted himself to that boy—bought him clothes, whole suits, took him everywhere a boy would want to go, and loaded him down with playthings. But just as quick as the sister went home "Hogskin" relapsed into his old habits.

I saw that the defenseless side of "Hogskin's" fortress was the children's side; if he was to be recalled from associating with himself alone it would be through his love of little children; women he had absolutely ignored since he changed his name from "Cy." to "Hogskin."

I invited him up to my place once, and he came and played all evening on the floor with the children, and seemed to enjoy it, but he wouldn't come again. When Fred had the scarlet fever, "Hogskin" asked after him every day, and sent him fruit, and flowers, and sweetmeats, and years afterward I found out that he did the same when any child was sick that he knew of. He bought many a pair of little shoes, filled many a little stomach, and many a poor mother had cause to feel sorry when "Hogskin" Thompson was banished from New England; but bless you, I never heard of his good deeds till after he had gone.

The strike of '77 sent a good many of us out West, but "Hogskin" Thompson was one of the first to leave for "parts unknown." He came up to bid me good-by, and I walked down to the depot with him, and going down there he told me the cause of his great change.

He had loved a daughter of the old man's—our general manager—and when he was promoted and proved himself a good engineer, had considered that he was worthy of her, as good as she, as clean and pure, as well educated and as well born, and had told her so, asking her to marry him. She thought well of him, but her father, who had become rich, pooh-poohed the whole idea, and talked the foolish girl into the belief that she was made of a superior sort of brickdust, and she declined him. If he had tried the bold knight not-to-be bluffed-or-fooled-with plan, the girl would have broken her father's law, and, I doubt not, her own neck, to have gotten him, but he went off into a half-morose, half-mad pet, and kept up his don't-care mien, and failed to wash his neck, and answered to the name of "Hogskin," till I rather guess the girl was glad she didn't get him.

"Hogskin" Thompson passed out of sight, and out of mind. Our boys were scattered far and near, and, of course, the fellows that took our mills did not know "Hogskin"; as for me, I thought of him once in a while, for a year or two, and inquired for him when I met some of the old gang, but I don't believe I had thought of him for ten straight years until the other day—then I met him face to face in the streets of Boston.

He didn't look much like the "Hogskin" Thompson that was exiled after the strike, but I knew him just the same. He wore a plug hat, and a good suit of clothes, had a clean, stand-up collar, patent leather shoes, side whiskers, and that same old smile he wore when he was "Cy.," and before he became "Hogskin"—I knew him by the smile.

I stepped up, stuck out my fin, and said: "This is Mr. Thompson, I believe; Cyrus Thompson?"

He wrapped my hand up in his, looked me in the eye, and said:

"'Hogskin' Thompson, sure enough; but bless me if you don't stick me—but keep still, let me see; can't be Alexander—old John Alexander, well, well, I be darned; how are you, old man?"

He pulled my flipper through his elbow, and we started off down street like a couple of boys; he asked me about eleven hundred questions, and I got in a little over a thousand on him when we brought up at the door of Young's hotel; nothing would do but I must come in and lunch with him, so in I went.

We went up to the parlor, and before my eyes had just got used to the light, in rushed about as handsome a young lady as you'd wish to look at, throws her arms around Thompson's neck, and calls him a dear, old papa, and wants to know where in the world he has been.

That girl was born long before '77, if I am any judge; and I am just trying to get it straight when in comes another, perhaps seven—a little dream of loveliness—and she has hugs for "papa," too.

That oldest girl is no daughter of "Cy.'s," and she certainly can't be the mother of the little one; but "Cy." sees my perplexity, and, winking at me gravely, he formally introduces each as his daughter, and—we all lunch.

A bright and happy pair of girls are these, and Thompson seems devoted to them.

Thompson and his girls went home with me that afternoon; the girls captured the heart of Mrs. A. on sight, and inside of fifteen minutes owned the place, and had taken possession.

But that night, long after they were in bed, Thompson told Mrs. A. and I how he came by them, and if it ain't equal to a romance then there is no romance on the railroad.

Sitting in the room I call my "den," Thompson and I mingled the smoke of our cheroots, and went over our lives since '77, until the house was still, then Mrs. A.—woman fashion—came in with her crochet work and sat down to listen until there was a lull in the conversation, when she put in her oar.

"I felt so sorry for your little girl to-night, Mr. Thompson," said she; "her and our Bess were playing with their dolls, and she said: 'I just wish I had a mamma like you has, I ain't got a mamma at all, and I do want one *so* bad; papa says my mamma got lost, but she will turn up all right one of these days, but I *do* want one just awfully awful, so I do.'"

Thompson laid his cigar on the window sill, crossed his legs, clasped his hands over his knee, and said: "I guess I'll have to tell you where and how I got those girls, but say nothing to them, they are happy as they are."

Now I'm trying to tell this just as Thompson told it to us. He said:

"When I left here in '77 I went to New York, where I looked around for a few days, and then took steamer for New Orleans. I hunted work around there for some time, but gradually worked my way west into Texas, where I finally struck a job; it was not much of a road then, but it is now; I kept the job, however, as I had learned by experience that jobs were far from being plentiful. They gave me an old engine that was in pretty bad shape, and as there was no shop on the road worth the name, I concluded to put the old scrap in as good repair as possible myself.

"I worked nights and Sundays facing valves, packing packing, filing brasses, etc., etc., until the old Roger was the best engine on the road. In order to do this I spent much of my time in my overclothes, and at the engine, and am afraid that I was about as untidy as ever, for it wasn't long before they were calling me 'Hogskin' Thompson again; I don't know where they got the name, I suppose I must have given it away myself.

"My run was over a desolate part of the country, good enough for grazing, perhaps, but not much else; houses were few and far between, and towns still scarcer.

"Away out on the middle of the division there was a family living in a hut formerly built by the graders on the road; this family had apparently squatted here and occupied the cabin, and had attempted, in a half hearted way, to cultivate a little strip of land along a creek bottom.

"There was an old wagon, with the bows for cover still up, standing near, one horse usually ambled around with his front feet hobbled, and a half starved cow was often seen tied to the wheel of the wagon, everything in the surroundings betokened abject poverty.

"The man was a typical 'mover' from the Southern States; he could be seen, as a usual thing, sitting on the sod banking on the shady side of the house idly whipping the ground with a stick, or smoking his cob pipe and gazing at the horizon with his brain absolutely at rest, he was laziness personified.

"The woman's form was often to be seen in the little garden, but her back was always turned, and a sun-bonnet forever covered up her head.

"The liveliest creature around there was a little girl five or six years old. She always stood barefooted and open-eyed beside the track when we went by.

"I noticed that she had made little houses and yards by sticking up twigs in the ground, and had made animals of cobs with legs of twigs. One day I bought a nice, dressed doll, put it in a box, and threw it to her, when I went back she had it in her arms, and smiled at me—we were acquainted. I got her shoes, stockings, hat and many other things, and threw them to her, and she wore them. I got to whistle for her as we came in sight, and, rain or shine she was out to see me, and the doll was always clasped to her little breast, dirtier each trip, but always there.

"The woman was not to be seen the next spring for some time, so one day I slowed down, and asked the little lady where her ma was; she answered simply, 'sick.'

"Coming back next day, I stole a large piece of ice out of an empty refrigerator car, and threw it off, and did so every trip for a week or more.

"But one day my little friend stood in the doorway of the hut, weeping as if her heart would break, and the Cracker stood outside with his hat off, in an awed manner, that told me at once that the mother had gone to her long home. I stopped, consulted my watch, and found we could stay there an hour, if necessary, then I went over to the Cracker. The little girl came running to me, laid her little head on my shoulder, and sobbed as if her heart would break, at last telling me her poor, dear mamma was dead, and 'all cold.'

"The Cracker moved up, and said:

"'Yes, sir, she's dead.'

"'How long ago?' I asked.

"'Yesterday.'

"'Any neighbors?'

"'No.'

"'What can we do for you?'

"'She left some writin', sir.'

"I took off my greasy cap, and stepped inside the cabin, it was barren enough, but clean; on the poor bed lay the wasted form of a once beautiful woman—once the picture of Lottie—she had evidently died of consumption.

"The Cracker took up a copy of the Book of Mormon, turned to the fly-leaf in the back, and handed it to me, saying,

"'I don't read.'

"I took it, and in faint pencil lines, but a handsome script, I read:

"'Bury me under the cottonwood by the brook. I am 28 years of age. Lottie was born at Salt Lake, Utah, June 4, 1873. I was the third wife. Her true name is Lottie M——'

"That was all; even the name was carried away by the dead; the writing bore evidence of having been done a little at a time, probably after the sufferer got too weak to use the pencil.

"Our crew dug a grave by the tree near the cabin, and wrapping the sheet around the wasted form, we laid it in the shallow opening and covered it over, the little girl weeping, and the father standing idly by, with a troubled look on his face.

"He said they had plenty in the house, and that he would pick up his traps, and move into town at once, where I promised to find him, and help him to get work, and put the little one in school.

"Our time was short now, so we hurried away, and I shall never forget the weeping little figure that stood outside the cabin, holding her doll, and watching us out of sight. The next day, going back, I noted that the cabin was deserted, and the wagon gone, and ten miles further on I passed the outfit; the one old horse hitched to the double wagon, the pole strapped up to his side, the weather-beaten cow limping along behind, and the Cracker sitting on the corner of the wagon box, his feet on the whiffletree, and his cob pipe between his teeth; he did not look up as we passed—perhaps he was thinking—I did not see the little girl.

"I went out the next night on the coal train, and ten miles the *other side* of the deserted cabin I saw something ahead, between the rails, that looked like a cyote or a dog, going from us, but when we got within a hundred feet or so, it stepped out of the way, and turned and looked toward the engine—it was my little girl.

"Clasped in her arms was her precious dolly, and in a little paper sack she had some corn bread, and a few childish trifles, as I afterward found. I called for brakes, left the engine with the fireman, and jumped off opposite her. She was overjoyed to see me, and said she was going home to my house to stay. I took her into the cab, and at the first stop turned her loose in my lunch pail—she was ravenous.

"I learned from her that she had followed my train away from the house two days before. She said that man wasn't her own papa, and she was afraid of him, and he wasn't good to her. When we got to the other end of the road the cracker was there, and saw Lottie, said he 'knowed she would go on the track till she met me, and that he didn't spend any time hunting for her.'

"He sold his outfit, got half drunk the next day, and came and wanted me to give him fifty dollars for his share in the girl. I told him I would give him the money, if he would get sober and tell me all he knew about Lottie and her mother. He said he would do it, but that I would find it a greater and wickeder story than I had ever read of in a book. I arranged that he should meet me the next morning and tell me the story.

"That evening I made arrangements with the sisters of a boarding school to take the girl until she was 15 years of age, and coming to my boarding house, through the yard, saw a lot of lanterns and a crowd around one of the switch engines; I went over to see what was the matter, and found that they had run over and mangled a man. I held a lamp down to the upturned face—it was my Cracker—Lottie's story was sealed up, and the key cast into the unknown ocean of eternity.

"I at once adopted her legally, filled out the name her mother had written in the book to Lottie M. Thompson, and she has now forgotten that she ever was anything else. Her influence made a man of me again. I 'braced up,' changed my appearance and name back from 'Hogskin' to 'Cy.,' and was happy, devoting my time and attention between runs to my new daughter."

Thompson picked up his cigar, lit it, and leaned back in his chair to watch the smoke curl toward the ceiling. Mrs. A wiped her eye on a corner of her apron, and I kept still.

"Whatever became of old man Hodges, John?" asked Thompson, by way of turning the subject. Hodges was our old general manager.

"Dead these five years," said I.

"Died pretty poor, too," spoke up Mrs. A., "lost money every move he made, late years, lost his wife, then the old homestead, and then his position; he was keeping books before he died. Clara supported him towards the last."

"Who did she marry?" asked Thompson.

"Nobody; never married, and it's a shame, too," (that sounds just like a woman). "Clara would have made some man a good wife, she's just as nice as she can be. She sews, why, she made this dress I have on, lives over at Newton, just opposite the depot;—but Mr Thompson, you never told us where you got your little girl—the one you call Dolor—that's a curious name."

"I forgot that, Mrs. Alexander. Her story is shorter and more mysterious than Lottie's," said he.

"Shortly after I found Lottie, my care of my Roger attracted the old man's attention, and he made me master mechanic. I held this job a couple of years or more, and was then made superintendent, and finally general superintendent. I held this position until six years ago this month, when our general manager died, and I was chosen to succeed him.

"Shortly after I took charge we acquired control of some other lines that placed in our hands quite a 'system,' and I went over all the lines to inspect and report on them. Time was limited, and I must be back in headquarters within a given time that called for my car traveling all night, and the next day. My engineer was worn out, and there was no one available to relieve him, so I agreed to run the engine over one division myself, letting the engineer sleep in the car.

"It was a dark night, but in nice weather, and we made very fast time, and I am ready to swear that I never took my eyes off the track for a minute, and did not see an obstruction. After running fifty six miles we stopped for water, and I started out to oil a little, remarking to the fireman that it seemed like old times. In going around the pilot I was horrified to find blood on the flag staff on my side, and a piece of torn black lace in a sliver on the pilot. In going back to the cab something white attracted my attention, laying on the running board between the cab and the air pump—it was a large wicker basket with a cover; I took it down carefully, and opened it, and there, sleeping peacefully, with her thumb in her mouth, was a girl baby five or six months old. She was neatly dressed, and on a button of her little slip was a bit of paper, on which was written the single word 'Dolores'—we call her 'Dolor.'

"I side-tracked my special till daylight and stopped all trains, then we went back over that fifty-six miles of track, but there was nowhere any sign of an accident, and none has ever been reported. Whether we killed that child's mother that night, or whether the child was put on the running board, and left to its fate, I never knew. The presence of the paper with the child's name would indicate the latter. Certainly it must have been there a long time, for the meshes of the basket were full of cinders. I adopted her at once, and she is a little jewel, too.

"Romantic, wasn't it?" said Thompson, knocking some ashes off his vest.

Then Mrs. A. wiped her eyes, and went up to bed, saying good night.

The next morning Thompson asked Mrs. A. to keep his girls for a day or two—which she was more than ready to do.

"Going to town with me, Thompson?" said I.

"No," said he, "I'm going to Newton."

What Will Cure Thoughtlessness.

Late in March there was an accident on the Staten Island road, a locomotive and one passenger car plunging into an open draw. The engineer claims that he did not see the danger signal until too late, being busy with something on the engine. Accidents of this kind are quite common, and only go to prove that, in addition to the regular signal, an auxiliary audible signal should be used to call attention. The *Railroad Gazette* has the following on the subject:

"This drawbridge accident was similar to that at Oakland, Cal., a year ago, except that in this case no one was killed or injured. There are, however, three points worthy of mention in the Port Richmond case. First, the engineman was intending to resign within a day or two to take a better job. No one can assert that the unusual matters on his mind exerted an undue pressure to drive out thoughts of his immediate duty, but cases like this and like that of the English runner, not long ago, who was worrying about a sick wife at home when he let his train run away, inevitably raise the question, How can runners with preoccupied minds be made to lie off? This is an obscure and ineradicable difficulty, but it is by no means certain that nothing can be done to mitigate it. Trainmasters who habitually permit men to work excessive hours when there is a rush of freight are responsible for *not* mitigating this evil, for their practice directly encourages men to take the risk of going upon an engine when their minds are unfit for work. A derailing switch is one radical cure for absent-mindedness. Second, the fireman was a temporary one, taken from the shop, and had not been examined. Examination rules must be rigid or the single dropped stitch will turn out to be the most important in the whole chain. Third, the drawbridge exists for the sole benefit of a single lumber yard. Drawbridges that are opened every day cause blasphemy enough, for the cases in which a scow-full of garbage hinders a thousand passengers are increasingly common, but here is a case where hundreds or thousands of passengers must daily ride over a specially dangerous spot, because a boatman wishes to go through once or twice a week. Quite likely the infrequency of the danger signal at this point was a factor in the runner's failure to observe it, but that only further illustrates the unnecessary burden placed upon a railroad by the multiplication of danger points."

J. H. Agnew has made such a record as superintendent of machinery of the South Carolina road in the last two years that he has been chosen as general superintendent. Mr Agnew is a young man yet, a progressive, earnest man, who has come up through the machinery department, and knows his business from A to Z. He will be general manager of some road in ten years—unless the world comes to an end.

The Erie has issued a pamphlet entitled *Summer Homes*, that is unique. It has a brief description of all towns on the road, within 150 miles of New York. Tells the distance, fares, population, and points of interest, and gives a list of hotels and boarding houses with their capacities, prices, etc. All this is done for the purpose of interesting people and building up a business for the road, and there are no advertisements in the book. It is a credit to the passenger department

CONTENTS

Circulation Liars—For Advertising Only.

The majority of railroad papers of this country are published for advertising purposes absolutely and solely. Stop their advertisements and they would starve in a month. Their whole effort is to please their advertisers and make them, and prospective advertisers, believe that railroad officials can hardly operate their departments on days that their particular paper does not show up.

They distinctly disclaim any subscribers or readers among the train or enginemen, and sneer to advertisers about this paper as an "employes' paper," of no use to anybody who has goods to sell.

Not long ago the *Railway Gazette* published an advertisement claiming to have more railroad officers as subscribers than all other papers combined. This stirred 'em all up, and some want committees to investigate, and others want to bet, and still others say the *Gazette* lies.

Now if the *Gazette* had said that they had more subscribers among the men who daily handle the trains and locomotives of this country, or the men who repair or build locomotives, not one of its *esteemed contemporaries* would have noticed it in the reading columns, and every advertisement hunter would have held the fact up to dealers and manufacturers as a reason why they should *not* advertise in it.

Facts are facts, and we do not believe we can be successfully disputed when we say that any one of the railroad papers would do anything on earth that a paper dare do to get and control advertising; they will show up and endorse, either by actual words, inference, or silence, any device that is manifestly of no earthly use to a road, if the promoters will only advertise. That is what they are publishing papers for.

Most of the papers make a specialty of one thing, and are pretty good in that line; thus the *Gazette* keeps a very good record of new roads, changes in name and in management, and sloshes around in a little of everything in the railroad line. The *Age* publishes a full record of accidents and financial news of interest to stockholders. The *Review* pays considerable attention to rate wars, but is, of late, the best edited weekly in the field. The *Master Mechanic* has a list of railroad offices, and has considerable in it about locomotives and cars, evidently written by men more familiar with the theoretical than the practical side of the subject, and the *National Car and Locomotive Builder* is the only one, other than THE LOCOMOTIVE ENGINEER, publishing matter of practical use to the men in the motive power and rolling stock departments. Yet they are careful to announce emphatically that "employes" don't take their paper.

There is a local railroad paper published at St. Paul that devotes a little of its space to cussing and discussing State railroad commissioners, rate wars, condemning strikes and strikers, and publishing advertisements. It has taken a hand in the fight, and calmly stands up and says who and which are the *leading* railroad papers. We quote:

"The fact is, of course, that the claim of the *Railroad Gazette* is ridiculous. The *Gazette* is a good paper—not as good as it has been nor half as good as it thinks it is—but we doubt if its circulation is any bigger than that of any one of the other papers mentioned, while it is quite certain that the combined circulation of any two of the half dozen leading railroad papers (which are the *Gazette*, the *Review*, the *Age*, the *National Car and Locomotive Builder*, the *Master Mechanic* and the *Northwestern Railroader*) will largely outweigh the circulation of any other one. To talk of any one paper having more subscribers than 'all others combined' is pure foolishness and pure falsehood.

"When it comes to a 'show down' of subscription lists the *Northwestern Railroader* itself will be on hand with a few surprises."

Mr. Forney's paper is not "in it." Forney does not run his paper exclusively to control advertising. THE LOCOMOTIVE ENGINEER is not "in it"—those dirty, greasy engineers read it.

Now the facts are these. Two of these "leading papers" cannot prove an honest, paid circulation of 3,000, and not one of them can show 4,000, and all run a big "free list." We do not know what circulation Mr. Forney's *Engineering Journal* has, but will venture to say that it is at least equal to any of those in the fight.

THE LOCOMOTIVE ENGINEER'S monthly edition of 16,000 copies does not all go to railroad officials, but they do get over a thousand of them.

The paper is published in the interest of the men, and to aid in supplying better service on the road and in the shop, and we don't want any man to take it who won't acknowledge that it has given him information worth ten times its cost in expediting his work, and making him a more useful and better posted man.

There is an era of education and improvement just opening up among the rank and file, and this paper is devoted to widening and developing that very field. THE LOCOMOTIVE ENGINEER *is* an "employes' paper"; it aims to make them better engineers, firemen or machinists, and claims that in so doing it is worth ten times as much to any road as any of its advertising contemporaries.

Next January will see a substantial increase of our list, and if every advertiser quits we will go on, and prosper. But advertisers won't quit; they will see the cat in this puzzle picture pretty soon, and kick out the advertising fiend who argues against a paper because it is read and respected by the bone and sinews of our roads—the men on the locomotives.

THE LOCOMOTIVE ENGINEER has 212 subscribers in Australia; have any of the other papers got that many in one of our own States? THE LOCOMOTIVE ENGINEER has 665 subscribers in the State of Michigan; 771 in New York, and over 500 in each of eight other States; it goes to every State and territory, and to many foreign countries—there is a neat little club of nearly a hundred at the City of Mexico; there is a club at Colon, Isthmus of Panama, and another at Solmgpur, India.

When the L. E. shows it has an audience, and many of the seats in the bald-headed row are occupied by railroad officers.

These circulation liars—for advertising only—make us weary, exceedingly weary.

Under the title of "The Newspaper Affidavit Liar" some unknown poet has left this crystal—it hits the point exactly:

The snake liar and the fish liar, both bowed in their gray old age,
Came traveling back from their journeys wide, from their earth-wide pilgrimage;
A tear drop stood in the snake liar's eye, and the fish liar groaned in pain,
And a death-like look of infinite grief came over the face of the twain.

"I cannot compete with the modern liar,' the sad-eyed snake liar said,
"In its limitless length and breadth and depth, and I wish that I were dead;
For I stand rebuked with a shame-faced look 'neath the triumphant gaze of the eye
Of the newspaper affidavit liar, with his circulation lie.

"For the snake liar and the fish liar and the horse liar own his sway,
And the easy going liars who work by the job, and the liars who work by the day;
The traveling liar, old inhabitant liar, and liars of low degree,
And liars who lie for the fun of the thing, and liars who lie for a fee.

"The horse liar, the peach crop liar, the sea-serpent liar and all,
With the wide, untraveled wastes of cheek and their soul less seas of gall,
All bend the knee to the sceptered sway of this crowned and peerless one,
And the father of lies looks tenderly down on his most accomplished son."

Book Review.

THE OFFICIAL RAILWAY LIST. Railway Purchasing Agent Company, Chicago. Price, $2.00.

This little book contains the names and addresses of all the operative officers of the North American railways, the names of traveling representatives of the different railway supply houses who advertise in the book and there are few who don't. The book is a handy size to carry, and is of great value to men who require a work of this kind.

CAR LUBRICATION. By W. E. Hall, B. S., M. E. John Wiley & Sons, 53 East Tenth Street, N. Y. Price, $1.00.

This is a neat little work by a practical man, assistant master mechanic at the Altoona shops of the Pennsylvania. The work treats of the design and material of journals and journal bearings, as well as the means of lubricating, and the value of the different kinds of lubricant. The book is especially valuable to men in charge of car repairs and maintenance.

ASKED & ANSWERED

(50) T. R. S., Brooklyn, asks:

If you plug up the hole in top of Richardson's balanced valve will it make any difference with the balance? *A*.—The hole is put there to allow any steam that may leak through the packing to escape to the exhaust; if it were closed a very slight leak would put as much load on the valve as there would be on a plain valve.

(51) Cal, Barstow, Cal., asks

How can I ascertain the amount of coal on a platform by measuring the same? *A*.—A bushel of bituminous coal weighs 76 pounds, and lump coal weighs about 50 pounds per cubic foot. By measuring your pile you can easily figure pounds and bushels. In measuring an uneven pile of coal, it is best to measure from a point where the coal is near maximum thickness and average the ragged edges, and estimate separately.

(52) Fireman, Arkansas City, asks:

1. Kindly state in your next issue how to chain front wheels of engine trucks in case of broken flange, wheel or broken journal. 2. What is the pressure in cylinder per square inch when steam gauge shows 140 per square inch; and oblige. *A*.—1. If enough of the broken wheel remains on axle so that it can be blocked, and the pair slid, do so; if the axle is broken, jack up the front of the truck and chain it up to the main frame of the engine. 2. The mean effective pressure (the average pressure) in the cylinder is figured as about half that in the boiler.

(53) S. & H., Wilmington, N. C., write.

Will you please inform two of your readers whether there is any set of rules for fitting with hydraulic pressure? There is no rule in our shop, and it's guess work. We refer to crank-pins, both steel and iron, also, driving axles, etc. Please give us some general information on this subject, and greatly oblige. *A*.—The general rule is to press axles into wheels with a pressure of nine tons per inch of axle diameter; thus, a six-inch axle would be forced home with a pressure of 54 tons. Crank-pins are forced home, when the hole is true and smooth, with a pressure of six tons; but if the hole is rough or uneven, this pressure is increased to as high as nine tons. A few shops make nine tons per inch of diameter the limit for axles and pins—no difference being made between steel and iron.

(54) B. H., Gordon, Pa., asks

1. What causes the right glass in a Nathan lubricator to break? We have one engine that it is impossible to keep a glass in. *A*.—If the right glass breaks more than the others, there is some local cause that puts an extra strain on the glass. Look for it. 2. Suppose you break both eccentric blades on one side. If you take off the back-up blade on the left side and put it in place of the right go-ahead, will the engine go? *A*.—Yes, if full-stroked slowly; but it would be quicker, safer and easier to take down the main rod and run on one side. 3. Does water, carried in the top gauge cock, cover the flues at front end of a Cushing 72" boiler on a grade of 120 feet per mile, wheel base of engine 51 feet? *A*.—You have no engines with that wheel base, you are counting the tank. Top gauge should cover heating surface with water on any grade the engine has to stand on. Get length of boiler and height of gauge above tubes, and figure it out yourself. There are 5,280 feet per mile. When there is water in sight in the glass, or at the lower cock, a man ought to feel safe about his heating surfaces on any grade; if not, the gauges should be raised.

(55) G. Cochener, Waco, Tex., asks

1. What about side rods pounding? Some of the boys here say they do, others say not. If they don't pound, what is the use of keys on side rod straps? *A*.—Side rods will not pound as a main rod will, but will rattle and chuck sideways very hard. Most of the trouble is caused by their being keyed too long or too short, so that they force the pins to or from each other when on the rigid points—the centers—this sounds like pounding. Keys are employed more to get the rods the proper length than to keep the brasses close to the pin. 2. What causes an engine to strip her side rods in slipping on a hill after running all right? *A*.—Side rods give motion to the second pair of wheels only after the first pair have used up as much as they can without slipping—they get what power is "spilled over." If the forward pair slip from striking grease or some such cause, the side rods are called upon to transmit the full power of the engine, and often fail to do so. Rods are very often broken, when keyed too short, by the sudden dropping of one wheel into a depression just as the side rod is on the center. The distance between the pins causes a rupture, and the engine "strips herself." Side rods should be keyed loosely on the pins on dead centers when the engine is hot, and ought to be loose enough on the pins to rattle. There is little danger of a side rod letting loose that will rattle in service.

One of the N. Y. Central's new passenger engines recently pulled a seven-car train, weighing, exclusive of passengers, 515,700 pounds, from Buffalo to this city, 440 miles, in eight hours and thirty-four minutes, almost fifty one miles per hour. The engine and tender weigh 201,500, this was no special, or race, but the every day train a little late.

Progressive Examination of Locomotive Engineers and Firemen.

By John A. Hill.

[Final Examination, after Three Years.]

Q. Suppose you were called to-night to go out in charge of an engine, what would you do on arriving at engine in the yard?

A. First look at the crown sheet and flues; satisfy myself about the water level; see that there was fuel and water on the tender, that her headlight and signals were in shape, and that she was supplied with necessary tools and sand; then inspect her machinery and oil around.

Q. Suppose you were to take the engine over the road without a train?

A. I should report for orders, and examine and check up the train register.

Q. Suppose you get out ten miles, between stations, with your train, and break down, what is your first duty?

A. To protect myself, both front and rear, against approaching trains.

Q. Suppose there was no train due coming toward you for some time, or you had the absolute right of the road—is it still necessary to flag?

A. Not always; still it is an additional safeguard, and takes little time and trouble to put out a flag or torpedoes.

Q. How high would you carry water in the boiler?

A. So that there would be steam and water show at the top gauge cock, or what is known as a "flutter."

Q. Why not carry solid water in the top gauge?

A. Because it is then uncertain how much water is being carried, and too much water is dangerous, in that it leaves very little steam room, and causes water to be carried over into the cylinders, cutting valves and packing, endangering the heads, and throwing water and ashes over the engine.

Q. Would there be exceptions to this rule?

A. Yes. In approaching a summit, enough water would have to be carried so that the engine could pitch over without uncovering her crown sheet.

Q. Suppose, after pitching over, you had only a "flutter" in the lower gauge cock, what would you do?

A. Keep supplying water, but instruct fireman to keep the fire bright, to prevent flues from leaking.

Q. Suppose your injectors stop working on the road, what would you do?

A. Stop, see if there was water in the tank. If the instrument would prime I should conclude that the trouble was in the injector, or the check, and attempt to fix them; but if it would not prime strongly, should take down hose, clean the strainer and wash out hose by opening the tank valve.

Q. What about your water level all this time?

A. Should watch that; open fire-door in the start to prevent popping off, and if water got low, should bank fire. If I had a pump, would take down and examine valves.

Q. Why is it that left-hand injectors and pumps are so seldom in working order?

A. Because they are neglected, not used, and not kept packed. They should be used every day.

Q. What is the difference between foaming and priming in a boiler?

A. Foaming is caused by oil, alkali, soda, or any such foreign matter that causes the water to assume the form of suds. Priming is when the whole or a large part of the water in the boiler lifts, caused by want of space for the steam formed to free itself, generally occurring when a boiler is being forced very hard.

Q. How can you usually detect foaming? and what would you do if your boiler commenced to foam on the road?

A. Foaming is generally indicated by the appearance of water at the stack. The valves are dried and pull the lever, and often valves or pistons will squeak or groan. When this occurs I would at once shut off throttle and let the water settle, to ascertain if boiler was actually foaming or had been over pumped. If there were three solid gauges of water, would conclude that there was no foaming; if water sank to or below lower gauge, should decide that there was foaming, and should keep up supply of water. If boiler had a surface blow-off cock, would use it, supplying extra water for it by the left injector or pump; would open cylinder cocks, to prevent damage to heads, reducing speed if necessary; should shut off occasionally, to be sure of my water level. In this way bad water can usually be gotten rid of. At first water station would try and have enough water so as to be enabled to blow out a couple of gauges of water.

Q. Suppose that you discovered that, through accident or design, there had been oil put in your tank?

A. Should proceed just as I have said until a water tank was reached, then would take water, allowing tender tank to overflow for a long time; this would carry off any substance that would float. Using the heaters would materially assist in raising the oil and sending it back to manhole.

Q. Suppose you found that you couldn't shut off the blow off cock, or you broke it off?

A. Should knock out fire at once, disconnect the engine, and send to telegraph office for assistance.

Q. In this case what would you disconnect?

A. Would take down the main rods and disconnect valve stems.

Q. Suppose you found that the tank valve had come off the stem and dropped into the seat, preventing the injector or pump from getting water, how would you get it out without stopping?

A. Put on the heater strong enough to blow it out of the seat; heater should be shut off quickly, to prevent rupture of hose.

Q. Suppose you were stopped on the road, and found that the water had dropped out of sight, what would you do?

A. By opening the throttle, or blower, the water level can sometimes be raised, as in working; if found it still low, would deaden fire by throwing water on it, shaking it out, or covering it with fine green coal.

Q. Suppose you found, on the road, that the throttle was disconnected and open, what would you do?

A. Reduce the pressure, so that I could handle the reverse lever safely, if the train had hand brakes, would notify the crew and ask them to act promptly; if I had air, would use it carefully, to avoid breaking in two; would take train to first telegraph station and report condition to headquarters.

Q. Suppose it became disconnected while closed?

A. My action would be governed considerably by the circumstances; would at once protect myself against approaching trains, send to nearest telegraph office for assistance, fill the boiler well up with water, knock out the fire, and blow off steam, unless, in very severe winter weather, I would thus endanger freezing up. If near division roundhouse on busy line, would disconnect and prepare to be towed in. If it was not a busy line, and no trains would be badly delayed, would take up dome cap and try to connect up the valve again.

Q. Suppose a flue got to blowing very badly?

A. Would plug it up.

Q. Suppose the whistle or one of the pops blew out of dome cap?

A. Would plug the hole with a wooden pin, tying it in with the bell-cord, held by a wooden lever.

Q. What would you do first if a check valve were knocked off?

A. Kill the fire, to protect crown sheet.

Q. Suppose when your throttle was closed you could not prevent some steam from getting into cylinders, what work would you report?

A. Should be sure the steam did not enter through the oil pipes before reporting a leaky throttle.

Q. How could you tell a leaky throttle from a leaky dry pipe?

A. The dry pipe will generally leak water if boiler is filled up pretty well.

Q. How would you go to work to disconnect an engine that had broken a steam chest?

A. Take up the chest cover and fit pieces of board over the steam passages to the chest, if they were on the cylinder casting, build up on top of them, using wood, the valve, or anything handy for the purpose; then bolt the cover down hard enough to prevent steam from entering the chest; disconnect the valve stem, take down the main rod, shove the piston ahead, and cramp the gland enough to hold it. If the steam pipe was connected direct to chest, and there were studs enough, or enough of the chest left, would try to block up the steam-pipe opening with wood and hold it in by fish plates and bolts.

Q. Why wouldn't you cover the ports with the valve?

A. Because no steam can enter the cylinder.

Q. What usually ruptures steam chests and covers?

A. Excessive pressure, generally caused by reversing the engine when running fast. This makes air-pumps of the pistons that fill the chests, steam and dry pipes, finally breaking the weakest.

Q. In case it becomes necessary to reverse, how can you prevent rupture of chests?

A. By opening the throttle it will be impossible to get more than boiler pressure in the chests, and they are designed to carry that.

Q. Suppose you struck something that demolished one cylinder and chest, how would you disconnect so as to run in?

A. Take down main rod, take valve stem off the rocker, or tie up the end so that it could vibrate; open the front end, loosen a steam pipe, and insert a piece of sheet metal in the joint, and tighten it up, or take out pipe entirely and bolt a piece of board over T-pipe.

Q. What would you do if you broke the reach rod?

A. Would fit blocks in top of link slots, so as to hold links as high as I wanted to cut off, as I could not reverse, would have to run carefully.

Q. If you broke a lifter?

A. Would fit a block in link, as for broken reach rod; take off lifter, engine must not be reversed in this condition, as one side would be in forward gear and one in back.

Q. If a piston rod broke and knocked the forward head out, how would you disconnect?

A. Place valve over center of ports, disconnect the stem, and fasten it there by cramping the gland, or blocking, if a metallic packing was in use.

Q. Why wouldn't you take down the main rod?

A. Because it could do no harm by moving the piston.

Q. Suppose you had an engine with only one pump in working order, and you broke a valve on that side, how would you get in?

A. Would cover ports with a smooth board, lay valve on top, block it from moving in chest, and block above enough to hold it down; put down cover, disconnect valve stem, take piston out of crosshead, and let main rod remain up, to work the pump.

Q. What would you do if you blew out a piston gland, breaking off one lug and one stud?

A. Would take out most of the packing, so as to let gland clear into stuffing-box, and bolt the lug solid to head by remaining stud.

Q. Suppose you broke off both lugs?

A. Engines have been run this way by wrapping the outside of gland body with cloth, a piece of overall stuff or signal flag, and forcing it well into the box by a jack, or by using wooden blocks between it and the crosshead. In case the body of gland was broken, would disconnect that side.

Q. Should you slip the right back motion eccentric on the road, how would you reset it?

A. Would place the engine on exact dead center on right side, place the reverse lever in full forward gear, and make a mark on the valve rod at the stuffing-box gland; then place the reverse lever in full back gear, and turn the slipped eccentric until the mark on valve rod came to its original position, being careful to see that the full, or throw of the eccentric, was in position nearly opposite the forward eccentric, then secure it there.

Q. In what way does the mark you made on the valve rod, while in forward gear, aid you in setting the slipped eccentric?

A. The forward motion eccentric being in proper position, by placing the reverse lever in full forward gear the valve is brought into proper position on the ports, and the mark gives the position of the valve when the back motion eccentric is in its proper position, thus setting the slipped eccentric by the good one.

Q. Should a valve yoke break, how would you test in order to determine which side was disabled?

A. Would first place the engine at half stroke on the right side, and admit a little steam to the cylinders, then move the reverse lever from back to forward motion, and if the steam could be shifted from the back to the forward cylinder cock, would conclude that the right yoke was good, and would test the left side in the same way.

Q. Why would you place your engine at half stroke on the side you wished to test?

A. In order to get the full movement of the valve over the ports on that side.

Q. After locating the broken yoke, how would you disconnect?

A. Would take off the steam chest lid, place the valve over the ports, and block it there securely, replace the lid, take off the valve rod, take off the main rod, block the crossheads, and proceed with a little over half a train to next telegraph office, report, and give judgment as to whether the engine would take entire train to its destination.

Q. Should you blow or break out a cylinder head, how would you disconnect?

A. First, take off the valve rod and close the ports with the valve, and secure it by cramping with the stuffing-box gland; take off the main rod and block the crossheads.

Q. How would you proceed to block the crossheads securely?

A. By placing crosshead at one end of stroke, and placing a block between end of crosshead and guide blocks, to prevent it from moving, would secure the block to the guides with cord to prevent any danger of its falling out.

Q. Is it always necessary to so securely block crosshead?

A. No. Where possible, the piston should be placed at one end of the cylinder and the valve placed at same end of the chest, so that the pressure will securely hold it in place.

Q. Does it make any difference which end it is placed at?

A. On engines having a driver back of the guides the forward pin will sometimes strike the piston key if the crosshead is blocked back; in this class of engines it should be blocked ahead or key removed.

Q. How can you tell the difference between valves blowing and cylinder packing blowing?

A. Valves blow more steadily than does cylinder packing. If you put reverse lever in center, and open throttle and cylinder cocks, you can test the valve; if they are tight, steam can only blow from one cylinder cock out of the four. If, in starting slow with cylinder cocks open, you watch the crosshead as it leaves the ends of stroke, you can at once locate the blow, both by sight and by hearing.

Q. In case you located it in right piston, what would you report?

A. Examine cylinder packing, right side.

Q. Why do you say cylinder packing? it's the piston that is packed.

A. To avoid confounding it with the piston rod packing.

Q. Suppose you broke the back-up eccentric blade on one side?

A. If there was no danger of link swinging against other parts of machinery would run ahead in full stroke with only the back-up blade down.

Q. Why not hook up?

A. Because that would cause the eccentric to swing the link around the link block pin, instead of moving the pin back and forth.

Q. Should you break a forward eccentric strap?

A. Take off both, cover the ports, and take down main rod?

Q. If you broke a lower rocker arm?

A. Would take down main rod, cover ports with the valve, and, if the piece of rocker hanging to link block pin could not strike anything, would let it alone.

Q. What if you broke the top rocker?

A. Would do the same, blocking the broken piece where it could not be struck.

Q. Suppose the pin in link saddle broke off?

A. Would take down hanger, block up on top of link, just as if the hanger or tumbling shaft was broken.

Q. What would you do if both front cylinder heads were broken?

A. Disconnect both sides.

Q. What would you do if one of the bridges between the ports should break out?

A. Cover all the ports with the valve, fasten it, take down valve stem, main rod, and block crosshead.

Q. What would you do if the soft plug blew out of crown-sheet on the road?

A. Protect train and disconnect both sides.

Q. How about the fire?

A. Water and steam from the plug would put that out.

Q. If you broke a crosshead?

A. Take down main rod, cover ports, and disconnect valve stem.

Q. Should you break the back section of a side rod on a six wheel connected engine, what would you do?

A. Would take off both back sections, and run in with main and forward wheels connected, with lighter train.

Q. Should you break a forward section, how would you disconnect?

A. Would take off all side rods and run in without train.

Q. Should you break a back or front section of a side rod on a consolidation engine, how would you disconnect?

A. Would take off both back or front connections, as the case may be, and run in with two-thirds of train.

Q. Should you break a middle connection on a consolidation engine, how would you disconnect?

A. Would take off all side rods and run in without train.

Q. Should you break a main crank-pin close up to the wheel, how would you disconnect?

A. Would take off all side rods, and the main rod on disabled side, and run in without train.

Q. Should one of the forward tires on a ten-wheel engine break, how would you manage?

A. Would jack the wheel up the thickness of the tire, take out the oil cellar, and cut a block to fit the bottom of the box and journal sufficiently thick to hold the axle up in its place when resting on the pedestal brace; would then run in without disconnecting, provided the rod had not been bent or damaged by the broken tire; would take in full train.

Q. Should you break a main tire, how would you manage?

A. Would first send messenger to nearest telegraph office and ask for assistance. Would then block up the axle and wheel the thickness of the tire, slack off the side and main rod keys, and run in carefully without train.

Q. Should the back tire break, how would you manage?

A. Would take off the back section of rods, block up the axle, run very carefully—especially around curves—to nearest telegraph office, report, and ask for orders.

Q. What would you do in case you lost off the back driving-wheel tire on an eight-wheeled engine?

A. Would block up wheel, take down side rods, and run very carefully to first telegraph station.

Q. How fast would you run in that condition?

A. On straight track, five or six miles per hour; on curves and over switches, very slow.

Q. Would it be safe for you to back up under those conditions?

A. No; there would be nothing to guide the engine.

Q. What would you do in case the back tank truck broke down so that you could use no part of it?

A. Would put a car truck under, if available; if not, would jack up tank and put forward truck back, chaining front of tender to frame of engine, would lighten load on tank as much as possible and run in light.

Q. What would you do if an axle in engine truck of an eight-wheeler broke?

A. Jack up that end of the truck and chain it to main frame of the engine.

Q. Suppose the front axle under tender broke?

A. Would jack up truck frame, and chain it to a cross-tie, or rail, laid across top of tank.

Q. Suppose you broke a wheel under the tank—say you lost about a third of it?

A. Would use a tie or piece of rail to block that pair of wheels from turning, and would slide them to the nearest telegraph station.

Q. Should you break a front driver spring or spring hanger, what would you do?

A. Would take the spring out, run the back drivers upon wedges to take the weight off the forward drivers, and block between the top of driving-box and frame; then run the forward drivers upon wedges to take weight off the back drivers, pry up the end of equalizer and block it level.

Q. If a back spring?

A. Would proceed same as in case of front spring, but in reverse order; would not take spring out if there was no danger of its falling to pieces, as it would consume too much time.

Q. What size wedges would you use to run your drivers upon, and how would you get them when needed?

A. I would use wedges of oak, about three feet long and four inches square, eight or ten inches of the top of wedge straight for wheel to rest on, and would see that I always had them on my engine ready for use.

Q. Suppose you were running an engine with a pony truck, and broke the center pin at front of long equalizer, what would you do?

A. Put in a new pin, if I had it, and could do it quickly, if not, would jack up front of engine and block down the cross equalizer at back of long equalizer, enough to prevent forward end from striking pony axle, and proceed with full train.

Q. In case of failure of water supply in tank under ordinary circumstances, what would you do?

A. I should leave my train and run to a water tank, except it was practicable to obtain a supply from some pond or stream near by.

Q. In case of snow blockade, and water low in tank, what would you do?

A. I should shovel snow in tender, and in this way make water enough to keep engine alive.

Q. Tell me how you would start a heavy train.

A. Should pull out easily, starting one car at a time, getting all in motion before opening engine out—this to avoid breaking train in two.

Q. After the train got to going nicely what would you do?

A. Hook the reverse lever nearer the center

Q. What good does that do?

A. Steam is worked expansively.

Q. How?

A. The steam is admitted to the cylinder for a shorter time, and the supply is then shut off, allowing that imprisoned in the cylinder to be expanded down to a lower pressure, thus doing work

Q. What do you mean when you say "cutting off in six inches"?

A. That steam is admitted for six inches of the travel of the piston, or rather that when the piston has gone six inches from the end of the cylinder the valve has closed the port, and what steam is then in the cylinder is used expansively.

Q. What is lead?

A. The opening of the port at the beginning of the stroke.

Q. Does it increase by hooking up?

A. Yes; the earlier the cut off, the more lead.

Q. What is lap—outside lap?

A. The distance that the edges of the valve overlap the outside of the steam ports. If the valve is two inches wider than the ports, it is said to have one inch lap—an inch on each side.

Q. What is the object of lap?

A. Lap is given for the purpose of enabling the engine to work steam expansively. Steam is held in the cylinder, and is expanding while the valve is traveling the distance of its lap.

Q. What is inside lap?

A. The distance that the inside edges of the exhaust cavity of the valve overlap the outside edges of the bridges when the valve is in the center

Q. What is its use?

A. It delays the exhaust, and therefore gets a little more work out of the expanding steam. It is not used on fast engines, as it is then desirable to get rid of the steam quickly.

Q. Could you change the lap or lead of your engine by adjusting the lengths of the eccentric blades?

A. No. Lap can only be changed by adding to or cutting off part of the valve. Lead can only be changed by moving the eccentric on the shaft.

Q. What can be done by moving the blades?

A. The valve can be made to travel evenly each side of the center of seat, that is all.

Q. If the lead can only be changed by the position of the eccentric on the axle, how is it increased as the links are hooked up?

A. The whole motion is moved back around the eccentric, instead of the eccentric being moved ahead through the motion, which amounts to the same thing.

Q. Is it your duty to adjust this motion?

A. No. I am to run the engine, and report such work at the roundhouse

Q. What work about the engine should you do?

A. I should adjust the wedges, keep the rods properly keyed up, all stuffing-boxes packed, and care for the headlight.

Q. How should wedges be set up?

A. They should be set up while engine is under steam, and be adjusted tight enough so as not to thump or knock, and yet allow the box to move freely in the pedestals. This is best done by moving them up tight, and then pulling them down enough to relieve the side pressure. Much damage can be done by getting them too tight and by adjusting them too often.

Q. How would you go about setting them up?

A. Would place the engine at half stroke on the right side, block the left wheels, admit a little steam, and thump the boxes hard away from the wedges. Would then get under, and put the wedges up solid with a short wrench, and make a side mark on the pedestals at top of wedge, then draw them down equally one-eighth of an inch; go over the left side in the same manner.

Q. How would you keep up or adjust the side rods of a ten-wheel or a consolidation engine?

A. Would place the engine on a level and straight track, and on a dead center, then slack off all keys on that side, would then key the main connection first, leaving it sufficiently free on the pin to be moved laterally by hand, then adjust the front and back ends in the same manner, before starting to key up rods, would see that wedges were properly set up

Q. Why would you place the engine on exact dead center, and begin by keying the main connection first?

A. In order to insure keying the rods of proper length to allow them to pass the dead or rigid points without strain.

Q. Can the side rods be keyed too long or too short when not standing on dead center?

A. They can.

Q. If too long or too short, at what point of the stroke will the strain be?

A. While passing the dead or rigid points.

Q. What provision should be made in the rods for the uneven movement of the wheels in the pedestals?

A. The brasses should be loose enough on the pins to accommodate the movement mentioned.

Q. How does an injector work?

A. Steam escaping from a boiler has a velocity many times higher than water would escaping from the same sized orifice and under the same pressure The steam used in the injector imparts to the water a measure of its velocity, at the same time giving up most of its heat It is enabled to deliver the feed water at the check at a greater velocity than water would escape directly into the air from the boiler.

Q. What is the difference between a lifting and a non-lifting injector?

A. The lifter has an extra steam jet ahead of the combining tube that draws the air out of the injector, allowing the pressure of the atmosphere to force the water in the tank up into the instrument.

Q. What make of injectors are in use on this road?

A. ———.

Q. How do you make a heater of that instrument?

A. ———.

Q. How should an injector be used?

A. Water should be supplied constantly while engine is at work, and the injector regulated to just supply the boiler.

Q. What brakes are in use on this road?

A. ———.

Q. What is meant by an automatic brake?

A. One that is self-operative under certain conditions.

Q. What is the principle of the automatic air-brake?

A. Air under pressure is supplied to the train, and a sufficient quantity stored on each car to do the braking of that car. This stored air, however, is held in equilibrium by the pressure in the train pipe. A reduction in the train pipe destroys this equilibrium, and the stored pressure, through the medium of the triple valve, sets the brake in proportion to the reduction in the train pipe. Should the train break in two, or any other accident happen that would rupture the train pipe, the brakes on each section would be automatically applied.

Q. What is meant by "straight air"?

A. The term "straight air" is used to designate the original Westinghouse system, which operates the brakes by applying the air pressure from the engine reservoir directly through the pipes to the brake cylinders of cars.

Q. What is your duty regarding air brakes before coupling engine to a train?

A. The air-pump is to be started and lubricated for the trip, maximum pressure pumped up with which to charge the brakes, and those which may be set should be released.

Q. What is your duty as soon as engine is attached to train?

A. First, charge the brakes, second, apply brakes at full force and hold them on while brakemen or inspectors go over train to make sure that all brakes are set; upon their signal, brakes are released; then wait for report regarding number and condition of brakes before starting out.

Q. How would you start your pump?

A. Would start slowly, and increase speed gradually, and thereby not force out the water of condensation, which would be injurious to the pump.

Q. How would you lubricate your air-pump?

A. I would lubricate steam cylinder with cylinder oil, and air cylinder sparingly with a small quantity of engine oil; would not use tallow or lard oils in air cylinder.

Q. Does water accumulate in air reservoir and air pipe? if so, what should be done to remove it?

A. Yes, the moisture in the air will condense and accumulate in the main reservoir, which should be drained off once a week in summer and daily in winter.

Q. How would brakes be applied in making ordinary stops for stations?

A. For ordinary stops the brakes should be applied lightly, by opening engineer's valve, and closing again slowly until the pressure has been reduced on the gauge from four to eight pounds

Q. When are brakes fully applied?

A. Brakes are fully applied when pressure, as shown on the gauge, is reduced twenty pounds.

Q. Should brakes be held fully applied until train comes to a full stop?

A. No.

Q. Why?

A. Because it causes a reaction in the motion of the train, which is very disagreeable to passengers.

Q. How can this be avoided?

A. By releasing brakes gradually before a full stop, so that all the air will be off at the moment stop is made.

Q. If some brakes are sticking after the train has started, how may they be released?

A. If all the excess pressure has been exhausted, or the amount is not sufficient to release brakes, the engineer's brake valve is put at "lap" and speed of air-pump increased, as soon as fifteen or twenty pounds additional pressure has accumulated in main reservoir, brake valve is thrown into releasing position, and kept there from ten to twenty seconds. If this does not release brakes, use the proper signals, calling attention of trainmen to release brakes by hand

Q. What is the maximum air pressure allowed on passenger trains?

A. Eighty pounds

Q. What is the maximum pressure allowed on freight trains?

A. Seventy pounds.

Q. With a passenger train of from twelve to fifteen cars, what air pressure would you keep the brake charged with, and how would you handle the brakes in making a stop?

A. Would carry from seventy to eighty pounds pressure. In making a stop, would apply brakes gently, reducing the pressure from four to eight pounds, as might be found necessary, and then gradually increase the pressure on brakes until train is brought nearly to a stop, without releasing the brakes more than once.

Q. Give the different positions of engineer's brake valve handle.

A. First, releasing position, handle against left-hand stop.

Second, running position, handle against middle stop.

Third, at lap, handle on left of service stop or service stop notch.

Fourth, applying position, handle to right. In the old valve the suddenness of application of brakes depends on distance to which handle is moved to right of middle stop.

Fifth, emergency position, stop to extreme right—only to be used to avoid accident.

As soon as all slack is taken up, would gradually increase the force of brakes as circumstances required, being careful to reduce the pressure on train pipe gradually, so as not to use full braking power until absolutely necessary. The object is to gently bring the slack against the air-brake cars, and to hold the brakes on until the train comes to a full stop.

Q. Suppose you were running this train thirty miles an hour, and, on looking back, found one or two cars at the rear were off the track, what would you do?

A. Shut off and apply air very gently, and call for brakes. If I applied the emergency brake it would very likely cause a bad pile-up of cars, as the brakes would all be ahead.

Q. Given a full train of freight cars, all connected with air-brakes, what air pressure would you carry, and how would you handle the brake in making a stop?

A. Would carry the pressure prescribed for freight trains—from sixty to sixty five pounds. In making stop would reduce pressure slightly, just enough to set brakes over entire train simultaneously, and gradually increase braking power until train is brought to a stop, releasing the brake, after once set, as seldom as possible. If the old style engineer's brake valve be opened wide, allowing the pressure to escape quickly, the brakes on a long train will set on front end some time before those on rear end, causing the cars to jam together with destructive force; then, if the engineer's brake valve be closed quickly, without giving time for the pressure to become equalized throughout the entire train, the forward brakes will become released, resulting in a severe jerk that will, perhaps, break the train in two. In any case, the use of brakes so released is lost. The new equalizing pressure valve automatically takes care of this itself.

Q. Give essential points to be observed in holding a train of air brake cars, while descending heavy grades.

A. 1. Have train charged with maximum pressure before bringing brake into use.

2. Regulating the force of brakes so as to maintain a regular and steady speed of train, also make as long a distance as possible to each application of the brakes. By doing this the pressure is used economically, and the pump is given more time to accumulate the necessary pressure for recharging.

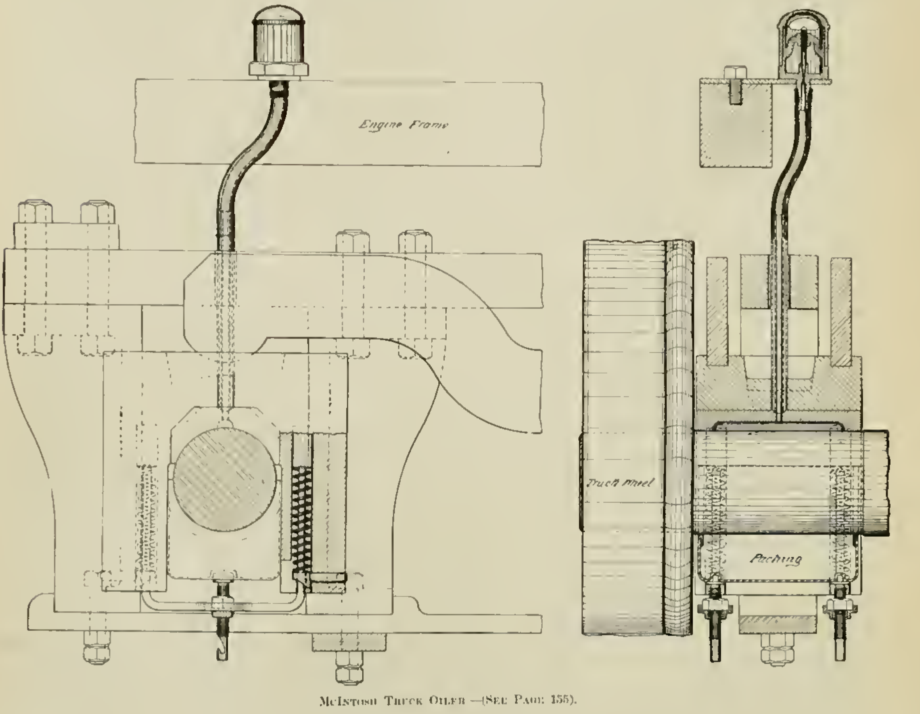
3. Always keeping brake valve in releasing position while recharging, thereby giving the brakes the greatest advantage in recharging quickly.

4. Making no new application of brakes until the full amount of pressure consumed in previous application has been restored.

5. Reducing the pressure, as shown on gauge, not more than fifteen to twenty pounds from one recharging to another, as it would be difficult to replenish the full amount in so short a time. Moreover, when the pressure, as shown on gauge, has been reduced twenty pounds, the brakes have been fully applied, and any further reduction is a waste of pressure.

Q. What is a pressure-retaining valve?

A. It is a small weighted valve, attached by a pipe to the exhaust cavity of the triple valve case,



McIntosh Truck Oiler.—(See Page 155).

Q. How much pressure would you carry on a passenger train of two to four coaches, and why?

A. Would carry same pressure for all passenger trains, regardless of the number of cars; because, with the automatic air brake, each car carries its own reservoir, charged with a pressure to be used for a given stop, and is, therefore, subject to the same braking power, regardless of the number of cars on the train.

Q. Given a freight train of thirty to forty cars, from five to fifteen of these in front end of train are equipped with air-brakes and can be used to aid in stopping the train, at what pressure would you keep the brakes charged, and how handle the brakes in making a stop?

A. Would carry from sixty to sixty-five pounds pressure. In making stop would apply the brakes gently by reducing pressure from four to five pounds; this will be sufficient to let the cars run together, with only a slight jar on any of them.

Q. What is the object of the pressure-retaining valve?

A. The object of this valve is to hold a portion of the pressure in brake cylinder. while the brake is being recharged when descending heavy grades.

Q. What are the two positions for handle of the pressure retaining valve, and what is action of valve in each?

A. Perpendicular, handle of valve is turned down; this allows the entire pressure to escape from brake cylinder when brake is released. Horizontal, handle is turned up; this retains a pressure of ten pounds in brake cylinder, but permits all pressure over that amount to escape when brake is released.

Q. When "double headers" are run, by whom and how should air-brakes be used?

A. By head engineer alone; second engineer closes stop-cock in train pipe under his valve, or, in absence of this stop-cock, he places engineer's valve in the "lap" position, in order to give forward engineer complete control of brakes. Second engineer also keeps his air pump working, and thus has air pressure ready for any emergency, such as failure of air pump on forward engine, in which case forward engineer proceeds as second engineer would in case just stated.

Q. The second engineer having once assumed control of the brakes, how long should he retain charge of same?

A. Until the end of the trip, except in a case of necessity, which may again reverse the operation.

Q. What should always be borne in mind when on mountain grades?

A. To keep train well under control

Q. Should descending at high speeds be practiced?

A No.

Q. Why not?

A. Descending at high speed must not be practiced with any train, for there may come a time when some part of the machinery may fail, and, while practicable to control speed by hand brakes at eight to ten miles per hour, it may be impossible at twenty to thirty miles per hour to regain its control.

Q. Are you familiar with the use of driver brakes on locomotives?

A. ——.

Q. How do you apply them?

A. I apply the brakes gradually, in order not to bring a too sudden strain on the brake rods and lever.

Q Would you reverse your engine when driver brakes are set?

A. I would not.

Q What would be the probable result of reversing engine with driver brakes set?

A. The effect would be to lock and slide the wheels, resulting in flat tires.

Q. In case of failure to any part of air or driver brakes during the trip, what would you do?

A. Report it promptly to master mechanic or foreman for inspection and repairs.

Q. What extra air-brake parts should you always carry on your engine?

A. I should always have on engine one extra hose for connection between engine and tank, and one hose for between tank and car.

LECTURE.

Your weakest point, as shown by this examination, is in . . . . You need to post up a little on that. I do not know just how soon you will be called upon to run an engine, but I wish to impress upon your mind the fact that you must not now, or then, sit down satisfied with yourself because you have passed this examination. The master mechanic or the traveling engineer have a right to demand that you be re-examined, if they think it necessary, should your promotion be delayed for another year.

The mechanical world is moving all the time—keep up with the procession.

It is not particularly necessary that you know how things are made, but do know *how* they work and *why* they work.

Study up every new brake, injector, or other device, so that in case you run across one you will understand its principle and can work it intelligently.

I cannot refrain at this time from calling your attention to the necessity of getting a good reputation on the road, and not a bad one.

If there is disagreeable work to do, do it as cheerfully as possible and with little "kicking." Say you *can't* pull cars after you have tried—never before.

Get the reputation of oiling around, taking water and getting ready to move quickly. Get the reputation of running on the road evenly, occupying card time between stations, and not running fast and stopping often.

If you find it necessary to run fast to a station for a meeting point, commence to run fast right then—not at the last moment. Get the reputation of doing well, and on time, anything you set out to do with an engine Make your fireman your partner; show him all your orders, interest him in his work and the engine—he will be of great service to you—and above all, don't forget that you fired a long time yourself.

Avoid the reputation of being "fly" on the road. Never be reckless or foolish; it's a grave business. Don't let your thoughts wander from your work Accept the responsibilities of your position with your eyes open and hand firm—just as a successful surgeon uses the knife near the vitals—know what you are doing and how to do it, just how far to go, and where to stop. A nervous, excitable, uncertain engineer is as dangerous as an ignorant one.

Don't ask many favors or make many kicks, so that when you do ask a favor it will be more likely to be granted, and when you do kick it will count.

Don't do anything because some engineer you know or like does so, unless you know he is right. Know *why*, and then do as your knowledge of the subject teaches you is right and best. You have an individuality of your own—develop it.

I wish to impress upon your mind the importance of telling the truth about affairs on the road. Never make out a false report about killing stock, or accidents. Tell the plain, naked, bald-headed truth—even when it shows you were in the wrong—it will be noticed and known, and credit given you for it; but once you get caught making out a lying report—and you will get caught if you do it—your word won't help you much in an important case. Lying to save a man's job is a pretty good way to jeopardize it when the lie is discovered. Railroad officers have a wholesome respect for a man who dare say, "I did so-and-so; it was a mistake," or, "It was my fault."

I hope you will pass your examination on time-card and rules before the superintendent successfully, but would advise you not to try until you are pretty sure

If you are temperate and industrious, I don't see why you should not become an engineer that every officer of the road will be proud of.

McIntosh's Automatic Oil Cellar.

The illustration on page 154 represents a self-adjusting oil cellar in use on the Chicago & Northwestern, the invention of Wm. McIntosh, master mechanic at Winona, Minn

Into the flanges of the truck axle box four holes are drilled from the bottom, into which the ends of two U shaped yokes, fitted with coil springs, are inserted. These springs bear against heads on the yokes, and are put under tension, and kept in the holes by collars below them on the stems of the yokes, said collars being held up by a key driven through the side of the flange, as shown at the bottom of each spring. The cellar is of thin material and fitted loosely in the box, held up only by the springs and yokes. The tension of the springs can be increased by set-screws located in each yoke under the cellar, these set-screws have a chisel point that fits a recess in the bottom of cellar, preventing the screw from turning and working itself loose.

The set-screws have hooked heads, and a rod can be laid in the hooks of the two, and the whole cellar pulled down by hand to examine, replenish or change the waste.

It is evident that with this arrangement the cellar packing must at all times be kept in full contact with the journal, insuring good lubrication.

In addition to this, Mr. McIntosh locates a large oil cup in a convenient and get-at-able place on the frame of the engine, and connects it by a pipe and hose to top of the box, as shown; this does away with the necessity for maintaining a gob of waste, cinders and oil on the top of the box, and guessing that the oil part gets down and attends to business and the cinders lay still and behave themselves.

Grief on the English Roads.

In the *Railway Herald* (London, Eng.) for July 11 there are a couple of pages of letters from correspondents, setting forth some of their troubles. We quote a few samples. How is this for examination questions

. . . In your issue of July 4th there appeared a letter on examination, written by one who signs himself "Truth." I think, however, your correspondent has not heard all the truth about the passing of firemen at Leeds I conclude that he has written his letter on account of two firemen who have lately failed to pass their examination, and been put back for six months. I will now state a few facts:

One fireman, after firing for seven years, was asked to point out his "sheaves or tumblers," and, incredible as it seems, could not do so. Now this shows that the man has taken very little interest in his work, and is not fit for a driver, as he does not know the different parts of his engine; and in my estimation the rejection of such a man is a duty to the public. Again, one of the candidates was asked to point out his "left trig-end" and failed to do so. No one could reasonably expect such a man to be placed in charge of an engine. Your correspondent asserts that they have three men to pass at Leeds; they have no more to pass there than anywhere else. There is the driver on whose engine the candidate is placed, the Westinghouse brake official, and lastly, Mr. Anderson, the locomotive superintendent, to pass, before he can be elected. The questions asked are always very simple and rudimentary. . . .

LOW WAGES AND RESPONSIBILITY.

"Struggles" reply to "English Tom's" "How to live, maintain and clothe a family of six on a weekly wage of 18s., paid fortnightly." "Struggles" says he cannot understand why a signalman in an important box should be paid less than an engine driver, when, he says, the signalman has perhaps eighty levers to deal with and all the trains, against the driver's one lever and one train. I should imagine "Struggles" has a very poor knowledge of what is taking place on the footplate; perhaps he is under the same delusion as I myself used to be before I started in the railway service. I used to stand on the bridge at one of our stations in the Midlands, and picture to myself what a fine life a driver and fireman have got, never for once thinking of the dangers and the inclement weather they were exposed to. Perhaps "Struggles" thinks that one lever and one train is all an engineman has got to think about, but far from that. If he be a diligent man he has to be on the alert from the time he signs on duty till the time he signs off. If he has not to work bodily he has to work mentally. It is the question of money that caused me to write. Now, I myself am a fireman in receipt of 4s. 9d. per day of ten hours. When first I entered the steam shed I was paid 15s. per week; remember there were no tips, and find your own clothes. From that time up to the present—though I have been very attentive to my work—it has taken me fourteen years to work up to a first-class fireman. What will it take to work up to a first-class engineman? Yet "Struggles" seems to me to begrudge us the money. I say let every man get as much as he can. I should be only too pleased to see all classes of railway servants better paid. An engine driver and fireman have a deal to do that many do not know about. We get no annual leave paid for, nor clothes, with the exception of an overcoat. When we are booked off we are not paid. I do not think there are many important boxes with eighty levers in that are not double-manned, so the anxiety of the signalman is greatly reduced. I do not know a lot about signalmen's duty in large boxes; there is another thing—I do not want to, either What we want, Mr. Editor, is to try and help each other to better our positions. . . .

Block signal dangers are shown by a Great Western engine driver as follows:

Don't rely too much on signals, because they often fail with the change of the weather. Only last Saturday, July 4th, a distant signal at Reading failed to act; when the train was approaching the up south cabin distant signal, which was standing at all right, when going round the curve the home signal stood at danger, and I looked back and saw the distant signal still off; the automatic vacuum brake had to be applied with full force, and the train was pulled up in a very short distance. The train was traveling at about fifty or fifty-five miles per hour, and I told the signalman when passing his cabin that the distant signal was off. The answer was that he could not see the signal from his cabin; it was beginning to get dusk at the time. Why not employ a locking bar close to such far signals from the signal cabins. If the signal then wouldn't go back to danger properly the signalman wouldn't be able to lock it, and then he would have to adjust his signal wire so that he could lock it. . . .

The "oldest man" racket must be in force there. Can any of your readers say, 1st, whether or not it is true that a porter of the relieving staff has been promoted to Canning Town, North Junction box, which I am given to understand is a fourth class, eight-hours box?

2d. Whether any signalman in an inferior position has had the opportunity of refusing the job?

3d Supposing the porter of the relieving staff to have been promoted as suggested in the first question, for what meritorious action was he raised from a relieving porter to an eight-hours signalman?

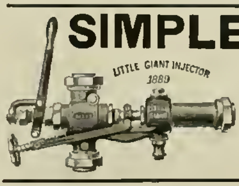
There seems to be evidence of long hours, low pay, strict observance of rules, and few privileges given to "railway servants" over there, though it is shown that the companies are making money.

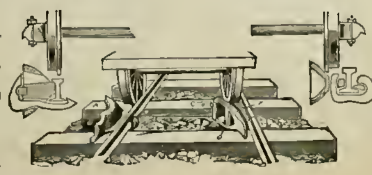
Geo. Royal, Jr., a well-known young engineer of the Wisconsin Central, has accepted the Chicago agency for the Lee Composite Railway Paint, the Ajax Metal Co. and the National Car Spring Co. George was a success on his engine and there is no doubt that he will be one in the supply field.

The Master Car Builders' rules of interchange were revised at Cape May this year, and will go into effect September 1st, 1891. Secretary Cloud already has them out and ready for distribution. The price will remain the same as before, 25 copies, $1; 50 copies, $1.75; and 100 copies, $3; smaller quantities, 5 cents each

The Brazilian system of railways now in operation comprises about 6,000 miles, while 2,500 miles are in contemplation, and will probably be constructed within the next few years The government owns and controls fourteen of the eighty-four different lines, while in thirty-five a partial control is still maintained.—*Bradstreet's*.

The *Engineering Magazine* has appeared in place of *Engineering*, which only appeared once. This was a wise move on the part of the publishers, as the English paper *Engineering* already has a world wide reputation. The *Engineering Magazine* treats on general engineering topics, for the benefit of those interested in a general way in engineering. No editor is announced, but the leading papers are signed by well-known writers on special subjects. The publication is of the regulation magazine size and style. Price, $3 per year.





GEO. WESTINGHOUSE, JR., President. T. W. WELSH, Supt. JOHN CALDWELL, Treasurer. W. W. CARD, Secretary. H. H. WESTINGHOUSE, General Manager.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 22,000 engines and 250,000 cars. This includes 160,000 freight cars, which is about 16 PER CENT. of the entire freight car equipment of this country. Orders have been received for 100,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, Manager. JOHN B. GRAY, Agent. C. C. HIGHAM, General Supt.

THE AMERICAN BRAKE COMPANY,

NEW YORK OFFICE, 160 Broadway, JOHN B. GRAY, Agent.

THE WESTINGHOUSE AIR BRAKE CO., Lessee,

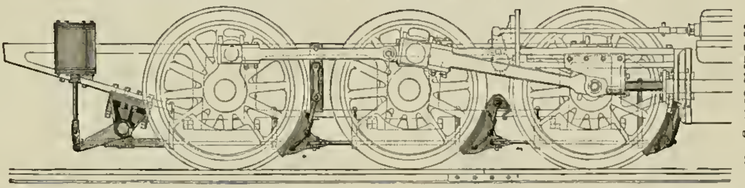
CHICAGO OFFICE, GRAND PACIFIC HOTEL.

MANUFACTURERS OF

LOCOMOTIVE BRAKES.

GENERAL OFFICE, ST. LOUIS, MO., U. S. A.

BRAKES Made to Order for any Special Form or Class of Engine.



All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear & Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM, AIR or VACUUM.

DIXON'S

GRAPHITE

PIPE JOINT

GREASE,

For Steam or Gas Pipes, Bolts, Screws, Etc.

Far Better and Cheaper than Red Lead.

Makes a tighter joint than red lead, that can be opened with perfect ease many years after.

No longer any necessity for

BROKEN PIPES, STRAINED TONGS or LEAKY JOINTS.

Put up in 1 lb., 5 lb., 10 lb., 25 lb. & 50 lb. packages.

☞ Send for Illustrated Catalogue containing more information concerning Graphite and its uses than is in print elsewhere in any language. ☜

JOSEPH DIXON CRUCIBLE CO.,

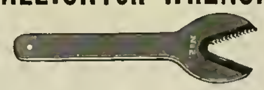
JERSEY CITY, N. J.

AMERICAN SAW CO.,

TRENTON, N. J.,

Manufacturers of the Celebrated

ALLIGATOR WRENCH



These Wrenches are forged solid in one piece, from best refined iron, with tempered steel jaws. They have ratchet teeth, cut diagonally across one jaw, thus enabling them to bite with three teeth at once.

INVALUABLE TO ENGINEERS, GAS-FITTERS AND JOBBERS OF ALL KINDS.

THE "LACKAWANNA" LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank-pins in hard daily service.

In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound is specially recommended for these cups, being first-class in quality and low priced.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

AIR BRAKE PRACTICE. THIRD EDITION.

BY J. E. PHELAN.

A book of 107 pages which can be carried in the pocket, and which covers the practical work of operating Air Brakes intelligently, explaining how and why they do certain things under certain manipulations and not under others. Tells how to handle, inspect, repair and adjust all the different systems of air brakes in use. Explains both the Hodge and Stevens System of Levers. Contains full directions for applying Driving Brakes to old equipment, and gives road kinks that are alone worth the price of the book.

Two large Removable Plates show the latest form of Air Brakes, complete and in detail, in perspective and section, so plainly that no one can fail to understand.

SENT POSTPAID TO ANY ADDRESS FOR $1.25.

PATENT PLATE BENDING ROLLS,

Specially adapted to this work.

The HILLES & JONES CO., M'f'rs,

WILMINGTON, DEL.

Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast iron bed-plate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started, stopped or reversed instantly.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formulæ patented by Mr. G. W. Lord. For decrees of court, etc., address G. W. LORD, 320 Union Street, Philadelphia, Pa.

VOL. IV, NO. 9. NEW YORK, SEPTEMBER, 1891. $1.00 per Year or 10c. a copy.

Details of a Model Soft Coal Burner.

Of all the fine appearing locomotives that run into the city of Chicago, the new eight-wheelers, Class 26A, built at the Rock Island shops there, are in the lead.

For a good many years this road has built and used "Twombly engines." These machines had their work all right, and saved the Rock Island hundreds of thousands of dollars, but many of them were unnecessarily ugly.

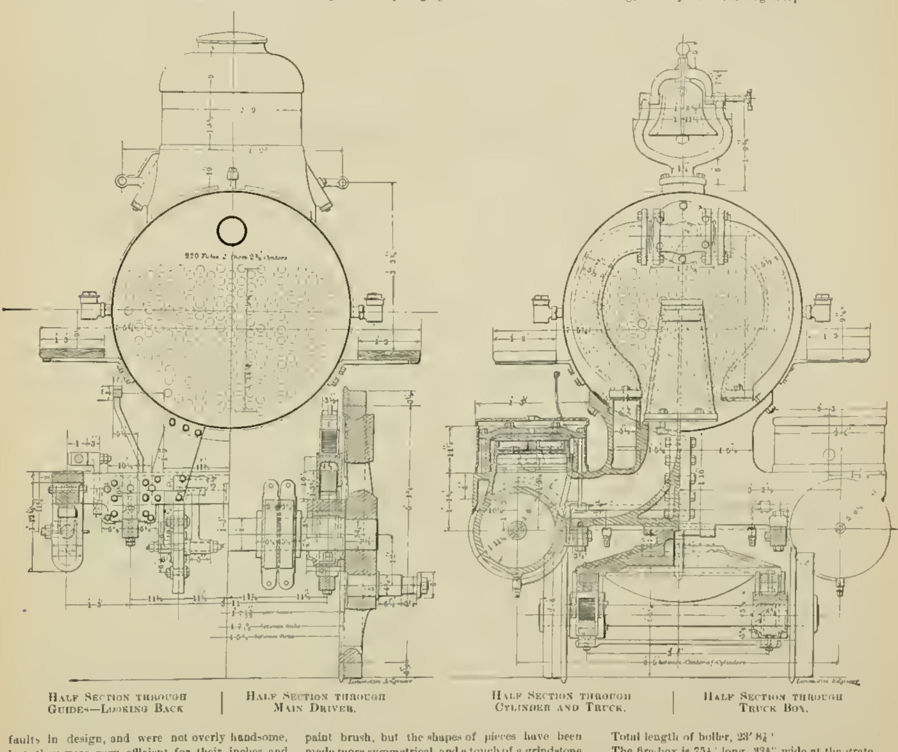
Mr George F Wilson, the present superintendent of motive power, has discarded none of Mr. Twombly's cheap and good devices. He has retained cast-iron where its service has been satisfactory, and many forgings are still finished with the

The boilers, cylinders and frames of these engines are heavy and carefully made

THE BOILER

The boiler is of the wagon-top variety, with crown bars, has an extension front, and brick arch.

The shell is 56 inches in diameter at the smallest ring, and 62½ across the wagon top



Half Section through Guides—Looking Back | Half Section through Main Driver. | Half Section through Cylinder and Truck. | Half Section through Truck Box.

faults in design, and were not overly handsome, but they were very efficient for their inches and weight, and Mr. Twombly was a long way in advance of his neighbors in getting rid of brass and polish, and making locomotives for utility He used a great deal of cast-iron and rough forgings, finished with a paint brush. These pieces did paint brush, but the shapes of pieces have been made more symmetrical, and a touch of a grindstone here and there has made some of the castings look like planed wrought-iron

The new engines have splendid boilers. We spoke about some of the details of their construction in our issue of February last

Total length of boiler, 23' 8¼"

The fire-box is 75¼" long, 33⅜" wide at the grate, 55" at the crown sheet and 78" deep

The shell is of ½" steel, and the fire-box of ⅜" steel, excepting the flue sheet, which is ½

The vertical seams are double riveted, lapped 4½", ¾" rivets, pitched 2¾" apart. These seams have a patch welt 10" wide on the lower side, and extending about a third of the way around the boiler.

The horizontal seams are lapped 4½", and have an inside welt 11' wide. There are four rows of ⅝" rivets, spaced 2¾" apart on the two lap rows, and 3½" on outside or welt rows.

All the seams in the fire-box are single-riveted on 2½' lap, with ¾" rivets, 2" pitch.

The sides and back of fire-box are stayed with ⅞" stays, spaced 4" apart, the water space being 3½".

There are 220 tubes, 2" diameter and 11' 7½" long.

Heating surface in tubes, 1,336.7 square feet; in fire-box, 145 square feet; total, 1,481.7. Grate area, 17.6 square feet.

The excellent plan of staying this boiler is fully shown in the drawings, particular attention being called to the independent feet of the crown bars. These are of cast-steel, free to move on the loose rivet shown, and supporting the double bar on shoulders on each side, said shoulders being rounded to admit of considerable movement. This plan insures a sure footing for each bar, and admits of using a very cheap form of crown bar—one that can be made in the bulldozer. The extension is of the Barnes pattern.

THE ENGINE.

The frame of this engine is heavy for her cylinder, and a great deal of care is taken in putting it together. Your attention is called to the manner of fitting the lower rail of frame between the driving-boxes, and the manner of fastening the splice. The frame ahead of the first box is 4½"x3¾", and between the boxes, 5½"x3¾".

The cylinders are heavy for 18", and a very heavy balanced valve of their own make is used.

The principal dimensions of the engine are given on the drawings. Suffice it if we describe it in engineers' parlance as "wheel, carrying 150 pounds pressure."

"Eighteen by twenty-four, five foot eight and three-quarter Laird guides are used. They are of cast-iron, the top guide being 4" thick in the center and 9¼" wide. No trouble whatever is had with this guide, or any other cast-iron bearing where ample bearing surface is provided.

The rocker arm is also of cast-iron, but is just the shape of a wrought arm. They are touched up a little on a grindstone, and are painted a very light lead color, looking at a little distance, and while moving, like steel.

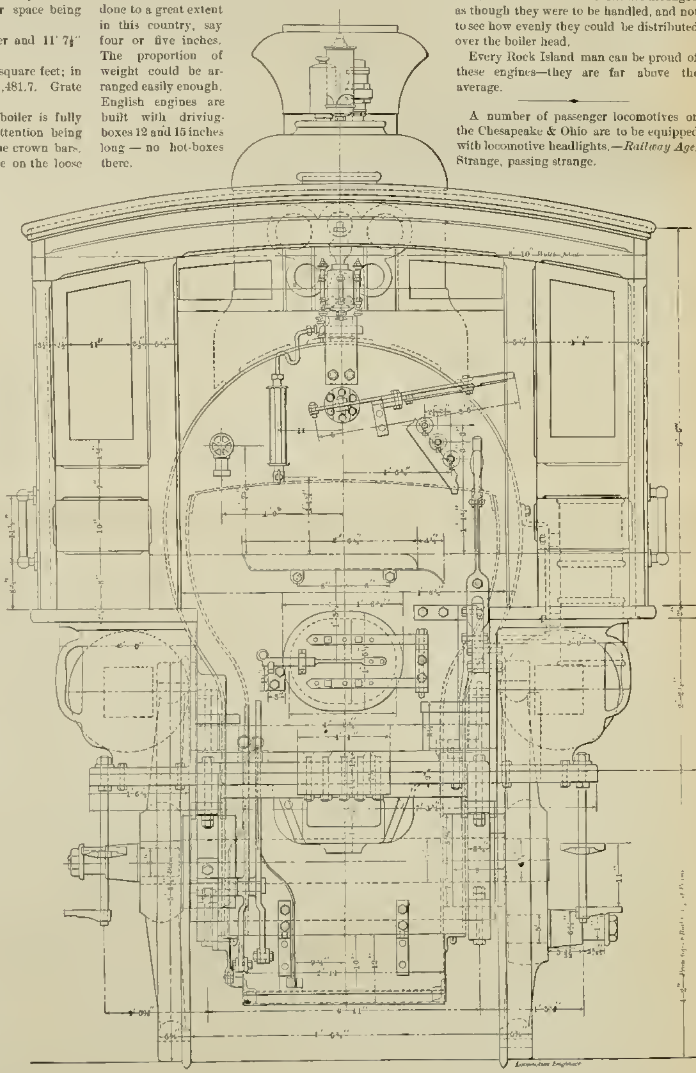
The tumbling shaft, with all its arms, is cast steel, all in one piece.

The valve rod, eccentric blades and such parts, are forgings made very neatly, and close to size, and painted, only the joints or bearings being machined.

The engine truck is a rigid one, with cast center. The pedestal jaws and the sides of the boxes are cast against chills, and the whole truck is made without machine work other than drilled holes, excepting planing of jaws and center where bolted to frames, the latter being straight pieces of iron, cut off and drilled. This truck costs less than half the usual engine truck, and has given first-class service here for years.

The engine is fitted with the Westinghouse automatic air-brakes, and has a vacuum driver brake—this is the only point we see to criticise. We believe it would be better and safer to use a driver brake operated by air and used in service stops with the train brake. The manner of fastening the safety chain to deck casting instead of tail-piece is unusual and has advantages.

Driving-boxes, 8"x9", are above the average in size, and are a step in the right direction. The box is extended in from the center of the frame slightly, and we fail to see any very good reason why this should not be done to a great extent in this country, say four or five inches. The proportion of weight could be arranged easily enough. English engines are built with driving-boxes 12 and 15 inches long — no hot-boxes there.



REAR VIEW.

The details of the rods, showing their design and finish, will be published next month.

The valve travel is 5½"; outside lap, 1", and inside lap, 1/16". The ports are 1¼"x17", the exhaust port being 2½".

The valve is of the Allen or "trick" port style, and is balanced by two round rings on top working against a balance plate, much the same as the Richardson. We never saw any ring packing that kept tight very long, but this is new and seems to be giving satisfaction. These engines have a record of considerably more than 60 miles an hour.

These machines are black, all the paint above the running board being jet, and the bands on the jacket being of Russia iron. Rods and running gear, usually finished, are painted light gray.

The cabs are roomy and convenient. The men are made comfortable by cushioned seats and back rests, and the levers and cocks are arranged as though they were to be handled, and not to see how evenly they could be distributed over the boiler head.

Every Rock Island man can be proud of these engines—they are far above the average.

A number of passenger locomotives on the Chesapeake & Ohio are to be equipped with locomotive headlights.—*Railway Age.* Strange, passing strange.

W. H. Silverthorn, of Cleveland, Ohio, has patented a piston car jack, operated by compressed air or steam. The bottom of the cylinder, which forms the body of the jack, has a two-way cock connection, and a length of hose terminating in a standard coupling. This is coupled to the train hose, and the pressure used to lift the car or box. For quickly changing brasses or packing boxes, this plan seems to have several points in its favor, not the least of which is the saving of time.

On the Foot-plate in the Argentine Republic.

The following communication from a fireman on the Caledonian Railway, in Scotland, to the *Railway Herald*, of London, may be of interest to some North American railroaders with the South American fever. His description of unfenced roads sounds as if he might have been over some of our own western lines.

"Having heard such good accounts of the Argentine Republic, I resolved to go there, and sailed from Southampton on the 18th of February, 1889, in company with seven other Midland men.

"We arrived in Buenos Ayres on March 14, after a splendid passage. I was engaged by the Great Southern Railway the next day, to start firing at $56 per month. The line extends south 450 miles, 425 miles of it is single line, worked on the ticket system, the movements of the trains being worked by one man at the head station in Buenos Ayres.

"The station wires to headquarters for permission to allow a train to proceed to the next station, and so on, so that there cannot be any mistakes made.

"My first trip, outside, was on a passenger train, 106 miles for the day's work, which, I can assure my fellow-firemen, is quite enough under the tropical sun. The heat is intense during the hot weather. The engines are fitted with a 'scum cock,' which must be open half the journey, on account of the bad water, which ruins the boilers very soon.

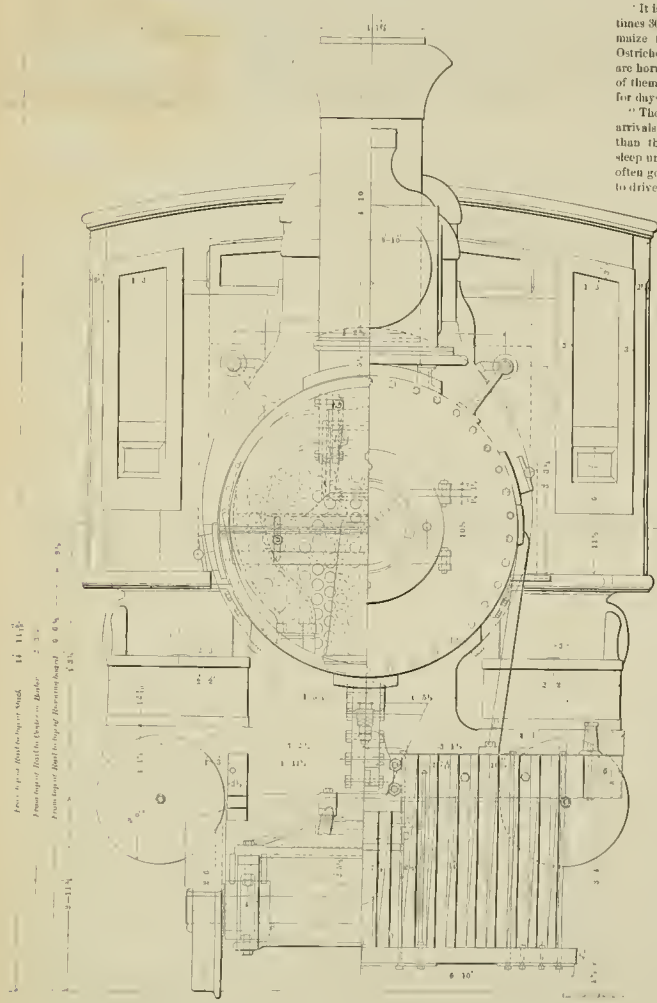
"The country is flat, and the herds of half-wild cattle, wandering all over the plains, stray on the lines, which are not properly fenced in. On my first trip, a horse went completely under the cow-catcher, scaring me very much. I have seen 16 horses dead and dying which had been knocked over by heavy passenger trains, all within 300 yards from the first to last, during the night. It is pitiful to see cattle by the line for days, dying by inches, frightened by an approaching train, and trying to get up, with both hind legs broken, sometimes hanging by a shred of skin, and walking on the stumps till they fall exhausted. The natives just take the hide and leave the carcase, which lies rotting for weeks, unless eaten by eagles or dogs, which are numerous on the plains.

"One sees some curious dwelling houses of the half-breed Indians, made of hides, stretched and dried in the sun, likewise others of dried dung.

"It is a beautiful sight to see the parrots, sometimes 300 or 400 together, when they rise from a maize field, when the sun is shining on them. Ostriches are numerous. The skunks, or polecats, are horribly smelling animals. If you knock one of them over by the engine, the smell will remain for days.

"The mosquitoes play the deuce with the new arrivals, on account of their blood being thicker than that of the natives. It is no use trying to sleep unless you have a curtain overhead. I have often got up during the night and have burnt waste to drive them out of the room.

"I would advise any one going out under contract to be paid in gold, as the paper dollar is only worth about 1s. 4d. I was given to understand that the dollar was worth 4s. 2d. by the Argentine Consul in England, but imagine my surprise on arrival to find that it was only 2s. 9d., and during the time I was in the country (thirteen months) it kept going lower, till it has reached its present value."



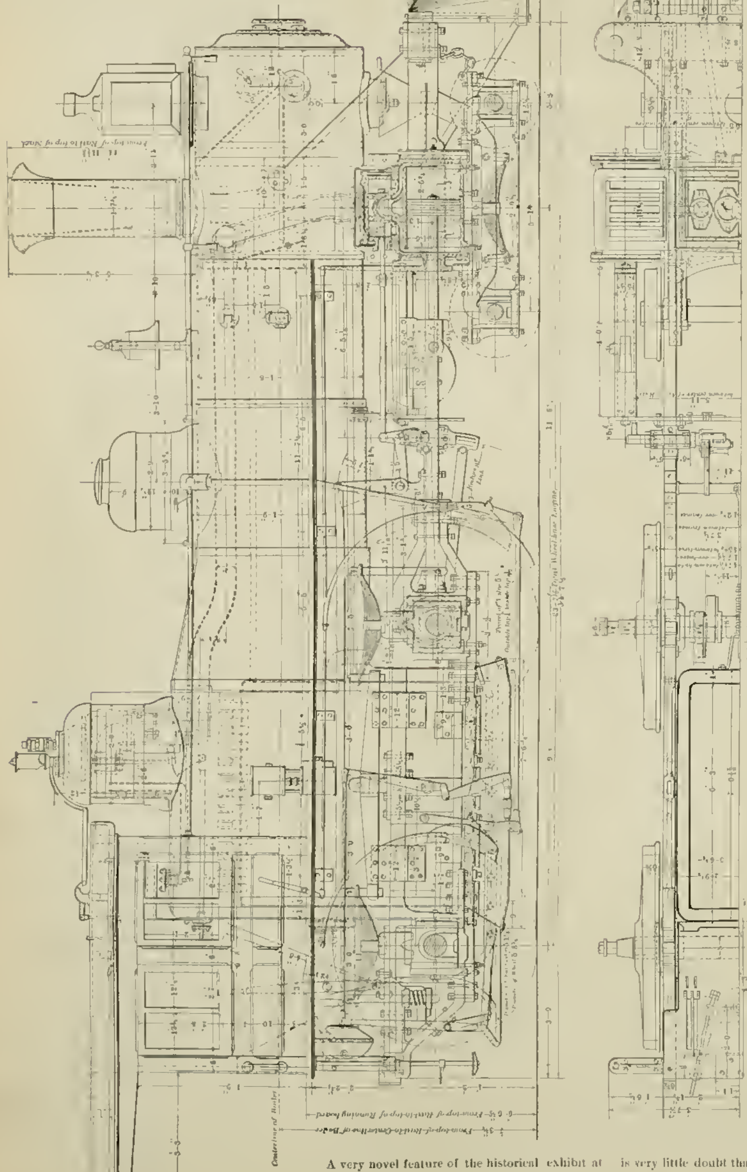
HALF FRONT, THROUGH SMOKE ARCH | HALF FRONT ELEVATION

The Lee Composite Manufacturing Company, of 29 Broadway, this city, are making and selling a paint for railroad purposes that has peculiar properties. The base is pure asphaltum, thinned and mixed with an impalpable powder of mineral slag. The slag used is from silver or lead ores and is extremely hard. Both the asphaltum and slag are mineral, impervious to water, and fire-proof. Acid does not affect them, and they will not rust. This paint is used for the tops of freight cars, and when applied, coarse slag is sprinkled upon it. This is firmly imbedded by use, is always sharp, and resists all ordinary wear, doing away with the necessity for running boards, and preventing the cinders from cutting the paint off. It is being used for cab and passenger car roofs, for engine running boards, and for roofs of roundhouses, stations, etc. It is furnished on canvas when desired, three strips just covering a car. This paint seems to be practically indestructible, is sold cheap, and is meeting with a large sale.

Harris Tabor, the well-known steam engineer, and the inventor of the Tabor indicator, has recently perfected a molding machine of novel yet simple construction. These machines are smaller than the usual molding machine, have no air-bags, loose rammers or small pieces. Ramming is done by steam. Where duplicate parts are made in large quantities they save money and produce uniform work. One of the smaller sizes of these machines is employed at the works of Samuel L. Moore & Sons, at Elizabethport, N. J., making brake shoes for the elevated road in this city. The shoes have two lugs with holes, which are cored in green sand. The work is absolutely uniform and smooth, and the holes always the same distance apart. There are but 110 flasks for this machine, so that a full day's work has never been done on it, but a laborer and a boy are doing the molding for $1 per ton. For car work these machines would be especially economical, and several are already at work on couplers and knuckles.

Don't apply your brake three or four times and then expect it to hold on the last application.

The Erie will consider itself fortunate if it can settle up the claims growing out of the butchery at Ravenna for a quarter of a million dollars. That much money would go a long way toward putting automatic block signals on the system, and would at least protect every station with automatic distance signals. This must be done. Brakemen will not go back a safe distance every time. He fails the hundredth time. When one thinks of the thousands of trains that are protected by flag daily, it is no wonder that there are accidents. The real wonder is that there are not more of them.



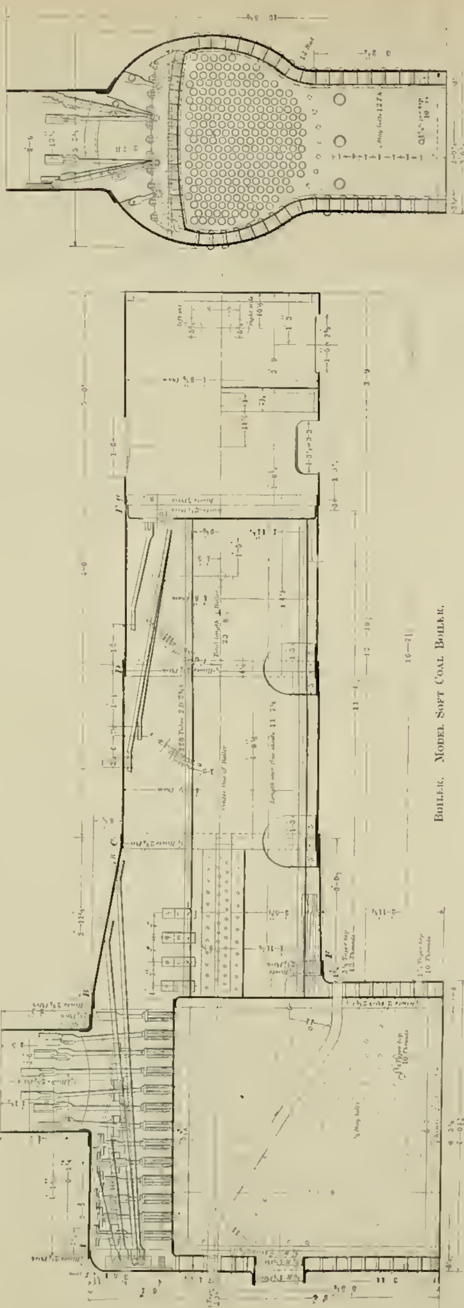
Vertical Longitudinal Section and Half Plan of Model Soft Coal Burner.

A very novel feature of the historical exhibit at the World's Exposition will be a fac-simile reproduction of the little ship "Santa Maria," in which Columbus sailed. Lieut. McCarty Little, of the United States Navy, has been detailed to go to Spain to superintend the construction of the ship. It will be manned by Spanish sailors, in the costume of the time of Columbus, and will be rigged as Columbus rigged his ship. There will be on board copies of the charts that Columbus used, and fac-similes of his nautical instruments. The crew will be of the same number, and included in it will be an Englishman and an Irishman, for it is a well-founded historical fact that William Harris, an Englishman, and Arthur Lake, an Irishman, were both members of Columbus' crew. In fact, the reproduction will be as exact as possible in every detail. The little ship will make its first appearance at the naval review in New York, where it will be saluted by the great cruisers and war ships of modern invention from all of the navies of the world. It will then be presented by the Government of Spain to the President of the United States, and will be towed through the lakes to Chicago. It is proposed that the vessel will be taken to Washington after the Exposition, and there anchored in the park south of the White House.—*Exchange.*

"Poor's Manual of Railroads" for 1891 is out, and the following is its estimate of the rolling stock in the United States: Locomotives, 32,241; passenger cars, 22,958; baggage, mail and express cars, 7,253; freight cars, 1,061,-970; total number of cars, 1,092,241. This is an increase over their last year's report of 1,200 locomotives and 11,-134 cars, but in all probability many of the returns on which they base their estimate were made from six to nine months ago. There is very little doubt that there are fully 33,000 locomotives in service at the present time. So many engines are built in small shops that it is hard to get correct figures.

The engineers and workmen on the Manchester Ship Canal had an exciting experience a few days ago, when the Mersey swept away 300 feet of a great embankment which had been constructed to divert the water at the mouth of the Shropshire Union Canal. Ten million tons of earth and masonry were washed away almost in an instant, and it was absolutely necessary to repair the damage between tides. The engineers had eight hours at their disposal, and set an army of men to work upon the construction of a new embankment of rock and clay. Railroads were laid as if by magic, and locomotives dashed through the advancing water with hundreds of truck loads of stones, refuse and gravel, at the risk of extinguishing their fires. Up to the last moment it was doubtful whether the water or human skill and energy would win the victory, but at last, when the men were almost exhausted, the baffled tide began to recede, and the embankment triumphed. It was made doubly secure before the water could get back again.—*English Exchange.*

The great accident near Paris, France, last month, by which 50 people lost their lives, and 150 were injured, was caused by the "permissive block signal system." Permissive blocking allows the signalman to admit a second train into a block after a certain lapse of time, whether the first train has cleared the block or not. These time block schemes are dangerous. They are deceptive, and offer no real security over the no block system. Absolute blocking is the only safe system, and no half-way schemes should be tolerated.



Boiler. Model Soft Coal Boiler.

New Tools at Baldwin's.

Since the Baldwin Locomotive Works have got into their new erecting shop, with its 100-ton electric crane, they can do lots more work than they used to, but improvements are constantly being made to cheapen production.

Supt. Vauclain takes one part at a time, and figures on reducing the cost of its production—in almost every case going farther, and accomplishing more than was at first attempted.

For making taper bolts for rod and frame work, they use vertical, gang, bolt cutters, six-spindle machines; the bolt is revolved by a socket wrench head in the live spindle, from above, and is turned by knives in a socket, or former, the cutting being done in a tank of oil. The bolt is roughed out in one cutter, and finished to gauge and standard taper in another. The job is a first-class one, and done by boys for forty cents per hundred bolts, some of the boys average $16 to $18 per week.

The sides of driving-boxes are finished in a rotary planer, built by Wm. Sellers & Co. The cutter head being some thirty inches in diameter, and carrying some forty tools, the head does the traveling, and the boxes stand still; there is room for twenty or more on the bed, and as the tool starts at one end and goes through, the boxes behind it can be taken down, and new ones put in their places, so that the tool finds another row ready for it just as soon as it is done with the first.

For making wedges and shoes they have a separate room, and the rough castings are finished complete by milling machines, a separate machine for each operation; one planes off the face of the shoe, another the edges, another the inside of the flanges, while a separate machine faces the flat side between flanges, one mills out the wedge bolt slot, and another does nothing but round off the corners for the fillets left between the box and the flanges. This kind of equipment would be impossible except in a place similar to this, and having, not hundreds, but thousands of them to make. Two men attend all the machines.

They are just now completing a mammoth hydraulic riveter for boiler work, this is of the usual vertical type, but has a seventeen-foot gap between the stake and ram, so that the largest boiler shell can be put together without turning it end for end.

The pattern warehouse is a mammoth building, but the science of changing patterns has been so developed that it is possible to make many different sizes of casting with one pattern by adding to or taking from it; cylinder patterns are all made so that the saddle can be raised or lowered, the spread of cylinders changed or the length altered at will. One large room is used by pattern makers who do nothing but alter patterns.

In the shop, at the time of our visit, there were seventeen compounds, most of them for foreign countries; there was one set of cylinders there for the Erie with 24' low-pressure cylinder—the largest yet built.

The charging floor of the foundry is some twenty feet above the ground, and the iron yard covers considerable space, through this yard are left tracks for iron cars, which are loaded by hand, when the car and its load are picked up bodily by a big hydraulic crane and set down on the charging floor, this has done away with all barrow-work.

In the erecting shop there were nearly completed six more of the handsome six-and-a-half foot wheel fliers for the B. & O., duplicates of the one shown in our May inset, except that they have a flange on the forward pair of driving wheels—a sensible improvement.

Mr. Vauclain has recently patented a new wrought iron piston head, made in two pieces, that go together on the rod like two pie plates, and hold the packing rings between them, they are very light and strong.

The "Teutonic," of the White Star line, has beaten the record of her sistership, the "Majestic." She arrived in New York August 18, having made the passage in five days, sixteen hours and thirty-one minutes. This is one hour and thirty-seven minutes better than the "Majestic's" time. At sea a day is reckoned as from noon to noon, and the "Teutonic" covered 517 miles in one day.

Jim Skeevers' Object Lessons.

Skeevers' fireman, Billy, has been "set up" a fortnight now, and the Old Man put Mike Kelly on with Skeevers.

It's Mike's next turn to do the "touch the button, the fireman does the rest" act, and the Old Man thinks Skeevers a good runner to graduate the boys.

Skeevers is no hog, he knows that Billy is the best fireman on the road, and does lots of *his* work, and that the next fellow will make it harder for him, but he's been thinking of Bill some, and rejoices in his promotion—he has an interest in his success.

Mike was born with a constitution that could stand worlds of rest, and probably he also inherited some of his propensity for never going to bed until the last cat is hung, and then hating to keep awake the next day.

Mike, in common with other mortals, must suffer the ills of his inheritance, but Mike, and all the rest of us, suffer more from the desires, habits and practices that environment has established than from inheritance—or anything else.

Mike didn't get the right kind of an engineer to start with, so now, after firing four years, Mike knows a lot of things about locomotives that is not so, and has learned a lot of things that he must unlearn, and formed a lot of habits that must be broken.

Perhaps the Old Man knew this, and put the job onto Skeevers, and blames Mike and his first engineer; but why didn't the Old Man tumble to all this three years ago, before Mike's crooked habits got "set," so to speak. These Old Men make lots of curious engineers out of firemen of their own selection, and then go off and kick about them—but that's nothing to do with Skeevers and Mike.

Mike's worst habit, as it struck Skeevers, was sleeping on the engine. Skeevers is down on that, he knows that it is dead wrong, to begin with, and Skeevers carries a big scar that he got one night, a long while ago, when he was firing for a man who slept on duty; the man has slept ever since—in a graveyard. That was an object lesson to Skeevers, and Skeevers maintains that one good object lesson is worth more than two books, or four or five hundred "tellings." So Skeevers concluded to give Mike a few object lessons on sleep, and how *not* to do it on an engine.

Skeevers pulls fast freight, generally having enough refrigerator cars or fruiters ahead to handle the train with air, the division is long and hilly, some places the train will run for eighteen or twenty miles.

The first trip out Mike attended to his duties pretty well, but got dozy on the long stretches between fires, but the second trip he went fast asleep, and Skeevers had to wake him up to get over Waxem hill.

The next night they had to double out, and as soon as they pitched over for a ten-mile run, Mike fixed up his fire a little, and sat down.

"Mike," said Skeevers, "don't let me forget, I have orders not to pass Ford's without orders—don't let me go to sleep."

"All right, Skeevers," said Mike, "where do you meet three?"

"At Ford's," said Skeevers.

Mike closed his eyes directly, just to rest 'em a little; then he looked around, owl fashion, kind of thought he saw his best girl ahead of the engine, nodded to her, made a profound bow, and—was off. The engine? No, no, off to sleep—"pounding his ear," Mike calls it.

Skeevers sailed right by Ford's, and took the siding at Sand Creek, all "unbeknownst" to Mike.

When "three" thundered by Mike jumped up, put in a fire, and asked Skeevers if he had his orders yet.

"What orders," asked Skeevers.

"That 'do not' at Ford's."

"We're by Ford's, and I didn't get the orders," said Skeevers, in an awed tone of voice, "it's a wonder we didn't hit three."

"You're in for it Skeevers, I guess."

"So are you."

"Not much, I'm no bold engineer."

"I told you to look out, and not let me go to sleep, I believe you were asleep yourself."

"No, sir, I was drowsy, but not asleep."

"Not asleep? well, you had your eyes shut."

"Yes, but it wa'n't sleep."

"What was you thinking about when we passed Ford's?"

"Nothin'."

"Well, Mike, if you shut your eyes and stop thinking, it comes nearer being sleep than anything I know of. We'll probably get fired, or get ninety days for this."

Mike was wide awake the rest of the way in, but Skeevers appeared glum and downhearted. The head gafter came over near town, and Mike told him about it, and the gafter said they had orders to meet three at Sand Creek, and no "do not" at Ford's. Mike accused Skeevers of "playing smart," and Skeevers asked Mike how different it would have been had the case been genuine.

A few trips later Mike started a snooze in good shape, and Skeevers quietly let the 48 drift against a slight grade and stop, steam low, in twenty minutes the conductor came over, swung up into the gangway, and asked Skeevers what was the matter with the 48.

"Nothin' at all," said Skeevers, "nothin' at all, but the fireman is worn out for sleep, and has laid off, I have no fireman."

Mike was awake then, and heard the talk.

"I ain't paid for firing or keeping the fireman on duty," continued Skeevers, "if Mike wants to lay off it's his business, and the Old Man's—not mine. I won't run without a fireman, though—not a mile."

The conductor consulted his watch.

"Can't get to Sand Creek for three now, what'll I say was the cause of delay?"

"No fireman," said Skeevers.

The conductor went back over the train, and Mike nursed his wrath awhile, and then turned loose.

"Skinny Skeevers, how long you goin' to work this racket, and make such a darned fuss about a man's dozin' a little, and reportin' every little thing?"

"Just as long as you sleep on duty, Mike," said Skeevers, "I won't run a rod with you when you are asleep; I will stop just as quick as you shut your eyes, let the circumstances be what they may. I shall not let the conductors lay any such delay to bad coal or leaky flues. It must all be charged up to 'no fireman.' If you stay on the road you will soon be running an engine here, and if you sleep on duty now you will then, and it will all end in your killing yourself, and, perhaps, some one else, very likely me. If you stay on the road, and on this engine, I will break you of sleeping—you are liable to be fired any day for good cause, however."

Mike kicked some, all to himself, but he is keeping awake pretty well, and if Skeevers just lets a little air out of the brake valve now, Mike will straighten up and say:

"Oh, I ain't asleep, Skinny, bet your neck I'm all right."

Skeevers says it will take six months to make a permanent cure, and remove the tendency of fatal symptoms to return, but Skeevers says he'll fetch him, and still has an abiding faith in object lessons.

A Graphic Method of Finding the Length of Radius Bar for Pony Trucks.

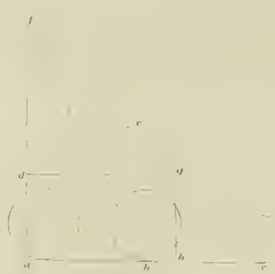
The object of the radius bar is to keep the wheels of the pony or two-wheeled truck radial with any curve that the engine has to take.

There has been a great deal written on this subject, and the subject has been much obscured by formulæ, but the matter is not so difficult after all.

The length of the radius bar must bear a fixed relation to the total rigid wheel base of the engine, and to the distance ahead of this rigid wheel base that it is desirable to run the truck.

From the advance sheets of an exhaustive work on locomotives, "Modern Locomotive Construction," by J. G. A. Meyer, we condense the following graphical method of finding this length.

Draw a horizontal line half the length of the rigid wheel base b to a, and the distance from front flanged driver to pony truck wheel b to c. Erect a perpendicular at the center of rigid wheel base, draw a line from the pony truck point at c to the perpendicular at an angle of 45°. This completes a triangle with two equal sides. Now draw a line from the top of the triangle through the forward point of rigid wheel base at b. Bisect this line at right angles, forming line d e. From the point of intersection d draw a horizontal line parallel to the base line, and from the intersection of this line with the line e f draw a perpendicular to the base line at g. The length of this line g h, or the length of the base line from its intersection to the pony truck wheel h c, is the correct length of radius bar, and this bar will keep the pony truck wheels radial with any curve.



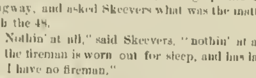
Length of Radius Bar.

In practice, it is customary to make the length of the bar about 10 per cent. less than the theoretical length, to insure the flange against climbing the rail.

Forging a Frame.

Mr. Stephen Uren, general foreman of the forge and rolling-mill of the Sacramento shops of the S. P. road, makes a locomotive frame in a way of his own, and gets excellent results.

He forges the upper and lower rail separately, welding on or drawing out parts of the pedestals on each piece, as shown in Sketch 1. These pieces are placed together and held by clamps while being welded together. The ends of the jaws and braces are scarfed sideways on each side, so that they meet only at the points. Triangular pieces are then laid into the depressions on each side, a welding heat taken, and the whole frame welded up entirely by side blows from a steam hammer. This done, the frame is relieved of the clamps, and can then be finished and straightened by lighter work. This form of weld is said to be much stronger and easier to make than plain side scarfs, while all frame makers of experience condemn the "jump" weld.



Forging a Frame

Railroad operators are daily quitting their positions to accept jobs as firemen, brakemen or switchmen. Even a commercial operator in this city recently resigned a comparatively good position for a chance to shovel coal on a locomotive, because it pays better. Organization has placed the salary of the unskilled workman far above that of the skilled workman.—*The Telegrapher*. Organization has placed the pay of firemen above operators, but if *The Telegrapher* thinks that firing a locomotive is unskilled coal shoveling, it is simply showing that it doesn't know what it is talking about.

The great tunnel under the Hudson River is nearly completed, and it is expected that trains will run from New Jersey direct to New York in the near future.

Correspondence

Bad Practices.

Editor The Locomotive Engineer:

Inasmuch as your sprightly paper is destined to develop a better feeling on the part of your readers among themselves, and with regard to their duties as employes, and will doubtless take its place as a leader of thought among those men, permit me to suggest that they be given, through your columns, a good sound lecture on the folly and evil results of reversing and slipping their engines, and the too constant use of their blow-off valve.

The young men I examine for promotion seem, as a rule, to have no intelligent ideas on these important matters.

F. S. GANNON, Gen'l Supt S. I. R. T. Ry.

New York.

[We have noticed that the habit of reversing the engine to avoid running by stations, etc., is quite common on the rapid transit lines in and around New York. In this class of service the plain vacuum brake is used, and driving brakes employed, and reversing with the brake on, means sliding the driving wheels in almost every case. This practice comes from the old days of hand-brakes, and of that later but not far distant decade when it was believed that driving brakes ruined an engine anyway. Have brakes on every wheel possible, keep the apparatus in condition to perform its important duty *instanter*, and don't take any chances fooling with the reverse lever.]

The Right Spirit—Who Knows About Water-brakes?

Editor The Locomotive Engineer:

I have been wanting to write to THE LOCOMOTIVE ENGINEER for some pointers for a long time, but have not done so on account of not wishing to show my ignorance. But I have come to the conclusion that I had better show it now than five years hence—so here goes.

I should like to ask information of L. C. Hitchcock about giving an engine lead. On page twenty-five of the February number of THE LOCOMOTIVE ENGINEER he says: "The requisite amount of lead can now be given the engine by moving the eccentrics on the shaft," but he does not give any rule for so doing. I presume he takes it for granted we ought to know how. I think his article on setting valves the plainest I have ever read, and it was a great help to me when I went to work to square up the old hog I have been driving up the mountain for several months. After I had gotten my blades all the proper length, I found she had $\frac{3}{32}$" lead in forward motion on right side, and was even, blind, on left. And in back motion she had $\frac{1}{16}$" lead on left, and $\frac{3}{32}$" on right side. Then I set about to give her the proper lead. And here is where I got stuck. How was I to get at the back eccentric set-screws? The only way that I could see was to take down the go ahead eccentric or strap, and, if I did either, how was I to tell how much to move the eccentric? The result was I did not get at them. As there was only $\frac{1}{32}$" difference, and that in the back motion, I concluded to let it go. I then put reverse lever in extreme forward notch, pinched engine ahead, caught front center, and had helper advance forward eccentric until valve tram marked $\frac{1}{16}$ in front of port closing line, and then did left side the same way. But what I want to know is how to get at the back eccentrics without taking down the forward eccentrics or straps, and, if I take them down, how am I to tell when I have moved the eccentric the proper distance? Well, I had the old mill square in the forward motion and was satisfied. If there is anything that will give me "the jerks," it is a lame or a slippery engine.

I would like to know something concerning the water brake. I have been using it for almost three years, but have much to learn yet. The McQueen engines here on the C. M. Ry. have single nozzles, extension fronts, and straight stacks. The Baldwins, double nozzles. While using the water-brake on the Baldwins, you will think your cylinders are not getting any water, when all at once she will throw a bucketful out of the stack, and it will come out of the cylinder cocks so strong you will think you are about to knock a head out. Then she will stop throwing it just as though you had shut the water off. The McQueens are not so bad in this respect; but I have run only one that I thought handled her water about right. I could let her down the hill (twenty-five miles) without throwing any water over her jacket, and still keep plenty in her cylinders. There is another that is as bad, if not worse than the Baldwins. She will squirt it out her cylinder cocks, and throw it out the stack, then she will stop, and her valves get so dry that if you lift reverse lever latch she will jerk you off the seat. I have talked with several on this subject, but they don't seem to know any more about it than I. Will some of the readers of THE LOCOMOTIVE ENGINEER enlighten me?

Aspen Junction, Colo. J. W. KAEFUS.

Sight-feed Glass Phenomena.

Editor The Locomotive Engineer:

I hereby send you two lubricator glasses taken from a No. 8 Nathan double sight-feed lubricator after about seven weeks' usage. As you will see,

one end is eaten down to $\frac{1}{16}$" smaller than the other parts of the glass. When these glasses were put in they were the same size along from one end to the other, and now they are reduced $\frac{1}{16}$ of an inch for the length of $\frac{3}{4}$" on the upper end of the glasses.

Now why is it that the upper end of the glasses is wasted away while the lower end is still its original size? There is only a rubber gasket on each end, and if this is the cause why does it not eat both ends alike?

In this manner most of the glasses are broken, and only by the Nathan lubricator, the Detroit lubricator has not yet been known to break the glasses like this.

Vacuum oil is used in the oil cup. I have been told that there are only a few acids that will eat glass, and they are not commonly found. I hope you will work it up for the boys.

Mt. Savage, Md. E. G. R.

[This is the second case we have heard of where the sight feed glasses of a Nathan cup cut out, while the same kind of glasses using the same gaskets on other cups were not affected. The glasses sent by this correspondent are on our desk, and the outside has the appearance of having been eaten with acid or reduced by a sand blast. Most water line glasses are cut out at the top, but on the inside. Who can explain this trouble?]

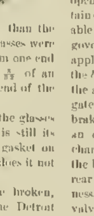

Fig. 3.

Some Faults in Machine Tools.

Editor The Locomotive Engineer:

I want to say a word about defects in machine tools and machine shop fixtures. Why is it that tool builders will adhere to the bevel ways, for slide rest in lathes, and the crossbeam and head, in shapers and planers? The bevel is not as solid in general practice on any machine as the form shown in Fig. 2. If a person will watch a lathe slide rest, or planer head, while cutting over irregular surfaces, it will be seen there is a sliding motion on the bevel, and no amount of metal will prevent it. It makes no difference how thick a gib we may use in a slide rest, as shown in Fig. 1, the points of the set-screws must take the thrust which is a very small bearing. In Fig. 2, with taper gibs 1, 2, 3, we have a solidity which no other shape will give us. Fig. 3 shows one of the worst forms for a crossbeam, they cannot be made without springing to the cut of the tool. The feed gear in shapers is too weak, more particularly that type where the vertical feed is produced by moving the crossbeam up or down, which, taken together with its load and the thrust of the tool, is too much for the feed gear, and it soon gives out. Some reputable builder will use a screw only an inch in diameter to support the load, when in most cases an eighth-inch steel pin transmits the power to move or overcome the weight of crossbeam, chuck, work, thrust of tool and friction of slides. Such construction shows bad judgment, to say the least. The feed dogs, or ratchets, on most planers are only traps to injure the operator. They should be constructed so they could be thrown in or out of gear while in motion, and yet be safe. The old wrought iron vise, and most of these so-called lightning grip vises, have no place in a modern machine shop. They are no good for variety work.

Corry, Pa. W. DE SANNO.

Danger in Testing Brakes from Rear of Train.

Editor The Locomotive Engineer:

I read with no little interest, nor less apprehension, in your July number, of the growing custom on the part of trainmen of testing air on trains by opening the rear train pipe stop-cock. Under certain conditions, this practice might seem unobjectionable, but I believe that one unvarying rule should govern in this matter, *i. e.*, to require brakes to be applied by the engineer, through the agency of the *brake valve*. The engineer is the brakeman on the air brake train, and he cannot afford to delegate such an important duty as the testing of the brakes to some one at the rear of the train. When an engine has coupled to a train not previously charged with air, the application and release of the brakes attending the opening and closing of the rear stop-cock indicate with reasonable conclusiveness that the train line from the engineer's brake valve to the rear stop-cock is charged, and intact; now let us change the conditions a little, suppose at some station the engine cuts off—a very common happening—to get coal or water, or both, it returns in a few minutes and couples to its already charged train, pressure reduced a trifle perhaps by the leaks common to the average freight train. The brakeman in testing his air opens the rear stop-cock, discharges part of the air in the train pipe, hears a number of brakes next to him go on, throws the handle back into its original position, when the escaping air is suddenly arrested, causing the pressure at the rear end of the train pipe to run up and release the brakes on several of the rear cars, the brakeman is under the impression that he has made an effective test of the air, and, if the head man has "cut in" the engine when coupling up, he will not know any better, but the results shown above can be gotten without the engine being cut into the train line at all. Your subscriber has witnessed such practices, and found it his duty to inveigh against them.

A better plan, and one which I observe is followed on some of our roads, is to require the employe acting with the engineer in making a test of the brakes, to start from the engine when the engineer makes the discharge of air from the train pipe, and pass back along the train, noting that the brakes have been properly applied, signaling the engineer to that effect when the rear end has been reached, then to walk back to the engine to see that the release takes place the same as application.

In view of the grave responsibility involved, too much care cannot be given the matter of testing and handling of air brakes, as with the best of care there are agencies at work that from time to time produce failures, and the casualties that follow often in their train. A very interesting list of such failures could be made from the experience of those engaged in operating air-brakes. As indicative of the fallacy of the rear stop-cock test, let me state an incident narrated to me by Mr. W.

R. Scott, one of the traveling engineers of the A., T. & S. F. system, a young man of rare good sense and judgment, with a splendid development of the perceptives and reflectives, and who, by the way, owes his advancement to his present responsible position to the possession of the above desirable qualities. Mr. Scott started on a trip out of one of the terminals of the middle division on this system, with a train of 30 cars, 25 of which were equipped with the Westinghouse automatic air-brake, properly charged, and in apparent good condition. On account of the inspector being engaged at a distant part of the yard, and to save time, the rear brakeman had made the air test by opening the stop-cock on the last car of the train. As all the cars between him and the engine were "cut in," the application of the brakes on quite a number of those next to him, and their release after the cock was closed, satisfied the brakeman as to the efficiency of the test. Mr. Scott, however, had no faith in this style of brake test, and proposed having it done in the proper manner; he accordingly discharged enough air through the brake valve to insure the application, and requested the brakeman to go back along the train, inspect brakes, and advise him if all were O. K. This was done, and the engineer notified by signal that they were all right. Results proved that the brakeman, disgusted at the engineer's unnecessary (?) caution, had simply walked along the train to gratify him, paying no attention to the brakes, and reaching the rear end had signaled him that they were all right. Here the experience and good judgment of the engineer came to his aid. He had noticed that the reduction on the gauge was too rapid, when making the discharge from the brake valve, to come from a train pipe 25 cars in length, and not wanting to wait longer, he decided to go, resolving mentally, however, to use extra caution in making his first stop, which was at a junction. When that point was reached he discovered very quickly, when trying to check the speed of his train, that his suspicions were well grounded, and that he had not the number of brakes operative stated by the brakeman. Having side tracked for an express train, he at once began an investigation of the trouble. The fireman was requested to apply the air, when Mr. Scott started back along the train, counting the cars, and finding that he had seven with brakes applied, and that while all the others were charged and "cut in," no application had taken place back of the seventh car. The brakeman, arriving at this juncture, was asked to explain why he had said that there were 25 cars with brakes working, when the test showed but seven. That gentleman, who had acted in good faith, requested Mr Scott to have the brakes released, and remain where he was, and he would show him that the brakes would apply through the entire train. This being done, the brakeman walked to the rear end, opened the stop-cock, and lo, every one of the 25 brakes applied with a snap. Here we see that while all the brakes could be applied from the rear end, but a small part of them were effective when the train pipe pressure was reduced at the brake valve.

In your experience as a practical manipulator of air-brakes, you have doubtless met with enginemen who would have promptly, and without investigation, relegated the phenomenon here witnessed to that realm of mystery in which some are wont to enshroud many of the unusual manifestations met with in air brake practice; not so with the man pulling this train; he had a habit of reasoning from cause to effect, and *vice versa*, and he at once began a search for the cause of the trouble. This in due time was discovered to be a plug of waste in the train pipe, behind the strainer, which drew into and stopped it up when the train pipe pressure was reduced from the front end, preventing any reduction back of that point, but when the air was exhausted from the train pipe through the rear stop-cock, the plug was drawn away from the strainer, allowing a uniform reduction to be made the full length of the train pipe, and the consequent application of the brakes. This was, of course, a very unexpected occurrence, but it is the recorded experience of most people that it is the unexpected that generally happens.

Moral: In testing air-brakes on trains made up and ready for the road, require train pipe pressure reduced through the engineer's brake valve, and always by the engineer in charge. T. Paxton.

Nickerson, Kan.

Packing Air-pumps.

Editor The Locomotive Engineer:

I am very glad that some one will take the trouble to discuss air-brakes in your columns. It has until a few years ago been made a mystery of by those who handled it, and only by debating such questions can information be obtained of others' practices. As to the lift of air valves, would state that I believe that the upper receiving valve preferably, or lower discharge valve, should have a little less lift than its mate, to balance the weight of piston and keep it from knocking on down stroke.

I assumed that the hot pumps under consideration had been put in the order that Brother Smith mentions as near as possible, and will state that with a poor conducting surface, such pumps can be red-hot, and will ask why pumps will get hot under bad management, and get cool again without oil while locomotive is standing, as sometimes occurs if his theory were right, as with oil burned his pump would churn worse than ever.

Any one interested on this subject can gain much information by sending 50 cents to *The Engineering News* Publishing Company, Tribune Building, New York City, for "Compressed Air Production," by William L. Saunders. I believe it to be one of the greatest of helps to an air man.

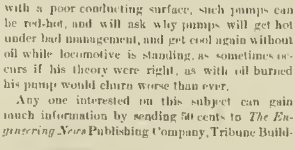

Fig. 1.

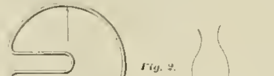


Dirt guard for front of Pump Fig. 3.

I do not wish to be understood as saying that no water will deposit at all times, but that more is deposited under conditions mentioned, and that it deposits only what is in the air, and that if there is more water in the air it will deposit in greater quantities, or, perhaps, enough to give trouble, which might be avoided if condition of air were known. Also that on some days air released from trains will carry out more water than at other times, as may be seen by opening cocks on trains for a few days, and noting results.

I wish to make a proposition to my brothers of the pipe wrench and burnt finger fraternity, if the editor is willing. I will state my way of doing something, and will invite criticism, and wish to be handled without gloves. Let some other air man tell what he knows about some job, and awaken a discussion—by which I, for one, hope to be greatly benefited—and to start will tell how I pack an air-pump.

I take an old sprinkler hose, if I can't get a new one, and when I have time I begin at one end, and cut it in a square strip round the hose till I have it all cut. On my spanner wrench I have marked the length required to go once round the piston rod. I cut my rubber this length, and untwist asbestos wick, and wrap my rubber with it, this will just fit the stuffing-box, and I lay it by till I have to pack a pump. Then I unscrew the bottom nut, start the pump slow, and blow out the old packing. I have a piece of brass spring wire $\frac{3}{16}$" diameter, bent as in Fig. 1. I hook the small end under the lower gland and spanner nut, and the open part over the top one, and proceed to pack the air part without the burning or cussing usually indulged in. I oil my packing well, and break joints, usually getting in three pieces, and do the top one the same. This, if not screwed down too tight, will not harden, and by occasionally adding a piece will last almost indefinitely; at least I have them now running on main line that were packed two years ago, and are good yet.

The piston rods wear smooth without scoring; there is not so much friction as on any other kind that I have used, and in consequence the pumps do not work so hard, and last longer. The best swab that I have seen is made as in Fig. 2, of hammered sheet brass, and wrapped with candle wick. An oiler can be put in the finger loop if thought necessary. I then have a guard made of Russia iron, with the ends bent to catch on the rear bolts of pump, as shown in Fig. 3, and wide enough to cover center piece; this will keep out sparks, lasts well, makes a very neat job, and gives very little trouble. When I have a pump that I am afraid of getting hot, I have smaller piston guards that just fit spanner nuts, and give more surface for conducting away heat. This is the best practice that I know of, can I learn of a better?

Roanoke, Va. George Holmes.

A Breakdown Puzzle.

Editor The Locomotive Engineer:

Once in a while you publish air-pump puzzles for air-pump doctors, but there are but a few of them to guess, so I am going to start the ball rolling among the boys by propounding a breakdown question. This will help those studying for promotion to think, and I think would be an interesting feature of the paper. The trouble with the gang is that they are afraid to guess for fear of going wrong. But for the puzzle:

Alex Cunningham was running an old eight-wheeler on the Mobile & Ohio a few years ago, and all at once she commenced to limp.

"Three legs," said Alex. to the fireman, "She's slipped an eccentric."

He stopped, got down and examined her carefully, but her eccentrics were in place, and her valve motion all right.

"It must be a broken valve yoke," mused Alex., so he got up and tried her.

Steam came out of the right back cylinder cock only, and Alex. took up the right chest cover, only to find the valve, yoke and ports all right.

He got up to move her to hunt farther, and she seemed to go all right, and he gradually increased speed and finally ran in.

The machinists took up both chests, looked into both cylinders, the front end and everything else, and swore she was all right, and Alex made another trip with his three legged pet.

He reported the right side examined again, and they found the trouble at once. What was it?

Philadelphia, Pa. Traveling Engineer.

[Studying practical questions like these will do every engineman good; he will think. Try an answer.]

Marks Reports the Franklin Institute.

Editor The Locomotive Engineer:

I see by yoor August number thet yu kort onto ther great skeem of Tom Shaw, which he tried ter spring at ther Master Mekaniks Convention about ther wonderful kompound goin up hill. Ef yu had been at ther last meetin of ther institoot yu wuld not wonder at anything they say.

Yu jest orter herd ther report as read by ther chairman, he of ther flowin whiskers and ther King-Solomon-I-am-ther-wisest-man expression of his voice, sorter komes down ter our level just ter akomodate us, and tell us a leetle of all his store of knowledge, particularly about kompound engines. Yu know him. Well, he sailed inter ther kompound buzines in great shape, and ther report sounded nice, even if we all knew (includin ther chairman) thet it wuz chuck full of statements that wuzn't so and never wuz and never will be.

He told us how, by havin four cylinders, yu could build ther engin narrower than if yu only had two, and proved it by diagrams drawn from natur. it wuz clear that ther two cylinders wuld take up ther most room. Ef yu don't believe it, just ask ther chairman, Mr. S. Lloyd Wiegand, Patent Attorney, etc., and he kan explain it to yu so yu kan't help but see it.

Then with the four-cylinder kompound yu kan kome home on one side if ther other side breaks down on the road. With ther others yu kan't, because it hasn't got but one cylinder left, and it takes two to run home—at least so ther chairman says, and he knows, ef he didn t, he wouldn't be on ther komity, because only ther railroad experts is on that. We used ter think that with ther old simple engins we could come home on one side, but sence hearin this report we hav kum to ther konklusion that we never did come home one sided, tho we thot we did then—jest dreamin, I guess—fer the chairman says it kan't be did, and of course he knows.

Then, too, ther Webb engin was supposed ter be able ter run in with any one of her three cylinders, ther other two bein disabled, but since hearin this report of the komity we know that was only a dream or fancy, too Strange how much a man kan learn from just hearin a report of this kind read, and not only read, but explained in sech an able manner by ther aforementioned chairman, yu orter heard it. If ther reports was fer sale it would pay ther railroad companies ter buy a few hundred and giv ter ther best engineers, for it givs sum valuable information; but I think ther reports must be scarce, for they have not been sent ter ther members of ther komity, as wuz ordered at ther meetin. But then, of course, all such orders are at ther option of ther chairman, who steered this report thro. It takes a good lot of steerin ter get a thing of such momentous valu thro without havin some one who isn't up to ther high grade of ther art, kick It says the report wuz unanamous, but I guess it means unanamous when ther chairman wuz alone.

If yu could make sum arrangment with this man fer editin part of your paper, I think it would giv it a good start in ther higher branches of railroadin, *i. e.*, savin fuel, on paper, and squeezin ther engins so as ter go in narrow places. Ther rule is this, ter make an engin narrower: "Add two cylinders, and pay a royalty fer usin the patent uv this one."

It must not be understood that this wuz a medal fer bein ther best engin, tho ther award duz say so, fer the chairman said thet it "wuz fer a departure from existing practice," and we suppose this means ther act uv squeezin by addin cylinders. That is a departure, surely. Ther medal orter be divided inter two pieces, fer ther first half belongs ter ther engin thet has been changed inter a simple one by ther B. & O., and the other half ter the one which Mr. Shaw described so accurately at ther konvention Don't know what they will do about splittin ther medal, but it orter be dun.

If yu hav anything novel, and a "departure from existin practice," jest bring it before this komity and get ther medal, and get ther chairman to explain it fer yu. He can do it better than yu kan. R. E. MARKS

Camden, N. J.

Suggestions for a Front End.

Editor The Locomotive Engineer:

The extended smoke-box was designed to catch and carry cinders, but you will go a long way and hunt a long time before you will find one that does that and lets the engine steam fairly well at the same time The successful ones are so arranged that they throw out 90 per cent of the cinders; then they steam

I do not believe that there will be many practical railroad officials who will dispute me when I say that the law requiring spark arresters, cones, netting, etc., is directly responsible for two-thirds of the fires laid to locomotives.

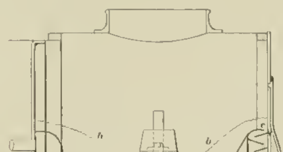
Every impediment put in the way of a free, easy exhaust, calls for a sharper blast to force the gases past or through the obstruction, the nozzles are contracted, the blast increased, and more fire is drawn through the tubes, and forced through the netting and stack

I have experimented enough to satisfy myself beyond all doubt that a straight open stack on a short front, entirely free from netting or other obstruction, will admit at once of opening the nozzle, and insure a free steamer and a stronger working engine without throwing fire

The extension arch is heavy in a place where lightness is desirable—on the truck. It is harder to keep tight than a short front; it costs more first, and more to keep up, and is very dangerous to strike stock with.

What is wanted is some device that will kill such cinders as may be drawn through the flues, and then throw them out, dead. Suppose we take a short front, put in the usual adjustable diaphragm, and a course netting, as shown at *b b*, then put in a partition sheet as shown at *a a*, making the bottom chamber *d* comparatively tight? The action of the exhaust will carry the cinders, too big or too heavy to go through the netting, up the incline and into the orifice *c*, where they can fall by gravity or be drawn down the inclined shelves to *e*. They are dead long before this, and are then drawn into the pipe at *f*, and thrown out by the exhaust. This pipe is only one form, easy to make, and is something on the exhauster plan for vacuum brakes, a pipe entirely around the nozzle might be used, or any of a dozen things that would accomplish the same end.

The inclined shelves would be half on the door and half on the lower cavity, so that when the door was opened the shelves would all be exposed. This lower cavity *d* may be made in the shape of a cast-iron box, say 12 inches wide, requiring no tight joints between it and the arch.



The way I am fixed here, it would take about nine thousand fathoms of red tape and four years to get permission to try this, so I throw it out as a hint to men who are not buried quite so deep.

One of the cleanest engines in this country is the Webb engine on the P. R. R., and she has a short front, open stack, and no netting

A SOUTHERN MASTER MECHANIC.

Valve Motion Question.

Editor The Locomotive Engineer:

I would like the views of some of the readers of your valuable paper on link and eccentric motion, and would ask What becomes of the oscillatory motion of the link when the reverse lever is put in the extreme forward notch with link blocked down tight, and the back-up eccentric rod taken down, and does it practically shorten the other, or go-ahead? If so, how much and why? if not, why not?

Duluth, Minn. L. L. HOOD.

Double-seated Throttle Valves More Than Forty Years Old, Anyway.

Editor The Locomotive Engineer:

I see in this month's number there is an inquiry about the early use of the double throttle on a locomotive The first one I know anything of was put in engine Philadelphia, rebuilt by James Millholland, for the Philadelphia & Reading Railroad Company, some time during 1848 It took steam from two domes. He used the same device on all the engines he built new or rebuilt for the P & R I believe he used same style of throttle on the Baltimore & Susquehanna Railroad prior to his coming to the Reading E. J. RAUCH.

New York.

Differences of Opinion on Examinations—A Plan to Insure Flagging.

Editor The Locomotive Engineer:

It is evident that a wrong construction has been put on my article on examination. I do not claim that engineers should file their brasses, or do any of their running repairs, but I do claim that they are so much ahead if they know how to do the work, and I claim still further that a year spent in the roundhouse and back shop is worth more to the coming engineer than two years on the left-hand side of an engine.

Engineers are sometimes promoted to the grade of Division M M., and the more they know about locomotive construction the better it will be for them in their new position. I know what it is to work under Engineer M. M.'s who had never learned these things in advance. I have been compelled to do work that was wrong in theory and practice, simply because he was M. M., and I was machinist.

The examinations are all right, and must result in good to all concerned. But I still insist that there is a class of men who will learn to answer these questions, parrot-like, who will never make good engineers. I quote a man who has been firing over four years and did not know what a petticoat pipe was until the writer told him, yet he is kicking to be set up. Another party is posting up on Mr. Cushings questions, and will learn them; but he will never know the most of the parts when he sees them. The examinations will weed this class out.

I make another claim—the man who will not make a first-class fireman after two years on regular duty will never make a first-class engineer, and the examination, or his ability to answer questions, will not make one of him. I take the stand I do on this question from my own observation of men on railroads, and I am not drawing on my imagination; so go right on in the good work, it is only taking out a company license instead of a State.

There is a question that should be included, it refers to losing the cap or collar off the end of crank-pin, when solid-end rods are used. Let me quote a case. A man was running a passenger engine with solid-end side rods; the side rods were outside of main rod. While oiling around he missed the collar from the right back pin; he run to the end of the division, over a hundred miles, with nothing to keep the rod on the pin, and got in all right. Now I would like to ask the readers of THE LOCOMOTIVE ENGINEER what they would have done under similar circumstances? A railroad man don't have to draw very hard on his imagination to know what the result would have been if the rod had come off while running.

The man in McCook, Neb., seems to be wedded to the headlight curtain; all right, my good brother, but I fail to see a redeeming feature in the system, but don't talk about brakemen flagging; the destitute widows and helpless orphans created in the last few months, proves that they did not wield a red light nor a flag in *their* defense And now, Mr Editor, I want to offer a solution of this flagging trouble:

I propose to locate a distance post in both directions from a station, put a locked box on each post, the station agent to carry the key When a train is going to make an irregular stop, by reason of hot boxes or other unexpected causes, a flagman must go out and drop a check bearing the number of his train in the box; we know now that he has been there; at the same time he must put two torpedoes down, and he must stay there until called in.

When called in he takes up one torpedo, leaving one to notify a following train to slow down and get under control until station is passed, but two torpedoes says stop; the usual red light or flag must be used in connection with the torpedoes. The checks must be returned to the division superintendent by the station agent.

The risk of being left, or the state of the weather, must not prevent the flagman going out. The conductor's report shows that a stop was made, and the check shows that a flag was out. An engineer is not at all times looking ahead, there are times when his attention is called to some of the boiler head attachments, and just at a time when he would miss a flag, but he would not fail to hear a torpedo. Anything to get these fellows out with a flag, take a shotgun, if necessary, to make them move and protect their trains. W. DESANNO.

CONTENTS.

Learning Late.

The examination of firemen before promotion seems to have suddenly struck some of our roads as necessary—time some of them woke up. Lots of eastern roads are now calling in their oldest firemen, and asking them questions of all kinds, some fitting the case, and others too deep for any one.

A couple of firemen from a Brooklyn Elevated Road recently called upon us to point them out the way to get properly posted, what books to read, etc.—they had just failed to pass a very easy examination.

Both seemed anxious to learn now; they had fired over three years, but never seem to have had the chance they were entitled to. Promotions had been made on age entirely, so they had waited. They had never been told what to learn, how to learn, or where to learn; they have to keep their engines clean, and do all a regular fireman's work on short runs where there is a lay-over at each end of only four to nine minutes; the engines are double-crewed, so they see them only in service. These men have even been, until now, debarred from entering the shop—yet the officers of the road expect them to know something about locomotives.

We claim that the officers of this road are at fault for having this kind of men. They should have told them in the start what they had to know, and where to find it out, and then have examined them occasionally to see if they were learning. One of the men said that when he asked his engineer how to set an eccentric, he was told that "that was an engineer's secret." The other fireman's engineer always looked wise at a question, and told him to "figure it out himself, then he'd know." A little examination of engineers might not be amiss here; a fireman ought not to be blamed for having a poor engineer.

These firemen are scrubbling around now hunting books, reading papers, and *thinking* about their business, they should have been doing this the three years past, but it's better late than never. We think, under the circumstances, that they deserve time to post up for another trial, and, perhaps a change of engineers

Out of a late "batch" examined on the N. Y Elevated they only got one out of four. These elevated roads won't hire an engineer, they put firemen where there is little time or opportunity to learn, and then expect the men to know their business thoroughly Roads placed in such peculiar circumstances in this matter should be provided with some place where men can get a chance to learn, extra care should be taken to see that engineers impart some correct information to the firemen, and that the latter have some opportunity to learn their business, and especially the peculiarities of their own engines and service.

The N. Y Central have recently begun examination of firemen and are finding lots of ignorance they didn't suppose existed—and for which the officers are not entirely blameless—and many old firemen who have been merely time servers are liable to be dropped out.

The reform comes none too soon; but many men whose principal fault has been indolence or indifference are liable to be punished, because the operating officers have been in the past recreant to a plain duty. This trouble is not confined to one road or one section of this country, but is, with very few exceptions, as wide as the continent. Are you posted?

Motive Power of the New York & New England.

Albert Griggs has resigned his position as Superintendent of Motive Power of the New York & New England road, and the office has been abolished

Mr. E. M Humstone, for the past ten years master mechanic of the western division, has been made general master mechanic of the system, with headquarters at East Hartford, Conn In selecting Mr. Humstone for this important position the management has, without doubt, chosen one of the ablest men in New England. He is a thoroughly practical man, and perfectly familiar with every detail of his office, and the able manner in which he has for so long a period under six different managements, handled the vast amount of business immediately under his supervision, should be a sufficient guarantee to his many friends that he will experience no serious difficulty in successfully coping with the most difficult problems of his new position. Endowed with integrity, intelligence and ability, he should be enabled to fill with honor and credit the highest position to which he could be called

It is to be hoped, however, that he will be given a little better chance than his predecessor, Mr. Griggs No man in New England could handle the motive power of a road better than Mr Griggs, he was trained under his father, one of the progenitors of the American locomotive, and has had a lifetime of experience. The Valley Falls shops of the Providence & Worcester, built and managed by Mr Griggs, have long been acknowledged as the model shops of New England

The New England seems to be managed (?) by men who imagine they can run a road forever without keeping up running repairs. They have kept Mr. Griggs down from the first; he has never had men or material enough to half do his work, and the record of the road for the past sixteen months will bear us out In that time there have been over *two hundred* accidents; and this on a road operating but 477 miles of track, a short time since there were twenty-four engines awaiting general repairs They are now having a lot of engines repaired at the R I. Locomotive Works. It seems that the less a manager knows about motive power, the more he wants to monkey with it, and the more he thinks he can choke it

Mr Humstone has appointed Mr. F M. Mast, general foreman of the East Hartford shops, in charge of the western division, and Mr. J. T Brady, of the Erie, general foreman of the Norwood shops. We hope the New England management won't tie Mr Humstone's hands, as it did Mr Griggs', and then expect him to work miracles.

One of our advertisers got "onto" a new scheme the other day. He makes a device much used in the coal regions, and tries to advertise there when possible, he knows something about advertising, and has been somewhat inclined to think that "folders, maps and guides" had their uses—he knows better now. He recently had a chance to invest half a hundred in a card on a map of the Lehigh Valley road, which the solicitor guaranteed would be hung up in every waiting room on the system. He paid his money on presentation of a map with his card thereon, and awaited returns—he's waiting yet. On a recent trip over the L V he noticed the maps and put on his specks to see how his "ad" looked away from home. There was no "ad" there, and diligent search along the line failed to show one. On returning home he inspected his map closely and found that his "ad," was neatly pasted on top of another.

We have before us a printed paper, 12 pages, published by the Government of New South Wales, giving the "Conditions of Employment of Staff in the Various Branches of the Government Railways of New South Wales" It is interesting reading, but all we have to say is that if government ownership of railroads calls for as much red tape as this for a man to get on the "staff" as cleaner, wiper or fireman, we are "agin" the government ownership scheme here

Harry D. Cozens, founder and first president of the National Association of Stationary Engineers, and for more than a year solicitor for this paper, has been appointed chief engineer and superintendent of the Prudential Life Insurance Company's magnificent 14 story building at Newark, N. J. Mr Cozens is now putting in the power, lighting and hydraulic plant, an outfit as fine as money can buy The building is the finest in the State.

The historical old locomotive "General," illustrated in our issue of August, 1888, and over the capture of which one of the saddest incidents of the civil war was enacted, has at length been noticed by the people of Georgia, and a bill introduced in the legislature proposes its purchase and placing on the capitol grounds as a monument The "General," though born in Paterson, was a rebel, first, last and all the time.

Book Reviews.

PROGRESSIVE EXAMINATION OF LOCOMOTIVE ENGINEERS AND FIREMEN By John A Hill Published by J A Hill, Box 1,736, New York. Bound in cloth, price 50 cents.

We have little need to tell just what this book is. It contains the articles already published under the title in this paper, and seventeen colored plates, showing positions and color of all signals carried upon trains or engines according to the standard code. The book is bound in flexible cloth covers, pocket size, 6x4 inches, and has been put into book form to meet a demand for it in convenient shape for preservation. The book contains several blank pages on which to note differences in rules, and other memoranda.

POOR'S MANUAL OF RAILROADS FOR 1891. H V. & H W. Poor, New York

This is the twenty-fourth annual number of this well-known and standard work. It grows with the railroads of the country, of course, and will soon need to be issued in two volumes, the present number having over 1,500 pages. This is the standard work of the country on the financial condition, history and extent of American railroads, and is to be found at hand in all railroad offices, banks and financial agencies

PROTECTION AND FREE TRADE By Henry George. Published by the *Standard*, 42 University place, this city. Paper covers, price 35 cents.

This work has reached a sale of upward of half a million, and is considered a standard work on the subject indicated in the title No student of tariff matters, no matter what his belief, can afford to do without reading this interesting book

ASKED & ANSWERED.

(56) F. E. B , Cumberland, Md., asks

1. Will a line drawn through the centers of the drivers of an engine with horizontal cylinders pass through the centers of the cylinder heads? *A.*—Only in some cases; most locomotives have their cylinders set higher than the center line of drivers 2 What is the rule (if there is one) regarding the position of the cylinders when they are slanting? *A.*—There is no rule 3 What is the "valve yoke" and what is the "saddle," and what are their respective uses? *A.*—The yoke is that part of valve stem forging that surrounds the valve The castings between the cylinders by means of which they are joined is called the cylinder saddle, and the bridge from the forward to back part of the link which carries the suspension stud is called the link saddle.

(57) C. M. B., Algiers, La., asks

1st Why is the bottom arm of a rocker shaft set back on a locomotive, and as a rule how much? *A* —When it is found necessary to incline the center line of motion—a line drawn through the axle and link block—below the center line of the engine—a line drawn through the cylinder and axle—the lower end of the rocker is offset enough so that it is at right angles to the center line of motion when the upper end is at right angles to the valve stem. This is done to equalize the motion 2d Why is the saddle pin on a link set back of the radial center? *A* —To equalize the cut off. Read Elementary Lessons on First Principles, October, November and December issues of 1889

(58) C. D., Fort Worth, Texas, asks

1. Is there a machine made for bending copper tubing all sizes up to 2"? If so, who has them? *A.*—Pipe-bending concerns, making many bends alike, use rolls, but for locomotive work copper pipes are bent by hand, being first filled with rosin to prevent flattening 2. What is a good composition for making metallic packing rings for pistons and valve stems? *A* —Genuine babbitt metal is usually used; this is composed of 3.7 parts of copper, 89 parts of block tin, and 7 3 parts of antimony. Good results have been had by using 90 parts of tin and ten of antimony

(59) D. D. C , Vicksburg, Miss , asks:

1. Is there any patent planished iron made that is not dished in the center of the plate? *A.*—We have never heard complaint about the dishing before; it is almost impossible to roll sheets so thin without the rolls springing some, rolling outside of plate thinnest. 2 Is genuine Russia dished? *A* —No more than ordinary sheet metals 3. How is Russia or planished iron measured? *A* —By wire gauge

---

A 140,000-mile run without any repairs is the published record of a locomotive on the Pennsylvania Railway. This engine runs between Altoona and Pittsburgh, and makes 468 miles per day Engine 337 of the Chicago division, in July, made the remarkable record of running 7,680 miles during the month.

Now while Mr. Hitchcock is writing on running repairs, we hope that every roundhouse foreman, mechanic or engineer, who wants to know the proper way to go about any repair job, to write us stating his wants, and we will interest Mr. Hitchcock in his behalf

Santa Fe Shop Notes.

Going around the country visiting railroad shops is, so far as the shops go, about like changing a horse from one field to another—there is a good deal of sameness. But I always manage to find something new and interesting in the men and in the way they do their work. Wherever there is originality or individuality there is interest, therefore the Topeka shops of the Atchison, Topeka & Santa Fe are interesting.

THE MEN

seem to do things a little different here than other places, sometimes doing them better and in other cases not quite so good, perhaps, but they *do* successfully.

I am an admirer and a lover of railroad mechanics—engine and shop men—and I am as much interested in them and their work as an astronomer can be in the spots on the sun, their successes are a source of gratification and pride to me, and I never saw one of their failures that did not do me good—taught me a lesson or pointed a moral. I read all I can find about my kind of people and listen to all I hear

WITH THE SUPREME JUDGES,

Our train was quite late out of Denver, owing to a freight train wreck and after getting started I went into the smoking compartment to suck a little inspiration out of a good cigar—a present to me.

There was a Hebrew drummer asleep in one corner, a merchant from the mountains, going east, and two young men who, from their dress and the color of their hands, I judged to be office men, and by their talk to be encyclopedias of railroad information, they were apparently employes of the claim agents or the auditing department of some road, but just then they were sitting in judgment on the Santa Fe system. They found fault with all the departments in turn, told how they would straighten out things, discussed the merits and demerits—mostly the latter—of men at the head of departments, and kindly explained to each other how the road could be saved from ruin from each source.

I shut my eyes, opened my think trap, and took no interest, knowing that sooner or later they would get to my department—the mechanical.

"There's another man that's fearfully overrated," said the younger one, pulling at a hand-raised moustache, "that man Player, John Player, the superintendent of machinery; seems to me they could get a man in America for that job; just think of paying that Englishman ten thousand a year It's pure luck on his side, just bull-headed luck, why he hasn't been in this country more than fifteen years, came here with a family, soon got to be master mechanic, and went right up ahead of everybody. Some men do have the darndest luck"—but I shut my think trap here and went to bed

I don't believe in lucky men very much, I've heard of quite a number in my life, and I always wanted to get acquainted with one, but came to sift each case down to bed rock I never failed to find a natural cause for success, altogether different from luck, so I concluded to stop off at Topeka and see what charm John Player had that made him lucky.

I found upon inquiry that Mr. Player served his time and worked as a machinist in the Woolwich Arsenal in England, that he came to this country fifteen years ago, with a family, and after some difficulty secured work as a machinist in the Iowa Central shops at Marshalltown, Iowa, was soon made foreman, and within a few years master mechanic, after several years of service here he went to the Wisconsin Central as superintendent of M. P., remaining two years, and making such a record as to attract the attention of the general manager of the Santa Fe road, and to finally put him at the head of the mechanical department of the longest railway system in the world—it does look like luck

NOT LUCK, BUT WORK

I kept watch of Mr Player for three days, and mentally took a few notes. Mr. Player seems to have plenty of time to spare, he can always see the division master mechanics, the foremen or the men; the drummer is invited in and talked with Mr. Player goes home to his regular meals, and don't thrash around and worry himself, but we noticed that somehow or other he disposed of every letter and report on his desk each day—lucky men don't do that—he seemed to know the location of everything and everybody around the plant, and had changed many things to avoid friction and facilitate getting out the work—not the traits of a lucky man at all.

I noticed that he was making use of many of the little things, plugging up small leaks and practicing small economies, that he kept a record of service of his rolling stock and figured on certain mileage for a certain cost, and was figuring to save by adopting the simplest devices and cheapening the cost of production and repairs—the lucky man cuts wages, it's easier

There is not a great deal of trouble locating the lucky charm worn by this mechanic—it's good judgment, capability, work and *system*.

But I started in to tell you something about

THE SHOP.

Well, the shop is not much good—the machine shop, I mean—it was originally built for a bridge works, and is dark and very badly arranged, the car shops and storehouse are splendid stone buildings, but, after all, the interesting parts are the men and other things inside.

LIGHT.

They used to use torches in the machine shop A nice, fat, greasy smoky torch on a hot day in summer, located just ahead of your nose, is a first class abomination Mr Player remembered that there had been an expensive electric train lighting experiment indulged in by the road a year or two ago, and found several dynamos and storage batteries piled up in Chicago—well, they are lighting this shop now

POWER

is furnished by a big Corliss engine, located in the middle of the shop. But I don't care so much for generalities. I am a specialist, and the first thing that really interested me was

A BROKEN FRAME,

no, a frame that *was* broken, it had been mended. This frame belonged to a consolidation locomotive that had been in a collision, and it was broken in five places, bent out of shape, and apparently hopelessly demoralized It had just come in from the blacksmith shop, and they were putting it under the boiler

WITHOUT PLANER WORK

The jaws were square and just where they belonged, yet one of the welds was between the jaws and on the main frame, the welds were smooth and the frame straight. Master Mechanic Smith said this was a regular thing with them, and I went right straight to the

BLACKSMITH SHOP.

I found this fairly well equipped with tools and in charge of an old-time Vulcan named Bill—I always forget the hind name—who was just superintending the welding of a frame, the weld completed, the boss squinted along the work a few times, made a measurement or two, had a blow struck here and a tap there, and said, "All right; cool her off." The men left the frame in the crane and laid straight bars of iron, as heavy as the frame, on each side of the weld, and bolted them fast with clamps, then turned a stream of water on the red hot iron. The false frame prevents the hot one from twisting or binding, and they cool off and measure to see if the frame is true and all right; if it is not, they take another heat and correct the error. It saves great expense in machine work This job did not need reheating, and was taken down. When I asked the foreman blacksmith if he "jumped" those frames together, he looked at me in disgust and said. "No jumped welds for me I 'he and she' every frame welded here, and make a job of it." Certainly the work I saw looked as if it had been drop-forged.

THE BOILER SHOP

is an important part of the plant, and a great deal of work was being done there. They have had considerable trouble from the cracking of the crown sheet or flue sheet near the seam on radial stayed boilers, and have adopted the plan of putting two crown bars in front, believing that they will admit of more expansion In this shop they have a simple flange furnace that seems to me to be a good thing. The bottom, or bed for the fire, is a sheet of boiler iron punched full of half-inch holes; this sheet has a space under it, into which the blast is introduced; the holes in the sheet are stopped up by large-headed rivets. When a piece is to be flanged, rivets are taken out just the shape and size of the fire wanted, and the live fuel piled over the bed and the blast put on; fuel will only burn where the blast is, and the result is fire where wanted, and there only.

HEADLIGHTS

are made in the shop; the lanterns are extra strong and rigid, made of galvanized iron on an iron frame. Shortly after Mr. Player took hold, he ordered all division master mechanics to send in all old reflectors on hand; the result was a crop of 105, these were replated, an ounce of silver being put on each one, to do this, they solder a piece of tin over the two holes on the outside and then fill the reflector with the plating solution.

MONEY IN THE SCRAP.

The 105 reflectors only show what might be expected if the scrap was looked over. One result was the shipping to Topeka from all along the 8,000 miles of road of over 12,000 air-brake hose-heads; these were sorted, new gaskets put in some, the torn hose cut off, and hose bought in coils to fit them to—the resultant saving will almost pay John Player's big salary for a year, and there are still great possibilities in that scrap pile

BABBITTED BRASSES

have the regulation two strips of soft metal from end to end of the brass, except that there is a strip at each end enclosing the space between the longitudinal strips, this holds oil.

A NEW IRON BRAKE BEAM,

designed by Mr. Player, is being used. It is made just opposite to the National hollow beam; the pipe section is the arch or compression members and are in two pieces, with the tension rod straight across. It works well. Mr. Player's driving brake shoe, with chilled cutting edges, is also giving good service.

RIGID CENTER TRUCKS

are being used for engines, tenders and freight cars The first cost and repairs are far below swing motion trucks, and extended experiment has shown them fully as safe, if not the safer of the two kinds

CAST STACKS,

base and all in one piece, are finished ready for the engine, at a cost of $1 85 per hundred pounds, and weigh about 350; they are cut off at the top straight, without even a bead, experiments showing that smoke is trailed in exact proportion to size of the top ornament of stack

NOZZLES

of very large diameter are used; they are annular, and of the pot-belly or reservoir order, the adjustment for size being at the junction of the two pipes, the upper or final opening being much larger. The exhaust from this pipe is the easiest I have ever noticed, except with the Smith triple expansion pipe.

SHORTENING FIRE-BOXES.

In a large class of consolidation engines, with ten-foot fire-boxes, they have bricked over the grates for the front four feet, making a large combustion chamber of the front of box; they steam well with the big nozzle and the poor Kansas coal—24 to 30 per cent. of carbon—and just think of the comfort to the fireman.

COMPOUND ECONOMY

There is a 2-cylinder compound engine in service here, and she has shown a saving of fuel over the ordinary engines, running from 29 to 31 miles for a ton of coal, against their 20 to 22 miles; but there is a new class of ten-wheelers, of the Brooks build, with the big nozzle, that is just about equaling the compound. The men have become interested, and are proving what I have for years contended, that they, the men, could be improved to show more economy than can be shown by compounds or anything else

THE PAINT SHOP

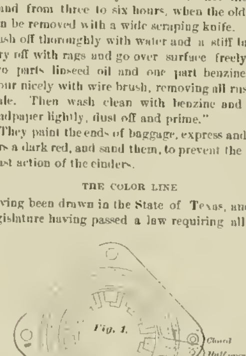
is very elaborate, but not large enough to do the work on hand. They are changing the passenger car color from yellow to Tuscan red, and they have cleaned up and fitted an abandoned roundhouse to help them out. They take in a coach that is not bad, repaint and varnish inside and out for less than $40. The system of keeping paints and painter's tools, and the system of standard lettering is worthy a special article longer than this. They have a mortar that they apply to old tanks, wheels, etc., to remove the paint, that works admirably. Master Car Painter Hogan has a set of rules and formulas for painting, and this mortar and its use is described as follows.

"When it is necessary to remove old paint from cylinders, tank, steam chest, driving wheels, rods, etc., use a preparation of 25 pounds potash, 5 pounds sal-soda, 1 quart light liquid ammonia, 25 gallons water, made stiff with dry slaked lime, and applied with bricklayer's trowel. Let the coat stand from three to six hours, when the old paint can be removed with a wide scraping knife. Then wash off thoroughly with water and a stiff broom. Dry off with rags and go over surface freely with two parts linseed oil and one part benzine, and scour nicely with wire brush, removing all rust and scale. Then wash clean with benzine and rags, sandpaper lightly, dust off and prime."

They paint the ends of baggage, express and mail cars a dark red, and sand them, to prevent the sand-blast action of the cinders.

THE COLOR LINE

having been drawn in the State of Texas, and the legislature having passed a law requiring all rail-



NEW VARIABLE NOZZLE.

roads in that State to furnish separate cars, or apartments, of the same class for colored people, the Santa Fe, with other roads, were hustling to comply with the law. During my visit the cabinet shop was busy on 46 partitions for cars to run in Texas. These were finished inside like the cars they were to fit, and an extra lavatory was being made for each coach.

NEW ENGINES

are mostly of the Brooks make, and they are building one or two eight-wheelers in the shop. The Santa Fe has every kind of locomotive put up in this country within thirty years, some good, some just middlin', and a whole lot absolutely bad. The last of the Strong engines built stands in the roundhouse Every effort has been made to make the engine a success, but they have given it up, and she will soon be rebuilt into a regular made-a-purpose locomotive, the wheels and frames being pretty good, and the tank and truck all right

TIRE WORK

on a road having over 800 locomotives is heavy, and three lathes are here kept on the jump. They turn from 100 to 140 tire per month, and a couple of Bement steel-tired car wheel lathes are busy on coach wheels.

Master Mechanic Smith has increased the output of his shop greatly by putting a tool on special work, and speeding up the tool to all it will stand.

TOOL-ROOM

A tool-room has recently been established, and a new feature, to me at least, is to so arrange the place for each tool that no other tool will go into that place, so that it is entirely impossible to put an inch S wrench in the place of the inch-and-a-quarter wrench J. A H

New Variable Nozzle.

While at Portland, Ore., a short time ago, the writer saw in use on the O., R & N road a new form of variable exhaust nozzle, designed by Mr. Fred. Mertsheimer, superintendent of the Cheyenne shops of the U. P.

The nozzle proper, or tip, is divided horizontally, the lower part having teeth projecting toward the center. A cover fits above these, and is held down by an external flange. This cover is a duplicate of the lower ring, having, in addition to the internal teeth, a handle, whereby it can be moved around so that the upper teeth match with the lower, forming a plain opening for the escape of the exhaust, or one set of teeth can be placed above the other, leaving the openings between teeth clear, thus increasing the area of opening.

The sketches make the matter clear.

This nozzle has been used to considerable extent on the U P, and a saving in fuel is reported from it We are of the opinion, however, that it is a very difficult matter to tell whether saving is made by such a device, or by the extra care of the men using it. Let the U. P. take their coal records for last year, and offer the crew one dollar a ton for all fuel saved over last year's performance, and the result will be something surprising. Some of the poor engines, with plain nozzles, short fronts, and other old-fashioned trimming, will be found to show big percentages of saving.

One of the greatest advantages, if not the greatest advantage, of a variable nozzle on fast engines, is the extra relief it affords the engine when running very fast shut off.

Free Scholarships in the Stevens Institute.

This year the Master Mechanics Association disposed of some $8,000, known as the Boston Fund, by purchasing four perpetual scholarships in the Stevens Institute of Technology at Hoboken, N. J. These scholarships will give to the association an educated ward every year, and it is hoped and believed that this will be worth more to the association than monuments in the shape of club houses or granite pillars. The following circular explains the conditions of awarding the free scholarships.

The scholarships which this association has secured in the Stevens Institute of Technology, Hoboken, N. J., will begin this year, and candidates are required to be in attendance for examination on the week beginning September 28. Candidates must be the sons of members or of honorary members of this association in good standing, or the sons of deceased members who died in good standing. They must also have worked for at least one year in a recognized machine shop, and they are required to take the course of mechanical engineering. The rules of the school require applicants for admission to be over seventeen years of age.

Candidates for the scholarships should apply to the secretary of this association, and he will supply them with certificates if they are found eligible.

There are four scholarships open this year, one for four years, one for three years, one for two years, and one for one year's course. The candidates for the four years' course will be required to pass the Freshman examination, those for the shorter terms will be required to pass the examination of the scholars belonging to the respective years.

Candidates for admission to the Freshman class will be examined in the Stevens Institute on the following subjects:

Arithmetic.—The preparation should be especially thorough upon the properties of numbers, the operations in common and decimal fractions, the methods of finding the greatest common divisor, and the extraction of the roots of numbers.

Algebra.—Simple equations, theory of radicals, equations of the second degree, arithmetical, geometrical progression, permutations by binomial theorem, indeterminate coefficients, logarithms, and series Great importance is attached to a thorough knowledge and readiness in the solution of simultaneous equations of the second degree and the reduction of radicals

Geometry.—All plane, solid and spherical geometry. The examination in this subject will be thorough, and the applicant must show a familiarity with all the fundamental geometrical forms and be able to demonstrate their properties and relations He should also be able to point out the most important ones.

Analytical and Plane Trigonometry.—The fundamental formulae and their demonstrations, as well as the solution of plane triangles by means of natural and logarithmic tables, will be insisted upon

English Grammar.—The requirements are a practical acquaintance with the parts of speech, their relations, agreements and government, the proper use of tenses and moods, the construction and arrangement of sentences

Composition.—An essay upon some topic assigned at the time of examination, and examined with reference to legible handwriting, correct spelling, punctuation, and proper expression.

Universal History.—In the examination in universal history but little prominence is given to dates The questions relate to the great events, their causes and effects. A conspicuous place is given in the questions to the history of the United States Text-books—Myers' or Barnes' General History and United States History, or Johnston's or Higginson's or Eggleston's United States History, or Montgomery's American History

Rhetoric.—The examination in rhetoric will embrace all parts of the subjects which are contained in the text-books on rhetoric. Text-book—Hart's Rhetoric.

French.—The examination will be on translation from Knapp's Modern French Readings, the first half of the book, or from some equivalent, such as Super's French Reader or Fontaine's Historiettes Modernes

Physics.—As much of physics as is contained in Part I. of Deschanel's Natural Philosophy. (D. Appleton & Co., New York, publishers.)

If there is more than one candidate for each scholarship, the applicant who passes the highest examination will be chosen. This will be settled by the school authorities.

ANGUS SINCLAIR, *Secretary.*

Subjects to be Discussed at the Next Meeting of the Master Mechanics.

Secretary Angus Sinclair announces by circular that President Mackenzie has appointed the following committees for conducting the business of the Master Mechanics Association for year 1891-92

No. 1. Exhaust Pipes, Nozzles and Steam Passages.—C. F. Thomas, A. W Gibbs, L S Randolph, J. M Wallis, George W Smith, Robert Quayle, John Y Smith

No. 2. The Present Status of the Car Coupler Question.—John Hickey, G W. Rhodes, Sanford Keeler, R. H. Blackall, M N Forney.

No. 3. Standard Tests for Locomotives.—To investigate the practicability of establishing a standard system of tests to demonstrate the fuel and water consumption of locomotives; also to ascertain the value of the steam engine indicated in locomotive tests.—J. N. Lauder, J. Davis Barnett, Albert Griggs, John D Campbell, F W Dean.

No 4. Compound Locomotives.—To investigate the relative economy of compound and simple locomotives; also the most valuable form of compound locomotive.—George Gibbs, William H Lewis, Pulaski Leeds, James Meehan, T W. Gentry, A. T. Woods.

Auxiliary Committee.—S. M. Vauclain, Baldwin Locomotive Works; Reuben Wells, Rogers Locomotive Works; H N. Sprague, Porter Locomotive Works; A J. Pitkin, Schenectady Locomotive Works; Joseph Lythgoe, Rhode Island Locomotive Works, F. J. Leigh, Canadian Locomotive Works; D A. Wightman, Pittsburgh Locomotive Works.

No. 5 Tests of Steel and Iron. To investigate the critical temperature of steel and iron. Also any other questions relating to steel and iron that the committee may consider of value.—William Smith, J N. Barr, A. W. Quackenbush, P H. Peck, D. L. Barnes.

No 6. Uniform Locomotive Performance Sheets.—To report on the practicability of establishing a system for recording the performance of locomotives that will fairly represent the work done.—George F. Wilson, J. S McCrum, John Player, James McNaughton, John A Hill

No. 7. Standard Bolts and Nuts. To report on the best taper for bolts, and the proper size of nuts, rough and finished, also to report on accurate measuring gauges.—William Swanston, William Garstang, T. W Gentry, W. Lavery, A. Dolbeer, L. R Pomeroy.

No. 8. Rollers for High Pressure Locomotives.—J M. Boon, H. D. Gordon, J. S. Graham, J. H. McConnell, W. H. Marshall.

No. 9. Air-Brake Standards and Inspection and Care of Air-Brakes.—R. C. Blackall, G. W. Stevens, David Clark

Committee on Subjects for Investigation.—J Davis Barnett, George Gibbs, William Smith.

For the Executive Committee,

ANGUS SINCLAIR, *Secretary*

A Signal Holder.

BY L. C. HITCHCOCK.

There are many different appliances on as many different railroads for holding signal lanterns on the back end of engines and tenders, but among the many I have never seen any which exactly fills the bill, according to my notion.

Some have tin or sheet-iron boxes, with tops and two sides of each left open, in which to place

Fig. 1.

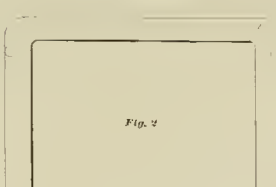


Fig. 2

Fig. 3.

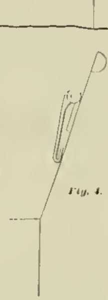

Fig. 4.

the lanterns These boxes are sometimes placed on the tender decking, one at each end of the back tool box. The trouble with these arrangements is that they are an expensive thing to make, and, as two are required for each engine, this is quite an item. Then they are clumsy looking, and lanterns placed in them cannot be seen to advantage. Another objection to their use is that when they are placed on freight engines the brakemen are liable—yes, almost certain—to use them as receptacles for links and pins.

In some cases these boxes are placed on top of the tender, back of the coal board, and when so placed they can be seen better, but are in the way of brakemen when they climb over the tender

Another plan I have seen adopted is to put hooks near the top of the flare or wing of the tender, on which to hang the lanterns by the bails. The trouble with this arrangement is that the lanterns swing against and injure the paint work of the tenders, besides being very dangerous things to trainmen. I have known men to sustain very serious injuries from being impaled on these hooks

Some take blocks of wood large enough to receive the bottom of a lantern, and cut them to such a bevel that when they are placed one on each back corner of the cab roof, lanterns placed on them will stand level, the lanterns being held in place by springs or some such arrangement This plan has its advantages over those previously mentioned, one of which is that it is more out of the way, and the lights can be easily seen; but the disadvantage is that they cannot be seen by the engineer or fireman, and are liable to be extinguished without the knowledge of either.

Not having any standard arrangement for holding signal lanterns on our engines while running light, and being required to find something which could be adopted for this purpose, I looked the field over pretty carefully, noted all of the imperfections of the appliances mentioned, and conceived the following idea, which, when put into practice, proved to fill the bill better than anything I had previously seen And for the benefit of those readers of THE LOCOMOTIVE ENGINEER who have no standard appliance for this purpose, I will explain what I did As it is cheaply made, and no patent on it, those who try it I think will be pleased with the results obtained.

Take two 6" strap hinges, and cut off one side 4" from the joint, the other end cut off 2' from the joint, bend a hook about ½" long on the longer end. Fig. 1 represents the hook ready to rivet to the tender. Rivet a hook on each side of the flare (on the inside), at about the points indicated by the small circles, Fig 2, allowing the hooks to just appear above the bead, as represented by Fig 3. Place the lower guard wire (not the bail) of a lantern in the hook, and the lantern will stand as shown in Fig. 3, with two of the upright guards resting on the top of the bead. Our experience here has proven to us that no ordinary jar will displace the lantern from this position. The only point that the lantern touches the tender is on top of the bead, and no injury is done the paint work

Signals in this position can always be seen by both engineer and fireman every time that they look out of the window. They can also be seen from all points in the rear of the light engine carrying them. When not in use, the hooks should be thrown down, as shown by Fig 4 In this position they are entirely out of the way and cannot be seen.

This device, we find, fills the bill in every respect, is cheap, and *unornamental.*

Talk to Your Fireman.

It is the duty of a locomotive engineer to show his running orders to his fireman. If you are ordered to sidetrack at Tolter for No 9, the fireman commences to figure on that If he has a good steamer he will let his fire burn low in nearing a meeting point, so his engine won't pop. If he has a poor steamer he will scheme to keep his steam up to the meeting point, and in either case, if the engineer pulls by, the fireman will be the first man to notice it. It will not detract from the engineer's position to mix up a little, socially, with his fireman in this way, and it will make the fireman a good engineer. If we were making train rules we would compel engineers to do this, and if that failed to work we would have an extra copy of the train order made for the fireman. The conductor should show his orders to the brakemen. The average brakeman is a much smoother man on train orders than the fireman, but he is not so sure to remember them, for the very reason given in the beginning of this article. Had Engineer Hopkins shown his orders to his fireman, the awful Carlile collision could not have occurred Many will object to this, and say it is unnecessary and takes too much time It will probably take some time to rebuild these engines and cars—it will take some time for the woundist to get used to their wooden legs—it will take some time to heal the broken hearts of the widows of the dead. Talk to your fireman —*Western Railway.*

The Russian Government has requested a Canadian syndicate to tender for the work of constructing 400 miles of the eastern section of the Siberian Railway from Vladivostock to the Amur River. The *Times* (London) says Mr. George Keefer, a leading Canadian engineer, will proceed to Siberia immediately.

"Pig-iron" is a mere play upon the word sow When iron is melted, it runs off into a channel called a sow, the lateral branches of which are called the pigs Here the iron cools, and is called pig-iron.—*Ex.*

Some New Grinding Machines.

The engravings on this page show three forms of a new and unique grinding device being placed on the market by Pedrick & Ayer, of Philadelphia.

They are built on a new principle entirely, and have the great advantage of simplicity. No pumps, troughs or separate tanks are used to handle the water. It runs by gravity to the center of the wheel, and is returned to the case, or tank, by centrifugal force. The No. 8 horizontal grinder is

No. 8 HORIZONTAL GRINDER.

the one usually employed for grinding machine shop tools. It has two emery wheels, the shaft running through removable bronze bushings in the head. The tank is filled at the top, and water turned upon the stone near the center. It remains upon the stone by capillary attraction until enough has accumulated to be thrown to the largest diameter of the wheel by centrifugal force. The edge of the stone is inclined, and the water is finally thrown into the iron rim around the wheel, and forced into an opening to the water tank again.

When the water becomes foul, it is drawn off into the bucket shown, and emptied, the bucket holding exactly enough to fill the tank again.

Repeated attempts to draw the temper of tools on these wheels has demonstrated that it is practically impossible, as the wheel will carry more water than can be used possibly.

The builders will make this machine in several larger sizes.

The twelve-inch upright wheel shown is designed for wood-working shops. The grinding face of the wheel is slightly beveled, to admit of the handling of long knives. The outside rim of the bowl can be lifted off if necessary. The shaft runs in removable bronze bushes, and the belt carrier is shown in the cut. This tool automatically supplies itself with water, and returns that used to the tank.

The coned wheel, bench machine is used for grinding inside gouges, cutters, formers, etc., and is especially useful in pattern and wood-turning shops, as well as for grinding molding and shaping machine cutters for car shops and planing mills.

Water is supplied to it the same as in the horizontal grinder, and the construction is plain from the cut.

These machines are new, very efficient, and can be made and sold for much less than more cumbersome and trappy grinding machines.

Life-savers in Overclothes.

An incident occurred on the Saginaw branch of the D. L. & N. road last Thursday, which adds laurels to the reputation of Engineer Weidman and Fireman Corbus, who go out on the passenger train which leaves Howard City for Saginaw at 8:40 A. M. The train was approaching a siding known as Belvidere, at a high rate of speed, when Mr. Weidman discovered, some distance ahead and close to the right-hand rail, an object which proved to be a little child, about a year and a half old. The brakes were applied in full force, the engine reversed, and every means used by the engineer to stop the train, but it was found impossible, and had it not been for the quick-witted and clear-headed fireman the child would have been struck and killed. He hastily climbed out of the front window, along the side of the engine, down onto the pilot, and when within a few feet of the baby he sprang to the ground, and grabbing it in his arms, jerked it from in front of the train just as the engine thundered over the place where he had been sitting by the rail. The act was a gallant one, which will no doubt cause him to be ever remembered with gratitude by the mother of the child. This is the second experience of a similar nature which that locality has furnished, a child having been struck there by an engine two years ago.—*Howard* (Mich.) *Herald*.

[Acts of this kind are not uncommon on railroads, but who ever heard of an engineer or fireman getting a medal?]

Growth of Our Railroads.

A wonderful story of growth is told in the following figures, showing the railway mileage of the United States by decades for the past sixty years

In 1830	23	miles
In 1840	2,818	"
In 1850	9,021	"
In 1860	30,626	"
In 1870	52,922	"
In 1880	93,296	"
In 1890	166,817	"

In the last ten years the increase was 73,521 miles, or more than 78 per cent.—an average of 7,350 miles each year. If the increase in the next decade is only 5,000 miles per year, our railway mileage in 1900 will be about 217,000 miles.—*Railway Age*.

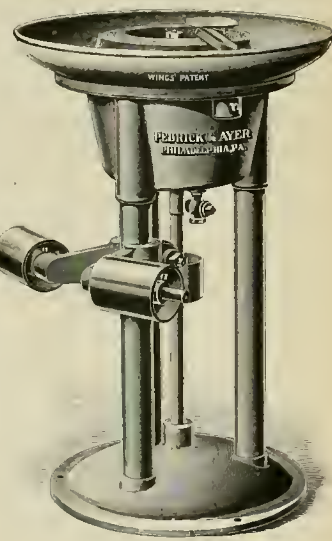
CONED WHEEL, BENCH MACHINE.

Orville H. Reynolds, chief draftsman of the Northern Pacific road, who wrote the splendid series of articles on drawing for this paper, has been appointed mechanical engineer of the entire system, with headquarters at St. Paul. Mr. Hickey has done the proper thing in recognizing a record of devotion to duty and an untiring effort to promote the interests of the road by a young man whose ability has been proven by years of service instead of importing an unknown quantity with some initials behind it.

Several inventors claim the first use of outside cylinders and plain axles—the "Rocket" had both

Cold Truth About Railroad Managers and the Motive Power Departments.

A well-known railroad man who has recently been appointed general manager of a busy road, sends us the following letter, which came into his possession with the other archives of his office. He says: "The former general manager has retired to private life, the M. M. is still here, got what he wanted, and deserved it all. The letter is too good to keep." The man who wrote



TWELVE-INCH UPRIGHT WHEEL.

this letter is well known to the readers of this paper:

G. P. X——,

Gen'l Manager X. X. & X.

DEAR SIR: Some days ago you sent your messenger boy to me with a note, asking what it would cost to grade and put in four new tracks in the repair yard that I had asked for, and requesting a reply by bearer. I told you that I did not know, but could find out if you had any aversion to referring the matter to the road master's department, and now have before me your sarcastic, ridiculous and amusing "roast."

You seem to think that the head of the mechanical department should be an encyclopedia of railroad information, and know everything for your special benefit—for two thousand a year.

I have on file in this office more than one hundred letters and notes from you, asking all kinds of questions on all kinds of subjects, to every one of which I have made some reply; I have gone with you to inspect bridges and buildings, helped formulate time tables, select petty officials, and, through your orders, interfered with the purchasing, track, bridge and storekeepers' department, until I am sick of it.

You have sought and received my honest advice about every subject coming to your attention, so far as I can learn, except the single one of rates, (and God knows that's in the worst muddle of them all).

You expect me to pull ten coaches, forty miles per hour, with a 17-inch engine. To keep more than one hundred engines and four thousand cars in repair with a handful of men—and make all my own material out of scrap.

I do not know how much it would cost to put in those tracks, nor how long it will take—neither do I know how long it took the Lord Almighty to make this county.

I pretend to know something about my own de partment, however, and wish to go on record as having called your attention to the following facts, to wit

I need 20 extra men, mechanics, to keep up running repairs and get power in shape for fall rush, and I need them now—if we don't get them we cannot handle business of last year, and you say this year will be heavier.

We have twelve 16-inch engines that are unsafe to run—they need new boilers. I advise their sale as scrap, and the purchase of eight consolidation engines with 19 or 20 inch cylinders—we are short of power. We need a new wheel lathe—been asked for in every requisition for three years—costs money to send wheels away for tire work.

I want permission to raise the pay of engineers on freight half a cent a mile, and firemen one-quarter of a cent—they earn it, and it will prevent a strike. I want to be relieved as general adviser and non-commissioned *factotum* to the general manager, and left time and opportunity to attend to the thousand duties of the M. P. department.

I want my title changed to Supt M P and R S., and credit given me for what I do, and nothing for what I do not do.

I want the roundhouse roof painted, a carpet for my office, the gas pipe fixed, and the flue rattler buried so that I can think, and then I want the pay of a Supt. of M P.—say $5,000 per year—I throw in all other service already rendered If you think this is too much to ask at once, please look into your letter file and see how far most of the requests reach back, and average them

Honestly, don't you think you have been unreasonable with myself and my department? Haven't you expected, asked and received too much? Sleep on it, and if you don't agree with me in each and every particular—especially the $5,000—please accept my resignation, to take effect at once.

Seriously yours,

[And there are many more who need to take the same kind of a stand.]

The Open Switch.

Cy. Warman, editor of the *Western Railway*, at Denver, Col., has written and copyrighted a new song with the above title. It has been set to music by H. B Iszard, and is being published and sold by the Railway Publishing Company, of Denver. Price, 50 cents. It sounds like Cy The words are as follows:

All the summer, early and late,
  And the autumn days so drear,
A maiden stood at the orchard gate
  And waved at the engineer
He liked to look at her face so fair
  And her homely country dress,
She liked to look at the man up there
  At the front of the Fast Express

There's only a flash of the maiden's eye
  As the engine rocks and reels,
And then she hears in the distance die
  The clinkety-clink of wheels
Clinkety-clink, and a mile apart,
  And the fireman seems to hear
The clinkety-clink of the maiden's heart
  And the heart of the engineer.

Over the river and down the dell,
  Beside the running stream,
She hears the clang of the engine bell
  And the whistle's screech and scream
Clinkety-clink, so far apart
  That nothing can she hear,
Save the clink of her happy heart
  And the heart of the engineer

Even the trembling steed of steel
  Seems to understand
Their sweet distress, and seems to feel
  The touch of a magic hand
Clinkety-clink, so far away
  In the twilight dark and drear;
But what does the heart of the maiden say
  To the heart of the engineer?

The subdued sound of the engine bell,
  As the Roger rolls away,
Seems solemnly to toll the knell
  Of the dim and dying day
Clinkety-clink—there's an open switch —
  Oh! angels, hide her eyes
Clinkety clink—they're in the ditch —
  Oh! hear the moans and cries.

Clinkety clink—and down the track
  The train will dash to-day.
But what are the ribbons of white and black
  The engine wears away?
Clinkety clink—oh! worlds apart—
  The fireman hangs his head;
There is no clink in the maiden's heart —
  The engineer is dead

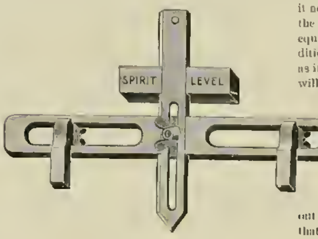
Last call—we won't mention it again No notice taken of letters without signature. No matter whether they ask questions or not, they go into the *scrap*. Believe we said this before

Air-pump Repair Kinks.

At the Mandan shops of the N P., they have a man on air-brake repairs of more than ordinary intelligence, and he has fixed up several little schemes of his own to help in his work. In the reversing cylinder there is a port very close to the bottom of the casting. Steam often gets to leaking from this port past the side of bush to the bottom, preventing the prompt work of the pump. Instead of throwing these bushings away, and putting in new ones, he turns a shoulder in the bottom of the piece, and fits a brass ring around it. This makes a steam-tight joint when put back into the head. They experienced considerable trouble here from the earlier pattern of 8 inch pumps cracking their top air cylinder head. This was on account of the spring of the casting connecting the two heads To obviate this he puts a stud from one cylinder head to the other, and exactly in front of the piston On the Central Pacific we saw some pumps braced the same way, except that the support was put onto the front of the heads and cylinders, and held by tap bolts entering the side of the cylinder flange.

A Guide Ranger.

The cut shown herewith represents a little tool now being introduced by W H Ermentrout, of Reading, Pa. It is used to put up guides, without using the crosshead or piston.



A line is stretched through center of cylinder, the lower guide put in place, and this tool placed upon it, instead of the crosshead. The pointer is used to point the line, and the guide can be fastened up parallel with the center line of the cylinders. A spirit level is also used when necessary. It is slipped off and reversed when putting up the top guide.

"Crazy Again."

Last month a well-known railroad official called on us and complimented the paper on the faculty it has of getting facts into men through a story or some other process than cold facts, tables, or algebra. Speaking of the disposition of certain classes of men to "skip" figures in reading, he made the assertion that not one man in a thousand would notice a couple of ciphers added to or taken away from a row of figures. One word led to another, and finally we selected an item containing figures, put on the same head as above, and deliberately changed 300 into 30, and made fun of the idea of there being 300 miles of locomotives in the United States

This item has been copied in two other papers and properly credited to us, and only two readers have written to point out the error in the figures—Mr. J. H Burrell, of Germantown, Pa , and Chas. E. Rice, Lockland, Ohio.

We have no doubt that many readers said, mentally, "He's off his base himself," but only two took the trouble to correct us. The fact remains that figures are not read with enough care, and papers should be careful to state facts only, especially when dealing in figures, for a large class of readers depend upon them for correct information

Discharging Employes in Times of Light Traffic.

Under the title of "Easy Lessons in Railway Economy," Wm. S Huntington is contributing a valuable series of articles to the *Railway Age*, the following being the best one we have seen so far.

It is a common custom on most railways to "shorten help" all along the line as soon as there are indications of a falling off of business, in order to keep the earnings ahead of expenses, and give an air of thrift and eke out a dividend, which makes a quarterly report read well. Net earnings are very desirable at all times, and the proper way to reduce expenses is to keep the road and equipment in such condition that trains may be run with the least possible wear and tear It should have been learned long before now that the better the condition in which a road and equipment is kept, the greater will be its profits per ton carried; in other words, if two or more roads are competing for traffic and cutting rates, the road that is in the poorest condition physically suffers the greater loss on a given amount of freight carried, because the wear and tear is greater than on a road that is kept in good repair Therefore, in view of rate wars, it is better to keep the road always in fighting trim, and in time of peace prepare for war.

Of course, when trains are laid off for want of business there will be no use for the crews, and they can take a vacation or seek employment elsewhere; but it hardly seems advisable to set the idle cars on the back track and discharge the shop hands. It would seem more like business to give the cars and locomotives a thorough inspection, and put them in for repairs When rolling stock is temporarily out of service is the best time to give it needed overhauling Then there is no rush, and the work can be thoroughly done, and when the equipment is called into service it will be in a condition to earn many times the cost of repairs, whereas if the repairs are neglected a revival of traffic will be very likely to strew the right of way with wrecks With a rush of freight and the back tracks half full of cars that are unfit for service comes confusion, loss of time, bad work done in a hurry, and the innumerable yard accidents that are unavoidable in rushing work in a crowded shop and yards Moreover, if cars are repaired soon after going out of service they will be ready to replace those that are disabled or destroyed in collisions or otherwise, without delay and confusion, both of which are unpleasant and expensive.

Some managers take advantage of a slack time for business, and put everything in good order for the rush, and these roads are classed as "lucky," because they can do an immense business with scarcely an accident When these officials discover that repairs are not coming in fast enough to require the full force of the shops, the spare time and machinery are employed on new work, which they will need in good time. As a rule, rolling stock that is made at home to wear out is more serviceable, and therefore more profitable than that which is made to sell. Of course, if this plan is pursued some material must be kept in stock, but the advantages arising would much more than pay interest on the cost But it is noticeable that those whose practice is in accord with what is here recommended are not obliged to pay interest on the cost of supplies, as they have enough left over after paying the damage account out of the earnings. The interest will be figured into the cost of keeping material in stock anyway, but there is a great difference whether the amount is found with the net earnings, or must be borrowed, as well as amount of the first cost. There are circumstances under which it is economy to shorten the pay roll, but the practice is far too prevalent for the good of the stockholders. To employ a sufficient force to put permanent way in good condition before winter sets in, and then reduce the force, is advisable, because nothing more than repairs that are actually necessary can be profitably done in winter Before shortening the pay roll it is well to study closely what the effect will be later on Not long ago when a great reform (?) party assumed control of the U S government they economized by discharging government employes. On the Atlantic coast a life-saving station was discontinued, and the crew discharged, as a great reform measure In less than a year several hundred lives and a war vessel costing a million and a half were lost there for want of a lighthouse and life-saving crew.

It is Time.

The Southern Pacific and the Rio Grande & Western have issued the following circular.

"On account of the large number of freight cars coming to us not equipped with automatic brake, our expenses have been largely increased, and the additional risk that we assume in allowing these cars in our trains has been the cause of many serious accidents.

"It has been decided that on and after August 1 we cannot receive on our line at any of our connections freight cars not equipped with the automatic brake. Cars that we have heretofore taken into our trains piped, so as to work the air through them to the cars equipped with the automatic brake, will hereafter be rejected."

These roads, having grades of over 200 feet per mile, cannot afford to risk their fine engines and finer men by hauling any sixteenth-century-brake-on-one-truck cars owned by railroads that are ten years behind the age. This stand is the right one for all the well equipped mountain roads to take.

William Thompson, who for the past five years has held down the job of general dispatcher and traveling engineer of the western division of the New York Elevated road, has been appointed general dispatcher in charge of the Mott Haven shops, and all the engines and men running into the Grand Central station, in this city. "Billy" is one of the best known railroaders in the East, capable, energetic and fair he manages to do his work and keep the respect and regard of his men, as well as the officers above him. "Billy" put in a good many years at the throttle—eight in India, as many more in South America, and has run in this country on both coasts. He is the best railroad story-teller in America, and shines as an after-dinner speaker full as brightly as Chauncey M.—after the kerosene is passed. The New York Central can congratulate itself on getting Billy. He'll keep things moving in the yard, and—what a team they have in "Chaunc' and Bill."

E. J. Rauch has been promoted to the position of general engine dispatcher of the western division of the elevated road in this city, to succeed Wm. Thompson, resigned. Mr. Rauch ran a locomotive over 40 years, and hasn't forgotten an incident of the experience.

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARO, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 22,000 engines and 270,000 cars. This includes 180,000 freight cars, which is about 18 PER CENT. of the entire freight car equipment of this country. Orders have been received for 120,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, MANAGER. JOHN B. GRAY, AGENT. C. C. HIGHAM, GENERAL SUPT.

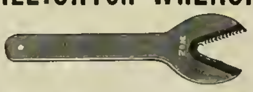
JERSEY CITY, N. J.

AMERICAN SAW CO.,

TRENTON, N. J.,

Manufacturers of the Celebrated

ALLIGATOR WRENCH



These Wrenches are forged solid in one piece, from best refined iron, with tempered steel jaws. They have ratchet teeth, cut diagonally across one jaw, thus enabling them to bite with three teeth at once.

INVALUABLE TO ENGINEERS, GAS-FITTERS AND JOBBERS OF ALL KINDS.

THE "LACKAWANNA" LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank-pins in hard daily service.

In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound is specially recommended for these cups, being first-class in quality and low priced.

LACKAWANNA LUBRICATING CO.,

SCRANTON, PA.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

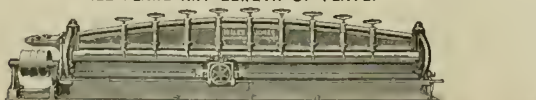
TOOLS FOR LOCOMOTIVE BOILER WORK.

THIS CUT SHOWS OUR

BOILER PLATE PLANER.

WILL PLANE ANY LENGTH OF PLATE.



Tools cut both ways and have independent adjustment. Table acts as a gauge for setting the Plate. Driven by a Steel Screw, which is supported its entire length so that it cannot be bent or sprung. Seven sizes.

THE HILLES & JONES CO., Mfrs., Wilmington, Del.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formulæ patented by Mr. G. W. Lord. For decree of court, etc., address G. W. LORD, 320 Union Street, Philadelphia, Pa.

"Old Betsy"—A Queer Specimen of Combination Railroad Equipment.

You don't talk of queer locomotives much out in California until some of the boys ask you if you ever saw "Old Bets." This peculiar combination of locomotive, tank, baggage car and coach is shown in our illustration.

She seems to be fatherless and motherless, and was doubtless made up of odds and ends from some scrap heap.

Her present engineer, W. J. Brennan, writes of her as follows:

"I am unable to give you many facts about the infancy of 'Old Bets,' but her boiler front bears this legend: 'Vulcan Iron Works, 1865.' [There is a Vulcan Iron Works at Wilkesbarre, Pa., and one at San Francisco.—Ed.] Her drivers are 48-inch car wheels, made by A. Whitney & Sons, Philadelphia, Pa., in 1869. Her pony truck was built by the C. P. road in 1884, and her rear truck by the M. F. G. Co., in 1874.

"Her boiler has a 33-inch barrel, and is 8 feet 4 inches long, containing 111 2-inch flues, the fire-box is 2 feet 8 inches long, 4 feet deep, and 22 inches wide.

"The link hanging to her stack is to hold the trap up to let her breathe. There is no sand-box used. She weighs, car and all, 21 tons with her tank full of water, 750 gallons, and 800 pounds of coal on. Her caboose carries 26 passengers.

"Her first running in California was on the Market street road in San Francisco, where she ran from Vilincia street junction to Point Labos; this was in 1872. In 1884 she was running on the Vacaville road, and went from there to the Oroville road.

"She was brought to Sacramento for repairs, in 1884, and then went to run on the Visalia road from Goshen to Visalia. She was condemned and discarded in 1886, but in 1888 they commenced to build the road from Tulare to Visalia, and 'Old Bets,' again found herself in harness.

"In 1889 she was bought by the San Joaquin Valley Coal Mining Co., and she still bears their initials.

"She has pulled 18 loads, and on a grade of 18 feet to the mile she does very well with 8 loads. The grade up to the mine runs from 112 feet up to 170 feet per mile, she takes three ordinary loaded cars or two 50,000 pound cars up this grade at once. She is very quick, slips some going up, *but never slips running down hill*, like some you have mentioned.

"When on the Vacaville road she ran 11 miles in 13 minutes, with a ten-ton car of water, and stopped for sheep at that. She struck a flock later, and killed 27 of them, but 'Old Bets,' has never killed or crippled a human being."

Specimen of Conglomerated Rolling Stock.

Some Show of Economy.

The Pennsylvania Company make out a fuel sheet for the New York division each month; this sheet gives the amount of coal per car per mile that the company expect the men to run with. When the engine crews run for less, the company take half the saving and divide the other half between the engineer and fireman, the men receiving sixty cents per ton each for fuel saved. Last month Engineer Hartman, who runs the Webb compound twenty days per month, scooped in a coal premium of $23 75, his fireman getting the same.

This shows a saving of $95 in fuel for 20 days; had the other man done as well with her the other ten days of the month, she would have showed up a saving of $140 in one month.

This plan of the P. R. R.'s is the correct profit-sharing scheme to use on a road, and will pay any road to try. Some of the men running simple engines make good premiums, some less, others run above the limit set.

There are enginemen and enginemen.

An Example.

The value of signals and safety switches was well illustrated the other day on the Long Island road. A train ran by the signals at Newtown Creek—the draw was open—and the safety switch put them onto the ground. The best of signals without the safety switch would not have prevented a bad accident—we need all the safety appliances. The engineer and fireman were discharged. The L. I. use vacuum brakes.

Railroading in Jamaica.

Mr. J. E. Sague, General Master Mechanic of the Government Railroads on the Island of Jamaica, West Indies, recently gave us a call. Jamaica is an English colony, and the road is only some eighty miles long, employing fifteen engines. Both engine and train crews are colored men, and Mr. Sague pays his engineers a high compliment, says they are very intelligent—all read and write English and are anxious to read; he was getting copies of this paper to get up a club among them; he says that they compare favorably with any engineers; are sober and careful men. Mr Sague is here buying machinery for his road, he was formerly mechanical engineer of the Erie, and was also employed in the motive power department of the C., B. & Q. some years ago.

The Prussian State railroads have officially adopted the Westinghouse automatic air-brake. The Carpenter air and electricity brake was formerly adopted, but did not give satisfaction; 5,000 of them will be taken off—so say foreign railroad papers.

The railway mail service first began on Aug. 28, 1864, when postal cars were run on the Chicago & Northwestern road from Chicago to Galena.

Some Interesting Collision Tests in France.

In the last few months the number of passengers killed by the collision of railroad trains moving in the same direction has been exceptionally large, both in this country and in Europe. The most recent collisions of this kind in the United States were those at Ravenna, on the Erie road, and at Montezuma, on the West Shore. At the first of these, nineteen lives were lost, and at the second the number of the victims was eleven. It will be recalled that at Ravenna a passenger train standing at a station was struck by a following fast freight, which had no air-brakes, and to which the prescribed warning had not been given by the rear brakeman of the forward train. At Montezuma a freight train was struck by a following passenger train, and in this case again the warning required by the rules to be given to the following train was not given.

One of the worst of the collisions of this kind that have taken place in Europe was the one of July 26 at the St. Mandé station of the Vincennes Railway, four miles from Paris. Fifty passengers were killed and more than a hundred were severely injured. At the scene of this collision some very interesting experiments have been made, with the purpose of testing the assertions and explanations made by the engineer of the following train.

We do not know that experiments of this kind have ever been made in this country under similar conditions and with such a purpose in view. The story of the collision shows that two long trains were returning to Paris from Fontenoy, where there had been a musical festival. The forward train stopped at St. Mandé, and while it was standing there the following train struck it with great force. Four cars of the forward train were wrecked, the ruins caught fire, and some of the victims, while imprisoned in the broken cars, were drowned by the torrents of water poured on them by the firemen of the village. The engineer of the following train declared that after he saw the danger lights on the rear car of the forward train he was unable to stop his train because the air-brakes could not be applied to all of his cars. It was asserted by him and by another employe that the valve of the air-brakes between the fourth car and the fifth car had been closed, so that the brakes did not act upon the ten cars beyond this valve.

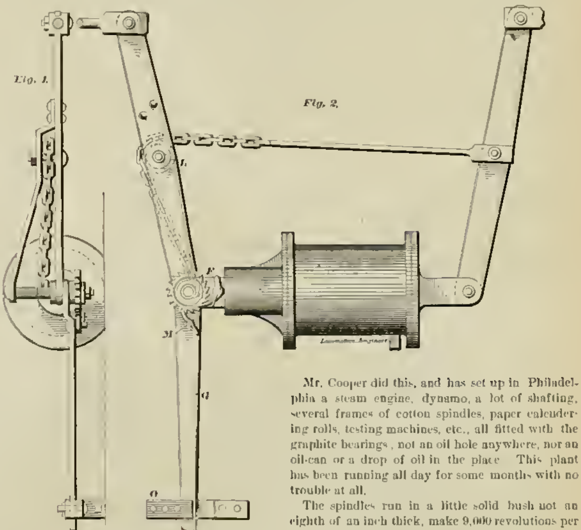
The experiments were made by the chief engineer of the railroad company, in the presence of a commission of State engineers. The following train had left the Vincennes station a few minutes before the collision took place. A train of the same length and weight was started from Vincennes by the engineers at the customary rate of speed, and the spot where the rear end of the forward train was standing at the time of the collision was marked by a stake which carried a danger light. It was found that this light could easily be seen by the engineer of the following train when he reached a point 853 feet from it. At that point the air-brakes were applied to the entire train, which was stopped in 131 feet, so that there were 722 feet to spare. In this experiment the steam had been shut off where it was customary to do this on a train approaching the St. Mandé station. In the next experiment the train left Vincennes under a full head of steam, and this time the steam was not shut off. The brakes were applied as before, when the danger light was seen, and the train was stopped in 311 feet. Here there were 542 feet to spare.

Then the engineers closed the valve between the fourth car and the fifth car, so that the brake would not act upon the ten following cars, and started the train from Vincennes in this condition. When the danger light was seen, the brakes were applied to the engine and the first four cars. The train was stopped in 443 feet. This indicated that there would have been 410 feet to spare, even if the engineer had told the truth about the condition of the brakes. The State engineers insisted that there should be one more test, in which the air-brakes should not be used. This time the only brakes applied were the hand-brakes, which acted only on the wheels of the locomotive. Under these conditions the locomotive passed the stake and danger light, but stopped only 46 feet beyond them. The engineers admitted that a collision under these conditions would have caused only an insignificant shock, for it is plain that the locomotive would have been moving very slowly at the point of contact. In none of the experiments was the engine reversed to assist the brakes.

By these tests the engineer appears to have been convicted of carelessness and falsehood. The official witnesses decided that the brakes did not fail to act on the day of the collision, and that "if the brakes had been applied, even tardily, the catastrophe would surely have been averted." To those who read the report of the experiments there seems to be no room for doubt as to the thoroughness and convincing character of them. But it is not probable that so painstaking an inquiry would have been made if a collision had occurred under similar conditions on one of our lines. The effect of the investigation was to place the responsibility clearly upon one man, and to show that the company had done its duty in the matter of equipment. It seems to us that the company was well paid for its work.—*N. Y. Times.*

Automatic Slack Take-up for Air-brakes.

Quite a number of schemes for taking up the slack of the brake rigging under cars have been invented of late, one of the most ingenious and simple of which is illustrated herewith. It is the invention of Mr. Alfred P. Riggs, an employe of the Colorado Midland road, at Colorado City, Colo.



As will be seen by the engraving, he employs a short shaft or spool, and a ratchet wheel, to take up the slack of the brake chain.

One lever, *G*, is pivoted loosely to the piston of the brake, and carries the pawl *M*; the other end is pivoted to the frame of the car by a bracket *O*. The brake chain passes over a roller at *L* on the floating lever, and to a permanent connection on the shaft. There is another pawl on the piston head *F*, that serves to hold the ratchet from moving backward at all.

When the brake is applied the inner end of the lever *G* is carried ahead, and if there is an inch too much travel the pawl *M* drops into another notch, and revolves the ratchet just that much, giving the pawl *F* a new "bite." Thus it will be seen that this simple device will take care of the slack occurring from the wearing away of the brake shoes or other causes.

There is now under construction a narrow-gauge road connecting the Oraya road, in Peru, with the mines of the Galena summit. It will reach an altitude of 15,850 feet—the highest in the world.

A New Friction Material.

Some years ago a maker of turbine water wheels, named Holmes, of Gardiner, Me., was experimenting with different substances to find a satisfactory bearing, or step, for water wheels, said bearing to run under water, and without oil. Among other things tried was a bearing of wood pulp hardened in molds under great pressure. This gave encouraging results, and he experimented with it further, finally mixing with it a small quantity of graphite. These bearing blocks were found to be hard and to run well, and were tried in other places, and under other conditions in the shop. The result has been something of more than passing interest.

Graphite is known to be a wonderful lubricant, but has generally been used with oils or other fluids. Holmes made bearings with greater percentages of graphite, using the wood pulp for strength, and soon found that no lubricant was needed at all. He put bearings made of this material to work in various places, with no means of oiling, and had no trouble with them. Some Philadelphia capitalists becoming interested, they employed J. H. Cooper, an old and well-known mechanic, formerly superintendent of the Southwark Foundry and Machine Company, to investigate the matter.

Mr. Cooper did this, and has set up in Philadelphia a steam engine, dynamo, a lot of shafting, several frames of cotton spindles, paper calendering rolls, testing machines, etc., all fitted with the graphite bearings, not an oil hole anywhere, nor an oil-can or a drop of oil in the place. This plant has been running all day for some months with no trouble at all.

The spindles run in a little solid bush not an eighth of an inch thick, make 9,000 revolutions per minute, and do not heat or cut; the bearings all look oily and polished.

The material can be turned, bored, drilled or planed just as metals can.

Should this material prove after trial to be adapted for bushings for valve motion work, solid-ended rods or crosshead gibs, it might make a great difference in the cost of running locomotives, to say nothing of gain, if it can be used, for car box bearings.

The saving of oil is far from being the only gain, as, so far, it has been impossible to measure the wear of any bearing used, and some of them have run over two years.

The writer spent a couple of hours in the place, and could see no trouble with the bearings then running.

The parties who control this invention do not claim the earth. When asked how it would work for car bearings, they said they did not know, they tried one bearing on an oil tester, where it worked all right, but it had never been in actual service under a car.

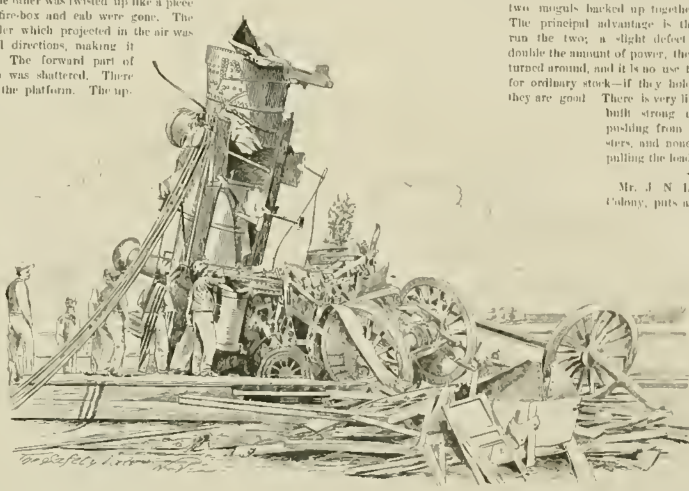
Brake tests are in progress all the time here, the graphite showing about one-third less friction than the best oiled metal bearing of the same size.

If the material cannot be used for railroad purposes it has a wide field of usefulness in textile machinery, where the absence of oil is of great advantage. It is the most promising "find" that we have heard of in mechanics for some time.

A Locomotive Boiler Explosion on the Long Island Railroad.

On Wednesday, Sept. 9th, the Long Island Railroad train No. 6, scheduled to leave Oyster Bay at 7.08 A. M. for Long Island City, and consisting of engine No. 113, a combined baggage and smoker and two passenger cars, was standing in front of the station awaiting the signal to start, when there was a terrific explosion. Conductor Jones stood on a platform near the forward part of the train with his watch in his hand, waiting to give the signal to start. Brakeman Michael Mahoney, who had borrowed a tool off the locomotive, swung himself on the tender to replace it. Engineer Donaldson was in the cab and Fireman Dickinson was preparing his fires for the run. Steam was roaring out the safety valve, and men and engine were only waiting Conductor Jones' signal.

Without warning of any kind the explosion came. The rear of the locomotive seemed to rise and open like a mammoth mortar, and big pieces of iron and three human bodies were shot high in the air, enveloped in a cloud of fire and steam. The explosion left the locomotive standing on its head, as shown. The driving wheels on both sides were shattered, and one of the driving rods was snapped in two, while the other was twisted up like a piece of rope. The fire-box and cab were gone. The end of the boiler which projected in the air was split out in all directions, making it funnel-shaped. The forward part of the tender also was shattered. There was a rush to the platform. The upturned locomotive told the story. Near by lay Conductor Jones, almost unconscious. He soon recovered. Brakeman Mahoney was found dead in the rear of the train. He was thrown directly back over the roofs of the three cars. Every shred of clothing was torn from his body, which was riddled as if by a discharge from a Gatling gun. Engineer Donaldson was found dead in a clump of trees about 100 feet from the north side of the locomotive. Fireman Dickinson was found a short distance away, on the south side of the engine. He lived about ten minutes. His skull was crushed.



The fire box was found with pieces of the cab 120 feet away from the south side of the wrecked locomotive. It was embedded deeply in the ground. Other pieces of the wreck were found scattered about. They included a number of the tubes out of the boiler. The shattered crown sheet of the boiler was found near the dead engineer's body. Near by lay the iron extension of the cab, which was turned inside out.

The frightened passengers left the train and crowded into the depot. The crown sheet of the fire box of the engine, with a portion of the cab, was thrown more than 150 feet, while other pieces of boiler plate were found more than 500 feet away.

The two front windows in car 125, which stood next to the tender, were shattered. No other damage was done to the train.

A wrecking train soon arrived, and by noon business on the road was resumed as usual. The real cause of the accident is unknown, and will probably never be learned. The railroad people say locomotive 113 was well built and in thorough repair. It was a powerful locomotive, and was run on express trains only. Master Mechanic Thompson, of the railroad, says the engine was thoroughly repaired in the company's shops at Morris Park six months ago. It was washed out in the shop Tuesday, and the flues cleaned. From the nature of the explosion it is thought to have been caused by the water running low in the boiler.

Locomotive No. 113 was built by the Rogers Locomotive Works in 1889, was one of seven forty-six tonners intended for the heavy summer traffic, and was run for two seasons on the main line. Early this year it was taken to the Long Island shops and thoroughly overhauled. Superintendent of Motive Power Charles Thompson, who accompanied the wrecking train to the scene of the explosion, after viewing the wreck, said in answer to my inquiries:

"I cannot tell anything about it. The explosion was evidently in the fire box, which is completely blown out. I do not think it could be due to any carelessness on the part of the engineer. Jim Donaldson was one of our best and most reliable men. There may have been some defect in the plates which could not be discovered during the overhauling. Whatever it may have been, the boiler was certainly sound enough to stand the full test to which it was put just before leaving the shops in the spring."—*Safety Valve.*

The first glass water gauge was used by James Watt, in 1780.

M. C. B. Standards.

The letter ballots on adoption of standards for the Master Car Builders Association are in, and the system of lettering freight cars; the plan of joint inspection, the form of joint inspection agreement, and the rules governing joint inspection, the form of report of defective cars received and delivered, and the joint inspection defect card have all been rejected.

The change of standard pins from $1\frac{1}{4}$ to $1\frac{1}{32}$ for air-brake rigging, rescinding the Fletcher lid as standard; the box bearing wedge and lid for 60,000 pound cars, and the new lid for old standard journal-box were adopted.

A great deal of thought and labor were expended in revising the interchange rules, some of which has been lost.

There are quite a large number of Fairlie engines at work in Mexico, these are of the double-end, four-cylinder type. Mr. Johnstone, Supt. of M. P. & M. of the Central Mexicano, has asked for bids in this country for six large engines something similar to the Fairlie's, they are to be compounds, have 12 drivers, be articulated, and weigh 230,000 pounds, 200,000 of it on the drivers. These engines will be something like two moguls backed up together, without tanks. The principal advantage is that one man can run the two; a slight defect in one lays up double the amount of power, they don't have to be turned around, and it is no use to inspect bridges for ordinary stock—if they hold up under them they are good. There is very little rolling stock built strong enough to stand pushing from one of these monsters, and none of it can stand pulling the load they can handle.

Mr. J. N. Lauder, of the Old Colony, puts a heavy iron hook on the inside beams or frame of his iron-framed tanks, and just over the transom of the truck, four hooks in all. When these tanks get off the track, and have to be jacked up, they put chains around the truck transom and over the hooks, then when they jack up the tank frame they pick up the truck too. Without this you simply lift your truck frame, leaving the heavy truck half buried, and in such shape that you dare not try to pull it on, for fear of knocking the frame off the jacks. These little tricks save lots of money when there is a "circumstance" on hand, and practically cost nothing.

An official of the Richmond & Danville road sends us a $10 bill, ten names, and the following note: "After reading your piece entitled, 'Circulation Liars—For Advertising Only,' in the August number, I could not help calling on a few of our 'dirty greasy' engineers who have access to and wear my paper out, to chip in a dollar apiece, and I would send on the list. I think I called on eleven, and ten of them gave me a dollar for an answer. The following are their addresses, to which please send THE LOCOMOTIVE ENGINEER for one year, beginning with September."

Master Car Builders Committees for 1891–1892.

Secretary John W. Cloud announces the subjects and the committees for the next meeting of the Master Car Builders, as follows:

1st. Joint Inspection—To prepare a supplementary set of interpretations and illustrations of the Rules of Interchange.—Committee: A. M. Waitt, H. C. McCarty, F. D. Adams, Wm. Gar-tung, Joseph Townsend, J. T. Chamberlain, D. W. Hunter.

2d. Air-brake and Signal Instructions—To review the instructions proposed at last convention.—Committee: E. W. Grieves, R. D. Wade, J. L. Greatsinger.

3d. Cast-iron Wheels—To investigate what improvements are being made in the manufacture of wheels, so as to secure greater uniformity in quality, in depth of chill and in distribution of metal for proper balance.—Committee: Geo. W. West, W. H. Thomas, John Player.

readily removed and another substituted in its place.—Committee: J. N. Barr, J. C. Barber, W. H. Lewis, T. A. Bissell, J. W. Marden.

7th. Steel-tired Car Wheels—To report upon relative merits of solid cast and wrought centers, and of plate centers bolted to hubs and tires.—Committee: R. E. Marshall, J. O. Pattee, C. H. Cory.

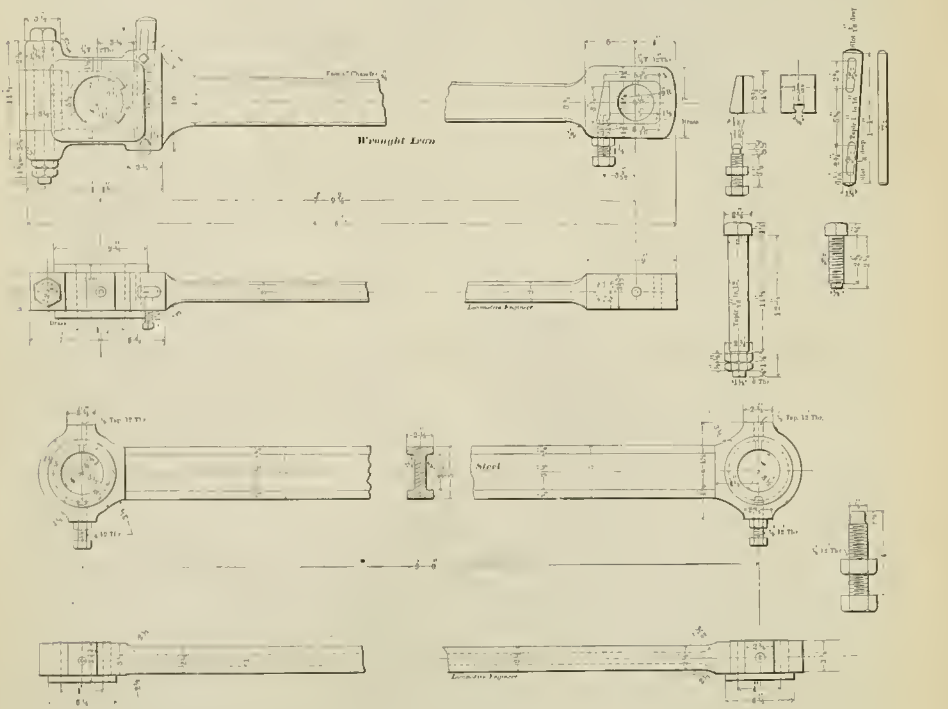
8th. Wheel Guarantee—To consider the communication from the Wheel Manufacturers' Association, read at last convention, and to report with recommendations.—Committee: J. J. Hennessey, Thomas Sutherland.

9th. Steel Plate and Malleable Iron in Car Construction—To recommend a standard for stake pockets, and a method in detail for attaching to cars. Also to recommend standards for center plates, in detail, showing one for iron transoms and one for wooden transoms. Drawings and models to accompany the report.—Committee: William Forsyth, John Mackenzie, E. D. Bronner.

10th. Standards of the Association—To consider

are we fail to see. It is certainly expensive, and in case of a break in the strap or fork, calls for expensive forging and machine work on the rod. Our personal experience with the rod was confined to one day's work—a very cold day, by the way—being sent to disconnect an engine badly wrecked by a rear collision. We found one rod on the forward dead center, and the truck in such a position as to prevent lowering the forward end if taken down, and we couldn't get it down. If the main rod had a strap on the back end we could have driven it off and got the rod down—but one swallow does not make a summer. It will be noticed that keying at either end of this rod tends to lengthen it. This style of rod is becoming very popular, notwithstanding.

James Heron, one of the best foreman boiler makers in this country, will leave Chicago when a favorable opportunity presents itself. Mr. Heron is an organizer and a specialist in his business. His present address is 5040 State street, Chicago.



C., R. I. & P. Rods

4th. Freight Car Truck Frames—To report upon the relative advantages of swinging and rigid bolsters and upon the Fox pressed steel truck as compared with the prevalent forms of freight car trucks.—Committee: G. F. Wilson, W. S. Morris, W. F. Turreff.

5th. M. C. B. Automatic Coupler Standards and Limits—To consider the standard measurements, and whether any additional or other measurements are desirable as standard, and to report upon proper limits of variation to be allowed from standard measurements.—Committee: J. S. Lentz, C. A. Schroyer, J. M. Wallis.

6th. Steam Heating and Ventilation of Passenger Equipment Cars—To report upon the general progress and the efficiency of different systems, and to present drawings for a proposed standard location of ends of train pipe, and a proposed standard connection in detail for a union between the hose and pipe, so that one style of coupling may be

the standards already adopted by the association, and recommend what measures are expedient to secure their general adoption and use.—Committee: R. H. Soule, E. Chamberlain, William McWood.

11th. Metal for Brake Shoes.—Committee: G. W. Rhodes, E. B. Wall, George Gibbs.

Details of Rods—C., R. I. & P. Eight-wheeler.

The accompanying illustration shows the rods used on the C., R. I. & P. engines illustrated last month, and gives detail measurements. The solid ended steel rod of I-section is now used on the majority of new engines built in this country, and is a much-needed improvement over the old strap rod.

The main rod is of a form known as the "Pennsylvania standard," having a solid fork at the crank end, and a block behind the brass, held by one large bolt, this rod appears to be very popular with our designers now, but just where its advantages

Asphyxiated in a Tunnel.

Engineer Jack Rochefort, of the through express, south-bound, S. P. road, on July 30, met death in an unusual manner in Tunnel 14, sixteen miles south of Ashland. Two engines are required to take the train over the Siskiyous. Rochefort had the front engine. When the train was nearly through the tunnel, the coupling between the mail and express cars broke. Twenty minutes were consumed in making a new coupling. The smoke and gas from the second engine blew directly into the cab of the one ahead. It was decided to back out of the tunnel, and when the train stopped outside, the engineer and fireman of the front engine were missing. Search revealed the engineer lying dead by the track, with his arm cut off. Fireman Fitzpatrick was lying unconscious by the track, but revived half an hour later. Both got off the engine to escape suffocation, and were asphyxiated before they reached the ground. Rochefort fell with his arm across the track, and bled to death when it was cut off.—*Daily Paper.*

Tunnels are dangerous places to stop to fix any thing: they should have backed out at once.

A Boiler Kills Four Men.

A locomotive explosion occurred on the Central Railroad of New Jersey last night, near Nesquehoning Junction, Pa., by which four men were instantly killed Yard engine No 335 was shifting freight, and had just passed out of the yard, in which there were several other locomotives and crews. When it reached Nesquehoning the fire underneath the engine boiler was noticed to be dying out, and giving off a quantity of vapor. Fireman Pope got down from the cab to examine the boiler. Instantly a violent explosion occurred. The four men who were on the engine were blown in every direction. The fireman has not been found yet.

The names of the killed are: Engineer Thomas Tripp, Mauch Chunk; Fireman J. Pope, Linsford, Brakeman Gallagher, Mauch Chunk, Brakeman Smith, Mauch Chunk.

The body of Engineer Tripp was found more than 100 yards away. His body was bruised and crushed. The brakemen were found in an opposite direction, and must have died almost instantly. The engine was totally wrecked, the boiler landing upon the mountain fully 300 feet from where it had stood.—*Daily Paper.*

If all four men on this engine were instantly killed, who noticed that mysterious vapor when the fire was dying out? The average newspaper reporter, in his constant endeavor to supply something exciting or mysterious, startling or shocking, seldom fails to put something into all his work that is purely imaginary. We were once running second section to a train that was wrecked and the engineer killed. The skeleton dispatch sent out stated that train three struck a washout near such a station, and Engineer Albert was killed. The papers all had different reports—one told how "the brave engineer stood at his post, a look of determination on his face and his hand on the throttle." No one saw the engineer; the fireman was on top of the tank and jumped from there before the washout was struck. Newspaper reporters have a propensity for having engineers die with their hands on the throttle. The simple, awful truth, with no glamour of heroics thrown about it, might do some good. Engineers and trainmen are sacrificed every day because of the greed of stockholders or manipulators in demanding dividends and not supplying safety appliances. There is nothing heroic or grand about murder—murder is revolting, no matter who commits it or how fearlessly it is endured by the victim.

Points from the Rio Grande Western.

Major Dailey, master mechanic of the Rio Grande Western road at Salt Lake City, has a small shop fairly well equipped with tools.

This road, like its parent, the Denver & Rio Grande, was formerly a three-foot gauge, but has been widened out in the past year. Some of the branches are still a yard wide, but the main line is now all standard.

The new equipment is good, and up to date, the cars are modern and well finished, lighted and heated.

Passenger engines are mostly ten-wheelers of the Rome build, and are nice working engines, except that they appear to be made of poor material, for they wear very fast. Engines that have regular crews, and had been in service only four months at the time of our visit, had worn their valve seats clear down, and had false seats.

Eccentric straps wear out in a few trips; they don't appear to cut, but wear much the same as you would expect them to do if made of lead. The hubs of driving wheels and sides of boxes wear very fast, and to a great extent in a remarkably short time.

The men are held in a great measure responsible for this, and, as there are no restrictions about the use of oil, they pour it on in copious draughts—and who can blame them? We never saw engines that got more oil, or got it oftener.

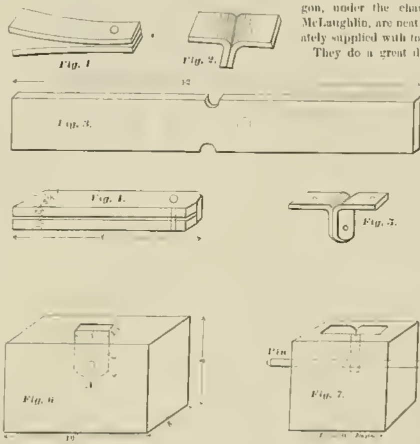
The road has very heavy grades on its eastern end, but the west end around Salt Lake runs through a garden for miles and miles.

In the shop we noticed a home made press that is of great utility, and one that would soon pay for itself in any shop, great or small.

A heavy table some four feet long, and perhaps thirty inches wide, of cast iron, is the foundation: each side of the center of this table there are bosses that carry the uprights, which are 3 inches in diameter and about 24 inches high, these are connected at the top by a heavy wrought-iron cross-beam, the whole resembling a copy press on a large scale, except that in place of a screw they use a hydraulic jack. For this purpose they use a 20 ton Dudgeon turned upside down, and fastened in the crosshead or beam, the weight of the ram being counterbalanced by weights. The table is planed up true and laid off with one-inch divisions each way, for convenience in straightening work.

This is used for all purposes any press can be, pushing in and removing bushings from bearings, etc., and for straightening work. It is much more convenient than a screw jack, far more powerful, and quicker, while one man can handle it to its full capacity.

The Old Colony Railroad have an iron jib crane at the Roxbury shops that is interesting. This crane was made in Liverpool, England, and shipped to Roxbury in 1836. It was not set up until 1850, and has been in constant use ever since for general shop purposes within its capacity, which is probably five tons. A mechanic who was about to build a new crane recently, examined this old-timer, and declared that the general features were no different, and fully as good as the average practice of to-day, of course the details of hoisting gear have been somewhat improved.



CROW FEET

Cheap Plan for Making Crow Feet.

Crow feet, the blacksmith's part of a boiler, have been used from the days of Watt to this, and the usual manner of making them has not improved very much since that time either.

In the splendid boiler illustrated in our last issue, built by the C., R. I. & P. road, there are employed some 46 crow feet. James Heron, foreman boiler maker there, used the regular crow feet, and made them in the usual way, by cutting up bars of Ulster iron ¾"x2½" into lengths of 7", and then welding the ends of two pieces together, as shown in Fig. 1, then they punched an inch hole in the welded end while hot, and then bent back the ends, forming the completed crow foot as shown in Fig. 2.

These pieces weigh about 6¾ pounds, and at 4¾ cents per pound have about 31 cents worth of material in them. Then the blacksmith gets 14 cents each for his work, and you have for 46 a bill for material of $14.26 and $6.44 for labor, making the crow feet cost $20.70.

Mr. Heron devised a "kink," and used scrap steel that was otherwise wasted, being too heavy for patches; he makes crow feet so that the labor costs but 1½ cents each, and certainly gets a far stronger foot.

Scrap from new boilers is cut into strips 2½" wide and 12" long, using material ⅝" or 9/16" thick. These strips are punched as shown in Fig. 3, these holes are 1⅛" in diameter, the side holes being about three-quarters full, so as to make the piece bend readily, and dispense with the necessity of cutting corners off the completed piece, leaving the piece like Fig. 4. These strips are bent, and a 1" barrel drift-pin is driven through the holes, thus bringing the holes fair in the two pieces, and leaves a clean, smooth hole, which is not the case in the old hot punched crow foot.

Mr. Heron then places the punched end of his double bar in a recess made in a cast iron block, as shown in Fig. 6; this block is 8"x10", and the slot is 1¼" wide and 3" long. When the piece is dropped into the hole a pin is put through a hole in the block and the hole in the piece, and a spreader and a blow from a hammer spreads the toes out and completes the foot.

All this is done at one heat, and all crow feet are made of a standard size. A boy can bend 300 in a day.

Some 20 years ago Mr. Heron used a kink something like this at the Baldwin works, and has used different modifications of it since.

An Item from an Oregon Shop.

The shops of the U. P. Ry.—the old Oregon Railway and Navigation Shops—at Portland, Oregon, under the charge of Master Mechanic D. McLaughlin, are neat and cleanly, but only moderately supplied with tools.

They do a great deal of heavy work for their steamers on the Columbia River and the coast, and keep up repairs on a great diversity of locomotives.

There is a foundry and blacksmith shop, both far too small, and a pretty fair machine shop.

All the buildings are of brick, and are good so far as they go.

The road in this locality is mountainous, but there seems to be an awful lot of small engines in service, and these are not very new or very good, either. With modern power a great improvement could be shown in the operating expenses.

The shops were being whitewashed when we were there, and otherwise cleaned up.

They put on air-brake hose fittings with compressed air, using a freight brake cylinder without attachments of any kind to it. The hose is held in a groove between two oak planks that are hinged together at the back and clamped by cams in front. Between the clamp and the cylinder there is a wooden stick, probably four inches square and three feet long; it is hinged at the back, some two feet from the cylinder, and the other end terminates in a handle. The vise has two grooves in it, and two pieces of hose can be put in at once. fittings are entered by hand, the lever brought up against them, and air turned into the cylinder, forcing them home. We have already mentioned the method of cleaning coaches by air jets employed here.

The Deadly Parallel.

The following notices recently appeared opposite each other in a railroad paper. Of course they are both correct.

The Brooks Locomotive Works, Dunkirk, have built a compound locomotive for the Lake Shore & Michigan Southern. It is of the two-cylinder type—cylinders 17 and 29x24. It is a 10-wheeler and has made some trial trips in freight service.	The Brooks Locomotive Works, Dunkirk, N. Y. have just built their first compound locomotive, and it is now running on the Lake Shore road. The engine is a mogul with one large and one small cylinder, intended for freight service. The cylinders are 16 and 29x24.

Locomotive building is quiet, no shops being crowded with orders.

Recent Fast Runs.

The Bound Brook division of the Reading has always been noted as a good place for a fast pace; but the story told of a run on August 27 with four cars, by the Wootten boiler engine 206, 68-inch wheels, of a mile in 39⅘ seconds, beats all previous records and is very hard to believe, although we are personally aware that a mile has been made there in fifty seconds and less

On September 14 a special train went over the N. Y. C. & H. R. R. from New York to Buffalo—436½ miles—in 439¾ minutes; counting three stops—one for eight minutes—actual running time was 61.44 miles per hour; including stops, 59.52 miles per hour. The best run was with an engine having 78 inch drivers; she made 150 miles in 140 minutes actual running time. It is altogether likely that the Central Hudson will put on a train guaranteed to make a mile a minute over their line, and all the roads between here and Chicago will have to do this, in self-defense for the World's Fair in 1892.

We have plenty of engines and plenty of engineers for this kind of work, but we have no roads with a track or signal system that are safe to make it on every day in the week.

Positive block signals are needed to-day the worst of anything on our double-tracked roads. Automatic brakes on all freight trains are necessary before any passenger trains on single-track roads are safe.

Four-cylinder Locomotives.

Under the heading, "Give credit where credit is due," Mr. Henry F Shaw, designer of the Shaw engine, writes us protesting against the publication, in another paper, of an article crediting Master Mechanic Richards, of the Reading, with proposing a four cylinder engine for fast speed. The four cylinders are supposed to, and probably do, do away with the necessity for counterbalance.

Mr. Shaw's engine, as almost everybody knows, has four cylinders, and she ran under Mr. Richard's care. Mr. Shaw seems afraid that some one will get credit that is plainly due himself.

Four cylinder—or rather four steam engines, complete have long been used experimentally for locomotives in different countries, but their care and cost always stood against them. Railroads have generally discarded them, on the principle that "of two evils choose the lesser." We don't believe any one wants to steal Mr. Shaw's credit for the complication.

Using four engines to get rid of the counterbalance reminds us of the old story of the quack doctor, who, when a patient came to him claiming to be afflicted with insomnia, said "That's a bad disease and I don't know much about it, but I'll tell you what I'll do, I'll give you some stuff that will throw you into *fits*—and *fits* is my specialty!"

The Houston, East & West Texas and the Shreveport & Houston Railway Companies are under one management, and our correspondent, E A Campbell, is Superintendent of M P. and Machinery. The road is narrow gauge, 282 miles long, using 16 locomotives. We notice from his monthly service sheet that the engines averaged for the month of July 51$\frac{1}{10}$ miles to a ton of coal, and the wood burners made 45$\frac{7}{10}$ miles on a cord of wood; 27⅘ miles were averaged to a pint of oil, and 32¾ to a pound of tallow. That's pretty good service.

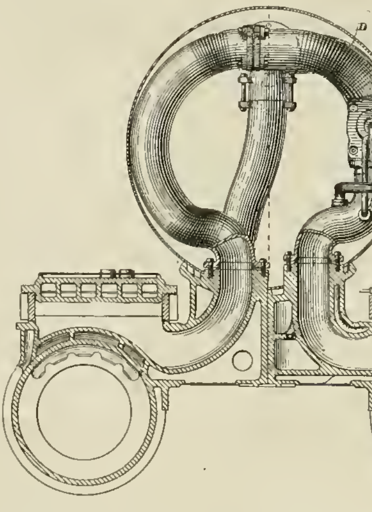
Mr. William C. Stroud, one of the members of the firm of Burnham, Williams & Co., proprietors of the Baldwin Locomotive Works, died on Sept 21st, at Rosemont, Pa. Mr Stroud was only fifty-three years of age.

The Dean Compound.

The new compound locomotive on the Old Colony road is in service. She is running light trains yet until she gets "broke in," but shows that she is ready for business even now. This engine is of the two-cylinder type, her high-pressure cylinder being 19", and the low pressure 28" by 24" stroke.

The high-pressure cylinder is steam-jacketed, and especial pains have been taken to prevent condensation.

Our large engraving shows the arrangement of the front end. Steam goes down the single steam pipe *D* to the high-pressure cylinder, and at the same time enters the small pipes to the valve shown upon the side of the arch; there it moves a piston and enters the receiver and steam chest of the low pressure cylinder by a small pipe, applying boiler pressure direct to the big cylinder to help start the engine. As soon as the high-pressure cylinder exhausts into the left pipe, Fig. 2, it lifts the swinging or clack valve, and flows to the low-pressure cylinder, through the receiver at the same time it enters the operating valve chamber, operating on a larger piston than did the live steam, and shuts off its supply of steam from the boiler. The steam from the low-pressure cylinder exhausts directly into the stack. The receiver pipe is double, and flattened out, to present a large area of heating surface; it is also covered with projecting rings of metal, to absorb and conduct heat.



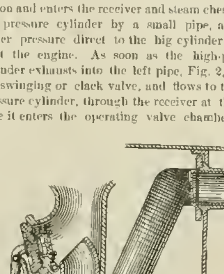


Fig 2

There is considerable of a slam when the intercepting valve shuts down, but that can be easily cushioned. The engine almost invariably slips when she starts, showing that she gets lots of steam into that big cylinder through that inch-and-a-half pipe.

The engine is Mr. Lauder's well-known plain, black, business-looking machine. She weighs 112,000 pounds, 66,000 of it on the drivers. This leaves a pretty heavy weight on the truck, due to the enormous cylinders, but Mr. Lauder has provided for that in a measure by getting in 38 steel wheels with a very large journal bearing, which he can increase to 6x8 if there is a disposition to heat. The engine gives promise of doing exceptionally good service.

Mr. Dean, the inventor, has designed a two-cylinder compound, now building at the Wilkes-barre shops of the Lehigh Valley, that will run in competition with a Baldwin four-cylinder compound of the same weight and capacity. This trial may go a good way toward determining the future design of compound for this country, as the question must eventually be settled by the survival of the fittest.

A Fairy Story.

The following item is floating around the press. Its "no smoke-stack" part reminds one of the story of Sam Slick's patent cook-stove:

"The Chicago, Milwaukee & St. Paul Railway Company is building, at its Milwaukee shops, two new engines which promise a revolution in locomotive building. The new engines consume their own smoke and have no smoke-stack. They are fitted up with an electric headlight, which is placed on a stand immediately in front of the boiler, thus giving the engineer an unobstructed view of the line ahead. The drive wheels are larger than on the ordinary locomotive, and intended for greater speed. The new engines are particularly designed to furnish power for lighting passenger trains with electricity and for furnishing steam heat. These engines will be used on the track between Milwaukee and Chicago, and it is intended to reduce the best time now made by one hour at least." The interesting part of the story is that the St. Paul folks are not building such an engine.

Describing a Crank.

Everybody who has had an encounter with Conductor Griffith, of the Lackawanna, will enjoy this story from the Dover *Index*: "An old and well-known conductor on the D., L. & W. Railroad has become noted among the patrons of that road for his solicitude to protect the interests of his employers in taking up tickets, and the lack of memory displayed when he demands tickets from persons who have already surrendered them to him. On a recent occasion he approached a young man of Rockaway with such a demand. The young man had passed through the same experience once before, and consequently had taken precautionary measures to prove that the conductor had received the ticket. After remonstrating with the young man several minutes, and accusing him of trying to beat the railroad company, the conductor finally threatened to stop the train and put the young man off. This was as much as the latter would stand, and Goodale said to the conductor: 'I gave you a marked ticket, and you will find it among the tickets in your pockets.' The conductor, who, by the way, is named Griffith, took out the tickets, and holding them in his hand, inquired: 'How was it marked?' The young man promptly answered: 'It was marked, "This conductor is a d——n fool."' Among the laughter of the other passengers 'Old Griff' found the ticket as described and angrily left the car."

Correspondence

Wants to Know About that Strainer in Train Pipe.

Editor The Locomotive Engineer:

In reading the article by Mr. T Paxton, on "Danger in Testing Brakes from Rear of Train," published in the September issue of your interesting paper, a question occurred to me which I should like to have Mr. Paxton answer.

In what part of the main train pipe is the strainer, against which he says the waste was pressed in such a manner as to prevent the passage of air?

PAUL SYNNESTVEDT,
Gen'l Air brake Inspector C. & N W Railway.
Chicago.

On Hood's Eccentric Question.

Editor The Locomotive Engineer:

I have read with a good deal of interest all the correspondence respecting Mr. Hood's running his engine with three eccentrics, without thinking of entering the list till I read his last letter, when I thought I would like to suggest a few thoughts on the question respecting the oscillation of the link with the back-up eccentric disconnected, and its effect on the movement of the valve. I would say that it depends largely on the pattern of the link Some builders make the link with the fork ends of blades coupled to the *ends* of link, so that the center of bolts of the fork ends are on center of a radius line running through center of link, and, of course, through center of link block, so that some inches intervene betwixt the centers of the two pins of fork end and block when the lever is in full gear I would ask Mr. H if he would feel safe to run an engine with such a link with three eccentrics.

I wish also to enter another query for the Reading Engineer as to his remark that by running with his back-up eccentric off, he threw the strain of two eccentrics onto one, which, I judge from the tone of his letter, he thought a serious matter. Now I knew an engine that run a number of years —and the owners and builder were very proud of her —that had but one eccentric to run both engines both ways (ahead or back up); this engine was in the exhibition at Chicago, in 1883.

I suppose "Reading Engineer" would say that this engine threw the strain of four eccentrics onto one. It is true that one did the work that most engines have four to do.

Marquette, Mich.

A Typical Letter from the Inventor of the Keely Motor.

Editor The Locomotive Engineer:

Some time ago there appeared several articles in your paper in regard to the extinguishment of the lights at several stations, on the arrival of certain locomotives, due to the vibrations caused by the sound of their whistles. A short time ago I mentioned the circumstances to Mr. John W Keely, who gave me the following theory of the cause spoken of.

W. B L. V.

"Theorizing on the condition necessary to bring about to induce molecular antagonism as between the radiating action of an illuminated center of theorem as activity, and sound force emanating from the whistle of a locomotive to induce neutrality or its extinguishment (the lights), the question arises, What are the conditions—the true philosophical ones —that govern such evolutions?

"All such conditions are brought about by the outreach of an antagonistic wave induced by sound or otherwise of differential lengths, as one to three, as between the one and the other from their radiating centers during activity, and are principally governed by the combination of chord masses by which they are immediately surrounded, such chord masses in combination may represent a resonating force as between the two agents as one is to three, the one on the majority subverting or overruling the one on the minority, and thus that peculiar audible tone of the locomotive whistle by its two-third wave neutralizing the one-third wave of the lights, and thus extinguishing it; but such conditions are very rare in their occurrence, but are not at all paradoxical in their solution. They only prove certain sympathetic facts that will cease to be paradoxical in their evolution to the general mind, when the principles are understood by which such demonstrations are brought about.

"Volumes (and not a few) could be written on this subject alone, as it takes in a wonderful sympathetic range of volume that reaches out even into infinity, and is included in the sympathetic link that associates the celestial forces to the terrestrial outreach.

"The action of the locomotive whistle on the lights is only a repetition of what occurred before the walls of Jericho, but brought about in a different way. The causes are the same, as also the results"

Double-crewed Engines—What are the Duties of Each Crew?

Editor The Locomotive Engineer:

Would you kindly state in your next issue, if in time, the duties of engineers who are double crewing one engine on a passenger run, that is, engine doubles the division every day. Myself and my opposite runner have only one engine in the place of two engines. Should either of us be held equally responsible for keeping this engine in shape, and what work should be expected by the locomotive department of runners who are double-crewing one engine, such as packing glands, cab, mountains, lubricators, setting up wedges, examining engine, headlight, trimming, etc., and all other small matters too numerous to mention, such as packing tender axle-boxes, and firemen coming on duty finding lubricators empty, and no stores on engine, gauge lamps not burning, etc This is a case of a night run.

ENGINEER.
Brandon, Manitoba.

[The question raised by our correspondent is one that needs some intelligent rules on any road where double-crewing is practiced. The very best plan is that in use on the Pennsylvania, there the roundhouse men do all the work, cleaning, packing, etc, the engineer will even report a wick put in gauge lamp on chain-gang engines. Most roads won't do this, at first anyway, and the men are usually left to shift for themselves The best plan we know of is for the men to agree and divide the work. Let one man do all the packing, set up the wedges, etc., the other to clean and keep in proper shape the headlight and all signal lights, keeping the tender packed, or any such division as can be fairly made, letting the work be done so as to have all lamps, headlight, etc., put in shape by the day man, and divide the work so as to take advantage of location or lay-over for each man. The firemen should divide their cleaning, one taking the cab, and the other the outside Supplies should be drawn where it is the least work. No hard and fast rule can be made that will be as satisfactory as an agreement by the men. No officer in charge of motive power should expect double crewed engines to be as well cared for or as clean as single crewed, unless he does this work by shop men.]

Information Wanted on an Injector Question, and Some Pointers on Balanced Valves.

Editor The Locomotive Engineer:

Just before my old mill went into the back shop I had considerable trouble with the right injector, and would like some good injector man to explain the trouble, it is a No. 10 Monitor. It got in the habit of not taking the water all up when it got low in tank, but would work all right with a full tank, but it gradually got worse, and finally refused to take it up with a full tank

Then it would work all right until about half over the division, when it would begin to "buck" again, and sometimes got so bad I had to shut it off and work the left one, which would not supply boiler, and would not work much better than the right one when the water was low, and, as I did not like to stop between stations and fill up, I had to do some pretty close figuring to keep the crown sheet wet.

I hunted for leaks, but could find none I oiled it regularly, took down hose, and did everything I could think of to locate the trouble, but failed. I reported it, and a machinist examined as well as he knew how, but everything appeared to be all right. I have done a great deal of thinking, but have not found out yet what the trouble was.

I also had trouble with the balance springs in right valve She got in the habit of breaking a spring every trip, and always did it coming down hill Generally it was the outside one, but sometimes she managed to break the inside one also. It was a regular thing when she came in to put in a new spring. The machinist's helper made the remark one day, that when the "Nine" came into the house the nuts on right steam chest would begin to work off themselves For my part I could not see what caused the springs to break. The engine had been running about two years and six months, and had worn quite a groove in the balance plate, and I first thought that was the cause of it, but after thinking it over I don't see how it can be. If the trouble was in the groove, why did she not break them going up hill as well as down? But the most mysterious part of it was, sometimes the oil would all blow through the hole in valve, and that side would get dry, no matter how much oil I used I have used a Detroit lubricator full, going fifteen miles, and it was just the same. And the next time she broke the same spring she would not get dry, although I used no more oil than when spring was in good condition. Now I have studied considerably on this, but cannot understand it I finally got tired, and tried to get the foreman to take the springs out and plug up the hole, but he refused. I thought it would be much better to run the valve "unbalanced" than without oil, and a big blow in it. Well, she will be out of the shop soon, and I am anxious to see if the springs will break after the balance plate has been planed off. Will some one explain this matter?

Aspen Junction, Colo.

J. W KAEFUS.

Examination of Enginemen on the C. & W. M. Ry.

Editor The Locomotive Engineer:

I met my old friend Doc the other day on our road going up north, trout fishing. We have got some of the finest trout streams in this State on the C. & W M. Ry. After a talk about old times and old friends he got around to the question of examination of firemen before promotion. We had a hot talk, both of us learned a few things—possibly Doc. learned the most. He said "This examination business is no good A man has got to have lots of experience and a good head to get along at all. Talk about knowing how to block up and disconnect in a breakdown, lots of machinists can take an engine apart and block up for all the breakdowns that ever happen to an engine, quicker and better than some engineers, because it is their business to know just how the machine comes apart the easiest way. Yet you would not trust them out with an engine on the road Trainmen know all about the questions asked on time card rules, but I would not let one of them touch my engine. You see an engineer nowadays has to know all about *all* these things just the same as he had to twenty years ago, asking him questions don't find out much about it. Our traveling engineer is examining the firemen before they are promoted, and I hear he is going to examine the engineers too after a while That is what works me up. I know how to get a train over the road in pretty good shape, but when it comes to telling how to do it I might get left. I hear you examine all the men on your road before promotion How do you do it? Do you ask them a lot of fool questions about lap and lead, motion curves, horse power of an engine, combustion, how many pounds of steam a boiler will carry, etc.? I would laugh to see some of these book engineers that can talk scientific and use big words get the old '93' over the seven mile hill on a bad night without doubling Then there is another thing about this examination business, lots of men that know all about it can't answer a dozen questions when they are called in the office, they 'get rattled'"

I answered Doc. something after this manner "Suppose it is a fireman's turn to be examined In the first place, look up the man's record and see if he has always been attentive to his duties, is clean and orderly, and has the reputation on the road of being careful and reliable. If he is all right in these points have a talk with him on the subjects you wish to examine him on, to find out how much he knows about them. If he is well posted, notify the master mechanic that Fireman Blank is ready for examination. As soon as convenient he is sent to headquarters, to the superintendent of motive power, who gives an order to examine him. He is not examined in the office, but we go down to the roundhouse and question him on all the breakdowns that are liable to happen to an engine. As all our engines do not have the eccentrics keyed on the axle, he is closely questioned on how to set a slipped eccentric the quickest and surest way, and why he does it that way. *A reason for each operation is asked.* Lots of questions about handling a train, about looking after an engine when off the track, stuck in the snow, or disabled, what to do with injectors when they don't work well, or won't work at all, and as most of our engines have air pumps and driver brakes, the examination on air is intended to be thorough. It takes two or three hours, is all oral, and right alongside the machinery we are talking about. If he passes successfully, any points he is not quite bright enough on he is posted about. Last May, when I found it to be a necessity to call their attention to facts about engines they should know, a list of questions was made up and written up in small memorandum books, which were passed around among the boys. There were no answers written in to any of these questions, as the idea was to call their attention and let them find out all these things for themselves, then they would know something. These books were issued to the firemen as fast as I could write them up at leisure moments, till now there are eight or ten copies out, besides those the boys copied off for themselves. The result has been good. You can see the young men (and some of the old ones) when they are off duty, looking around the shops seeing how engines are put together, getting down to bed rock in valve setting, finding out how air pumps and everything connected with the air-brake is made, and where it is liable to give out; in fact, posting themselves up on everything connected with their engines. We have a small link motion model or instructor, which any one can get to study on, or experiment with, any time they want it. They are spending some money on books like Forney's Catechism, Angus Sinclair's book, and lots of time studying them, and asking each other hard questions. They ask me questions every day, some of them hard ones."

Doc. kept quiet while I was telling him all this, but finally broke in, asking if I had one of those question books with me. He got it right off and settled back to look it over. I could see his nose turn up once in a while, as he went down the list, but before he got through he looked pretty sober.

He took the book with him. When he came back from his fishing trip he called in the office at Grand Rapids, handed it back, saying, "I am converted, I will tackle my fireman as soon as I get home, and brace him up for business so he will pass O. K." The September number of THE LOCOMOTIVE ENGINEER was on hand; I called his attention to the editorial on page 170, and to the ad. on page 171 about the book of examination questions and answers. Doc. said he had seen THE LOCOMOTIVE ENGINEER, but had never taken the trouble to read it. Then I opened up on him, told him he was in the same rut he had been in for fifteen years, that he must get out of it, "right away quick off," let go of his old-fogy notions and keep up with the procession if he did not want to get stepped on. *He will do it.* If studying on a list of questions about his locomotive will wake up an old fellow like him, what will it do for a young man anxious to get ahead?

I believe in examinations, the progressive kind such as Brother Hill has described in this paper. A man should be examined when first employed as fireman, to see that his eyesight is good—not on colored yarns or fine prints, but on objects near and at a distance, on switch lights and colored signals. He should be a fair writer, and have passed to the eighth grade in our common schools. At the end of his first year the traveling engineer should take him in hand—find out what he does know about an engine, post him up on what he should know. That will give him a start in the right direction, so he will post himself up for the next two years. When he has fired three years, call him in and give him a thorough examination. If he cannot pass, set him back six months; at the end of that time, if he does not know enough to take an engine on the main line, drop him off the list—make a hostler of him, or place him where he will be out of the road of any other promotion. The effect of this will be to keep the men who know they cannot make A1 engineers from entering the service, and encourage the bright ones to work for a good job, instead of waiting for some one to die or get discharged, and they get promoted because they are at the top of the list in age of service. Seniority should be first—all other things being equal—but if the oldest man on the list does not fill the bill let the next man on the list have a chance. There is no use waiting for a man to have an accident, to prove him incapable, before you set him back, that is not safe.

Right here, examinations alone do not make smart men or good runners, but they generally show up the poor, ignorant ones. It will show how much knowledge of their business they possess, and give a fair idea of their general ability. A knowledge of what to do in case of accident gives an engineer presence of mind that the inexperienced one does not have. Call his attention to all the difficulties he will have to encounter; when he does meet them, he will not get rattled so quick.

As to examination on time card and running regulations, no one will dispute the fact that it is absolutely necessary before a man goes out on the road either as an engineer or conductor. All should understand the rules alike, there is no other way to get their exact understanding of the rules except by an examination. With us this is done by the general superintendent, and any men hired that have seen service on any other road, no matter how capable they are, are examined on our rules before going out in charge of an engine or train.

Grand Rapids. C. B. CONGER.

Headlight Signals on the Southern Pacific.

Editor The Locomotive Engineer:

Seeing some discussion in your valuable paper in regard to darkening headlights at meeting points of trains, will say that it is practiced here (on the Southern Pacific, Atlantic system), and liked very much by the employes using it. But the system is not used as W. de Sanno says. I notice he says "The headlight and *all* train lights must be darkened on the trains in siding." In the Book of Train Rules S. P. Co. on page 10, Rule 34, Train Signals, reads: "Each train running after sunset, or when obscured by fog or other cause, must display the headlight in front, and two or more red lights in the rear." Now on p. 14, Rule 74 reads: "When a train turns out to meet or pass another train, the red lights must be removed and green displayed as soon as the track is clear. But the red must again be displayed before returning to main track."

"Headlights on engines—when on side tracks waiting for trains—must be covered as soon as the main track is clear and train has stopped."

Now Mr. de Sanno says: "In the writer's experience, when making a meet, to see the headlight of the other engine on the side track, and know they are in out of the way, is a great deal more satisfactory." Well, now here is right where the shoe pinches, as there are many side tracks on these western roads where one can see a headlight for miles, and you take a dark, rainy night, and poor steaming engine, with a bad working injector perhaps, so that much of the engineer's time is occupied in watching the steam gauge and water level, and trying to get his injector to work, and at the same time trying to get every turn out of his old mill he can, with a train of time freight, it is the easiest matter in the world for him to lose himself, or not be able to tell just where he is on these prairies; now let a headlight loom up in front of him, and if he can say within a mile or two of how close they are to him, or whether they are on the siding or not, he is a dandy, and can do far more than the average man can. The average man will, under such circumstances, shut off, and likely lose five or ten minutes coming up to where he is certain that the main track is clear.

Now we will take the same conditions here on the S. P. R. R., according to the extracts from book of rules previously given, and as practiced here; if the runner sees a headlight in front of him he knows right then that the main track is not clear, and is governed accordingly. On the other hand, if he sees a faint white light and a green light in the distance, he knows the main track is clear, and goes whirling by at full speed, not even slacking up. Now you ask, What is the faint white light just mentioned? Well, you see, all the engines here have their numbers painted on front glass of headlight, also the number of engine cut through headlight curtain, or cover, to tell the number of engine in the night time; and the light that shines through these numbers can be seen for a long ways, although of course not as far as a headlight could be, and is easily distinguished from the uncovered headlight. As to safety, I cannot see how there is the slightest chance of accident, except by the grossest negligence and disobedience of plain rules, as when we pull into the siding we must not cover our headlight until the green lights are displayed on caboose, which tells us we are in to clear.

Now after we are in siding, and green lights displayed and headlight covered, suppose another train comes up behind us, say a second section. We must immediately uncover our headlight and display red instead of green lights on caboose until both trains are in to clear main track. In case siding will not hold both trains, headlights are left uncovered and *red* caboose lights displayed.

When meeting a train which is on siding, the runner instinctively looks first to the caboose of the train he is meeting for the green lights, and then sees that the number of the engine, as shown by the light shining through the numbers cut in the headlight cover, is the one specified in his order, provided he has orders to meet them.

I have never heard of an accident happening from the system yet, and it has been in use here for years, and, as I before said, is well liked by all the employes. All the engines here are equipped with air-brakes, as are all the S. P. cars. I believe the track is the finest in the Southwest, and that they have the cleanest and best kept roundhouse and engines. W. C. PARSONS.

San Antonio, Tex.

The Traveling Engineer's Breakdown Puzzle.

Editor The Locomotive Engineer:

In reply to the Cunningham breakdown puzzle, I should say that the engine had a double nozzle, and blew the right-hand nozzle out.

Brooklyn, N. Y. T. R. S.

Editor The Locomotive Engineer:

I will try to give an answer to the breakdown puzzle that is published in the September LOCOMOTIVE ENGINEER. As Mr. Cunningham found eccentrics in place, and valve yoke and ports all right, and machinist reported cylinders and all O. K., would say one of his rocker arms or rocker shafts might have been bent or sprung, causing engine to be lame. B. R. WOODLIEF.

Brookfield, Mo.

Editor The Locomotive Engineer:

I would like to solve the puzzle in last number of THE LOCOMOTIVE ENGINEER, by placing the trouble to a nozzle that wanted cleaning out, or one of the bushing rings had blown out of nozzle, or the rods were not lined up right, or link block bolt might have worked loose on bottom of rocker arm. I have seen the latter affect an engine in the way spoken of in your paper, and this is my idea of the matter, and I would like very much to know more about it. J. D. MCKENZIE.

Palatka, Fla.

Editor The Locomotive Engineer:

In looking over THE LOCOMOTIVE ENGINEER there came to my notice a question by a Traveling Engineer concerning a lame engine on the Mobile & Ohio, which was in charge of Alex Cunningham.

In answer to the question would say that, as the engineer had looked his engine over very carefully, and could discover nothing loose, and the shop men had taken up the steam chest cover and found everything all right, that the only thing that comes to my mind, or rather the one which I think is right, is that the lower rocker arm was sprung out of true with center line of motion.

Detroit, Mich. BRANDON LEONAN.

Editor The Locomotive Engineer.

In answer to question signed Traveling Engineer, Philadelphia, Pa., I would think the trouble was with the forward bridge being broken or a piece being broken out of valve. H. R. YARD

Portsmouth, Va.

Editor The Locomotive Engineer:

That traveling engineer's question is worthy the attention of the best engineers, but I am going to try it, if I am a fireman.

There might be such a thing, although hardly possible, that a bridge would break and move in such a way as to close the port.

I think the real trouble was in the eccentric blade becoming loose on the strap and moving with each stroke of the engine so as to make her miss an exhaust. J. C. SICKELS.

Winchendon, Mass.

The Answer.

Editor The Locomotive Engineer:

I suppose the boys will all want to know what was the matter with Alex Cunningham's engine, but, for fear they won't all understand it, I will restate the case:

Alex. Cunningham was running an old eight-wheeler on the Mobile & Ohio a few years ago, and all at once she commenced to limp.

"Three legs," said Alex. to the fireman. "She's slipped an eccentric."

He stopped, got down, and examined her carefully, but her eccentrics were in place, and her valve motion all right.

"It must be a broken valve yoke," mused Alex., so he got up and tried her.

Steam came out of the right back cylinder cock only, and Alex. took up the right chest cover, only to find the valve, yoke and ports all right.

He got up to move her to hunt farther, and she seemed to go all right and he gradually increased speed and finally ran in.

The machinists took up both chests, looked into both cylinders, the front end and everything else, and swore she was all right, and Alex. made another trip with his three-legged pet.

He reported the right side examined again, and they found the trouble at once. What was it?

Almost everybody that I ever mentioned this case to said it was a nozzle that got plugged, but if that was true she would not have gone on three legs.

When the machinists took off her right cylinder head she stood on the forward center on that side, and the piston stood close up, apparently all right. But the second time they took off that head one man touched the piston with his hammer and found it loose. The piston rod had broken off close up to the head, and the Dunbar packing had dropped into the counterbore and port, and held the head there, shutting off steam from the forward end of the cylinder and disturbing nothing else.

Of course the piston rod played back and forth innocently, the exhaust from the back end of the cylinder was regular, but the forward end was laying off. It was a puzzle while it lasted.

TRAVELING ENGINEER

Philadelphia, Pa.

Those Worn Lubricator Glasses.

Editor The Locomotive Engineer:

I wish to answer E. G. R's. question, in the Sept LOCOMOTIVE ENGINEER, regarding the wearing of the top end of the Nathan lubricator glasses. I think I have the explanation, which will be made plain by referring to page 447 of Forney's Revised Catechism of the Locomotive, of 1890. At the top of the glasses there is, when the lubricator is in operation, a continuous circulation of water and steam, down from the top of the steam chamber or condenser, through two small pipes, one on each side, past the top end of the glasses, and out through the pipes, which lead to the cylinders. There is *no* circulation of water around the *bottom* end of the glasses, hence they are not worn at the bottom. The only opening at the bottom is the small nozzle through which the oil feeds. The wearing of the top of the glasses is not caused by any chemical action of any acid in the oil, but by the purely mechanical action of the water circulating past the top end of the glasses. There is not necessarily any circulation of water *in* the glasses sufficient to cause much wear. About the only acid that would injure the glasses is hydrofluoric, which would be very injurious to valves, valve seats, and cylinders. I have frequently noticed, in taking broken glasses out of the Nathan lubricator, which is used almost exclusively on the O & M R R, on which road I am employed as fireman, that the top end was worn almost entirely away. This I think is the only explanation.

SAM. M HUFFMAN

Seymour, Ind.

[Our correspondent does not seem to understand that the trouble with the glasses illustrated was wear *on the outside* of the glass, just where it is protected by a rubber gasket, and can, apparently, receive no wear.]

Something About Bulletin Boards.

Editor The Locomotive Engineer

With little hope of its reaching a point where it will do any good, I want to submit a few thoughts and suggestions that have claimed my attention while in the motive power service. The bulletin boards for the use of the motive power department with which I have been most familiar have been located in the roundhouse, where the orders soon become unintelligible from exposure to the variously charged atmosphere of the place. This plan has one advantage, however, for a new order always appears conspicuous, but the large "acreage" of space required for the display of a few hundred "full sheet" orders is so great that one board after another is put up in different parts of the building, and when all the available space is occupied, or all the lumber the company will furnish is used up, the leaflets begin to appear on the window casings and cupboard doors.

A man who takes it into his head to look over the bulletin board before departing on his run, and be ready to make affidavit that he has left no order on the board "unnoticed," has a very respectable excursion in quest of knowledge before him, and one which "thirty minutes before departing time" will hardly suffice for him to complete. Especially is this the case with a "new" man just entering the service, when the orders are tacked up two or three deep, with only a small margin of some of the first few layers visible.

Another crying evil of this bulletin board—lack of—"business" is that of allowing orders that are void, or have become inoperative from any cause, to remain on the board. This has an effect similar to that produced by leaving slow flags out for bad track for days after the track has been put in condition for the usual speed. It gives the impression that the whole thing is old and out of date, and the company does not attach much importance to it anyway.

Another thing that would relieve the bulletin board of much of its overload would be to transfer all orders that are of a permanent nature, and have been in effect long enough to show that they represent the fixed policy of the road, to the general rules on back of time card. By a judicious cleaning out of the old and obsolete, and condensing the old and permanent into print, and then providing a separate "clip" for each official who has authority to issue bulletin orders, and then placing the orders in the clips in the order in which they are issued, the task of checking over the bulletin board would be much simplified, and the company be much more sure of its being done.

Chillicothe, Mo. A. H TUCKER.

One of our 'steemed contemporaries mentions a starting valve designed and *patented*, and says, "the details have not been made public." How can a patent be issued without describing the invention to the public?

The Norwood Car Replacer Company, of Baltimore, are building an extensive shop at Lambert Point, near Norfolk, Va. This company are doing about all the replacer business done in the country—they are alive.

The Old Colony put an extra inside check behind the regular check valve; this, it is hoped, will close up if the outer or common check is broken off. They also use an automatic valve under the fountain, or combination stand, in the cab.

Some Russian Methods.

The Central Association of Railway Officials, which is composed of officers at Cincinnati, Indianapolis, Columbus and Louisville, has under consideration a plan for uniformity in the way of discipline, which was formulated by the committee on subjects. The majority report is as follows:

Leaving key open, 30 to 60 days or indefinite suspension.

Grounding line unnecessarily, 30 to 60 days or indefinite suspension.

Failure to deliver order, 30 to 60 days or indefinite suspension

Failure to complete order, 10 to 30 days or indefinite suspension.

Failure to deliver message, 10 to 30 days or indefinite suspension.

Failure to try air-brakes or whistle, 30 to 60 days or indefinite suspension.

Untidy uniforms, 10 to 30 days

Running through switch, pay, or two weeks to 30 days suspension.

Breaking draw-bar, pay, or 1 to 2 weeks suspension.

Burning off journal, 30 days or indefinite suspension.

Breaking machinery of engine, 2 weeks, 30 days or indefinite suspension.

Break in two and collision, 30 days, 60 days or indefinite suspension.

Killing stock, 10 to 30 days suspension.

Damage to public, and personal injury, 30 days or indefinite suspension.

Derailment through carelessness, 10 to 30 days suspension.

Yard collisions, 10 to 30 days suspension

Violation of flag rules, 30 to 60 days or indefinite suspension.

Violation of speed orders, 30 to 60 days or indefinite susnension.

Failure to register, 10 to 30 days suspension.

Failure to sign bulletin orders, 10 to 30 days suspension.

Failure to give or to answer signals, 10 to 30 days suspension.

Striking inspector's flag, 30 to 60 days or indefinite suspension

Running on incomplete orders, 30 to 60 days or indefinite suspension.

Running past block or other signals, 30 to 60 days or indefinite suspension.

Running by trains loading passengers on double track, 30 to 60 days or indefinite suspension.

Drinking on duty, indefinite suspension.

Intoxicated off duty, indefinite suspension.

Burning engine, indefinite suspension.

Refusal to take runs, indefinite suspension

Insubordination, 30 to 60 days or indefinite suspension.

Anger and fighting on duty, 30 to 60 days or indefinite suspension.

Hauling cars wrong, pay 2 cents a mile or 10 to 30 days suspension.

Rough handling of cars, pay damage or 10 to 30 days suspension.

Setting switch wrong or leaving switch unlocked, 30 to 60 days or indefinite suspension.

Failure of engineer, fireman or brakeman to keep lookout, pay damage or 10 to 30 days suspension.

Failure to examine switch after using, 10 to 30 days suspension.

Failure to set brakes or block wheels on siding, 30 to 60 days or indefinite suspension

Tying down block signal, 30 to 60 days or indefinite suspension.

Asleep on duty, 30 to 60 days or indefinite suspension.—*Indianapolis News.*

If the above iron-clad rule is put into force we can promise the roads in question one of the most decisive and destructive riots they ever read about. People who can calmly sit down and formulate a plan like this for keeping up rolling stock, paying wages and wear and tear for nothing, deserve something better than minor official positions—say perpetual exhibition in a cage provided by an admiring public, or crucifixion.

The Railway Age and the Northwestern Railroader is a pretty long name, but that is the way the consolidation of the two papers leaves it. Mr. Harry P. Robinson, founder of the *Northwestern Railroader*, will have control of the combined properties. Mr. H. R. Hobart, editor of the *Railway Age*, becomes vice-president of the new concern. Mr. Talbot, founder of the *Age*, retires. The new paper will be better than either of the old properties, and, with the enterprise and push found in young blood, ought to be found up close to the band wagon in the procession of general railroad and financial papers. Success to it.

The word knot, signifying a certain distance over water, is one-sixtieth of a mean degree of the earth's meridian, which in figures is 6,070.818 feet, 2,023.6 yards, or one mile and 2,650 yards.

CONTENTS.

Some Points on Radial Stayed Boilers from the D. & R. G. Ry.

There is probably no other road in the country where they have had more experience with radial stayed boilers than has the Denver & Rio Grande. They have used this class of boiler for some fifteen years or more, have had all kinds, styles and sizes, and opinions on this subject from Mr. Sample, the Supt. of M. P., or Mr. Mitchell, the foreman boiler maker, are valuable.

All engines on this road are of the Baldwin build, and those built to the specifications of the road have extended wagon tops, and a nearly flat crown sheet.

This form of crown has been used in narrow gauge boilers for a good many years with the best of results.

One of the beneficial results claimed by some is the enlarged heating surface, caused by the possibility of getting in from four to six more flues than with the arched sheet, but this we think a doubtful advantage. This form of crown has little strength of itself, and depends for support entirely upon its stays, and its friends claim, and not without reason, that this is a safety element. The arched sheet has a great deal of strength from its form, and would doubtless withstand considerable pressure without crown stays at all. When this crown sheet gets bare and becomes overheated its form helps support it, and it will in consequence stand more pressure before collapse. When the water leaves it, the center rows of stays and surrounding sheet are heated first, and get hotter, and consequently weaker, than the others. When the pressure is great enough, the center starts first by tearing out the central stays, then there is only one row of stays to pull out at a time—a shearing action—and the collapse amounts to an explosion, often taking the crown, and occasionally the whole firebox out of the boiler.

The flat crown is heated more evenly, and will pull off the stays at a much less pressure, giving a large number of holes for the relief of the boiler—an enormous safety plug. The sheet seldom tears out the outside stays or injures the side or crown sheets, and can be put back to its original position with jacks.

A large number of these flat crown boilers have been scorched there in the past, but in no instance has the crown sheet gone to the grates, nor has a single individual been seriously injured by the collapse.

The Rio Grande have some arched crowns, but they have given the same trouble there that we hear of in other places—they crack near the front flue sheet, or the flue sheet is cracked there, while no trouble is experienced with the flat crowns.

Boiler maker Mitchell thinks the cracking in their case comes from the constant expansion or rolling of tubes to keep them tight; this enlarges the holes in the flue sheet, and raises it at the seam, relieving the forward stays of strain, and making the joint higher than the rest of the sheet. When the arched crown boiler is fired up, the expansion throws this strain to the center, and causes a crack, while the flat crown can "go somewhere" with its expansion.

A great deal of trouble has been avoided in a lot of new boilers built in the Denver shop, by putting in sixteen less flues, and keeping them down from the crown. In staying these crown sheets the stays are put through the crown straight, and allowed to strike the shell where they will—it's the crown that needs to be stayed, not the shell—on the side opposite the corner seam of the side sheet and crown; the stays in the shell are 16" apart, and no trouble is experienced with them—these crown sheets are only arched about three inches.

Considerable trouble was experienced here in cracking of the side seams between crown and side sheets, and it was believed to come from burning of the rivets and joint, or to undue expansions, caused by the fire striking these seams, and an experiment was tried in covering them with a cast-iron shield held on by studs; where this was done no trouble was had, and the shields have been put into a great many of the boilers; they burn out in four or five weeks.

Mackey beats the record from Frisco to New York.

Instruments of Torture.

Can't you do something to relegate to the scrap heap that damnable implement of torture, the common check valve? Hundreds of unfortunate human beings—most of them enginemen—have been cooked alive by them.

A check screwed directly into the boiler is the worst form, the one with flanges held by studs is better, in that it is stronger, but both are dangerous. The inside check is an improvement if of good design, but checks placed on the boiler head are better, cost less for pipes, make the engine look better, are less liable to freeze up, and are far safer. There is no trouble in using them, running an open pipe from the check, inside the boiler, to near the front.

If all the victims of this device could be exhibited at once to a select audience of railroad officials, who have the power to change this thing, there wouldn't be many running in a month, and the man that retained them would be mobbed.

Just as We Talk of Electricity or the Flying Machine.

When a railroad was proposed from Boston to Albany the Boston *Courier* of June, 1827, said: "Alcibiades, or some other great man of antiquity, it is said, cut off his dog's tail, that quidnuncs might not become extinct for want of excitement. Some such motive, we doubt not, moved one or two of our natural and experimental philosophers to get up a project of a railroad from Boston to Albany, a project which every one knows, who knows the simple rule of arithmetic, to be impracticable, but at an expense little less than the market value of the whole territory of Massachusetts, and which, if practicable, every person of common sense knows would be as useless as a railroad from Boston to the moon."

Engineer Mort. Winters, of the P., Ft. W. & C., was pulling an excursion train on the 13th of Sept., when a side rod let loose, broke a driver, knocked the cab into splinters, and made worse havoc when it began to cut off the boiler attachments, and let loose the steam and boiling water. The engineer got onto his feet all right, but couldn't get to the brake valve, so he climbed over the tender, and, crawling partly under the platform of the first car, uncoupled the hose, thus setting the automatic brake. The train came to a standstill, and no one was hurt. You may call this heroism or what you like, but it shows above everything else that this engineer was the right man in the right place, and made of the proper material for engineers of the best grade.

Beheaded in His Engine.

Richard Nash, of Philadelphia, engineer on the fast Reading express, while on the lookout, September 2d, was struck by an obstruction near Oreville Station, and his head was severed from the body. His body hung out of the cab window some minutes before the fireman discovered what had occurred.—*Daily Paper*.

This is the second engineer killed on the Reading in the same way within a year. How would it do to remove some of those obstructions, fasten some of the water cranes, and destroy some of the things they call mail catchers?

Scrambled Geography.

It is interesting to note that the largest locomotive yet built in England weighs 84 tons, and is 46 feet over all. On a gradient of 1 in 40 the engine can, by exercising its full capacity, move 200 tons. It is a product of the Hirschen works in Munich.—*Railway World.*

A dust guard for cab windows has been patented by Frank C. Bond, of Port Jervis, N. Y. It consists of a narrow pane of glass hinged to the window frame in front of the loose, or sliding pane. It is held out at right angles to the side of cab, and acts as a dust or cinder guard, the runner being able to see through it while looking ahead.

ASKED & ANSWERED.

(60) I. C. B., Washington, Pa., asks:

How could I become proficient in the art of sketching, making free-hand drawings of machinery or other objects? Is there any book that treats exclusively of this art? *A.*—There is no work of this kind that we know of. If you have a talent for that kind of work you should secure a teacher; practice is the great essential.

(61) T. R. S., Brooklyn, N. Y., asks:

1. Does a direct-motion engine increase her lead when hooked up the same as an indirect? *A.*—Yes. 2. Has the old original patent on the Richardson balance slide valve run out, or has it been renewed? *A.*—The original patent has expired, but there are a number of patents still in force on details and parts, the device is still pretty well protected.

(62) R. H. Man, Ludlow, Ky., asks:

Do you know of roads in other sections of the country where an all round machinist, used to running repairs, can get a show to become a locomotive engineer? A farm hand gets a better show here than a mechanic. *A.*—Perhaps you are too old to go firing, as that is the only way to learn locomotive engine running. We know of no road where machinists are encouraged to go on the road. The best way is to have a square, honest talk with your superior officer on this subject, tell him what you want and why you want it. If you are thirty five don't try it unless you want to wear yourself out about four years ahead of time.

Book Reviews.

HOW TO MAKE MONEY OUT OF INVENTIONS. AN ADVISER FOR PATENTEES. By August Schemmel. Published by C. A. Rohde Co., Milwaukee, Wis. Paper cover. Price 50 cents.

This little book is a collection of facts about inventions, patents and inventors. It tells pretty nearly everything an inventor wants to know about getting patents in this and foreign countries. It is not published in the interest of a patent lawyer, and is in no sense an advertising scheme. Part second contains a long list of firms who build machinery and patented devices, dealers who sell, and newspapers who advertise articles that inventors want, or should have. To any young man, or old one either, who has an inventive bug in his ear, this little work will be worth many times its cost.

THE NATIONAL CAR AND LOCOMOTIVE BUILDER "SUPPLEMENT." Yearly. John N. Reynolds, 110 Nassau street, New York. Free.

This publication is a monument to the skill of its publisher, John N. Reynolds, as an advertising solicitor, for it does not contain a line of reading matter. There is, beside advertisements, the list of railroads officials, etc., published monthly in the parent paper, and an index to the advertising. It is really an indexed collection of trade catalogues, and as such is useful.

POOR'S DIRECTORY OF RAILWAY OFFICIALS AND MANUAL OF AMERICAN STREET RAILWAYS. H. V. & H. W. Poor, 70 Wall street, New York. Price, $2.00.

This is a complete directory of the railroad officials of North America, with their titles, address, etc. The street and private railroad directory covers the entire western hemisphere. The entire work is very carefully indexed, and no official, town or shop, is hard to find. There is also a statement relative to the lines of railroad now projected in this country. The book is well bound in boards, and is the best and most accurate list of officials we know of. There is so much change in this field that any list is good but for a short time.

A Good Pumper.

The pretty little romance about "A Woman at the Throttle," on the Cairo & Kanawha Valley Railroad, in West Virginia, proves to have a slight basis of fact. Miss Ida Hewett, the daughter, not of a "heavy stockholder" but of a farmer, tends the engine at a pumping station. It is no doubt true that, as the story states, she has no mean ability as a machinist, but on the other hand it is only fair to say that the engine of a pump house is seldom mean enough to make very pressing demands upon the mechanical skill of its custodian. Miss Ida "makes her daily run with as much regularity as the most veteran engineer," but the run is only from her dwelling to the pump house.—*Railway Gazette.*

The grocer who is old fogy, don't keep the best stuff and follow business methods—who is not up to the times—fails, and has to get out. The railroader who falls behind modern practice, who is old fogy, and who studies prize fighting or agriculture more than his business, is held up by the company and his companions, if he stood on his merits he would be set aside, like the grocer. Study your business.

The Evolution of the Modern Brake Shoe.

SOME HISTORY OF AN AMERICAN INVENTION.

In our issue of February we asked who invented the common cast iron brake shoe now almost universally used on all rolling stock.

Mr. Wilson Eddy, for many years at the head of the motive power department of the Boston & Albany road, and whose railroad experience dates back to 1840 and a little beyond, at once answered that the cast-iron shoe was invented and patented by Stephen Morse, Feb. 23, 1858.

The Westinghouse Air-brake Company took considerable interest in the matter, and sent out some inquiries on this and other brake subjects, receiving many interesting replies. Their letter, sent to the men who were railroading in the long ago, contained the following questions:

First. If wood brake shoes were ever used, to your knowledge, state where and when.

Second. Was their use general or special?

Third. What kind of wood was used?

Fourth. On what class of equipment?

Fifth. When was their use discontinued, and why?

Sixth. Have you any knowledge of the use of any other kind of brake shoes than wood, cast-iron, steel, or such as are in common use at this date? If so, of what was their composition?

Seventh. Have you knowledge of the use at any time of what is known as the sledge brake in steam railway practice; that is, a shoe capable of being forced against the rail, and what was the material of which such shoes was composed?

Eighth. Give as complete historical facts as possible regarding the use of brake shoes of any kind other than those in common use at the present day, and suggest the names of other persons most likely to be acquainted with the desired information.

The answers having been submitted to us, we take great pleasure in collating the following from them.

REUBEN WELLS,

Supt. of the Rogers Locomotive Works, Paterson, N. J., gives some interesting historical data as follows:

"In reply to your first question: Yes; wood brake shoes were exclusively used on the cars and tenders of the equipment of two or three coal roads in the State of Indiana, of which I had charge of the machinery, in the years 1852 and '53, and had been used there for four or five years previous. These roads were about 25 miles from Indianapolis, and were then known as follows: Rushville & Shelbyville R. R., 20 miles long; Shelbyville & Edinburgh R. R., 16 miles long; and the Knightstown & Shelbyville R. R., 27 miles long.

"These roads were laid with 'strap' rails—iron 2½" wide by 1" thick, laid on and spiked to longitudinal timbers, which were in their turn laid on cross-ties notched out to retain them.

"Our cars were light, but were of the same weight and pattern as the Madison & Indianapolis, and other western roads. The M. & I. was at that time laid partly with strap rails, and partly with light T rails. The cars of this road ran over the small roads with which I was connected, and I remember that they all had wooden shoes, passenger cars and all.

"In 1854 these little roads were consolidated with the Jeffersonville & Indianapolis R. R., and I went to Jeffersonville in charge of the machinery, where I found wooden shoes on everything. The wood used was generally white oak, but sometimes beech and hickory.

"The usual shape of these shoes was about as in Fig. 1 (next page), the dotted lines representing the wheel, *A* the brake shoe and head, in one piece, with the grain of the wood vertical, *B* brake beam held by a bolt and tenant, *C* brake hanger, *D* a bolt through the shoe to prevent splitting, *E* pin through hanger and shoe, *H H H* wooden pins about ⅝ or ¾ inch diameter were generally put in, their ends flush with the face of shoe, to insure durability.

"This was the general form of the shoe; in some cases for freight cars the shoes were hung to the truck and between the wheels, while others hung from the body of the car. This, I think, answers your 2d, 3d and 4th questions.

"It was probably 1855 when the use of wooden shoes began to be discontinued. At first the increased braking power required, as the cars and loads became heavier, caused rapid wear, making their maintenance troublesome and expensive. To avoid renewing the whole shoe when worn down, wooden pieces were cut out by machinery and spiked onto the old blocks, as shown at *A*, Fig. 2. These very soon wore out or got loose and came off, and were abandoned, and wrought iron pieces of that shape were bolted on by two countersunk head bolts, as shown at *B B*, Fig. 2.

"On the road mentioned, these wrought-iron pieces were made mostly from old 'strap' rail, as it was taken up and replaced with T rail. In going down long grades this shoe would get hot enough to burn or char the wood to which it was bolted, and it then became loose and gave trouble. Then a cast-iron shoe was used, having air spaces between it and the wooden brake head, as at *D D*, Fig. 3; these shoes were held by two bolts *B B*.

"The use of this cast-iron shoe began about 1855 or '56, but in a year or so the cast-iron brake head and its detachable head began to be used, and gradually took the place of everything else, but I cannot fix the exact date. I have no knowledge of steel brake shoes being used at that early date.

"The only case of a 'sledge' brake being used, to my personal knowledge, was in the case of a ten-wheeled coupled engine, which I built in either 1867 or '68 for working on the one and a half miles of 320 foot grade on the M. & I. road, as it was then called, at Madison, Ind.

"The 'soles' or 'shoes' of these sledges were made of wrought-iron, and were fastened to wrought-iron backs or tops; they were forced down by two steam cylinders, *C*, Fig. 4, the pistons of said cylinders being so connected by levers that about one-third of the whole weight of the engine, 112,000 pounds, could be thrown upon them. These sledges were located as at *A*, Fig. 4, the engines always worked with the front end up the grade, and these brakes were for use only when the cylinder power or other brakes failed to hold, but when used they answered the purpose very well, and were used until very lately, the engine being still at work there.

"The braking force used in letting trains and engines down this grade was the cylinders of the engine. A valve and attachments were in use that connected the two steam passages to the two ends of the cylinders, so that the valve between them could be opened wholly or in part by a lever in the cab. In descending, the valve motion was reversed, and the valve between the two ends of the cylinders opened, so as to allow the air on the compression side of the piston to flow to the opposite side through this connection, the valve acting as a regulator of the resistance. This arrangement answered the purpose so well that no other brake force was required, and the 'sledges' were seldom used."

WILLIAM SWANSON,

General Master Mechanic of the Pittsburgh, Cincinnati, Chicago & St. Louis Ry., spent long years on the Little Miami and Pan Handle. He says:

"Speaking of the brakes in use in 'ye olden time,' I recollect that on the Little Miami, in the early '50s, that is, about '53 or '54, we used a wooden brake head without a shoe, both for cars and engine tenders, they were made of oak, and hung from the body of the car. On passenger cars a piece of wrought-iron about 8 x1", made in the form of a gib, was bolted on the wooden head, these gibs were made of old arch bars or such scrap material as came to hand. The increasing number used, and the expense of new bar iron, was, I think, what led to the use of the cast iron shoe, which was also used on a wooden head. This kind of shoe and head was continued in use, as near as I can recollect, until near the close of the '60s, when cast iron brake heads began to come into use, and the process of evolution has continued ever since.

"We had a sledge brake on one of our Madison inclined engines, the shoes were about 24" long, and were forced upon the rail by two direct steam cylinders, it was applied by Mr. Reuben Wells in 1868, and used up to 1885, when air-driver-brakes were applied."

ALBERT GRIGGS,

for many years in charge of the motive power of New England roads, writes:

"Wooden brake shoes were in use on the Boston & Providence road long before 1848, and for years after that. They were of oak, and were in general use on freight and passenger cars, as well as for driver brakes and on tenders. Their use was discontinued about 1856, on account of their burning out on grades.

"Leather was used on the Boston & Maine on passenger equipment in 1845, and a long time after; some leather was used before that time on the Boston & Providence; the leather was fastened to wooden shoe with nails.

"A sledge brake was also used on the Boston & Providence on one or two cars as an experiment; this was in 1847.

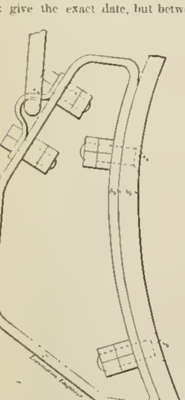
"Stone shoes were used about the year 1853, but with what success I never knew.

"I wish to mention that about the year 1847, my father Geo. S. Griggs, had passenger trains on the Boston & Providence road equipped with automatic brakes on all cars, and the tender and steam driver brakes, all of which were his inventions. He patented the automatic brake."

ANDREW J. CROMWELL

has been with the B. & O. all his life, and says:

"Wooden shoes were used on the B. & O. from its opening until some time in the early 50s, cannot give the exact date, but between '50 and '53, perhaps. Wood was in general use except on iron coal cars, ash and oak being generally used; their use were discontinued on account of their taking fire and burning out on our mountain grades.



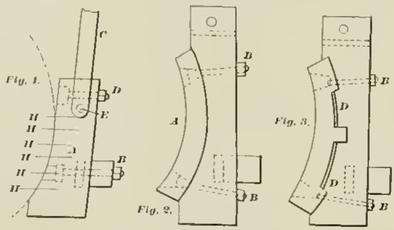


Fig. 1. Fig. 2. Fig. 3.

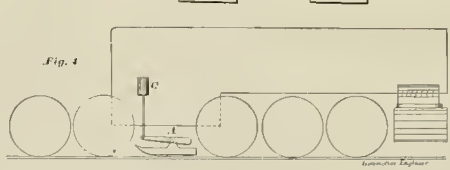

Fig. 4

"Wrought-iron shoes riveted to cast-iron blocks superseded the wooden shoe. We never used sledge brakes.

"Wrought-iron shoes were used on the B. & O. passenger equipment until 1882, when the Christie cast-iron shoe was adopted. Cast-iron shoes were applied to our freight cars in 1872 and '73."

G. B. HAZLEHURST,

the General Supt. of M. P. of the B. & O., refers to Mr. Cromwell's letter for the facts, and sends the sketch shown at left of page, which shows the form of wrought-iron shoe and head used on his road for passenger service up to 1882.

F. D. ADAMS,

General Master Car Builder of the Boston & Albany, has had no small amount of experience; he says:

"My experience is not so great as some others, but dates back into the '40s. When I first went at the business, wooden brake shoes were used exclusively, the head and shoe were in one piece, and when this was worn down it was often shod with another piece of hard oak, nailed on. We had no steel or wire nails then, and the cut nails broke off easily, and after a few renewals the head would be so full of broken nails that no more could be got in, then it had to be taken down and a new one made.

"I have seen leather used, but it cost too much, and it was hard to get a supply.

"I do not know of cars built prior to 1865, with other than wooden brake shoes.

"When I came to this road in 1870, nearly all the cars had wooden shoes, but we began to use iron shoes about that time.

"It was considered doubtful if iron would do as effectual braking as wood, but after their introduction this notion was dispelled."

JOHN KIRBY,

General Master Car Builder of the Lake Shore & Michigan Southern Railway, is president of the Master Car Builders Association, and has had over 40 years of experience.

"My first railroad experience was in 1848, and wood was then used for 'brake block'; no 'shoes' were used. In 1854 I went to Adrian, Mich., as foreman for the Michigan Southern, and there found them putting shoes onto the worn blocks, they were nailed on, toe nailed we called it.

"In 1856 cast-iron shoes were fastened to the wooden heads, and while these would not get on fire as easily as the wood, they would get hot enough to set fire at times; it was not a very uncommon thing to have a train come in with several brake heads burned off entirely; cast-iron heads were introduced in 1860.

"A good many years ago I saw a passenger car with a heavy shoe between each pair of wheels; it was turned up at each end, and when applied bore on the rail; I believe they were of cast-iron, but am not positive.

"In 1857 I equipped one coach with the shoes hung on top of the wheel; they were cast-iron shoes; it required too nice adjustment, and did not run long."

WM. BUCHANAN,

Supt. of Motive Power, New York Central & Hudson River R. R., has been with the Hudson River road about half a century, most of that time as master mechanic; he says:

"Wooden shoes were used on the branches of the N. Y. Central from 1847 to 1860, were made of oak and used on all kinds of equipment. We commenced to discontinue the use of wood in 1860, and since that time have used iron. I have never seen a sledge brake in actual use."

ROBT. McKENNA,

Master Car Builder of the Delaware, Lackawanna & Western, writes:

"Wooden shoes were used on the Hudson River road from 1858 to 1870; they were made of soft oak, and were on both freight and passenger, and were still in use when I left the Hudson River road, in 1870."

L. B. PAXTON,

Supt. of Rolling Stock of the Philadelphia & Reading, says:

"Wood brake shoes were used on this road when I entered the service, in 1847; they were in pretty general use on passenger, coal and freight cars.

"I think the discontinuance of wooden shoes commenced pretty soon after James Mullholland took charge of the motive power, in 1848; I suppose the object in changing to cast-iron was economy. I have no knowledge of any other form or material for brake shoes than that now commonly used."

E. FERGUSON

is now the head of a private enterprise, but was one of the Michigan Central's early officers; his recollections are interesting.

"When I commenced work on the Michigan Central, in 1844, there were no brakes used on cars or engines except on tenders, and this consisted of a large wooden block between the tender wheels, concaved and made to fit outside the wheel flange; they were worked by means of a long lever on the fireman's side of the tank, when not in use the end was hung on a hook; to operate it the fireman threw it off the hook, and put his foot or feet on it, and pressed down.

"In 1847-8 they put wood brake blocks on passenger equipment, and operated them by a chain and wheel, and, as they wore down, faced them with wood, using oak, elm or maple. These wore rapidly and burned off, and in 1850 they commenced to face them with wrought-iron, cast-iron, chilled-iron, steel and other patented devices until separate heads and shoes came into use."

JOHN HEADDEN

was one of the early master mechanics of the New Jersey roads, and was one of the experts in locomotive building who built the good, old, light weights, from the time of the war up into the '70s. He was Superintendent of the New Jersey Locomotive Works in Jersey City, and there is many a 16-inch "Headden" engine doing light service to-day; he says:

"Wooden shoes were used exclusively on the New Jersey R. R. up to 1850. The solid cast-iron shoe was then introduced, and preferred.

"There were several experiments with sledge brakes, cast-iron chilled blocks, made under my inspection—all failures.

"The common practice with me at first was to line the wood shoes with old leather fire hose, then I used spring steel fastened with wood screws well countersunk, then wood nailed on; this was the practice up to the introduction of iron brake heads, and these were soon followed by loose rubbers or shoes, bolted or keyed to the heads, as now commonly practiced."

DAVID CLARK,

one of the old stand-bys of the Lehigh Valley, now and for many years past Master Mechanic of the Lehigh Valley at Hazelton, Pa., related some of his experience to another officer of the road, who in turn states:

"Wooden shoes were used on the Beaver Meadow & Hazelton road from its beginning up to about 1854, when iron was substituted, as being more economical.

"Some years ago this road equipped two coal cars with a sledge brake invented by W. H. Hoffecker, the shoes were forced against the rails by screws, it was used on 4-wheeled cars only, and was not a success."

OSGOOD BRADLEY

is the senior member of the firm of Osgood Bradley & Sons, car builders, Worcester, Mass., and was early in New England railway service; he says:

"All roads in this part of the country used wooden brake shoes up to 1845; then they were faced with wrought-iron. We used two or three thicknesses of sole leather on passenger cars, to make them hold."

CLEMENT E. STRETTON,

the well-known railway expert of England, consulting engineer for the Association of Drivers and Stokers, and the author of historical and other works on railways, contributes the following interesting facts, showing that wooden brake shoes are still used in England, and placing the credit of the introduction of cast iron shoes there to an American, Mr. Geo. Westinghouse; his letter is interesting.

"From the earliest introduction of railways in Great Britain to the year 1871, the brake blocks or shoes were made of wood, willow and poplar being both considered very good for the purpose. In 1865 it became the practice to bore large holes in the wooden blocks, and to fill them with rosin and sand; this was done to increase the friction, as the introduction of steel tires in place of iron had reduced the hold of the band brakes. Numbers of more or less continuous brakes were introduced, and Fay's, Newall's and Clark's were tried, but they all had wooden blocks.

"Towards the close of the year 1869, information reached England that the Westinghouse air (direct) brake had been invented, and that at a trial, on the 18th of September, 1869, upon the Horseshoe Curve, Pennsylvania R. R., the brake blocks were of cast-iron. I was well acquainted with the forms of brakes in use in this country, and am convinced that only wooden blocks were in use in Great Britain in 1869, and also that the above mentioned trial upon the Horseshoe Curve was the first occasion upon which I ever heard of cast-iron brake blocks. Reference to reports and notes also shows that 'wood' was the only material then used.

"In 1871 the Caledonian Railway ordered some Westinghouse brake fittings for a trial train (and, as you well know, Mr. Geo. Westinghouse came over here). The brake fittings sent included cast-iron blocks for engine, tender and vehicles. Prejudice against engine 'driver brakes' was so strong that the Caledonian Co. declined to allow Mr. Westinghouse to fit any brake to the engine wheels, and would not allow him to replace the wooden tender blocks by iron. Mr W. therefore had to attach his brake cylinder to the tender hand brake and wooden blocks.

"An old Westinghouse reference book, published in Pittsburgh about 1874, Sheet 1, shows the engine and tender No. 92, just as it was when fitted at Glasgow in 1871, where I saw it. Mr. Westinghouse induced the Caledonian Co. to let him fit iron blocks to the carriages, and the first trial train was completed on the 23d of October, 1871. Those I believe to be the first cast-iron blocks ever used on a train in Great Britain.

"On March 23d, 1872, a second trial train with Westinghouse brakes was put into traffic, but still Mr. W. was not allowed to place brakes on the engine wheels, nor to put cast-iron blocks on the tenders.

"The London & Northwestern Ry. fitted a train of Westinghouse brake, and it was put into traffic between Euston (London) and St Albans, 13th of May, 1872. That company would not allow Mr. W. to fit his brake to the engine wheels, nor would it let him fit cast-iron blocks to the carriages; he therefore had to attach his gear to the existing wooden brake blocks, as used with the old chain blocks.

"The Metropolitan District Company fitted a Westinghouse trial train, and it ran its first trip 12th of Feb., 1873. That company allowed Mr. W to apply cast-iron blocks to its engine wheels and to all coaches.

"The London, Chatham & Dover, in Feb., 1873, fitted up the first 'boat train' with the air-brake. That company was not in favor of the cast iron blocks. It, however, allowed Mr W. to fit them to the carriages, but declined to let him put any brake upon engine wheels.

"At that period there was a strong prejudice against cast-iron brake blocks; some persons believed they would damage the wheel tires, others urged that wood held better, and could more effectually skid wheels; at that time, it must be remembered that the general impression in England was that a brake was of no use unless it skidded the wheels.

"It will be seen from these facts that Mr. W had some very uphill work to get engineers to adopt cast-iron brake blocks, but his few trial trains in time convinced many that cast-iron was far better than wood, both as regards holding power and expense.

"In June, 1875, the great Newark brake trials took place, and turning to my note-book, I find a record showing that the

Chain brake had 120 cast-iron blocks.

Smith's vacuum train had 74 cast-iron, 12 wood.

Westinghouse automatic train had 64 cast-iron.

Clark's hydraulic train had 64 cast-iron, 8 wood.

Barker's hydraulic train had 104 cast-iron, 8 wood.

Fay's train had 60 wood blocks.

Steele McInnes' train had 32 iron, 32 wood.

Westinghouse vacuum train had 60 iron.

"Kitson & Co. sent an engine and tender to that trial with a steam brake, but in order 'to prevent its doing injury to the tires,' they arranged jets of water to play upon the cast-iron blocks. It will thus be seen that in 1875, both cast-iron and wood were in general use, and as a fact much difference of opinion existed. That was not cleared away until 1878 to 1879, when Mr. W. Cap't. Galton and their experimental van upon the Brighton Ry completely settled the matter, and since that time cast-iron blocks have been generally adopted.

"I am of opinion that cast-iron shoes were first used in America, and were brought to England by Mr. Geo. Westinghouse, in 1871.

"At the time of Mr W.'s first visit to England, 1871, the only blocks that were in use on British railways were of wood. At the present time, all continuous brakes are provided with cast-iron blocks. There, however, still exists a large number of tenders and guards vans for goods traffic, which still have hand-brakes and wooden blocks, but these are being gradually replaced by cast-iron. Wrought-iron blocks Mr. Westinghouse found damaged the tires very much on the Brighton line, 1878. Leather shoes have not been tried for trains in this country. The question under notice is one relating to brake shoes which press upon the wheel tires, and does not in any way refer to 'sledge brakes.' In 1842, 1844, 1846, 1851, 1852 and 1858, various forms of sledge brakes were tried which had no shoes on the wheels, but simply sledges to press upon the rail; these sledges were tried made of steel, wrought-iron, cast-iron, wood, and wood and iron in small squares, the power being applied by hand-screw or by steam. All these sledge brakes proved failures, and lasted only for a few months each."

An Exciting Experience.

On September 2d a train on the Louisville, Evansville & St. Louis road was wrecked, and a dispatch from Hawesville, Ky., dated September 3d, tells the following story:

"Engineer App, of the train wrecked at Tell City, has arrived here to seek refuge from a mob, composed of the relatives of the passengers killed and injured in the wreck. The engineer was himself badly hurt, and had been taken to Troy on the relief train. When his wounds were dressed he was able to return home to Evansville.

"He boarded the train, and when it reached Tell City an angry mob began to assemble, declaring they would lynch App to prevent his escape. The track was obstructed, and the frenzied crowd gathered around the coach which contained the crippled engineer. The trainmen succeeded in placing App in a carriage, which was driven rapidly out of the little town, followed by a volley of stones and curses. The fugitive was driven to the river and ferried across to Kentucky.

"The people at Tell City attribute the wreck partly to the bad equipment of the road, and partly to the reckless speed at which the engineer took the train around the sharp curves. The whole community is excited, and threatens to tear up the tracks and demolish the road-bed."

It is altogether likely that Engineer App had to make time or give up his job; cases like his are not uncommon. If he is one of those fellows you see occasionally who run like the very devil over the worst track they can find, just to make some one "squeal," we are kind of sorry the crowd didn't get him. A locomotive is nothing to fool with—they are always loaded.

There are some good cars being built in this country with "squeeze" or "clasp" brakes—a shoe each side of each wheel. This form seems to be adopted for fear the one shoe form will do damage, but it don't seem to do anything of the sort, and few persons will claim that one shoe does not give braking force enough. The two shoe form calls for the provision and maintenance of almost double the amount of brake rigging, where simplicity is greatly desirable, and does not seem to offer anything in return but the doubtful satisfaction of having the "latest" thing out. Isn't it expensive style?

A Peg-legged Romance.

By John Alexander.

Some men are born heroes, some become heroic, and others have heroism thrust upon them—but nothing of the kind ever happened to me.

I don't know how it is, but some way or other I remember all the railroad incidents I see or hear, and get to the bottom of most of the stories of the road. I must study them over more than other men, or else the other fellows enjoy the comedies and deplore the tragedies, and say nothing. Sometimes I am mean enough to think that the romance, the dramas and the tragedies of the road don't impress them as being as interesting as those of the plains, the Indians or the seas—people are so apt to see only the every-day side of life anyway, and draw all their romance and heroics from books.

I helped make a hero once—no, I didn't either. I helped find the golden setting after the rough diamond had shown its value.

Miles Diston pulled freight on our road a few years ago; he was of medium stature, dark complected, but no beauty. He was a manly looking fellow, well educated enough, sober, and a steady-going, reliable engineer—you would never pick him out for a hero.

Miles was young yet, not thirty, but somehow or other he had escaped matrimony; I guess he had never had time. He stayed on the farm at home until he was of age and then went firing, so that when I first knew him he had barely got to his goal—the throttle.

A good many men when they get here take great interest in their work for a few months, until experience gives them confidence, then they take it easier, look around, and take some interest in other things. Most of 'em never hope to get above running, and so set down more or less contented, get married, buy real estate, gamble or get fat, each according to the dictates of his own conscience, or to the inclinations of his make-up—Miles figured a little on matrimony.

I can't explain it, but when a railroad man is in trouble he comes to me for advice, just as he would go to the company doctor for kidney complaint. I am a specialist in heart trouble—Miles came to me.

Miles was like the rest of 'em—they don't come right down and say, "Something's the matter with me, what would you do for it?" No, sir, they hem, and haw, and laugh off the symptoms, until you come right out and tell them just how they feel and explain the cause, then they will do anything you say.

Miles hemmed and hawed a little, but soon came out and showed his symptoms—he asked me if I had ever noticed the Frenchman's girl.

The Frenchman, be it known, was our boss bridge carpenter, and lived at a small place half way over my division—I was pulling express—but the freights stopped there, changing engines.

I knew Venot, the bridge carpenter, very well, met him in lodge occasionally, and once in a while he rode on the engine with me to inspect bridges. Venot's wife was a Canadian woman, and good looking for her forty years and ten children.

The daughter that was killing Miles Diston was the eldest, had just graduated from some Sisters' school, and was home. She was a very handsome girl, but you could fairly read the romantic nature of her being through her big, round, gray eyes.

Marie Venot was vivacious, and loved to go, but she was a dutiful daughter, and at once took hold to help her mother, in a way that made her all the more adorable in the eyes of practical men like Miles.

Miles made the most of his opportunities, but, bless you, there were other eyes for good-looking girls besides those in poor Miles Diston's head, and he was far from having the field to himself, this he wanted bad, and had come to get advice from me.

I advised strongly against wasting energy to clear the field, but to put it all into making the best show and in getting ahead of his competitors.

Under my advice, Miles disposed of some vacant lots, and bought a neat little house, put it in thorough order, and made the best of his opportunities with Marie.

Marie came to our house regularly, and I had considerable chance to study her; she was a sensible little creature, and to my mind just the girl for Miles, as Miles was just the man for her; but she confided to my wife the fact that she could never, never consent to marry, and settle down in the regulation, humdrum way—she wanted to marry a hero, some one she could look up to, a king among men, a marked man.

Mrs. A. told her that kings and heroes were scarce just then, but a whole lot of pretty good women managed to be comparatively happy with common railroad men—but Marie wanted a hero, and would take no substitute.

It was on one of these visits to Mrs. A. that Miles took her out for a ride, and accidentally, of course, dropped around by his house, induced her to look at it, and told her his story, asking her to make the home complete—it would have caught most any girl.

When Miles delivered her at our door, and drove off, I knew that there would be a "For Rent" card on that house of his in a few days, and that Marie Venot was bound to have a hero or nothing.

Miles took his repulse calmly, but it hurt; he told me that Marie was hunting for a different kind of a man than he was, said he thought perhaps if he would enlist, and go out to fight Sitting Bull, and could come home in a new, brass-bound uniform, with a poisoned arrow sticking out of his breast, she would fall at his feet and worship him. She told him she liked him better than any of the town boys, his calling was noble enough, and hard enough, but she failed to see her ideal hero with blue overclothes on, and cinders in his ears.

If any of Miles' competitors had rescued a drowning child, or killed a bear with a pen-knife about this time, I'm afraid Marie would have taken him—but as I said before, it was a dull season for heroes.

About this time our road invested in some mogul passenger engines, and I drew one. I didn't like the boiler sticking back between me and Dennis Rafferty. I didn't like six wheels connected. I didn't like a knuckle joint in the side rod. I didn't like eighteen-inch cylinders. I was opposed to solid-ended rods; and I am afraid I belonged to a class of ignorant, short sighted, bull headed engineers who didn't believe a railroad had a right to buy anything but 15x22 eight wheelers—the smaller they were the more men they would want. I got over that a long time ago, but I was cranky at the time I write of. The moguls were high, and short, and jerky, and they tossed a man around like a rat in a corn-popper.

One day as I was chasing time over our worst division, holding on to the arm rest, and watching to see if the main frame touched the driving boxes as she rolled, Dennis Rafferty punched me in the small of the back, and said:

"John, for the love ave the Vargin, lave up on her a minit. Oi does be chasing that dure fer the lasth twinty minits, and dang the wan'st has Oi hit it fare—she's a divil on the dodge."

Dennis had a pile of coal just inside and just outside of the door, the forward grates were bare, the steam was down, and I went in seven minutes late, too mad to eat—and that's pretty mad for me. I laid off, and Miles Diston took the high-roller out next trip.

Miles didn't rant, and write letters or poetry, or marry some one else to spite himself, or take the first steamer for Burra-burra-ga or Equatorial Africa, as rejected lovers do in stories. It hurt, and he didn't enjoy it, but he bore up all right, and went about his business just as hundreds of other sensible men do every day. He gave up entirely, however, rented his house, and said he couldn't fill the bill—there wa'n't a hero in his family, as far back as he could remember.

Miles had been making time with the Black Maria for about a week, when the big accident happened in our town. The boilers in a cotton-mill blew up, and killed a score of girls, and injured hundreds more. Miles was at the other end of the division, and they hurried him out to take a car load of doctors down.

They were given the right of the road, and Miles tested the speed of that mogul—proving that a pony truck would stay on the track at fifty miles an hour—which a lot of us cranks had disputed.

A few miles out there is a coaling station, and at that time they were building the chutes; one of the iron drop aprons fell just before Miles and the mogul got to it; it smashed the head-light, dented the stack, ripped up the casing of the sand-box and dome, cut a slit in the jacket the length of the boiler, tore off the cab, struck the end of the car, and then tore itself loose, and fell to the ground.

The throttle had been knocked wide open, and the mogul was flying. Miles was thrown down, his head cut open by a splinter, and his foot pretty badly hurt. He picked himself up instantly, and took a look back as he closed the throttle; everything was "coming" all right, he remembered the emergency of the case, and opened the throttle again; a hasty inspection showed the engine in condition to run—she only looked crippled. Miles had to stand up; his foot felt numb and weak, so he rested his weight on the other foot. He was afraid he would fall off if he became weak, so he had Dennis take off the bell cord, and tied it around his waist, throwing a loop over the reverse lever, as a safety element.

The right side of the cab and all of the roof were gone, so that Miles was in plain sight; the cut in his scalp bled profusely, and, in trying to wipe the blood from his eyes, he merely spread it all over himself, so that he looked as if he had been half murdered.

It was this apparition of wreck, ruin and concentrated energy that Marie Venot saw flash past her father's door on its way to the relief of the victims of a worse disaster, forty miles away.

Her father came home to dinner in a few minutes from his little office in the depot. To his daughter's eager inquiries, he said there was some big accident "in town," and that the "extra" was doctors from up the road. But what was the matter with the engine, the old gentleman didn't know; it was the 170, so it was old man Alexander, he said—and that's the nearest I ever came to being a hero.

Marie knew who was running the 170 pretty well, so after dinner she went to the telegraph office for information, and there learned that the special had struck the new chute at Coalton, and the engineer was hurt. It was time she ran down to see Mrs. Alexander, she said, and that afternoon's regular delivered her in town.

Like all other railroaders not better employed, I dropped round to the depot at train time to talk with the boys, and keep track of things in general; the regular was late, but Miles was coming with a special, and came while we were talking about it.

Miles Diston didn't realize how bad he was hurt, until he stopped the mogul in front of the general office. So long as the excitement of the run was up, so long as he saw the absolute necessity of doing his whole duty until the desired end was accomplished, so long as he had a reputation to protect, his will power subordinated all else. But Miles was badly hurt, worse than he thought, and when several of us engineers ran up to the engine, we found Miles Diston hanging to the reverse lever by his safety cord, in a dead faint. We carried him into the depot, and one of the doctors administered some restorative, while we got a hack and started him and the doctor for my place, but Miles came to himself, and insisted on going to his boarding house, and nowhere else.

Mrs. Bailey, Miles' boarding house keeper, had been a trained nurse, but had a few years ago invested in a rather disappointing matrimonial adventure. She was one of the best nurses, and one of the crankiest women I ever knew. I believe she was actually glad to see Miles come home hurt, just to show how she could pull him through.

The doctor found that Miles had an ankle out of joint, the little toe was badly smashed, there was a bad cut in the calf of the leg that had bled profusely, there was an awful black bruise over the short ribs on the right side, and a button-hole in the scalp that needed about four stitches. The little toe was cut off without ceremony, the ankle replaced, and hot bandages applied, and other repairs made, which took up most of the afternoon.

When the doctor got through he called Mrs. Bailey and myself out into the parlor, and said that we must not let people crowd in to see the patient, that his wounds were not dangerous, but very painful, he was weak from loss of blood, and his constitution not in extra good shape; the doctor, in fact, thought that Miles would be in great luck if he got out of the scrape without a run of fever.

Miles' case was turned over to old Doctor Black that night, and Mrs. Bailey referred all visitors to me. I talked with the doctor and the nurse a few minutes, and we all agreed that it would stop most inquisitive people, to simply say that the patient had suffered an amputation. That evening when I went home there were two anxious women to receive me, and the youngest of them looked suspiciously as if she had been crying.

I told them something of the accident, how it all happened, and about Miles' injuries. Both of 'em wanted to go right down, and help "do something," but I told them of the doctor's order, and his fears.

By this time the reporters came, and I called 'em into the parlor and let them pump me.

I detailed the accident in full, but declined to tell anything about Miles or his history; "Fact is," said I, "that you people won't give an engineer his just dues; now, if Miles Diston had been a fireman, and had climbed down a ladder with a child, you would have his picture in the paper, and call him a hero, and all that sort of thing; but here is a man crushed, bleeding, with broken bones, and a crippled engine, who stands on one foot, lashed to his reverse lever for eighty miles, and makes the fastest time ever made over the road, because he knew others were suffering for the relief he brought."

"That's nerve," said one of the young men.

"Nerve!" said I. "Nerve! why that man knows no more about fear than a lion, and think of the nerve of the man; this afternoon, he sat up and watched the doctor perform that amputation without a quiver, he wouldn't take chloroform; he wouldn't even lie down."

"Was the amputation above or below the knee?" asked the reporter.

"Below" (I didn't state how far).

"Which foot?"

"Left."

"He is in no great danger?"

"Yes, the doctor says he will be a very sick man for some time, if he recovers at all."

"Boys," said I, "there's one thing you might mention, and I think you ought to, and that is, that it is such heroes as these that give a road its reputation; people feel as though they were safe behind such men."

If Miles Diston had read the papers the next morning, he would have died with flattery, the reporters done themselves proud, and they made a whole column of the "iron will and nerves of steel" racket about that amputation without ether.

Marie Venot felt awful sorry for Miles; she wanted to see him, but Mrs. Bailey referred her to me, and she finally went home, inquiring every day about him. I don't think she had much other feeling for Miles but pity.

She was down a week later, and I talked freely of going to pick out a wooden foot for Miles, who was improving right along.

Meanwhile, the papers far and near copied the articles about the "Hero of the Throttle," and the item about the road's interest in heroes attracted the attention of our general passenger agent—he liked the free advertising, and wanted more of it—so he called me in one day, and asked if I knew of a choice run they could give Miles as a reward of merit.

I told him, if he wanted to make a show of gratitude from the road, and get a big, free "ad," in all the papers, to have Miles appointed superintendent of the Spring Creek branch, where a practical man was needed, and then give it out cold that he had been rewarded by being made superintendent of the road. This was afterward done, with a great hurrah (in the papers).

The second Sunday after Miles was hurt, Marie was down, and I thought I'd have a little fun with her, and see how she regarded Miles.

"There's quite a romance connected with Diston's affair," said I at the dinner table, rather carelessly. "There is a young lady visiting here in town, I hear she is very wealthy, that saw Miles when we took him off his engine. She sends him flowers every day, calls him her hero, and is just crazy for him to get well so she can see him."

"Who is she, did you say?" asked Mrs. A.

"I forgot her name," said I, "but I am here to tell you that she will get Miles, if there's a chance in the world. Her father is an army officer, but she says that Miles Diston is a greater hero than the army ever produced."

"She's a bossy," said Marie.

I don't know whether you would call that a bull or a bear movement on the Diston hero stock, but it went up—I could see that.

A week later Miles was able to come down to our house for dinner, and Mrs. A. asked Marie to come also. I met her at the depot, and after she was safe in the buggy I told her that Miles was up to the house. She nearly jumped out, but I quieted her, and told her that she mustn't notice or say a word about Miles' game leg, as he was awful sensitive about it.

Mrs. A. was in the kitchen, and I went to the barn to put out the horse. Marie went to the sitting-room to avoid the parlor and Miles, but he was there, I guess, and Marie found her hero, for when they came out to dinner he had his arm around her. They were married a month later, and went to Washington, stopping to see us on their way back.

As I came home that night with my patent dinner pail, and with two rows of wrinkles and a load of responsibility on my brow, Marie shook her fist in my face, and called me an "old story teller."

"Story teller," said I. "What story?"

"Oh, what story, that *leg* story, of course, you old cheat."

"What leg story?"

"Old innocence, that amputation below the knee, you know."

"Wa'n't it below the knee?"

"Yes, but it was the little toe."

"John," said Miles, "she cried when she looked for that wooden foot, and only found a slightly flat wheel."

"That's just like 'em," said I, "here Marie only expected a part of a hero, and we give her a whole man, and she kicks; that's gratitude for you."

"I got my hero all right, though," said Marie, "you told me a big fib just the same, but I could kiss you for it."

"Don't you do that," said I, "but if the Lord should give you many blessings, and any of 'em are boys, you might name one after me."

She said she'd do it—and she did it.

A Flue Cutter Kink.

At the Denver Shops of the Rio Grande road they use an old pipe cutter for cutting off and scarfing flues. This tool has the usual hollow spindle and chuck, the dies have been removed, and the tool holder for the cut-off attachment left in place. Into the tool post they put two tools, side and side; one of these is the regular cut-off tool, while beside it is clamped a tool whose end is bent toward the head of the machine; this tool is clamped far enough back of the cut-off tool so as not to interfere with its work. When the end of the flue is cut off the carriage is moved far enough from the end of the flue to let the angled tool pass it, the carriage is moved forward a turn or two of the screw, and the angled cutting tool enters the end of the flue, and scarfs it out neatly and quickly, leaving clean metal. For making safe ends to splice out tubes, the same kind of a rig is used, except that the cutting edge of the angled tool is on the other side. It is run down, and the *outside* of the end of the tube scarfed off, then the tube is run forward to a stop, the cutting-off tool brought down, and the cut completed, the scarfing tool being in position to scarf the next piece, while it is held close to the chuck.

Flues welded in the machine are almost perfect after this treatment, as the weld is made in new, clean iron, the scarfs fitting each other, and no dirt gets into the weld—their loss from bad welds is now almost *nil*. An intelligent laborer who was put on this tool to do the cutting off saw the chance to do the scarfing, and suggested it, and it is to the credit of the foreman in charge that he gets the credit for it.

The Johnstone Compound.

In response to a number of requests for details of the Johnstone compound locomotive as used on the Central Mexicano, we publish the valve and cylinder details herewith.

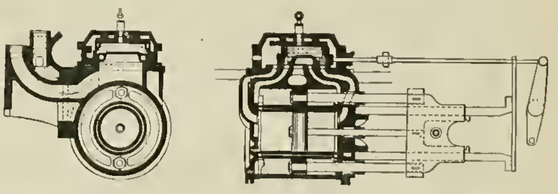
The high-pressure cylinder is inside of the low pressure, the piston of the latter being a ring, and packed inside and outside.

The high-pressure cylinder, which is 14 in. in diameter by 24 in. stroke, is placed within the low-pressure cylinder, which is 30⅞ in. diameter by 24 in. stroke, or equal to a cylinder of 24¼ in. diameter after deducting the area of the high-pressure cylinder and the sleeve surrounding it. The ratio of the cylinders is three to one. The low-pressure piston is provided with two rods and the high pressure with one. The three rods are secured to the same crosshead, both pistons acting in the same direction.

The valve, which is a very important feature of this design, distributes steam to both high and low-pressure cylinders, requiring but one valve stem, which is actuated by the link motion as commonly used on locomotives. The valve is made in two sections, the outer portion distributing steam to the high pressure cylinder, and the inner section to the low-pressure cylinder. The inner section is carried by the outer, and has one inch less travel, the outer traveling six inches, the inner traveling five inches. The object of this is to retard the point of cut-off to the low-pressure cylinder, and also to reduce the compression on the front of the high-pressure piston. When the high pressure admission is cut off at 9 in., the low pressure continues open to the admission of steam for 17 in. The compression on the high pressure piston, which would begin at 9 in. piston travel were both sections of valve made to move together with the same point of cut-off, does not take place until 17 in. in the high-pressure piston and 19 in. in the low-pressure. With 14 in. cut-off in the high pressure cylinder, there is 20 in. cut-off in the low-pressure cylinder, compression beginning at 20 in. in the high-pressure and 22 in. in the low-pressure.

A simple arrangement of starting valves enables the engineman to throw the engine into high pressure, steam being admitted through a reduced opening into the low-pressure cylinders. When this is done the high pressure piston is put into equilibrium, but the two low pressure pistons act with a force equal to two 24¼ in. pistons, therefore the engine has much greater starting power than any high-pressure locomotive of ordinary build.

Several of these engines have been built at the Rhode Island Locomotive Works. The inner valve is not rigidly attached to the rod or main valve, but is loose within the valve cavity and is knocked back and forth by the main valve.



Praise from an Englishman.

At last a real, live English "dook" has given unstinted praise to an American road, and has published the following in an English periodical—1891 is indeed a great year of improvement and advancement.

A more agreeable journey through diversified and attractive scenery than that which can be made by one of the two daily vestibuled fast trains of the Baltimore & Ohio Railroad, between Chicago and Washington, Baltimore, Philadelphia and New York, would be hard to find. The Baltimore & Ohio Railroad of to-day is a vastly different institution from that which it was a few years ago. The antiquated locomotives and cars which then constituted its equipment have given place to rolling stock of the latest and best patterns, and the through trains, vestibuled from engine to rear sleeper, and, including dining-cars and Pullman cars of the most modern and luxurious character, compare favorably with those of any in the world. The sleeping cars, especially built for these trains a few months ago, have some admirable improvements. The elegant simplicity of the interior decorations is in marked contrast to the louder ornamentation which not long ago was considered the height of art in such places. The wood is of mahogany, with little carved or raised work, but brought down to the highest finish, carefully selected for fine grain and texture, and showing highly artistic cabinet work which the eye does not tire of admiring. The improvement in the locomotive equipment is equally remarkable. In order to climb the Alleghanies, from whose heights the passenger enjoys views of sublimity and beauty which he never forgets, heavy grades and numerous curves were necessary in constructing the road, and until recently it required the help of extra engines to get a train to the summit. Now when the foot of the mountain is reached, instead of two or more engines being called into service, there is attached to the train a single engine weighing 67 tons, having six coupled drivers and cylinders 21x28 inches in size, and this powerful machine takes the heavy train up the long stretches of grades, reaching as high as 118 feet to the mile, at a lively pace. The daylight ride over the mountains, especially in the time of verdure, shows a wonderfully attractive panorama, in which grandeur and beauty are constantly mingled, and indeed the entire journey between Washington and Chicago proves the propriety of calling this road "Picturesque B. & O."

Who Can They Trust, Then?

If union meetings serve no better purpose than to permit grand officers to come together and form schemes and intrigues, which always result disastrously for the interests of the railway employes, they had better be abandoned. The editor of the *Gazette* honestly believes that the various railway organizations of this country have more to fear from the schemes and intrigues of the officers who are paid to promote their best interests, than from any other source.—*Railway Service Gazette.*

A Wonder on Wheels.

Some daily paper reporter, presumably just escaped from the incurable ward, or an interview with a division superintendent, gives us the following:

> The Pennsylvania Railroad is building at Altoona an immense locomotive for hauling the limited trains at the necessary speed. It will be more than twice as long, it is said, as the average locomotive, and will have two sets of driving-wheels. The wheels will be under trucks, so that the locomotive can round curves. Two firemen will be necessary.

The conventions of the Master Car Builders Association and American Railway Master Mechanics Association will meet next June at Saratoga, N. Y. Congress Hall has been selected as the headquarters of both associations. The members and all others attending the convention will receive accommodations at the uniform rate of $3.00 per day. Application for rooms should be made to H. S. Clements, Congress Hall, Saratoga, N. Y. The Master Car Builders convention will meet on Wednesday, June 15th, and the Master Mechanics convention on the Monday following.

Woman and the Steam Engine.

It takes sand to run an engine, so it does to run a woman.

There is usually a great bustle about an engine so there is about a woman.

It makes a fellow mad to get left by an engine; so it does by a woman.

An engine is an object of much wonder and admiration to men and of fear to horses, so is a woman.

When an engine goes off the track it usually takes a man or more along with it; so does a woman.

An engine is known by its company, so is a woman

An engine will sometimes blow a fellow up if he puts on too much pressure; so will some women.—*New York Herald.*

Man and the Locomotive.

A locomotive is noisy when she is hot; so is a man

When a locomotive gets too full she lays down; men do

A very old locomotive is apt to be lame; man is the same.

A locomotive's draft is governed by a petticoat, the drafts of men are often affected by the same influence.

On a damp, dark night, a locomotive is slippery and treacherous; man too.

A locomotive, when run by night, should always have a pilot, a man should have two.

The best of locomotives have to be "jacked up" occasionally, and men.

A locomotive that is always out nights soon becomes faded, we have seen faded men.

A dead locomotive has no pull; dead man same.

Locomotives spark nights; so men do.

As a locomotive changes from warm to hot she perspires; and a man.

A locomotive is always hot when there is an "Injin-near"; heap so white man.

Water is good for a locomotive, try it on a man.

A smoking locomotive is a nuisance, man.—*Western Railway*

Don't get a notion that there is forty or fifty per cent. saving of fuel possible with a compound locomotive. The best ones made now may find twenty-five, but the simple engine, or the men who handle it, will be at once improved, so that the compound will have to scrabble to show ten, or, perhaps, keep above five.

Angus Sinclair, secretary, has got out the Master Mechanics Association Report for 1891 with his usual promptness. The work is larger than any previous one, and is ably edited and neatly printed Editing speeches so as to get the cream and discard the whey is a delicate operation, but Angus is an expert skimmer

Secretary John W Cloud, of the Master Car Builders Association, has sent out the twenty-fifth annual report. The book contains 275 pages of text, and plates of all the standards of the association. These reports represent a great deal of hard work by the secretaries, that does not make an extra big show.

L. C Hitchcock's article on Locomotive Running Repairs came to hand too late for this paper; it will appear next month, and the series be finished, we trust, without interruption These articles have been appreciated as much as any other feature of the paper

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 22,000 engines and 270,000 cars. This includes 180,000 freight cars, which is about 18 PER CENT. of the entire freight car equipment of this country. Orders have been received for 120,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, MANAGER. JOHN B. GRAY, AGENT. C. C. HIGHAM, GENERAL SUPT.

THE AMERICAN BRAKE COMPANY,

NEW YORK OFFICE, 160 Broadway, JOHN B. GRAY, Agent.

THE WESTINGHOUSE AIR BRAKE CO., Lessee,

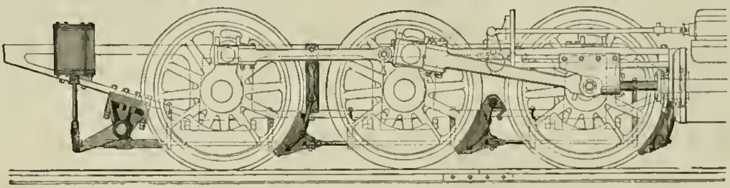
CHICAGO OFFICE, GRAND PACIFIC HOTEL.

MANUFACTURERS OF

LOCOMOTIVE BRAKES.

GENERAL OFFICE, ST. LOUIS, MO., U. S. A.

BRAKES Made to Order for any Special Form or Class of Engine.



All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear & Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM, AIR or VACUUM.

DIXON'S

GRAPHITE

PIPE JOINT

GREASE,

FOR STEAM OR GAS PIPES, BOLTS, SCREWS, ETC.

Far Better and Cheaper than Red Lead.

Makes a tighter joint than red lead, that can be opened with perfect ease many years after.

No longer any necessity for

BROKEN PIPES, STRAINED TONGS or LEAKY JOINTS.

Put up in 1 lb., 5 lb., 10 lb., 25 lb. & 50 lb. packages.

☞ Send for Illustrated Catalogue containing more information concerning Graphite and its uses than is in print elsewhere in any language. ☜

JOSEPH DIXON CRUCIBLE CO.,

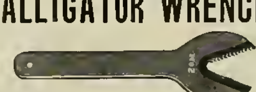
JERSEY CITY, N. J.

AMERICAN SAW CO.,

TRENTON, N. J.,

Manufacturers of the Celebrated

ALLIGATOR WRENCH



These Wrenches are forged solid in one piece, from best refined iron, with tempered steel jaws. They have ratchet teeth, cut diagonally across one jaw, thus enabling them to bite with three teeth at once.

INVALUABLE TO ENGINEERS, GAS-FITTERS AND JOBBERS OF ALL KINDS.

THE "LACKAWANNA" LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank-pins in hard daily service.

In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound is specially recommended for these cups, being first-class in quality and low priced.

LACKAWANNA LUBRICATING CO.,

SCRANTON, PA.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

Main Office: FRANKLIN, PA. Refineries: FRANKLIN, PA. OLEAN, N. Y. ERIE, PA. OIL CITY, PA.

A Stove Train.

The Central Railroad of N. J. have one train that runs semi annually—the stove train. In the spring they start a train out over the road, that collects every stove along the line, from depots, section house, pump houses, switch shanties and what not. This train load of iron is taken to the Elizabethport shops, where the stoves are stored in a building kept for the purpose. During the summer each stove is put in thorough repair, blackened, numbered, and put away. When the October winds begin to move, the stove train starts out again, and peddles out the load it collected in the spring. A gang of competent stove artists put up and take down this array of stoves, thus confining the profanity to a crew who have given up hope, rather than spreading it broadcast throughout the system, as would be done if the stoves were stored under the stairs and the pipe kept in the hen-house—system and organization may yet redeem the world.

A Crippled Confederate.

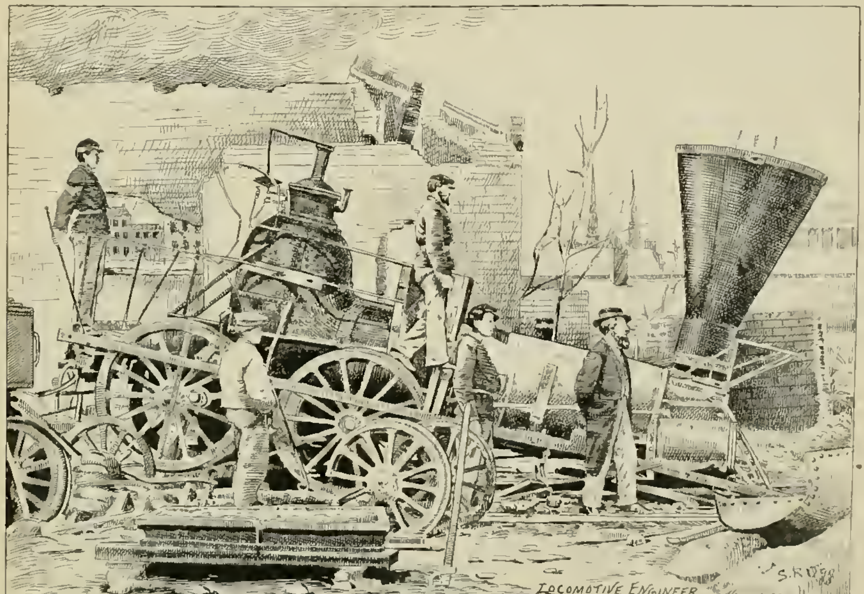
During the war of the Rebellion, from 1861 to 1865, the United States government had two official photographers with the main army, and during the four years of carnage they took some thousands of negatives "at the front." These truthful pictures, painted by the sun more than a quarter of a century ago, have recently fallen into the hands of a company at Hartford, Conn., who are making magic lantern slides and views.

The one shown herewith was taken at the fall of Richmond, at the depot of the Richmond & Petersburg road, and shows the crippled condition in which the Confederate soldiers left the locomotives in the besieged city.

The trucks were taken out and broken up, the rods and motion work stripped off, in fact, everything that could be moved by hand was moved.

The buildings about bear the marks of the victors' shot and shell.

As will be seen, the engine was an eight-wheeler, wood-burner, with a dome, or Bury boiler. Who built her?



A CRIPPLED CONFEDERATE.

The Northern Pacific has brought east from Tacoma, Washington, 180,000 packages of tea this season. This commodity was valued at over $2,000,000, and is always shipped from the seaboard east by fast trains.

All names on our list before Nov. 1st will have their subscription continued by the enlarged paper just as if the price had not been raised; there can be no disappointed subscribers then. All subscriptions for next year received after Nov. 1st must come in at the $2 rate. Subscriptions for all back numbers will be received at the old rate, $1.

The Northwestern have fitted up one suburban locomotive to burn hard coal; this is being done to abate the smoke nuisance. Hard coal will work all right, it's the expense that stands in the way.

Locomotive Running Repairs.

By L. C. Hitchcock.

MOVING ECCENTRICS.

In the September, 1891, issue of The Locomotive Engineer, on page 167, Brother J. W. Keafus asks for information in regard to moving eccentrics on the shaft, and states that in the February number of The Locomotive Engineer, under the head of Running Repairs, I gave no rule by which a person would know how much to move an eccentric on the shaft to give a required amount of lead. I gave no rule, for the reason that the distance an eccentric should be moved on the shaft depends materially on how much throw the eccentric has, and on the length of the rocker arms Different builders making a wide difference in the dimensions of these parts renders the application of any rule to all engines impracticable. From what Bro. Keafus says I conclude that in the case cited the back motion eccentrics were outside, next to the driving-boxes, and also that the eccentrics were not keyed to the shaft. Assuming this to be the case, I should have proceeded as follows: Now this may be called by some a "cut-and-try" way of working, but I think it a quicker way than to have endeavored to figure out a rule to apply to that particular engine After having given the engine the desired amount of lead in the forward motion, I would have placed the reverse lever in the extreme back notch of quadrant, then pinched the engine backward and caught the forward dead center, would then have taken down the back half of the forward eccentric strap, and pushed the forward half with the rod as far forward as possible The top part of the strap would then have rested on the eccentric at about the point A, Fig 1; in this position the set-screws in the back eccentric may be reached. Now, before slacking off these set-screws, scratch a good, plain line $B\ C$ across the lower part of the back eccentric and strap. Now as the eccentric is moved on the shaft the lines $B\ C$ will separate, and on most engines the proportion of the distance these lines will separate to the distance the valve stem will move is about 5 to 1; thus, if the valve stem is to be moved $\frac{1}{16}$" the lines $B\ C$ should be separated $\frac{5}{16}$"; but, as I have stated, no rule will apply to all engines, and this proportion will change as the outside diameter of the eccentric cam decreases by wear.

After having separated the lines $B\ C$ five times the amount of lead I desired, I would have replaced the back half of the forward strap, and pinched the engine forward nearly one-half revolution; then by pinching the engine back would have again caught the forward center, and noted the lead obtained; by carefully noting the amount of lead produced by separating the lines $B\ C$ a given distance, the exact lead could be given at the second trial, if necessary to move the eccentric the second time; then if I was running the engine regularly, and was expected to keep its valves square, I would write down, and keep in a handy place for reference, the proportion of the separation of the lines to the lead produced. It was one of my duties at one time to set the valves of all engines turned out of the Brainerd shops of the N. P. R. R., and to facilitate my work I kept a table of these proportions as required for the different builds of engines. Thus:

Baldwin's = line separation 5 times the lead produced.
Hinkley's = " " 4½ " " " "
Rome's = " " 5¼ " " " "

I do not give this as a correct table, but only to show the manner of keeping it. These tables were made, of course, after having obtained the proper proportion by trial. By this scheme I could give those eccentrics next to the driving-boxes the desired amount of lead eight times out of ten by one trial. A word now in regard to moving eccentrics which are keyed to the shaft. When I was doing this class of work I desired the gang boss in the machine shop to place the eccentrics on the shaft, so that the keyways in the cams came exactly in line with those in the shaft, and hold them in place with the set-screws, leaving out the keys After getting the eccentric rods the proper lengths, I would move the inside eccentrics to produce the desired lead, then move those next to the driving-boxes in the manner here described. After all were in their proper positions the keyways in most instances would appear similar to those represented by Fig. 2. I would then take a small, thin wedge of soft wood about one-quarter the width of the keyway, and place the edge of it against the side of the keyway in the eccentric, then by lowering it bring the thin end in contact with the lip A on the shaft; by rubbing it forward and backward a few times under a slight pressure a clear impression of the width of the lip is made on the wedge.

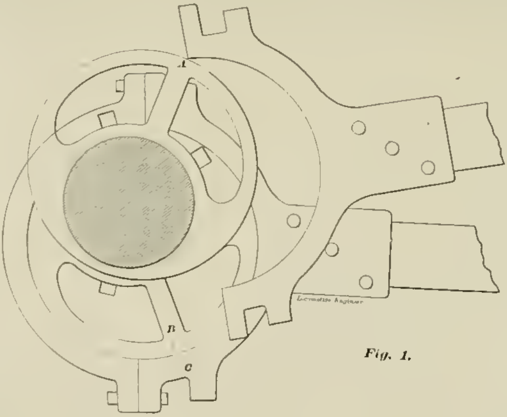


Fig. 1.

This impression shows exactly the amount of offset required for that key.

If a person is careful after having moved an eccentric to go over the work a second time, to insure its being in the proper position, and makes an accurate measurement of the impression of the lip A,

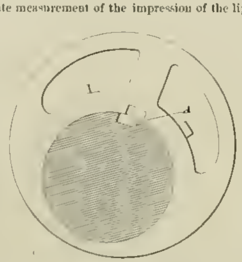

Fig. 2.

and is careful while making the keys, it is but a short job to put in a set of keys, and it will not be necessary to run the engine over in full gear after the keys are in place.

On the Western & Atlantic Railroad—famous for its war memories—down below Dalton, Ga., stands an old car body, now used as a tool-house, bearing on its weather-beaten side this legend, "U. S. Military Railroad, Engineering Dep't." Ah, what stories that old car could tell!

The Journal of Railroad Car Heating has been merged into *The Railroad Car Journal*, with Edward A. Phillips as editor and manager. Its mission in life will be the "improvement and perfection of passenger cars." We heartily wish it success, and wish it would start on the window nuisance.

An Awful Wreck.

"Speakin' o' wrecks," said the old-timer, carefully spreading his coat-tails before the grate and shutting his left eye toward our blonde type-writer, "speakin' o' wrecks reminds me of onct when we was shovin' the mountain division acrost the Rockies, Sam Chambers lenned his ingine up agin a rock slide and piled up fourteen of fifteen cars in a little gulch.

"I were behind Sam with a load of ties and no dinner pail, and laid back and fasted, religious-like, all night. My conductor were from down south somewher's, a keerless-like cuss, and along to'ards mornin' he walked down to the wreck.

"Whilst he were gone the general manager's bob-tail come up behind us and the old man and a few of his gang walked alongside of my train.

"Jest at the engine they met my conductor comin' back.

"'How bad is that wreck?' sais the old man.

"'Bad,' sais Ike, 'awful bad; fact is, it's the worst I ever see.'

"'I had no idee it was so awful,' sais the old man, kinder scratchin' his head and lookin' worried. 'There wa'n't no one hurt?'

"'No,' sais Ike, 'but it's mighty bad, worst——'

"'How many cars?' sais the old man, kinder stoppin' him.

"'Leben,' sais Ike.

"'Leben cars and you a sayin' it's so awful bad. Why, 'leben cars is not much of a wreck.'

"'Worst wreck I ever seen,' persisted Ike. 'Bad, bad,' he muttered, sorter to hisself. 'I never seen a 'leben-car wreck afore where a man couldn't make a raise of a pair of boots or a hat—'leben cars, 'leben great big cars, all mashed to smithereens, and nothin' but ties and coal. Wreck?' sais he, still sorter musin', 'it's a little the d——ndest worst wreck I ever see!'"

In the past ten years the Brotherhood of Locomotive Firemen have paid out $2,704,935.98 Of this, $446,399.75 went for experience in the "Q." strike; the grand amount of $1,875,252 has been paid for sickness and deaths. Those people who howl about organized labor would be a long time collecting $1,875,252 for the widows and orphans of the locomotive firemen of the land The order has helped its members in other ways, raised wages, helped secure positions, added to the *morale* of the membership, and published a magazine of use and interest to its members and their families. It may have blundered, it may have harbored bad hearted men, it may have made mistakes, but from many a widow's heart there goes up a blessing and a prayer for its prosperity. It has made men independent in providing for their families by paying for their protection, and not appealing to charity

---

Recent trials of the Johnstone compound on the Santa Fe road has proven the efficiency of the principle. With a blanket of cooler steam around the high pressure cylinder, and an annular piston packed inside and out, one would be led to expect the least of this machine of all the compounds, but her work proves that "there is something in it"—the compound. We are very much afraid that this engine will be hard to keep up—a good new engine, but a bad old one—but in this we may be mistaken, this compound locomotive business will be settled finally by the "survival of the fittest," and, of course, results being equal, the simplest machine will stand at the head.

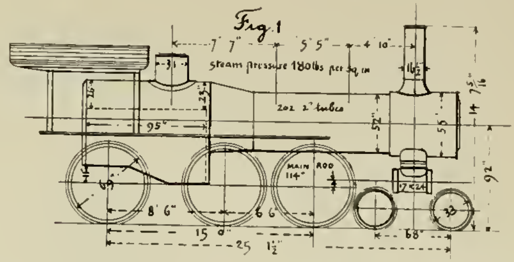
Wm. C. Stroud, one of the firm of Burnham, Williams & Co., proprietors of the Baldwin Locomotive Works, left $200,000 for the establishment of the Eliza Cathcart Home for Incurables, named in honor of his mother.

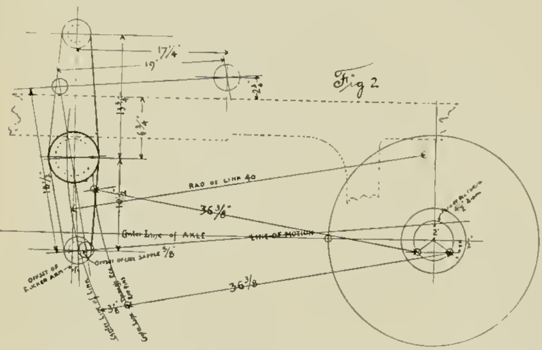
Notes from a Rambling Correspondent.

Cleveland was the first point touched by your correspondent, and here was found quite a busy railroad center

Arriving by the Lake Shore, and having come the whole distance from Buffalo by daylight, a good opportunity was afforded for noting the general features of the road. Any one making this trip cannot help but be impressed with the alignment, freedom from curves and grades, and fine roadbed.

These exceptional conditions admit of safe fast running, which is made good use of in getting the many fast trains over the road. The constantly increasing passenger train loads have called for frequent expansion in the power to keep pace with the growing loads, until the demands upon the power are quite beyond the limit of weight per square inch of journal contact possible in an eight-wheel locomotive. And the next step in the process of evolution was their ten-wheel passenger engines, and Mr. Stevens has succeeded in designing a very superior machine, which satisfactorily meets the growing requirements, and has come to stay. The general features of this engine will be noticed by an examination of the outlined sketch (Fig. 1). One very noticeable feature in this design, which has been the pioneer of a number of the same class, is the location of the rocker arm and link between the forward and main drivers, doing away with the heavy curved rod in common use, and reducing the excessive weight, frictional





resistance and distortion of steam distribution by springing of these long curved rods.

To many of us with old-fashioned notions, this wide departure from our ideal, say 72 inch, eccentric rod, is at the expense of good steam distribution; but the particular difficulty with these short rods, viz.. the inordinate increase of lead as the engine is hooked back, is not so serious a difficulty in fast running engines as in slow freight service, and Mr. Stevens' experience bears out this fact, because he gives unqualified testimony as to the satisfactory and economical service with this class.

Figure 2 is a skeleton outline of the valve motion, which certainly makes a very convenient and compact arrangement

Mr. Stevens, being one of the pioneers in high pressures, has again demonstrated the wisdom of this practice by carrying 180 pounds pressure on these engines.

Next, in looking over the Nickel Plate, we found our friend Mr McKenzie very much up to the times, and the results, upon careful inspection of his motive power, showed that a marked improvement has been made in bringing up the general condition of the power, and some recent engines designed by him are fully abreast of the times. The boilers of these engines deserve special mention, as they exhibit a very ingenious method of doing away with the old-time crown bars and their excessive weight, and also the increased weight of the extended wagon top radial stayed type of boiler, but retain the good features of the wagon top in a novel way by placing the dome on the sloping portion, which extends from the wagon top to the barrel.

And a further improvement is in making this sloping segment a true frustum of a cone, and in one sheet. This produces a radial stayed wagon top boiler, with a minimum weight coupled with maximum strength, and enables all the weight possible to be utilized in making the boiler as large as possible. After a two years' test, these boilers speak for themselves. The writer was also interested in the method of compactly classifying the power on this road, an outline of which is given in the table below.

Also at Cleveland we had the pleasure of meeting Mr. John Bean, the genial Superintendent of Motive Power of the Cleveland & Canton Railroad. His road is a very busy coal road, with heavy traffic for the physical condition of the road, and is very hard upon the power, but from the results accomplished Mr. Bean has good reason to be pleased, as the general condition of the rolling stock is very good.

At Detroit, the home of the Michigan Central, there were no special features, but thrift is apparent on every side One is especially impressed with the improvements in the passenger cars, but we did not find the motive power quite as modern as we expected. At the same time this road is endeavoring to find the ideal type of passenger engine for their service, and this point led them at a very early day to the use of the ten-wheel passenger engine, and very fine specimens of this type the road has now in service. Besides these, they have two compounds, which, all things taken in consideration, are of the most successful type in use, as they have been in constant, active, every-day service for a considerable time, and, necessarily, these people, having used this type longer than any one, are better prepared to speak concerning the merits or demerits of this system. So far, these engines have shown a decided economy. Thanks to the courtesy of the General Master Mechanic, Mr. Smart, we were afforded an opportunity to ride on the compound, hauling the North Shore Limited, from Jackson to Detroit, 75½ miles, schedule time of this train being 1 hour and 48 minutes, or 42 miles per hour, including two stops. After a run of 38 miles the forward high-pressure cylinder head blew out. The train was immediately stopped, the main rod taken down, piston and valve stem disconnected, and pushed to forward end, securely blocked, and the intercepting valve blocked open, and the train hauled in with a low pressure cylinder. Query: Was it necessary to have done anything with the intercepting valve?

At the Jackson shops they are turning out unusually good specimens of boiler work, besides doing a good deal of general repairs. Mr Smart's efforts and plans for furnishing every facility for educating his engineers and firemen, and the provisions for instructions in drafting for the shop apprentices, is deserving of special mention. P E. L.

The present stock of bound volumes of THE LOCOMOTIVE ENGINEER, and handy binders for home binding, will be sold out and no more made. We can supply papers from the beginning of the publication—four years. Orders for bound volumes will be placed on file, and copies sent out while the stock lasts. Get yours in early.

We will give 25 cents each for 100 copies of March, 1890 issue. Must be clean enough to bind.

CLASSIFICATION OF ENGINES.

Class	Wheel Base. — Driving	Wheel Base. — Total Engine	Wheel Base. — Total Engine and Tender	Wheel Diameter — Driving Center.	Wheel Diameter — Truck	Brakes — Westinghouse Automatic on Tender and 6 Drivers	Westinghouse Automatic on Tender and 4 Drivers.	Westinghouse Automatic on Tender Only.	American Steam on 4 Drivers	Surfaces Square Feet — Grate "G"	Heating "H"	Ratio "G" to "H"

It's a good deal of a relief and a change from the usual to pick up the bill of fare on a Santa Fe diner, and read this legend "No fees. Please do not deteriorate our service by bribing the waiters—all money left on the tables will be turned in to the company." The Santa Fe employ white waiters, have the finest cars and the best service in the country.

Where They Are.

The following list of the railroad mileage by States shows the location of our iron paths. As will be seen, the West leads by far; in a few years Texas will lead, with Illinois and Kansas close behind her, while New York and Pennsylvania will slip down the list to near the middle.

1	Illinois	10,129	9	Missouri	6,142
2	Kansas	8,900	10	Indiana	6,106
3	Texas	8,710	11	Wisconsin	5,615
4	Pennsylvania	8,710	12	Minnesota	5,545
5	Iowa	8,415	13	Nebraska	5,407
6	Ohio	7,988	14	Georgia	4,593
7	New York	7,748	15	California	4,356
8	Michigan	7,106	16	Colorado	4,291

Standard Brakes and Car Couplings in India.

The last official report concerning the railways of India has the following items:

"During the year under review 57 locomotives and 178 vehicles on the Northwestern Railway were fitted with the vacuum automatic brake gear, and passenger trains so fitted have been running on the Sind-Pishin section since November, 1890.

"On the East Indian it is proposed to fit up 18 engines and tenders and 87 vehicles with vacuum automatic brake gear, and 34 vehicles with pipes only for working the suburban and vice-regal trains. Also to fit up 34 engines and tenders and 130 vehicles with vacuum automatic brake gear, and 100 vehicles with pipes only for the chord and loop line mail trains, and joint stock for through service with the Great Indian Peninsula.

"On the Great Indian Peninsula 63 locomotives and 64 vehicles have been fitted with the vacuum automatic brake.

"Two locomotives and 15 vehicles are already fitted with the vacuum automatic brake on the Eastern Bengal State railway.

"On the Oudh & Rohilkhand the government of India has sanctioned the provision of continuous vacuum automatic brakes for the locomotive engines and passenger stock used on the mail trains of the line.

"All standard gauge lines in India, with the exception of the East Indian, have screw couplings at both ends of all their passenger stock. The East Indian company is now providing second screw couplings to the joint passenger stock of the East Indian and the Great Indian Peninsula railways, as well as to postal vehicles.

"A committee of locomotive and carriage superintendents for India has been formed, with a view to the introduction of a system of standard patterns."—*Indian Engineer.*

Ninety-two Miles in Ninety-two Minutes with Four Stops.

Ninety-two miles in ninety-two minutes is fast traveling, and, all things considered, is worthy of special comment, even among the feats recently accomplished on the "rapid transit" line. This run was made by a Royal Blue train on the Baltimore & Ohio Railroad on Sunday, Oct. 4th, without any preparations for the event. The train consisted of a combination car, two passenger coaches, and the Pullman parlor car "Dahlia." It was in charge of Conductor L. H. Bender, and drawn by locomotive 853, built at the Baldwin works, mate to the one illustrated in this paper in May last, with Engineer J. W. Hanson at the throttle.

The train left Camden station on scheduled time, 8.50 A. M., reaching Locust Point a few minutes later. There its progress was blocked by a fire at Elevator A, directly alongside of the ferry slip. The heat was so great that General Agent Beeler was afraid to let the transfer boat enter the slip, being confident that if he did so the boat would catch fire and cause a panic among the passengers, of whom there were a large number, and perhaps possible loss of life would ensue.

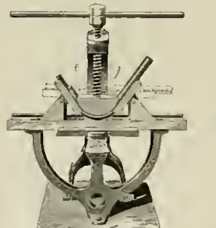
Finally, the transfer boat was taken to the wharf of Elevator "C," the passengers put aboard and carried to Canton.

The run from Canton to Newark, Del., 54.4 miles, was made in a little less than 56 minutes, including a stop of about two minutes at Bayview Junction. From the latter point to Newark no stops were made. From Newark to Philadelphia, 37.2 miles, the time consumed was 36 minutes, including stops at Wilmington and Chester. A part of the time the train was run at a speed of 72 miles an hour.—*Baltimore Paper.*

The Brownson Pipe Bender.

The illustration on this page represents a handy and efficient bench tool, the invention of Mr. G. B. Brownson, foreman coppersmith of the St. Louis & San Francisco shops at Springfield, Mo.

With this device, finished copper and brass pipe, as well as ordinary iron ones, are bent to any de-



sired angle and with any desired radius, without filling of any kind and without flattening the pipe at the bend.

As will be seen, the pipe is laid across two curved blocks, as shown in the dotted lines, these blocks rest on hinges which are fast to movable rests. The distance apart that these rests are placed determines the sharpness of the bend.

The power is applied by a screw, as shown. The whole device is simple and easily operated.

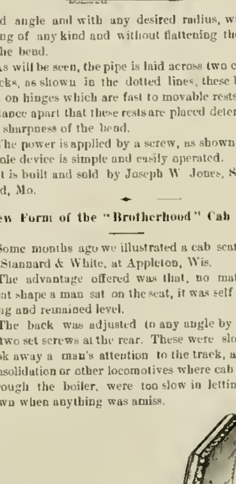
It is built and sold by Joseph W. Jones, Springfield, Mo.

New Form of the "Brotherhood" Cab Seat.

Some months ago we illustrated a cab seat made by Stannard & White, at Appleton, Wis.

The advantage offered was that, no matter in what shape a man sat on the seat, it was self equalizing and remained level.

The back was adjusted to any angle by means of two set screws at the rear. These were slow and took away a man's attention to the track, and for consolidation or other locomotives where cab comes through the boiler, were too slow in letting seat down when anything was amiss.



The new seat, shown herewith, has a ratchet and pawl on the seat that enables the engineer or fireman to instantly let the back down to any angle or entirely flat.

These seats are very strong, occupy little room, and are a source of great comfort to a class of men who need all the comfort they can get. The back and cushion are covered with horse hide, which is very serviceable, lasting and easy to keep clean.

The London, Brighton & South Coast Railway have tried for twelve years to use electric lights in their cars, but have at last given it up and put in the Pintsch gas system.

Wonders will Never Cease.

A convict in the Massachusetts State Prison has recently invented a marine engine which entirely revolutionizes all those of previous makes. It is stated that no eccentrics are used, that it can be reversed without slacking the speed, this action being done by pressing a button on a small or medium engine, while on large ones a treadle is substituted. But three valves are utilized, and they are self-acting. There is no steam chest, and no steam can get into the cylinder. It is claimed that it is more powerful and capable of more speed than the Corliss, and, owing to the dispensation of a large percentage of the friction, there is less expense attending it. He is also at work upon an improved fire engine. A well-versed mechanic states that there is no other cylinder like that used in this case in the world.—*Manufacturing Gazette.*

An engine that can be reversed without slacking the speed, let alone stopping it, and one without a steam chest, is wonderful, and the cylinder into which steam cannot enter will be handy for the engineer to carry his lunch in, or, perhaps, to keep the monkey-wrench and dope bucket.

Not Unreasonable.

Among the better class of roads a movement is on foot to make parlor cars more pleasant to travel in. These cars, if first-class, cost \$20,000 to \$25,000, and it is proposed to educate the traveling public, more especially the male part, up to being better mannered. The educators are willing that a man should make himself comfortable, but he must pay more attention to the little civilities of travel. In a parlor, or even a sitting-room, no man would think of sitting for hours with his hat on in the presence of ladies, nor would he push the spittoon into the middle of the room and expectorate tobacco juice in it at the rate of a pint an hour. The position is taken that man can travel just as comfortably and act as a gentleman should in the presence of ladies.

Economy in Rain.

According to a reputed statement of Mr. Robert Hill, chief engineer of the Chicago City Cable Railway Co., the power required for the operation of the system on rainy days, when the tracks are wet, is fully 20 per cent. less than on dry days, and at the same time it is estimated that fully 25 per cent. more passengers are carried at such times. This gives a very large showing in favor of wet rails where the cable traction is used and the adhesion between wheel and rail is not depended upon for traction. Under these circumstances, rainy days must be a greater blessing to the cable roads than we supposed. It is a fact generally appreciated that the nickels taken in on such occasions are more numerous than on fine days, but that the increased traffic at such times should be carried at a reduced cost is very much of a good thing for the stockholders. Nature evidently smiles upon them.—*Ry. Review.*

The economy will probably be found in the fact that rain does away with a great deal of the sand and dirt on the rails, making the cars pull easier. A *damp* rail is a slippery footing for a locomotive, but a driving rain makes them take hold far better than they do on a dry rail. Water in place of sand has long been used on mining locomotives where much fine dust covers the rail. Next to oil, dust, coal or charcoal dust especially, are the slipperiest things a locomotive strikes in her travels.

Romance in the Office—Reality in the Cab.

On October 15, three reporters who had been sent out by the Chicago *Inter-Ocean* to write up an account of a midnight trip in the cab of a fast express engine, on the Chicago & Eastern Illinois, were killed.

An open switch threw the flying train into an old roundhouse at Crete, Ill. The engine turned over and the roundhouse collapsed, killing the engineer and the three reporters. The fireman escaped.

Zero weather in October made the boys think of covering up the slot around the reverse lever and getting up the side curtains.

A New Molding Machine.

Some time ago we made mention of an ingenious and simple molding machine invented by Harris Tabor, inventor of the steam engine indicator which bears his name, and manufactured by the Tabor Manufacturing Co., 111 Liberty street, New York.

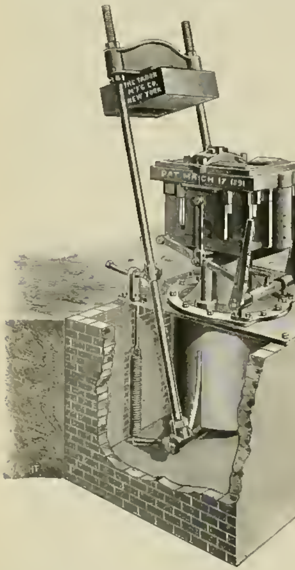
Labor-saving tools are always of interest, but there are few made for molders or for foundry use

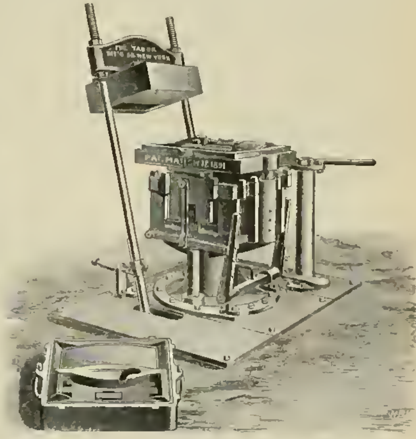
The machine illustrated herewith is a small one, capable of handling patterns that go inside of a 14x17-inch flask

The inventor furnished the following description:

The cuts show the machine in the foundry as set for work, with the floor cut away in one case to show the arrangement of cylinder below. The piston takes steam on the under side only, its weight being sufficient to return it promptly after ramming the mold. The piston rod projects through suitable length, which engage the ends of the levers on the downward motion to draw the pattern. The ramming head is carried on the strain bars at the side, which are trunnioned on a shaft below, and bolted to the cylinder Springs are connected so that as the head is moved backward the springs are put in tension and made to counteract the weight The ramming head is usually of wood, roughly cut out over the pattern, to avoid too hard ramming on the high places This block may be readily changed to suit any size flask not beyond the capacity of the machine The stops on the tripping arms can be changed to suit any draft within the range of the machine. The steam pipe enters the machine at the bottom, and from the throttle to the cylinder serves as exhaust pipe.

The operation of making the mold is simple. The half flask is put on the machine, with the sand box as an extension, to hold the sand that is compressed, and both are filled with sand, when the ramming head is brought up over the flask, and against stops, to prevent it going too far, and the throttle valve opened; the upward motion carries the sand up against the ramming head, and the sand is compressed to the top of the flask; the throttle is then closed, the same motion opening the exhaust, and the flask descends, the stops in the meantime engaging the free ends of the levers, which reduce the downward motion of the stripping





A NEW MOLDING MACHINE

the cylinder head and supports the upper part of the machine, which consists of a table with lugs projecting upward and supporting the pattern frame upon which rest the patterns; the stripping plate frame, directly over the pattern frame, and resting on it, to which the stripping plate is attached; the stool plate, suspended to the stripping plate frame and moving with it, side levers and tumbling shaft for tripping after the pattern is drawn. The pattern frame has an annular passage connected to the steam in the cylinder by means of a pipe extending through the piston rod The object of this passage is to keep the patterns warm, to prevent sweating, and to assist them in drawing from the sand The stripping plate frame is guided in two bored sockets in the front and back of the machine, these sockets have air holes to cushion the drop of the stripping plate frame after it is tripped The stool plate is really a part of the stripping plate frame below the pattern frame, and its object is to support stools or internal parts of the stripping plate used in holding green sand cores or heavy bodies of hanging sand when the pattern is drawn. The side levers are pivoted at one end to the table, and are connected in the middle, by links, to the stripping plate frame, the outer end being free. The tumbling, or tripping shaft, is in front, with arms projecting upward along the line of travel, followed by the free ends of the side levers; on these arms are stops of plate one-half, while the motion of the pattern is not arrested, when the piston has finished its descent the pattern is drawn, the ramming head is then turned back, the sand struck off the flask, and the flask ready to be taken from the machine As the operator lifts the flask from the machine he steps on the treadle attached to the tripping shaft, which disengages the stops, and the stripping plate drops noiselessly to its place, and the machine is ready for another half flask The operation of making the mold is very quick. The writer has seen a complete half mold, as shown in the cut, made by one man in 10 seconds after the sand was in the flask This time included taking the flask from the machine and putting on the floor for inspection.

This machine uses steam, but air or water can be used, steam is preferable, as it warms the patterns and keeps the whole machine in better working order, besides being cheapest The machine shown is at work on standard Christie brake shoes—making two at a time—and at the rate of about 25 per hour, worked by a man and a boy, who shovel their own sand Where a large number of duplicate parts are used, as in car works, etc, the machine is an economizer

The motive power and car departments of the Concord division of the Boston & Maine have been consolidated, and Mr. Charles H Wiggin placed in charge, with the title of master mechanic

On Oct 8th Judge Barrett imposed a fine of $7,000 on the New York, New Haven & Hartford, for violation of the Passenger Car-heating Act. The suit, which was regarded as something of a test case, was brought by the Attorney-General, and was the result of the recent tunnel accident, in which a number of persons were burned to death by the stoves in the cars. The defense of the New Haven Road was that, it being partially a Connecticut corporation, did not come under the jurisdiction of the New York State laws. This matter should be pushed, not only on the road in question, but on all roads Car stoves, hand-brakes, and running "by smoke," are things of a past age We want steam heat, automatic air-brakes, and absolute block signals—and we want them bad.

The Great Western Railway, of England, was the leader of broad gauge lines there, and its main line is to-day seven foot gauge, and the rails laid on heavy timbers which in turn rest on cross-ties. The directors of the company have just voted to adopt the standard gauge of 4 foot 8½ inches, on account of the interchange of cars. Two thousand years ago the wheels of Roman chariots were 4 feet 8½ inches, and it came down to us in stages, and seems bound to stay with us to the end, the only thing that threatens to get away from it is the flying machine—and we are not sure about that

French engine drivers and foremen are hereafter to be recruited by the railways of France according to rules and requirements of fitness fixed by the Minister of Public Works, M. Yves Guyot In an official circular just issued, M Guyot calls the attention of managers of railways to the fact that the law of November 15, 1810, distinctly states that "No one can be employed as an engine driver unless he produce certificates of capacity filled out according to forms determined by the Minister of Public Works" This law has not been enforced until now, as it was deemed essential to first make uniform, on all the railway systems, the signals to be used, and to otherwise improve upon the practice on these roads. This uniformity of practice is now an accomplished fact, and the minister believes that the time has come to enforce the old law, in the interest of the greater safety of travelers He therefore demands that each manager inform him as to the rules in force on their lines in this connection, how these mechanics are recruited or trained, and what are the conditions of fitness required for service He wishes them at the same time to send in such suggestions as they see fit for a standard set of regulations covering the points in question.—*Ex.*

The Richmond Locomotive Works had a slight fire in their foundry on the night of October 14th, but it in no way interfered with the work

Consolidation Compound Locomotive for Heavy Gradients, built by The Schenectady Locomotive Works.

The question of the application of the compound principle to locomotives in heavy service for both passenger and freight traffic, becoming so prominent with various roads, the Schenectady Locomotive Works, who have already built a number of the two-cylinder type, which are giving excellent results, have designed the heavy compound consolidation engine illustrated and described in our present number. The general dimensions of the locomotive, as will be seen by reference to specification, are very similar to the 22"x28" consolidation engines on the Union Pacific, which we believe are the largest and most powerful locomotives at work in regular road service at the present day. The compound locomotive has cylinders arranged for giving the same power as the simple 22 x28 cylinders, and the proportion between the high and low-pressure cylinder is that found to be the most economical on other compound engines built at the Schenectady Works. Although the low-pressure cylinder is exceptionally large, being 32 diameter, the extreme distance outside of cylinder does not exceed that of other two-cylinder compounds now running, as the centers of the cylinders are carried toward center of engine, the frames being placed 45' from center to center, and the lower rail of frame being depressed where attached to cylinder. As will be seen, ample bearings are provided for crosshead, rods and axles. The cut of the engine shows location of the new intercepting valve which has been used on all of the compound engines recently built at these works, and which is giving excellent results, enabling the engine to start more promptly than the simple locomotives, and entirely eliminating the possibility of the engines "balking," as has been reported to the discredit of some of the compound locomotives now in service. The intercepting valve is entirely automatic so that the engineer has no more care in handling the compound than a simple locomotive

As will be seen, the claims made by the designers for simplicity are demonstrated, there being—aside from the intercepting valve—no more parts on this exceptionally heavy engine than on any simple consolidation.

The design demonstrates the fact that the popular two-cylinder type of compounding can be applied to the heaviest locomotive in road service at the present time.

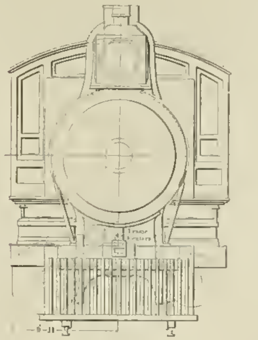
The circular issued some weeks ago by the Lake Shore management, strictly forbidding the use of intoxicating drinks by employes, has given offense to many saloonists, who will, it is said, boycott the road wherever possible.—*Ex.* Let 'em; we wish they wouldn't let a trainman come into their saloons.

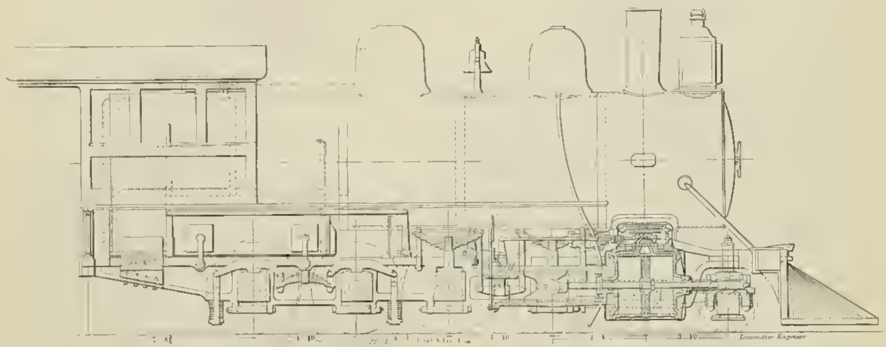
During the year ending June 30th the Manhattan Elevated Road carried 196,714,199 passengers, an increase of 10,880,567 over the year before.

All subscriptions that do not begin with January will have to be supplied with two sizes of paper—the new form of *Locomotive Engineering* will be four column—those who desire it can have back numbers of 1891 to complete their year

---

A dollar's worth of rubber or felt weather strips on the cab doors and windows will keep out about four dollars' worth of wind a day—and it will last all winter. Every road should supply the strips if they do not apply them.





CONSOLIDATION COMPOUND LOCOMOTIVE FOR HEAVY GRADIENTS.

Correspondence

Another Story of Old Betsy.

Editor The Locomotive Engineer:

The cut of the odd looking locomotive on front page of the October number looks just like the engine it represents, but it does not look at all like the one it is said to represent, namely, the "Betsy"

The locomotive shown in the cut is the "Visalia," built by the Vulcan Iron Works in San Francisco; her drivers are single plate driving wheels Any one who has seen the old Norris engine, Wm. Penn, about the Sacramento shops, will remember her having a pair of the same kind of drivers; they are a grand humbug about oiling. Mr. Brennan speaks of the so-called Betsy running from the junction of Valencia St.; it should read (from the junction of Valencia and Market), to Point Lobos.

If the writer knows anything about the topography of San Francisco, Point Lobos is a telegraph station out near "The Heads," or the Golden Gate. If a railroad ever ran out there I never heard of it before; furthermore, don't know what a railroad to Point Lobos would be used for, at the time this engine was built Claiming to know the history of the true Betsy, I want to tell it. When the S P. Co. got control of the Santa Cruz & Watsonville narrow gauge road they made a standard gauge road of it; soon afterward the writer was sent with a gang of men to Pajuro (pronounced Paharo) to load up the narrow gauge rolling stock and send it to San Francisco. The company had some interest in the Guatemala Central, and the rolling stock was sent to that country

After we got through at Pajaro we went to Santa Cruz to stay over night, and returned to Aptos the next morning. Aptos is the junction of the Loma Prieta branch It was at this place we found the true "Betsy" She was a diminutive specimen of a four-wheel locomotive built by the Pacific Iron Works, in San Francisco, and run by a tall, lank, old man named Pope, if I remember right—as in most cases the smaller the engine the larger the engineer

The Betsy had finished her work the evening before, and on our arrival there in the morning we found this poor, little, insignificant locomotive decorated with calla lilies and other beautiful flowers, as a floral offering to some loved one about to be laid away to their eternal rest. This was the work of a few children living near-by. The children along the line of the road loved this little engine, and often while switching they would follow her back and forth as though she was some animate being and they wanted to help her do the work in hand. The little engine looked very much like the Mulholland narrow gauge engine on page 199 of THE LOCOMOTIVE ENGINEER. When we started to load her on a flat car, some of the hands wanted to take the flowers off, but the writer, having charge of that part of the work, would not allow a flower to be removed. We deposited the remains, flowers and all, in the narrow-gauge engine-house at Pajaro. Whatever became of the little engine the writer never knew. This is the story of the true "Betsy."

Corry, Pa W DE SANNO.

Criticism of the Critic.

Editor The Locomotive Engineer.

A great deal of space has been taken up in your columns by Mr W. de Sanno He makes comments on the merits (or demerits) of certain classes of railroad employes, which I think unjust.

To commence with, he quotes some firemen out his way who did not know what a petticoat pipe was, and then decides that such men could not make successful engineers. Now, Mr. Editor, I have fired on one of the roads that run into Pittsburgh for three and a half years, and although I have a knowledge of the uses of a petticoat pipe, I have never seen one on any of this company's engines (something near 500). They all have high exhaust pipes with double nozzles. There are some men on this road—P., C., C. & St. L.—who probably could not say much about petticoat pipes, who, I think, could give Mr. de Sanno a few pointers.

Regarding the learning of examination questions parrot-like, it seems to me that it would be much harder than a study of the different parts of an engine.

A railroad man *would* have to draw very hard on his imagination to believe an engine would run with *nothing* to keep a side rod on. What was the collar on the main pin doing, anyhow? I know an instance where a collar was lost off a main pin on a consolidation engine (class 8) and run eleven miles before it could be replaced; part of the distance—about seven miles—was down grade, and at the rate of at least 40 miles per hour. There was not enough lateral motion of the main rod to make it rub the guide yoke.

About flagmen. If the majority of flagmen were like de Sanno's ideal, it would not be safe to railroad. While we read occasionally of one shirking his duty, yet the many thousands of trains that pass safely across this continent show beyond doubt that our brethren, the flagmen, are not all to be slandered. There are times and places on all roads where flagmen do not find it very pleasant. I heard one saying the other day he did not feel altogether at ease when standing for hours at night at the place where a few days before his friend had been killed. There are cases where flagmen have been found dead on the track "Killed while sleeping on duty" is what some may think, when probably the circumstances suggest assault, robbery, and a sure way of hiding the facts by placing the victim on the track. Let us do them justice; if they fail in their duty they are soon dropped De Sanno's idea of compelling men to do anything will not work His scheme of a box key, ticket, etc , is only a modification of a system illustrated in a June issue of *The Scientific American*.

I was pleased to note the stand taken by your correspondent, T W Benjamin, of the Burlington, and W. C. Parsons, of Texas, which ought to show any ordinary person the advantage of darkening headlights. The glare of a headlight once prevented the writer from observing an engine backing down a grade while we were backing up the same track with light engine; both engineers took the same signal—result, two tenders completely ruined, and the writer a sore foot This was before the adoption of headlight curtains on this road. There is no doubt that the rule of darkening headlights on side tracks was adopted, with others, for safety, after careful consideration, and is a step in the right direction. JOHN BRUCE.

Pittsburgh, Pa.

What Became of this Device?

Editor The Locomotive Engineer

I should like to hear whatever became of H Chamfield's double exhaust valve. It was gotten up at Susquehanna, on the Erie, in 1880 At that time F. M Wilder was Supt. of M P

The engine equipped with this device "led the chase" in those days. I should like to see some indicator cards taken from her at 25 miles per hour —Mr. Wilder was a champion card faker. Some of the Prays of to-day would be interested, for getting rid of the steam seems to be the mountain in the way yet. PROGRESS.

Garrett, Ind.

An Air-brake Question.

Editor The Locomotive Engineer.

Would like to ask an air brake question · I was running an engine on the Park & Ocean R. R , San Francisco; we had the automatic system Sometimes while switching, the driver-brakes would jump on without any action on my part, and the brake would not release; at other times it would set while the engine was standing still, and it was not a gradual setting of the brake, but suddenly, and could not be released except by bleeding I spoke to the air brake company's man about it, but received no information or explanation , also spoke to the M. M., Jack Wilson, but he told me I did not know how to handle it , that was his way of getting out of it. Now what was the trouble? I never could find out. W DE SANNO.

Corry, Pa

Air-pump Capacities, and the Lift of Valves.

Editor The Locomotive Engineer :

I have read with interest two or three articles in THE LOCOMOTIVE ENGINEER lately on air-pumps, lift of air valves, etc. One writer says ⅛ lift for receiving valve, and $\frac{1}{16}$ for discharge valve; this is right for the 6' air-pump, but for 8 air-pumps the receiving valves should have $\frac{3}{32}$ lift, and discharge valves ⅛ lift, so says Westinghouse instruction book, page 11—and that is good authority.

This book is a valuable work, and should be in the hands of all air brake men, as it gives all information concerning pump, train signal, apparatus, engineers' brake valve, old and new triple valves—that is, old style and quick action—Hodge and Stevens' system of brake levers, the Master Mechanics Association's standard of brake rigging for freight and passenger cars, sizes of all bolts, pins, etc , used in the construction of brakes in the Westinghouse system, with many valuable plates, with a chapter or little book entitled "Don't," telling what an engineer should not do; and it is a good thing to know what you should not do sometimes as well as what to do

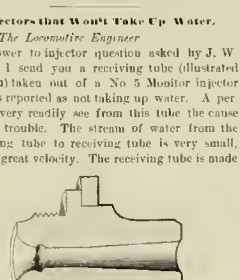
I should have said when speaking of air-valve lift that with 125 pounds of steam pressure an 8 pump in good condition should compress nine cubic feet of air to a pressure of 70 pounds in 88 seconds, and from 20 to 70 pounds in 62 seconds The efficiency of the pump may, therefore, be readily ascertained at any time desired. If other reservoirs are used of a different capacity, the duty of the pump may be calculated in the same proportion. FRED B. ARMSTRONG

Camden, N. J

Injectors that Won't Take Up Water.

Editor The Locomotive Engineer

In answer to injector question asked by J. W Kaefus, I send you a receiving tube (illustrated herewith) taken out of a No 5 Monitor injector that was reported as not taking up water. A person can very readily see from this tube the cause of such trouble. The stream of water from the combining tube to receiving tube is very small, and has great velocity. The receiving tube is made



flaring-mouthed, to receive this stream. All the water which this tube cannot receive goes to overflow. As you can see by this tube, the water has worn a very large cavity in the mouth of it The water now striking this is diverted from its direct course, and some of it returns to overflow. This is probably the cause of Mr Kaefus' trouble although it may be that the steam is cramped either in valves or pipes between boiler and injector, causing a supply insufficient to siphon water from bottom of tank, and then to force it against boiler pressure, while with a full tank it would not need as much steam to siphon, leaving more to force.

New York City. R. B. READING.

A Nut for Air-brake Manipulators.

Editor The Locomotive Engineer :

I had a little experience with air-brakes a few months ago that it might do engineers and firemen good to think over One night we were waiting for orders at the summit on a western road, and as the grade for the first six miles is more than 200 feet in some places, a fireman's anxiety oftentimes runs very high, especially if there are new brakemen on the train, which was the case this night I kept my eye on the brakemen for some time, and finally came to the conclusion they were not going to examine the air brakes, so I called the head man and told him what was necessary in order that we have a safe ride down hill. "It was news to him" I therefore exhausted thirty-five pounds of air out of the train pipe, sufficient to set all brakes full, for we were only carrying ninety pounds The brakeman and I then started for the rear of train, giving every brake beam a kick to see that all were set, when we reached the caboose there were only two cars in the train of fifteen that had brakes set on them, and these were the two head cars

Thinking there was a stop-cock shut, I opened train pipe on rear of caboose, and air came out.

We returned to engine, I recharged, and allowed one minute for auxiliaries to fill up. I then placed engineer's valve on lap, and told brakeman to open train pipe on rear of caboose, while I stood eight cars back along the train; when train pipe was opened I thought every brake beam in train was smashed, for the quick action got its work in in good shape, and fortunately only one brake was damaged

I again recharged, but could not set the brakes from the engine, but could set them from rear end every time. The engineer and conductor, after getting orders, came around to go, but found that the pump was stopped, and the fireman and brakeman looking for the trouble

Everything was O. K. on engine, the trouble was between forward end of head car and rear end of caboose. What was the trouble. G J. H.

San Bernardino, Cal.

Study of Water-brake Diseases.

Editor The Locomotive Engineer

The water-brake, as used on American locomotives, is one of the most unsatisfactory subjects I have ever undertaken to study up. Am very glad J. W Kaefus has again started the ball rolling , and am going to give a guess as to the cause of his Baldwin engine throwing water intermittently.

It is a fact that the exhaust cavity in the saddle, in passing from exhaust port to nozzles, passes entirely below these two points, also that the exhaust cavities carry a large amount of water before becoming entirely filled, or before the level of the water rises to the exhaust port or nozzles.

All engines running forward, reversed, have a "grunt," caused by the release, through the exhaust cavity, of a portion of the air compressed by the reversed action of the valve and the piston. Now, when Mr. K reverses his engine and puts on the water-brake, this cavity commences to fill. When it is partly full it does not interfere with the exhaust of compressed air , but when the cavity is entirely full then this exhaust throws the water out of the stack, and it again begins to accumulate for another discharge At the same time, some of this water goes to the valve and cylinders, showing at cylinder cocks

According to my idea, no water should strike valve or cylinder for water-brake to work successfully Whenever water shows at cylinder cocks there is too much water

It is a fact that water on valves and cylinders through throttle valve is bad , now why not as bad if it comes through water-brake valve? This is the same experience Mr. K speaks of with one of the McQueen engines. Of course, when an engine's valves have been washed with water (whether it comes through priming or water-brake valve) the reverse lever will pull you off the seat What you want to show at cylinder cocks is steam, not water There is no harm in running with cylinder cocks closed They can be opened once in a while to see that the steam shows right. If the discharge shows blue, there is not enough steam or water. It shows that hot air and smoke are being sucked back into the cylinders, and that the action of the valve oil is being destroyed.

Water from a boiler carrying 160 pounds of steam has a temperature of several hundred degrees, now this water, being released from this pressure, a portion of it is going to be generated into steam , and it is this steam, going to the valves and cylinders, that produces the same condition of things, with the engine in back motion, that you have with engine in forward motion working steam.

Water becomes steam at 212° F at atmospheric pressure , now why does not a portion of this water become steam when released from boiler pressure at 363 or 361° temperature? Have any of you noticed that it took more water when your steam was low and your water not the hottest? In this case, the hotter the water, the more of it that will be converted into steam when released, and therefore the less water it will take.

I am like our friend Kaefus, anxious to learn something on this subject.

Deadwood, So. Dak BLACK HILLS

Alex. Cunningham's Breakdown.

Editor The Locomotive Engineer :

I read the conundrum proposed by "Traveling Engineer" in your September issue, and gave it some study, but at last concluded that it was too deep for me, and would patiently wait and see if any one else solved it. Now imagine how mad a fellow will get when he finds that he has been made the victim of a joke. T. E. tells us in the October LOCOMOTIVE ENGINEER that the rod broke and let the piston travel far enough for the rings to spring into the port That is easy enough, but the springs must have been very stiff to keep the steam from blowing the packing out of the port, provided, of course, that the rings were about as wide as the port, if the rings were not near as wide as the port they would not obstruct it, and a few admissions of steam—first on one side and then on the other—would soon reduce that Dunbar packing to atoms. It is barely possible that the head would wedge itself in the cylinder so tight as to resist the pressure of steam.

When a piston lets go of the rod, the thump it would make in striking the cylinder head ought to be of sufficient importance to arouse the curiosity of an engineer of an inquiring turn of mind into examining his right-hand connections. This he could have done by reversing her several times with some steam on, or got the fireman to do so while he felt for the pound. This would have given him a clue to work from, as there is always some perceptible movement to the crosshead with steam on There is nothing like feeling the "pulse," especially when it is so easily done. I will say here, to prevent the possibility of being misunderstood, that it will be necessary to have the engine standing so the steam will be admitted to alternate sides of the piston when feeling the "pulse."

That a locomotive in the condition that this one is represented to be should be pass d on by a lot of shop mechanics as O. K speaks volumes to their discredit; but what caps the climax of thick-headedness is that a man should run three trips with one side wholly disabled, and only complain of "three legs." An engineer who can get over the road as well with the use of one cylinder as two, deserves great credit. This is a saving of 50 per cent.—about 25 per cent. more than the compounders claim, and is well worth investigating before the questionable expediency of compounding.

We now come to the utter impossibility of running an engine on one side only, and make repeated stops and starts without getting stuck on the center, without taking the greatest precaution to prevent it. It will be in order now to say that the road was down grade all the way both ways.

With the reader's permission, I will say that I am not an engineer, or even a fireman, but that I have always looked upon a locomotive with admiration, and take pleasure in reading anything that relates to them ("Modern Locomotive Construction," for instance). I am also acquainted with several engineers who accord me the pleasure of riding with them occasionally, and by this pick up some practical information. I say this that those who are engineers may know that if my conclusions are not well grounded, that this was written by A. FARMER.

Youngstown, Ohio.

How About This? Traveling Engineer Called Upon to Explain.

Editor The Locomotive Engineer.

I read the question and answer of Alex. Cunningham's engine in the October number, allow me the privilege to ask for an explanation.

Taking the construction and size of his eight-wheel engine, we would suppose that he was running a freight train at the time on the Mobile & Ohio Railroad.

When he first observed the defect in the exhaust of his engine, it was natural as an engineer to inquire into the defect

No doubt after examining his first start of his engine and train, he had the luck to have the other side of his engine not on forward or backward dead center

If such would be the case, he would be required to use a pinch bar, or cut loose from his train and run forward a certain distance, and then re-attach to his train to bring the engine in position for starting.

Now the question I wish to bring before his notice is How did he make another trip handling whatever train he would on a railroad, with the working capacity of only one side of his engine, and do the work satisfactorily? This is a misconstruction for railroad men, which should be avoided if possible. HENRY B STOFT.

Philadelphia, Pa.

Traveling Engineer, Please Stand up While the Boys Ask You a Few Questions.

Editor The Locomotive Engineer

I would like to have Traveling Engineer (of Alex Cunningham's puzzle) answer following questions through your valuable paper

1.—Was the M. & O engine that Cunningham run on the puzzle trip an every-day locomotive run by steam?

2.—Was Alex. Cunningham an every-day engineer?

3.—If he was, did he pull a full train, and not have any trouble starting a full train with an engine working on one side, and not know it?

Galesburg, Ill. R L. F

Editor The Locomotive Engineer:

If consistent with space, would like to ask "Traveling Engineer" a few questions He says piston head was found—after second examination—in front end of cylinder. Dunbar packing had dropped—I should have said sprung—into counterbore and port, holding piston head there, shutting off steam from front end of cylinder. According to that, head must have broken off piston rod while engine was making stroke from back dead center to front dead center, or from back end to front end of cylinder. The first question I ask Traveling Engineer is, What prevented the piston head from breaking out, cracking, or at least making a mark on cylinder head when follower bolt heads struck it, as strike it they must, for the piston head to get into counterbore? He says that when machinists took off her right cylinder head she stood on the forward center on that side, and the piston stood close up, apparently all right. I would ask him how a piston can appear all right to a mechanic when it is far enough ahead for packing to spring into counterbore. Another question How came it that Engineer Cunningham ran that locomotive more than a round trip without finding out that she was working but one side, or one engine? If he can answer these questions mechanically, I may ask him more in regard to this breakdown, for I want to learn all about it, as it is a new one on me

Superior, Neb. ROUNDHOUSE MAN

Editor The Locomotive Engineer.

In reading your October number I note the answer by "Traveling Engineer" to his "Three-legged Puzzle" about Alex Cunningham's engine. Calling to mind the original story, I was "stalled" on one or two points in the answer

In the first place I would like to ask At what part of the stroke of an engine, running, would there not be sufficient energy or momentum to carry a broken piston head up against the cylinder head? Of course, if the break occurred after the opening of the exhaust, the steam pressure would be greatly reduced—perhaps reduced to zero. Supposing the break had occurred at that point, which would leave the piston head with but one force behind it—the piston rod; then the lead which would take place before the piston head had reached the end of its stroke would force the head back, and at the next forward stroke it would go through the cylinder head. I am not trying to condemn the question, nor say that it is untrue, but I do say that I cannot see how a piston rod can lose its head without said head showing itself through cylinder head.

And then another thing After the head breaking off and lodging in front end of cylinder the engine only had *one side*. Then Mr. Alex. Cunningham made a trip over the road with one side, did he? He *must* have found out that he only had one side before he took his train out. Strange things they used to do a few years ago. (?)

N. Y. City R. B. READING.

Editor The Locomotive Engineer:

I read about the Cunningham engine. How is that about running an engine *another trip* with only the end of a, say, 3-inch piston rod, to work the right side, as against the, say, 16-inch piston, on the left side? About how much help would this end surface of the piston rod give towards moving the engine, should the left-hand piston be on the center? Is not this Cunningham's engine rather too much at once? H K. B

Kansas City, Mo.

Editor The Locomotive Engineer:

Noting Traveling Engineer's explanation of the alleged Cunningham trouble on the M. & O., will say that in my opinion it goes to show the incompetency of the parties examining the locomotive.

I fail to see how a man could look into a cylinder and not notice that the piston packing had dropped into the counterbore and port, and knowing that trouble was reported did not even measure piston clearance On most locomotives the follower bolt-heads would fetch up against front cylinder head before packing would drop out; have seen exceptions, though.

T. E. says Cunningham moved her to look further and found she went all right, and ran her in

Does he mean that she ran along all square apparently? If so, under the circumstances, would like to have him explain how such a thing were possible—after the so-called machinists examined the locomotive and discovered nothing wrong, she still appeared to take steam at three corners only—to allow her to go out on the road.

Where was the traveling engineer? H.

Boston, Mass.

Editor The Locomotive Engineer:

I should like to ask Traveling Engineer if he has any idea what Alexander Cunningham thought was the matter with his three-legged pet, if, when wanting to pull out of a station, he found that she was standing on either center on the left side In my experience with engines working on one side, I have usually had to start them with a pinch bar when standing on center on the working side.

Saginaw, Mich. FRED TAYLOR.

Editor The Locomotive Engineer:

I have just read with no little amusement the answer to Traveling Engineer's breakdown puzzle, which was published in September number of your paper, and I must say that Mr. Cunningham must certainly be a dandy to run an engine one round trip practically on one side and not find it out.

The Mobile & Ohio must be a peculiar kind of a road—a little down hill both ways (so to speak). I think Mr C was extremely fortunate in not having stopped his engine on the left dead center at any time during the trip, or he might possibly have found use for a pinch bar I would suggest to Traveling Engineer to give us something a little more reasonable the next time Perhaps some of us starters and stoppers here in the wild and woolly West may accidentally stumble onto a correct answer. F F. D.

Colo. Springs, Colo.

From Alex. Cunningham Himself—Hard Times in Dixie.

Editor The Locomotive Engineer.

I see in your September LOCOMOTIVE ENGINEER that some one has been using my name in vain, so I will inform Mr. Traveling Engineer that I am not dead yet, and to enlighten my numerous engineer acquaintances, and keep them from thinking I resemble one of those things used in turning a grindstone. Now, I suppose, Mr. Traveling Engineer gets this question up for instructions, or maybe he is going to start a guessing school; but I think his puzzle is simply ridiculous.

According to his explanation in the October number it is barely possible, but not probable, that I should finish out that trip with numerous stops, and make another round trip with numerous stops and not get her stuck on the center; and what kind of machinists would take off both cylinder heads and not notice the piston head on right side being close against the cylinder head? It had to be clear ahead, so as to stop up the porthole in the cylinder.

I did have a piston to break off while I was running there, close to piston head, but with a different result from what Traveling Engineer explains it The first indication of it was a thump which cracked the front cylinder head; I immediately shut off steam and stopped; I told my fireman to give her steam very lightly, which caused another thump in the left side; I then located the trouble at once and put her on one side, started along and made up my lost time. I am the only Alex. Cunningham that ever ran on the Mobile & Ohio road; I ran there thirteen years.

Right after the war the track was very rough; I had a great many accidents of most all descriptions, and came near getting killed several times; I was once dug out from under an engine; she turned over on me; the company was poor, and I worked for them when they owed me eight months' pay, and when the bondholders took the road and got it up in good condition, and my job got to be worth keeping, then the Assistant General Superintendent, Mr. Cecil Fleming, and Master Mechanic M. T. Carson, discharged me and three or four other engineers simply because we belonged to the B. of L. E.; then all the others belonging to the order were induced to finally withdraw or give up their situations. All this was done without the knowledge of Col. Rives, the General Superintendent. Afterwards, I am told, Cecil Fleming repented of what he had done, and committed suicide, and I am expecting every day to hear of Carson doing something the same. I wish he would, I would erect a monument to his memory—a fine one, too. I will make it out of pulverized stone. Carson's enmity to the B. of L. E. started at Mattoon, Ill. For particulars I will refer any one to my brother, J. M. Cunningham, who is now running on the Canada Southern road, between St. Thomas, Ont., and Buffalo, N. Y.

Pine Bluff, Ark. ALEX. CUNNINGHAM

Those Lubricator Glasses—Testimony of the Jury.

Editor The Locomotive Engineer:

I see in your last issue of THE LOCOMOTIVE ENGINEER a cut of two Nathan cylinder lubricator glasses, sent you by E. G. R., Mt. Savage, Md. He states that the glasses are eaten away at the top on the Nathan lubricator, and not on that of another make. I have often noticed this same thing myself. My idea about the matter is this. The glasses in the "Nathan" are worn or eaten away at the top by the action of the steam coming through the dry pipes of the lubricator and into the tallow pipes running to steam chests. You know the old adage: "A continued dropping will wear out a stone." I think the dry steam continually sweeping around the top of glasses in time wears them away. On the Detroit lubricator the steam does not have the same chance at the glasses, as the top of the glasses are covered with a part of the arm holding the glass, and the oil or tallow, whichever it may be, passes through an automatic safety valve placed directly over center of the glass; this valve is forced open upwards to permit the drop to pass through, and all around the ends of the glass is the water, which seems to have no current, but remains stationary—having no motion it does not wear away the glass. These safety valves close automatically when a sight-feed glass breaks, while in the "Nathan" you have to screw down the valve by hand to prevent the steam escaping.

Camden, N. J. FRED B. ARMSTRONG

Editor The Locomotive Engineer:

My attention has been called to an inquiry on page 167 of your September issue, signed E. G. R., headed "Sight-feed Glass Phenomena," in which information is asked regarding the cause of the wasting away of the upper ends of the sight feed glasses in the Nathan Locomotive Lubricators. E. G. R. also states that "sight-feed glasses" in the Detroit lubricators do not break in this way. In reply to your "Who can explain this trouble?" I should say that the reason of the wasting away of the upper ends of the glasses in question, as shown in the illustration, is found in the construction of the lubricators, which is such that, when steam is shut off from the cylinders at the throttle, and the equalizing pipes are thereby thrown into action, the velocity of the steam through these pipes carries the water of condensation from the condensing chamber over with it, a strong current of steam and water, therefore, impinges upon the tops of the glasses which stand above the rubber gasket, and cuts them away in the same manner as would be done by a "sand blast." It may be argued that the glass is below the line of current; I grant this, but the velocity of the current is such as to cause a strong eddy in this chamber acting in the manner described, as is also done in water gauge glasses in boilers; on the other hand, the Detroit lubricators are so constructed that the steam from the equalizing tubes is prevented from entering the chamber where the glass is, by a small "check valve" placed over it.

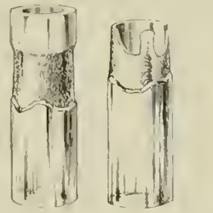
In the Nathan lubricator, the *excess* of water of condensation over that required to feed the drops of oil to cylinder is discharged from the condenser of cup by the equalizing tubes, the Detroit cup returns this surplus water to boiler direct, through the same pipe that supplies the steam to condenser, and take the equalizing pipes from a much higher point. W. ALLEN PENDRY.

Detroit, Mich.

Editor The Locomotive Engineer:

I see in the September number of THE LOCOMOTIVE ENGINEER a communication from E. G. R. in regard to the eating away of the upper end of the Nathan sight-feed glasses, and the cause.

I have had some experience with the Nathan sight-feed lubricator, and always find the glasses as per cut after they have been in use two or three months, and I think it is caused by the action of the steam and water in circulation, as there is always more or less circulation at the top and none at the



bottom. Again, I think the steam plays the most important part, for the reason you will find water glasses eaten away the same at the top, while the bottom will maintain the original size. I send you a sample of water glass taken from a locomotive boiler head, the glass being a little long, the part eaten away being opposite the opening in the cock, while the part extended above is of the original size, showing the action of the steam.

I would like to hear from others on this subject.

Osawatomie, Kan. D. K. BURNS.

Editor The Locomotive Engineer:

We notice in your comments, in the October number, on the "Wear of Sight-feed Glasses," in an article signed by Sam F. Huffman, that your position is not exactly correct. The facts are that the illustration in your September issue shows the glasses worn away *down to the gaskets*. This is easily accounted for by the fact that the glasses extend *up through the gaskets*, at least as far as the illustration shows the damage to have been done.

Detroit, Mich. DETROIT LUBRICATOR CO.

Cast Brake Shoes.

Editor The Locomotive Engineer:

I see in your excellent paper an inquiry as to the first use of cast-iron brake shoes in place of those made of wood. O. E. Stevens, M. M., put on tenders and passenger cars of the Northern R. R. a cast-iron head hung with Rice & Kimball's patent hangers in 1851 or '52, and afterwards changed the pattern to use a shoe bolted on. Before that we used wood and leather.

Lowell, Mass. BEN. F. BUNKLER.

Water-brake Experience.

Editor The Locomotive Engineer:

I got sight of one of your papers the other day, and became so smitten with it that I immediately wrote you for a year's subscription. In the September number, I see J. W. Kaefus, of Aspen Junction, Colo., asks you for pointers on his eccentrics, and wishes to hear from some one on the way his water brake is bothering him. In April, May, June, July and August of 1889, I was watching a 60-ton, ten-wheel, Baldwin engine, with double nozzle, on the Montana Division of the N. P. Ry.; we were building 21 miles of track on a 4 per cent. grade, and a nasty hill it was, too. The engine was equipped with a straight-air driver-brake, with a separate engineer's valve. This was, of course, simply intended to catch the speed with, and help the automatic. We had to use lots of old foreign cars that had no air on them, and the hand-brake attached to only one truck at that, so that it necessitated the use of the water-brake all the time, and it acted just as Mr. Kaefus says his does.

She used to wet the Hobo's every time she brought them down to the boarding train. They made a kick about it, and Mr. Hannibal H. Mayhew, my engineer, told them he could not help it, and was telling me about it one day, and this is the explanation I advanced to him.

The engine does not act that way except when influenced by a system of curves. The level of the valve seat is a trifle higher than the exhaust passage in the saddle, so that when an engine gets into a 12° or 15° curve the valve seat on the outside of the curve will be at an angle of from 15 to 20 degrees above the exhaust passage of the saddle, and the valve seat on the other side will be about level with the exhaust passage of that side. The consequence is that water collects in the high side of the saddle until there is a resistance formed in that branch of the water pipe by the water plus the compression when the flow nearly stops for that side, and that valve and cylinder will be dry. But on the other side the exhaust passage of the saddle has dumped its collected head of water into the exhaust cavity of the valve, and the piston acting as a pump, the vacuum stroke sucks some of the water into the cylinder, while the compression stroke drives a great deal out of the nozzle, and two-thirds of the capacity of the brake pipe is being discharged into this side, to help the cylinder sprinkle the right-of-way, and the engine will continue to act this way away out onto a piece of straight track, caused by the unequal compression pressure on first one cylinder and then the other, thereby causing an excess pressure in one or the other branch of the brake pipe.

Mr. Mayhew thought my suggestion a good one, and went at it to prove the truth or falsity of my ideas. We both found by watching her actions closely that when the heaviest flood of water was in one cylinder, the other one would be perfectly dry, or nearly so, and by the time she had got into the middle of a 15° reverse curve the valves would be trying to tear the reverse lever loose from the quadrant. Mr. Mayhew would also shut off the water when coming out of a curve onto a long straight piece of track, put on his driver-brake, throw the lever ahead, and throw all the water out of the cylinders and nozzles, then hook her back again, release the driver-brake, and turn on the water, and it would work all right till she got almost around the next curve, and then one cylinder would run dry, and she would begin to cut up as bad as ever.

Of course, he only did that as an experiment, but he made up his mind that there was no other remedy for her but to put a pair of cylinder cocks in the exhaust passages of the saddle, which, of course, is naturally the first thing a man will think of. I have seen several of the boys try to work their water brakes on the big hogs running out of Livingston, and Helena, Mont., but they would all squirt water out of the stack. This may not touch Mr. Kaefus' brake, but I have endeavored to give my idea of the cause of his trouble.

Joplin, Mo. GEO. SUART.

On a good many roads out of eastern cities, special club cars are provided, and are paid for by well-to-do business men who want a sofa chair insured, a chance to play chess, or read undisturbed. On the Old Colony road out of Boston, there is an entire club train of special cars that runs down "the wild and rock-bound coast" for some fifty odd miles without a stop. This train is a fast one, and has earned the name of "The Flying Dude," given in derision for the exclusiveness exhibited by its patrons. In addition to the regular fare, the subscribers pay $1,000 a month for the train.

CONTENTS

Business Announcement.

Owing to the demands upon the time of the executive officers of this company, required to meet the steady growth of our other business, as publishers of the *American Machinist*, we have, under date October 5, 1891, disposed of THE LOCOMOTIVE ENGINEER, also heretofore published by us, including all right, title, and interest in same, to Angus Sinclair and John A. Hill, who will fulfill all contracts of whatever nature heretofore made with us relating to the business of THE LOCOMOTIVE ENGINEER. We bespeak for the new proprietors of THE LOCOMOTIVE ENGINEER the favorable consideration of its patrons.

AMERICAN MACHINIST PUBLISHING CO.
New York, Oct. 5, 1891.

A Change.

On the first of October, Angus Sinclair, editor of the *National Car and Locomotive Builder*, and John A. Hill, editor of THE LOCOMOTIVE ENGINEER, formed a partnership and purchased of the *American Machinist* Publishing Co. THE LOCOMOTIVE ENGINEER.

The paper will complete its present volume to January next exactly in its present form. For 1892 the name will be LOCOMOTIVE ENGINEERING, with "a Practical Journal of Railway Motive Power and Rolling Stock" for a sub title. The page will be enlarged to four columns, so as to admit of the use of larger and better engravings, and the number of pages will be increased very much—twenty pages of reading matter anyway—and the price advanced to $2.00 per year.

Mr. Sinclair, who is well known as the author of "Locomotive Engine Running and Management," and as Secretary of the American Railway Master Mechanics Association, will hereafter devote all his time and attention to this paper, while John A. Hill will continue just as he has, only with increased zeal.

The present owners have secured for the next year a number of new and intensely interesting features, and propose making the paper a model of its kind.

The educational features will be kept up and increased, historical matter, current events, and, in fact, everything new that can be of interest to any man employed in the motive power or rolling stock department of an American railroad, will be sought and shown.

Our readers have repeatedly assured us of their complete satisfaction with THE LOCOMOTIVE ENGINEER, many have expressed a wish to see it a weekly, and hundreds have written that it was worth a dollar a number.

Now, we believe that a *good* monthly is far better than a *poor* weekly—the average railroad man can't keep track of a weekly.

We will have room to show everything of interest in the new paper; we are conceited enough to think we can make the best *practical* paper in the field—both of us have earned our bread with the scoop and the throttle—and we propose putting LOCOMOTIVE ENGINEERING on trial for her life. Will you be on the jury?

We have established an office at 912 Temple Court, corner Nassau and Beekman streets, where we will be glad to welcome all our friends.

ANGUS SINCLAIR.
JOHN A. HILL.

Good and Bad Tool Steel.

A short time ago, while standing watching the work going on in a railroad machine shop, the writer was admiring the deep cut taken by the tool in a lathe of a well-known maker, when there was a sudden stoppage of the work, and the machinist took out his tool and went to the grindstone. The cutting point had broken off. In conversation with the machinist, afterwards, we found him full of enthusiasm about the lathe, and the work he could do with it if he could only get the tools to stand. The foreman was a man who believed in making the machine tools work up to their capacity, but his management appeared to result in great hurry and small speed, for more time was lost in sharpening tools than there was extra progress made with the deep cutting and high speed of the machines. The machines were designed to perform the heaviest cutting without distress, and the difficulty was in the character of the tool steel used. The purchasing agent, like many others of his class, considered that he was serving his employers zealously by saving a few cents in the price of tool steel bought, and his action reduced the value of all the good tools in the shop. The loss that resulted to the company in this case from purchasing cheap tool steel impressed us so much, that we investigated the matter in connection with a variety of shops, with the following result: manufacturers that have to meet sharp competition in business rarely purchase anything but the best brands of tool steel. When they purchase from reputable makers, they say that the quality supplied is very uniform in character, and stands the severest work without failure. The first cost of the steel is high, but that does not count beside the loss in reduction of work that results from the employment of inferior tool steel. In some railroad shops the tool steel is satisfactory, and is of the best quality, and the results obtained on machines as good as could be desired; in others, and by far the majority of railroad shops, the tool steel is of inferior quality, and the speed and work of lathes and planers are regulated to suit the durability of the tool. In one large railroad shop noted for the slow-going movement of the machinery, we asked why they did not speed up the machines, and were informed that the cutting tools would not stand it. Where inferior steel is used, we invariably find among the tool dressers, secret and mysterious receipts for making cutting points durable. Most of them are like the remedies of other quacks. An old saying tells that, "Good wine needs no bush." For similar reasons we might say, "Good steel needs no doctoring."

Long vs. Short Eccentric Blades.

A correspondent calls attention, in another column, to the use of very short eccentric blades on some new ten-wheelers for the Lake Shore.

These short blades are used here to avoid a long, curved rod around the forward driving axle, or, what is worse, an intermediate rod around the axle, and hung on links or guides at the rear.

The great trouble with the long, curved rod is its weight and consequent excessive friction on eccentric at high speed; then, its curve makes it, even when pretty heavy, a springy affair under heavy work. With it the rocker is carried close up to the steam chest, and, to avoid excessive wear of packing, a knuckle at the rear, and a horn on yoke, and an extension on the front of chest are needed; this objection also obtains where the intermediate rod is used.

The intermediate arm has an added objection, in its extra joints to get lost motion, and their proneness to break down.

The single objection to the short radius is the excessive lead when hooked up, but this, it seems, has never given any trouble except on paper, and in the imagination.

At high piston speed, more lead is necessary for quiet running, and we have yet to hear of trouble from this cause on a road using short radius links.

The Denver & Rio Grande have something like 200 narrow gauge consolidation locomotives, with 36-inch wheels, having links with a radius of less than 30 inches (if we remember rightly 27 inches), these engines have run with a tenth of an inch lead, at full stroke, for years with satisfaction. They are freight engines, but very small wheels, and the old speed recorder sheets of the road show miles upon miles made with these engines at and above 30 miles per hour, this is high piston speed.

The best ten-wheelers on the Santa Fe have short eccentric rods and long valve stems.

This plan makes the valve gear as simple as the simplest; the long valve rod can have a guide near its center to prevent trembling, and the vibration at the stuffing-box is practically *nil*.

With the long eccentric blades the friction of the eccentric, multiplied by the leverage of the long blade, has too much chance to make the reverse lever dance, as well as the man who handles it.

The Big Four are in the market for thirty engines and forty passenger cars.

Rapid Transit Plans for New York.

The commissioners appointed to propose a plan for rapid transit for the city of New York have made their report, and recommend what is known as the Worthen plan. This provides a four-track road under the streets, Broadway, the Boulevard, and other streets. The lower end will be a loop at the Battery, thus preventing the switching of trains There are also other cross-town and diverging lines The road will run near the surface, and far up town come out upon a viaduct, and cross the Harlem River on a drawbridge The two outside tracks will be used for local business, and the two inside tracks for express trains, depots to be located a quarter of a mile apart. The length of the line will be something over twelve miles The motive power will probably be electricity, but the commissioners only demand that it shall be capable of pulling express trains at the rate of forty miles per hour, and operate without combustion. It is estimated that this great undertaking can be completed in two years, but it is probable that it will take at least twice that long.

Pulaski Leeds, Superintendent of Motive Power, of the Louisville & Nashville road, is making a stir among the men about posting up a little better. He has adopted a progressive plan of examination and gotten the firemen of the road really interested in getting information. The company bought a quantity of Sinclair's "Locomotive Running and Management," and Hill's "Progressive Examination of Locomotive Engineers and Firemen," and furnish them to the men at wholesale rates. Mr Leeds has arranged to mount one of their old ten-wheelers on rollers, and make provisions for crippling her easily, and will take men ready for final examination to her and make all examples practical. The engine will be in steam and in same condition as for the road. Mr. Leeds will have a lot of well-posted men the first thing he knows.

We hope that the enlarging of this paper to almost three times its former size, and the addition of Augus Sinclair's work on its pages will entirely satisfy those who have written us so many letters asking for a weekly or semi monthly. The time for a weekly in this field has not arrived—we doubt if one is needed. We will promise that this paper shall contain all that is new and interesting to men in the motive power and rolling stock departments of American railroads, and trust that they will appreciate and support the effort—it's time we were all posted a little better

Non-combustible material for locomotive boiler covering has lately been found valuable in keeping heat out An engine-house was burned a few months ago, belonging to a road that were using asbestos boiler lagging. Two engines with that covering happened to go through the fire, and they came out with their boilers unscorched. The boilers of the engines that had a wooden covering required extensive repairs before being used again

The present Erie management are progressive. It is now said that they will abandon a tunnel scheme to shorten the line, and spend the money in putting block signals on the entire line. This is good business sense, and, if done, the line will reap the reward always accorded to the *first* with the *best*. Safety on our roads can only be said to be honestly attempted where there are automatic brakes and block signals.

John Wiley & Sons, of this city, have in preparation "Modern Locomotive Construction," by J. G. A. Meyer, a new and valuable addition to the literature of the locomotive. It will be very large and elaborate, several hundred engravings, and be worth probably $10.

If your subscription laps over into 1892, and you would like the complete volume instead, you can have back numbers to fill out your year. The paper for 1892 will have a larger page, and more of them.

Georgia has passed a law to prevent railroads from working trainmen more than twelve hours consecutively.

Book Reviews.

ELECTRICITY FOR ENGINEERS. By Charles Desmond. Frederick Keppy, publisher, Bridgeport, Conn Price, $2.50

The first part of this book has been out for a year or so, and has met with a very favorable reception by the engineering profession and the endorsement of the electrical press The new part treats of the more recent developments in the electrical field, and brings the work up to date. The intention of the author seems to have been to take intelligent engineers and mechanics, who know little or nothing about electricity, and using language with which they are familiar, explain everything about electricity about which they want to know in order to handle ordinary installations for lighting or power likely to be entrusted to them The book will give any mechanic a clear idea of the principles of any electrical device how to use it intelligently and care for it It is a good book.

ASKED & ANSWERED.

(63) G E R, Westtown, Pa., asks :

Is the so-called Richmond & Danville cast-iron stack narrow in the middle and flaring at both ends? *A* —The R. & D. stack is bell-shaped near the saddle, and smallest about a foot above base.

(64) J. C. D. Carlin, Nev., writes :

What breaking power has a jet of water one-quarter inch in diameter turned into the cylinders of an engine when engine is running reversed I claim the only effect it has is that it keeps the valves and pistons moist, and all parts cool. Am I correct? *A* —You are quite correct.

(65) T. J. H., San Bernardino, Cal., asks :

Why will an injector not work when an engine is reversed running down hill without water brake being applied, but as soon as water is turned into cylinders the injector will work? *A* —The water-brake can have no influence on the action of the injector. Something else prevented its working.

(66) ——, Oxford, Pa., asks .

What should I do if I break the main pin on a mogul engine having solid-ended rods? *A* —Take down broken side completely, and take side rod off the other side; disconnect your valve stem; push the valve *ahead* and the piston *ahead*, if the cylinder is all right; if not, cover the ports with the valve. Leave your train and run in.

(67) E C., Albany, Ga , asks :

1. How would you get at the length of an eccentric blade if you broke an eccentric strap and had a new strap sent you from shops to be put on on the road? *A.*—Measure other eccentric blades, and make the new one same length 2 If you was to slip an eccentric blade, how is best and quickest way to set it? Can it be set by marks on valve stem same as setting an eccentric? *A* —Yes

(68) I. E. B , Dalton, Ga., asks .

What is the best way to fix a broken driving-box to get engine to shops, say box is broke parallel or vertical? *A* —Anything can be done to relieve the load carried by the box to prevent cutting of journal where box is broken through bearing. A box broken horizontally below the bearing will usually run all right by blocking above it and blocking equalizer down Much depends on the design of engine and the shape of the break

(69) J. S. M., Danville, Ill., writes :

I wish you would advise me how or with what I can pack an iron throttle stem so that it will not leak inside of a week anyway and also handle easily *A* —Much depends on the opening in the back of stuffing-box Winding a rubber gasket with asbestos wick for the back ring, and using rubber gaskets ahead of it, is as good common material as we know of Jenkins packing disks or Selden's rubber-cored packing is highly spoken of for this kind of work

(70) K G , Selma, Ala., asks .

1. Does a blow occur just after crosshead leaves extreme center, or just before leaving dead center? *A.*—Usually at and after leaving the center 2 Suppose you were running a mogul engine and you broke the equalizer of pony truck of engine, what would you do to get engine to shops? *A* —Block so as to keep long equalizer from rubbing the pony truck axle, and between the front cross-equalizer and the boiler to keep spring system level. Run slow over bad frogs, etc

(71) G E. R., Westtown, Pa., writes :

Forney's Catechism, page 522, in answer to Question 668 says. "All cocks in the train line air pipe should be opened, excepting that of the cock at the rear of the train, which should be closed by turning its handle so as to stand parallel with the train pipe." Is this not incorrect? I think the cock handle should be turned at right angles to train pipe *A.*—On old-style brakes the handle stands parallel with pipe when shut off; on the latest brakes the handle stands at right angles when shut off, and paralleled when open.

(72) J W , Kaukauna, Wis., writes.

Will you kindly decide the following argument for two readers of your interesting and valuable paper? Will a locomotive boiler steam as well or more economically with three or four gauges of water than she will with one or two gauges? My friend says she will not I think she will, for the reason that the feed water will not cool the larger amount as easily as it would the smaller. *A.*—The boiler with the most water will steam the best, for several reasons, one of which is that there is more water to carry latent heat, the cold feed has less effect, and the feed can be safely lessened to admit of using more steam on hard pulls

A "Holy Terror" Steamer in the Hands of Jim Skeevers.

Skinny Skeevers, him of the object lessons, ran Mike Monnihan's engine for a long time, while Mike went to visit the "ould sod," and Skinny's engine got a new fire box and a coat of varnish.

The first time Skinny oiled around, he hollowed up to Patsy Killigen, the fireman, to put on the injector, and cool her off, so he could see the oil holes; she was howling so it gave him the blind staggers.

"How does she steam, Patsy?" asked Skeevers, as they started out.

"She's a 'Holy Terror' for wind," said Pat, proudly. "She's always crazy wid it."

Skeevers was somewhat annoyed at the constant howl of the pop, but it did little good to speak to Pat—Pat fired by the pop, and a "Holy Terror" was his ideal.

Skeevers thought he'd try an object lesson.

"What size nozzle has she got?" asked Skeevers

"Oh! Lord, you ain't a goin' to go monkeying with her nozzles are ye, Skeevers? They are two-and-a-half or three inch, now "

"She burns too much coal, and howls too much."

"There hain't another steamer like her on the road," moaned Patsy. "Why, you can never shut off her throttle, but up goes her white tail—steam! Why, she's the darlin' of 'em all, Skeevers "

Skeevers got a smaller scoop, but Patsy plied it industriously, and the "96" still held the first prize as a "Holy Terror" for steam.

Skeevers bribed the coal shovelers to put on a tank load of lumps, none to weigh less than two hundred, but Pat paralyzed them, and reported the coal shovelers beside.

Skeevers thought of putting a flat car between the engine and tender, but gave the idea up as impracticable.

Patsy would put in a fire within two minutes of a regular stop, and be happy when the black smoke rolled, and the white feather stood proudly up forty eight feet above the howling pops of the "Holy Terror" Skeevers was in despair.

"Pat, did you ever stop to think that you were shoveling a lot of coal through that pop for nothing?" he asked.

"I don't mind the work, Skeevers," said he ' Don't mind it a bit, it makes the other lads green wid envy to see how she do steam."

"But it wastes coal."

"Bless ye, me boy, the company own their own mines, and it's proud they ort to be to have such steamers."

Skeevers couldn't get Patsy mad, and could awaken no other feeling in his heart but worshipful admiration of the prolific steam production of the "Holy Terror."

The run was a light passenger one, and after some scheming Skeevers got Pat and the "Holy Terror" on heavy freight run for a week. Skeevers managed to use all the steam that was made on the road, but Pat insisted on a pop solo at every stop.

Skeevers hated to disturb the front end adjustment of another man's engine; he finally determined to enlarge the nozzles, but concluded that this might give them trouble on the road, and besides that, Skeevers didn't believe in patching an engine to repair a man, any more than he believed in feeding a fireman Lord's compound to keep scale out of a boiler.

But right here the road got a new master mechanic, and the very first month he put up a bulletin of the amount of coal burned on each engine, and the "Holy Terror" was away down in the middle of the passenger engine list.

Pat was pretty mad about it, and said, if they would figure on who made the most miles or the most hours with the steam pressure at or above 140, he and the "Holy Terror" would take first money.

The next month he stole a few lumps of coal, gave the shovelers cigars for big measures, etc., but the bulletin appeared again with the Holy Terror advanced but one point.

Then came a bulletin notice that firemen would be promoted on merit, especial preference given for a coal record.

Pat had a nightmare that night when he thought of the "Holy Terror" and himself in eighth place, and Jim Bean, who was hired four months after he was, leading the list for coal and promotion.

That evening after they got to going up the hill, and the pop sat down to rest a minute, Skeevers called Pat over, and, in a friendly way, told him that the "old man" had said he should have to promote three or four men in the fall, and that he was afraid that Pat would lose his chance and see a lot of younger fellows pass him, if he didn't mind Skeevers suggested that the main trouble was with the "Holy Terror," and not Pat, and proposed that they prove it to the "old man" by having Pat transferred for one month to the "94" that was then leading the coal burners

Pat agreed to this if Skeevers would arrange it—he didn't know that Skeevers had arranged it.

When the next bulletin came out, the Holy Terror was at the head, and the "94" was fifth—Pat was improving some

Pat was glad to get back with Skeevers and the "Holy Terror"—said old man Martin on the "94" kept "picking at him" about opening the door and monkeying with the dampers.

Jimmy Bean was set to running switch engine in a week or two and Patsy's heart was broken

"Skeevers," said he, "I'm disgraced. Whatever the devil is the matter with the '96,' or—or—me?"

"The '96' is, without a doubt, the best engine on the road, Patsy," said Skeevers, "and honestly I think you are the best fireman, or rather would be the best, except that you haven't figured out plainly just what you are trying to do—you don't realize what you burn the coal for"

"To make steam, of course," said Patsy

"What do you want of the steam?"

"To pull the cars av course?"

"Where do you put it for that?"

"Into the cylinders, surely"

"Suppose you have more than you want?"

"Out of the pop she goes—can't hurt nothin'."

"But the coal pile?"

"Coal pile?"

"Yes, don't it take as much coal to make steam to blow through the pops as it does to make the same amount of steam to be used in the cylinders?"

"But there don't much go out of the pops."

"That's where your mistake has been made, Patsy. Pop Martin told me this morning that if he had all the steam that the '94' made and wasted at the pops while you were on her, he could make four round trips without coal or water."

Pat put in a fire and gave a big lump a few vigorous whacks with his coal pick, and then came back

"I've a notion to quit, Skeevers," said he.

"You fire this engine the best you know how for another month, take my advice, and if she don't head the list, I'll quit," said Skeevers.

"You want to remember that in making steam to throw away, you not only waste fuel to make it, but you waste water. Water is cheap, but it takes coal to haul it around, and the '96' takes more water than the other engines do, and hauls many tons of it a month for nothing; then we have to stop for water oftener, and that takes coal—takes coal to stop and coal to start."

"Coal to stop, how d'ye make that out?"

"There you are again, Pat, you see you haven't figured on your business or followed cause and effect up very much. Don't you know that it takes just as much power to stop a train, leaving out friction, as it does to start it?

"When you set the brake it commences to use up and loose 'stored energy' that has been put into the train by the coal, through the medium of the cylinders.

"Then your brake will use more steam to get its pressure back again, and the '96' will get rid of more coal to get the train back into motion, and use more to haul the extra water. It all counts, Pat, because we do this all day, every day in the month, if it was only once it wouldn't amount to much Think about your work, and figure on how *little* you can do in the way of coal shoveling to get this train over the road, and I will bet on the result"

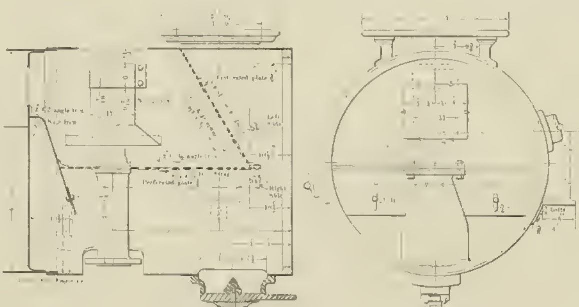
Last Thursday the new bulletin was put up, the "Holy Terror" stood at the head, and Patsy Killigen hummed "Comrades" as he was polishing the hand rail in the roundhouse, when the "old man" came along, touched Pat's leg with his umbrella, and said.

"Come into the office after dinner—I want to talk with you."

The gross earnings of the Westinghouse Air-brake Co. for the year ending Sept. 1, 1891, were \$5,004,179 26, the expenses being \$3,308,383 28, leaving the comfortable little sum of \$1,695,795.98 for net earnings The air brake has saved millions of dollars for the railroads, thousands of lives for the employes, and made our modern railroad system possible. We wish the prosperity of the air-brake company was ten times as satisfactory as it is.

Front End Arrangement of Wilson's Model Eight-Wheeler.

By request of several readers we publish herewith the front end arrangement of the new engines of the C., R I & P. road. The arrangement is a modification following pretty closely the Barnes extension as used on the Wabash, U P, and other lines of roads in the West.



The principal features are the short petticoat pipe adjustable from the outside, the use of perforated plates in lieu of netting, and the arrangement of the sheet in such a way as to present a very large area of opening for the hot gases and smoke Sizes of all parts being given on the engravings, no detailed description is necessary

---

Making Lock Washers.

Railroad men are becoming familiar with a peculiar form of open washer which acts as a most efficient nut lock, made by the National Lock Washer Company, Newark, N J. The washer is a circle of a spiral spring, and has one side projecting beyond the other, which is closed by the turning of the nut, and always keeps the amount of pressure on the nut, due to the spring of the spiral. There is a thin rim round the neck of the washer, which impinges against the thread of the nut, holding the latter so firm that no amount of vibration will loosen it. There are several features about this washer which act to hold the nut in place The spring tension tends to hold the nut secure, there is a sharp lip on the cut in the washer which presses into the metal of the nut, holding it tight, and the pin already mentioned makes the thread cling to the bolt. With all these provisions provided against the loosening of the nut, it is not surprising that the National Washer is making headway for railroad rolling stock where the constant vibration shakes off so many nuts held in the ordinary way. We know of nothing that would be more likely to keep nuts on running gear from being worked off. These washers are used very extensively for track joints

Another form of washer made by the same company, and adapted principally for light woodwork, has two small projecting fins that catch the thread. This washer is not cut open, the spring being obtained by making the washer convex towards the outside.

The manufacture of these washers is an interesting operation, and is a good illustration of the enormous increase of production obtained by special machinery Rods for making the washer are specially rolled of spring steel, with the fin spoken of on one edge. A rod of this kind is wound round a mandrel in a special lathe about as fast as a woman winds a ball of yarn. When the whole rod is twisted round the mandrel, it forms a long spiral spring. Six or eight rows of these spirals are then firmly secured on a table, like the table of a small planing machine. This is moved under revolving saws which cut an opening along the top of each spiral When this cut is completed the whole spiral falls apart, and there is a washer for every turn the rod made round the mandrel.

The washers are then taken to furnaces, and heated to a cherry red, and then dropped into an oil vat for hardening. After getting this oily dip, the washers are taken to a revolving cylinder and rattled in a cleaning mixture till they are bright and shining. This is necessary to show the color while the temper is being drawn. Next operation is drawing the temper, which is done by revolving them at a low heat over the furnace till the color shows that the proper temperature has been reached. After quenching they are ready for use The percentage of carbon in each batch of rods is ascertained by analysis, and the color for drawing the temperature is regulated accordingly. Each lot of washers is thoroughly tested by closing a certain number in a machine before any of them are shipped.

The length of a nautical mile or knot, as given last month, was wrong; it is given by Bessel as 6,086.44 feet The printer that set up the big number had been seasick, and put in the distance from memory.

Wanted a Little Lay-off.

Uncle Lorenzo J. Patton has been running a locomotive pretty close to half a century, and can be found to-day switching in the Providence yard He pulled one train, the fast freight, for more than forty years, on the old Boston & Providence.

A couple of years ago the Old Colony leased the road and made some changes in the men.

They gave the fast freight to an *older man* than Patton, and otherwise disturbed his routine life.

Uncle Lorenzo went into the office to make a kick, and a dapper young Old Colony clerk stepped up and asked what he could do for him.

"I guess I'll lay off," says Patton, "I don't exactly like the new management of us old Boston & Providence men, and I guess I'll take a little lay-off *till the Old Colony lease runs out*."

The lease was for 99 years.

An exchange says that thirteen engineers, firemen and brakemen on the Cincinnati, Wabash & Michigan were discharged for smuggling beer into the cabs and cabooses, and drinking it while on duty. Good enough, only be sure your men are guilty.

If you are in any way anxious to preserve bound volumes of THE LOCOMOTIVE ENGINEER send in your orders now, as when this stock is gone there will be no more—we can supply a few of each year 1888-'89-'90 and '91.

At the N. Y. Railroad Club.

At the first fall meeting of the New York Railroad Club an informal discussion on flue setting and flue repairs bad. Mr. West, of the Ontario & Western, stated briefly the practice on his road and the difficulties encountered. He uses copper ferrules from $\frac{1}{16}$ in. to nearly $\frac{1}{8}$ in., according to the size of the hole. He aims to reduce a 2-in flue about $\frac{1}{32}$ or $\frac{1}{16}$ in., and has a good deal of trouble with leaky flues in the fire-box. At the smoke box end he has no trouble He asked whether other roads find that reducing or swedging the flues is good practice. Mr Blackall, of the D. & H., suggested that the trouble might be with the engineers, which Mr. West did not doubt, but still thought that that did not explain the whole difficulty

Mr. W H. Lewis, of the D., L. & W, has had a good deal of trouble with semi-steel tubes, but not with iron. He uses copper ferrules, but does not swedge the tubes; they are drawn down with a taper mandrel, driving the ferrule in around the tubes. Mr. Kells, of the Erie, sets the ferrule in the tube sheet first, and Mr. Stinnard had followed the same practice, setting the thimble and expanding the flue through the thimble, leaving about $\frac{1}{16}$ in. outside the sheet. Mr. Lewis uses a No 11 flue, that is, 11 wire gauge, and expands it with a Dudgeon tube expander, run by Stow's flexible shaft. The flues are beaded at the back end, but not in front He finds the life of a semi-steel tube about ten months, and has a good deal of trouble with them. Mr Lewis further suggested that if a tube is a little loose it is very easy to put a hand tool in and tighten it, but Mr West suggested that if that was done half a dozen times there was no flue left. Mr. Lewis controls this by a gauge.

Mr. West has three consolidations built by the New York Locomotive Works, in which the flues cannot be kept tight three months, while with some mogul engines from the same works they have very little trouble. He asked whether any one present had tried flues set in the sheet without a copper ferrule. Mr. Stinnard had tried it a good many years ago on the Erie, and gave it up.

Mr. West said that he had watched the matter carefully and was convinced that it was not the fault of the men, nor was there any trouble with the water. He uses a very good quality of bituminous coal. It was suggested that perhaps his men ran with the door open. This, however, Mr. West denied. He had tried using a layer of fire-brick over the forward part of the grate to prevent cold air coming in there, but got no benefit from this. Mr Lewis was inclined to think that there must be cold air coming in somewhere; either the fire is carried too shallow or the door is left open.

The president called for further suggestions for subjects for discussion at future meetings. Mr Lewis suggested methods of handling coal for locomotives, that is, the best method of getting it from the track onto the engine. Mr. Blackall suggested the care of air-brakes as another topic Mr. Andress was requested to prepare a paper on the qualities and uses of paints.

Mr. Besler in the Soup.

A party of Chicago, Burlington & Quincy officials were out on a tour of inspection mixed with pleasure in the general manager's car, and a fine muscallonge, which one of the party had captured, was to be the leading attraction of the dinner The cook devoted special attention to making the fish a triumph of his culinary art, and the most appetizing sauce known to cooks was prepared to give the muscallonge a good send-off When dinner was called, General Superintendent Besler sat down and continued the story he was telling The waiter carried in a dish and set it down beside Mr Besler, who took up a spoon and began to eat without letting the act interrupt his talk Presently Mr. Harris rang for the waiter, and said, "Why don't you bring the soup for the rest of us?"

"Why, Mass'r Harris," said the waiter, "dar's no soup to-day."

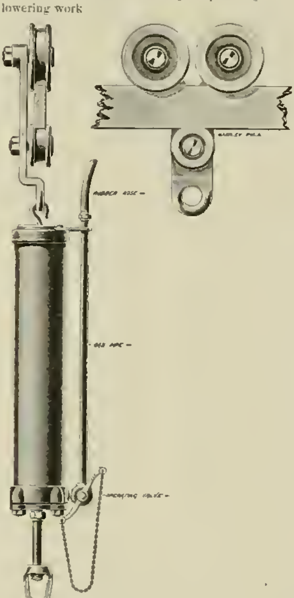
"No soup? Why, Mr Besler is eating soup"

The startled darky gazed at Mr. Besler, and when he could find breath, exclaimed, "Fo' de Laud sake if Mr Besler has not eat all de fish sauce!"

The Mexican Central Railroad has ordered five double-ended locomotives of the Johnstone compound type, to be used on mountain service. Mr. John Player, superintendent of motive power of the Atchison, Topeka & Santa Fe, who accompanied one of the Johnstone compounds over his road lately, speaks very favorably about the performance of the engine. It was found that the provision for working the engine simple at the will of the engineer was sometimes the means of getting the engine over the summit of a grade when the less cylinder power of compound working would have led to stalling. The direct steam is admitted to the big cylinders at reduced pressure, but with sufficient tension to materially increase the power. This is practicable when used merely to make a difficult start, or to prevent stalling, although the boiler would not have capacity to provide steam direct to the big cylinders all the time.

Hall's Pneumatic Hoist.

The hoisting device shown in our engraving is being used with great success over lathes, planers, wheel-boring mills etc., for quickly lifting and lowering work



This device has an improved operating valve that makes its action positive, and its speed entirely in the hands of operator

These hoists are preferably handled with compressed air, but any fluid present may be used.

Their usefulness is not limited to lifting, but they are worth half a dozen "hands" in helping move machinery or other heavy objects, and can be used in any position.

Their advantage over chain hoists is their speed, no manual labor required, and the additional amount of work a tool can do when quickly served.

The sizes and capacities are as follows (eighty pounds of air being used):

3" diameter	450 lbs.	6 diameter	1,800 lbs.
4 "	800 "	8 "	3,200 "

These handy little lifters are made by the well-known tool makers, Pedrick & Ayer, Philadelphia, Pa.

What men can save in oil and fuel is shown in the improvements made when oil companies oil a road by contract. The Galena Oil Works have brought the car service of the U. P. up from 18 to 50 cents for a hundred miles

The Crescent Steel Co. send out a little circular of advice occasionally that is good; here is one of them: "Some tools do not need to be made of as good steel as others, but those which are in constant daily use, planing, turning, chipping or working metals, ought to be made of the best steel you can get. A certain amount of time and labor are expended in making a tool of any kind, and if this is put on good steel, it is saved many times over in the quality and quantity of work done. The difference in value between the best and an ordinary steel, in an average machine shop tool, would be from ten to fifteen cents. The better steel does more work, requires less frequent sharpening, and stands more re-working without injury, so that at a much higher first cost per pound it is actually the cheapest to use, and you buy fewer dollars worth in the course of the year."

At the conductors' fair, at New Haven, Conn., last month, there was on exhibition one of the old time baggage boxes, used on what is now the New York, New Haven & Hartford road, in 1839 These were strongly framed boxes about six feet high, five wide, and perhaps seven long. They were mounted on wheels about a foot in diameter and were provided with a handle at one end. These were loaded with baggage and mail, and several of them run upon a flat car hauled in all passenger trains for this purpose. When the old, hook-motion flat-boat, with a graveyard fence around the boiler head, where the cab is now, came into town with her train, the agent pulled the truck-mounted band box, billed for his town, off the flat, and ran another on, and the train sailed away without the aid of the modern baggage smasher—he was invented later

The friends who have written us, expressing their good feeling, and offering their congratulations at our acquisition of the leading mechanical paper in the railroad field, have been many. We take this opportunity of thanking them, one and all, and promising to do our best the coming year. Watch the paper.

The standard torch of the Delaware & Hudson Canal Co. is a casting that can be made for less than ten cents. The top is joined to the body by a connection that is like an air-hose coupling. Spurs are cast on the torch that keep it from lying flat and setting fire to the floor or platform.

Engineer Robert D. Morton, an engineer on the Richmond & Danville, died of hydrophobia on Oct. 24th. He was bitten by a mad dog on Aug. 5th, and received treatment at the Pasteur Institute in this city, but without avail.

Our friends who advertise have been so enthusiastic about our new combination, that we have been obliged to add four new pages to the paper this month, with prospects of more for the month following

Mr William Hassman, formerly division master mechanic of the Chesapeake & Ohio at Huntington, W. Va., has been appointed superintendent of motive power of the Newport News & Mississippi Valley

Master Mechanic Campbell, of the Lehigh Valley, is having a Pedrick & Ayer tire heater built that will be mounted on a car, so as to be taken from one place to another, where tire work is to be done.

Mr. A F Stewart has been appointed master mechanic of the Cincinnati & Huntington divisions of the Chesapeake & Ohio, Wm. Hasman having resigned, to accept a better position.

The Boston & Albany are having twenty-seven engines built at the Rhode Island works. They will be 18x26 freight engines, with a ten-inch port and short valve travel.

The Burton Car Co. have ordered 500 new cars, divided between the Michigan Car Co. and the Lacona Car Co. To use automatic couplers and N. Y air-brake.

The Schenectady Locomotive Works are building fifty new engines for the New York Central. Several of them will be compounded.

With the Fastest Regular Train.

On October 26 the New York Central Railroad Company began running daily what they call the Empire State express, which is the fastest regular passenger train in the world. The running time between New York and Buffalo, a distance of 439½ miles, is 8 hours and 40 minutes, calling for an average speed of 52½ miles per hour. When the first train making this run started out, a large company of newspaper men and others were on board, and intense interest was manifested in the performance. The train consisted of five cars, weighing in all 178 tons, a phenomenally heavy train for fast speed. Three locomotives were used for the different divisions. From New York to Albany the work was done by engine 870, with Mr. Archie Buchanan at the throttle. This is an exceptionally heavy eight-wheel engine, with cylinders 19x24 inches, and driving wheels 6 feet 6 inches diameter. The run of 143 miles over this division was made without a stop, and the engine seemed to have no difficulty in making the schedule time. In fact, the engineer got ahead of his schedule several times, and had to kill time to fall into it again. The road from New York to Albany is very crooked, and speed had to be reduced frequently for curves, but the engine seemed to have no difficulty in forcing the train quickly into a mile a minute gait. The average running time between New York and Albany was 52 miles an hour.

At Albany, engine 876, with Mr T. Dormody at the throttle, took hold of the train. This engine is of the same cylinder and boiler capacity as the 870, but the driving wheels are only five feet ten inches in diameter. The smaller wheel gives an engine an advantage in starting a heavy train away from a station, but when a speed over fifty miles an hour is attempted the high piston speed necessary increases the back pressure in the cylinders so much that loss of power is soon apparent. In this run the superiority of the big wheel engine was apparent to every one on the train. Dormody had a hard struggle to get the train over the division from Albany to Syracuse, at an approach to schedule time. He had a tank loaded with slack coal of the smallest quality Inferior fuel falls short of its purpose when used to supply the heat for a locomotive fire-box that has to provide the demands of 19-inch cylinders, for more than eleven hundred charges per minute "Tom," in spite of all the efforts of energy and skill lost time all the way, and arrived at Syracuse close on nine minutes late, his running time having been 48 8 miles an hour.

Some of the best runs made on the New York Central system have been performed by engines having Mr Charles Hogan at the throttle. When the news gatherers, and other interested parties on this train heard that engine 862, with Hogan as engineer, was going to pull the train from Syracuse to Buffalo, they exclaimed, with one accord, "Now, we will gain the time lost." "Charlie" made a plucky effort to satisfy some of those who were betting on him, but making up 9 minutes in 150 miles was not in it, when a running speed of 60 miles an hour, after subtracting for delays, had to be maintained to hold to the schedule. He made an average speed of 55.2 miles an hour, and took the train to its distination three minutes late. In doing this he covered one mile in 51¼ seconds, and several times 53 seconds was recorded for a mile. The running of this train from Syracuse to Buffalo was an unparalleled feat in locomotive engineering. A train of this weight was never before run at the velocity maintained. The time throughout the whole run was kept by Mr. A. G Leonard, secretary to Vice president Webb, and by Mr. Angus Sinclair, of this paper. The locomotives that did the work were built at the Schenectady Locomotive Works after dimensions supplied by Mr. William Buchanan, superintendent of motive power of the New York Central.

Many disputes are indulged in between railroad officers and shippers about overloaded and improperly loaded cars. Master Mechanic Turner, of the Western New York & Pennsylvania, saves himself lots of trouble, and fortifies his arguments, by photographing every car complained of as over, or improperly loaded.

At the recent conductors' fair held at New Haven, Conn., the Hall Signal Company, of this city, had a very handsome exhibit of their automatic block signal system and other signaling devices. They had a complete double track road equipped with automatic electric signals, crossing alarms, etc., all built on a scale of one inch to the foot. They showed this plant in actual operation, and, it is needless to add, always had an audience. This company have recently secured control of the Bezer lock and block system and the Bezer & Burley interlocking machine, a device that seems to have decided advantages over any other machine in use. The latest auto-manual block signal of this company seems to be the best that human ingenuity can devise for the protection of trains.

Reports have been received by the Bureau of the American Republics to the effect that the experiment of using petroleum for fuel on the Oroya Railway in Peru has been entirely successful. The trials were made at an altitude of 5,800 feet aboue the sea level, with the two locomotives from the Rogers Works at Paterson, N J. The oil used was a residuum oil differing from crude petroleum In the trials the average consumption of oil was 38.55 pounds per mile, while with coal it was 79.30 pounds. The reports state that the Oroya road has decided, owing to the experiments, to use oil fuel on all its locomotives. Coal is very expensive down there, and in some districts oil is plentiful.

"Condensed Suggestions for Steel Workers" is the title of a neat little thirty-page book issued by the Crescent Steel Co., of Pittsburgh, Pa. This little work is not an advertisement, except that it is issued by a steel-making concern; they do not mention their brand of steel in the book There are six short chapters full of valuable information to any mechanic who has to forge, dress, grind or use steel tools. Annealing, Heating to Forge, Heating, Temper and Furnaces are subjects treated. This little book would be a valuable addition to any mechanic's library It is sent free by the above company. Send for it.

As shown by the last annual report of the directors, the growth in passenger business on the New York, New Haven & Hartford Railroad in the past five years has been phenomenal. In 1886 the road carried 8,267,310 passengers, at an average fare of $1.02; during the fiscal year ending June 30, 1891, the road carried 14,030,868 passengers, at an average fare of $1 92. The train mileage in 1886 was 4,973,243 miles, in 1891, 7,805,078.

The two orders of railway conductors have been amalgamated, as have the two branches of Railway Telegraphers "In unity there is strength," is a maxim true of railroad orders as well as other things The day will come when the railroads of this country will be a unit in policy and management, and the employes will be organized on the same plan; in fact, we expect to see them set the example of unity rather than follow one.

The new order of conductors recently founded at New Haven, Conn., have as their corner-stone a law that they will not, as an order, or as individuals, engage in any strike or other labor agitation. The men on the road who believe in taking care of their interests, even if they have to fight for them, have named the members of the new brotherhood, "The Angels."

Roadmaster James R. Smith, who has charge of the track of the Pennsylvania between Newark and Deans, has just won, for the eleventh time, the prize of $100 offered yearly by the management for the best kept division on the system. Mr. Smith is an old locomotive engineer, and always divides the premium money between his section foremen.

On Oct. 20th a consolidation engine just out of shop exploded her boiler at Tucker's Watchbox, Pa., killing four men. An investigation should be made in such cases, with a view to remedying the cause of such disasters. Low water has come to be regarded in the same light as the insanity dodge—thin.

The Wells & French Car Works have taken contracts for building 500 box cars for the C., B. & Q., 500 box and 500 flats for the Lake Shore & Michigan Southern, and 300 furniture, 200 stock and 200 box cars for the C., R. I. & P. road.

The Chicago, St. Paul & Kansas City Road have added ten more engines to the order of 15 now being turned out of the Cooke works.

The New York Central are asking bids on sixty passenger cars and have ordered fifty new locomotives from Schenectady.

The Lake Shore have divided an order of fifty passenger cars between the Lacona, Bradley & Smith and Billmeyer & Small.

The Grand Trunk has notified the men whose salaries were cut some time since that the old rates will be restored.

The N Y., N H. & H. have ordered two large Forney engines and are contemplating the building of ten others.

The Old Colony Railroad has placed an order with the Wason Manufacturing Co. for 34 passenger cars.

Specifications are out for ten new engines for the Central Railroad, of New Jersey.

John Alexander has promised to tell the boys a story in the January issue.

The Boston & Maine are in the market for 500 freight cars.

The Manhattan Elevated have bids out for twenty new engines.

ANNOUNCEMENT.

PROSPECTUS FOR THE ENLARGED PAPER FOR 1892.

LOCOMOTIVE ENGINEERING.

A Practical Journal of Railway Motive Power and Rolling Stock.

VOL. V, No. 1. NEW YORK, JANUARY, 1892. PRICE, { 20 Cts. Monthly. $2.00 per Year.

PROSPECTUS OF *Locomotive Engineering* FOR 1892

With the January, 1892, issue, THE LOCOMOTIVE ENGINEER will take the above title, come out with a large 4-column page, and a substantial increase in the number of them—anyway twenty big pages of reading matter

ANGUS SINCLAIR, for the past six years Editor of the NATIONAL CAR AND LOCOMOTIVE BUILDER, the author of "Locomotive Engine Running and Management," well known as the Secretary of the American Railway Master Mechanics' Association, and JOHN A HILL, Editor of THE LOCOMOTIVE ENGINEER from its birth, have bought out the paper and will devote all their energies to making it the best practical railroad paper in the world.

It is proposed to keep it up to the times and devoted exclusively to subjects interesting to all men in the motive power and rolling stock departments of American railroads.

Old readers of THE LOCOMOTIVE ENGINEER shall not miss a line of Mr. Hill's work, and will in addition secure all the writings of Mr Sinclair

The new owners propose to spend a large sum of money next year for engravings to keep up the interest of every engineer, fireman, shop man and officer in the machinery department

We believe a good monthly is better than a poor weekly

The working, every-day engineers, firemen and shop men of our railroads have been slandered by papers containing little of interest to practical men, which have long contended that enginemen would not read a railroad paper, much less pay for one Four years' experience with THE LOCOMOTIVE ENGINEER has proven the falsity of this claim—16,000 names are now on the list The men *will* read, and profit by it, if practical matter by practical men is furnished, instead of abstract reasoning and cloudy theories Both editors of this paper have bent their backs to the coal scoop and taken care of the reverse lever, the throttle and the 3-way cock "Been there."

We believe that THE LOCOMOTIVE ENGINEER has done good, and we believe that the new and enlarged paper will do much more good; however, we will leave that to you

Now, this enlarged paper will be worth $2.00—can't furnish it a cent less—all we ask is that you will try it for one year; if you are willing to give it up then we won't say a word. Are you with us?

BACK NUMBERS.

We have some hundreds of back numbers of THE LOCOMOTIVE ENGINEER that we will dispose of at once, any, or all, of the four years, at $1.00 per year, unbound. They will be out of print in six months, or sooner. If you want to fill out your set do so now.

BOUND VOLUMES.

We have on hand less than a hundred bound volumes for each year (only 28 of last year), which will be sold at $2.00 per volume until the supply is exhausted—then there can be no more procured

We have 175 binders on hand that we will sell at 50 cents in the office, or 75 cents by mail, and 38 other binders marked "COMPLIMENTS OF" in addition to the title of the paper (otherwise just as good), which we will sell at 35 cents in the office, or 50 cents by mail. No more of these binders will be made, as they are too small for the increased size of the paper. Order now

ABOUT CLUBS.

We pay a cash commission for getting up clubs. If there is no one at work in your field, write us for club rates

FINALLY.

We do not like to make a lot of promises, blow our own horn and swell up prematurely. We have plenty of new matter laid out, a lot of historical railroad lore as interesting as a novel, some new departments to add, some elementary matter of the right sort, and engravings galore—we propose to lay awake nights scheming to make the paper valuable and interesting to our readers. Our time and abilities shall be all yours. But we would far rather you would tell us how well we have succeeded in a year from now than to blow about it in advance. Will you be on the jury?

OPINIONS DIFFER!

Some men would rather have two knobs to a door than one, for the same money; perhaps they would rather write with a set of pens—some to make marks on the down stroke, some up, and a few for different "slants"—the more the better It always seemed to us that simplicity was a good thing—no one wants a pair of pants with three legs, because two are plenty One lever is enough for stopping and starting a good Injector One handle to regulate feed, put on heater, or shut lazy cock, is better than two—simpler The best Injector is the one that will do the business with the fewest parts and the least repairs—you're looking at its photo now

THE WESTINGHOUSE AIR BRAKE CO.,

PITTSBURGH, PA., U. S. A.,

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE

THE WESTINGHOUSE AUTOMATIC BRAKE

is now in use on 22,000 Engines and 270,000 Cars. This includes (with plain brakes) 160,000 Freight Cars, which is about 18 per cent. of the entire Freight Car equipment of this country and is about 60 per cent. of those engaged in interstate traffic, affording the opportunity of controlling the speed of trains by their use on railways over which they may pass. ORDERS have been received for 120,000 of the IMPROVED QUICK ACTION BRAKES since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

Below is a graphical illustration of the progress made in the application of the AUTOMATIC BRAKE to Freight Cars since its inception:

YEAR.	NO. PER YEAR.	GRAND TOTAL.
1881	105	105
1882	1,085	1,190
1883	4,966	6,156
1884	15,051	21,207
1885	10,410	31,617
1886	8,846	40,563
1887	9,281	40,644
1888	27,896	77,540
1889	26,065	103,805
1890	50,502	154,107

154,107 Freight Cars fitted with the WESTINGHOUSE AUTOMATIC BRAKE, which is more than 15 per cent. of the entire freight car equipment of this country.

Monumental Scrap.

Out back of the Erie shops, at Jersey City, stands a monument to the memory of the wasted dollars of a man who thought he could improve the American locomotive. The monument consists of one complete "Raub Central Power Locomotive." Just what the inventor of this miscarriage of ingenuity was trying to do it is very difficult to understand—what he actually made is very plain. At a glance, end on, the engine looks like a pile of air drums, tank boxes and ash pans around a boiler front. There are two separate and distinct small boilers of the regular pattern mounted on four drivers each, making eight in all; the boilers have a door on each side of both fire boxes, and none in the ends. The frame is continuous, mounting both boilers; between the fire box ends of the boilers there is a round iron dome or tower, and on each side of this dome there are mounted vertical cylinders, these are in the cab, the heads being taken off through the roof. The main rods are coupled to disk cranks on a master shaft running in boxes on the frame, and rods run from this pin to the crank-pins on the wheels; the links are inside the central dome. From the top of each smoke arch a large square pipe leads back to the central dome, and one smoke stack answers for both boilers. The water tanks are hopper-shaped affairs, located on the four corners of the engine, and there are also four coal bins, holding about a ton each. The air-pump and other rig is all in the cab, and the fireman can dodge around over the engine and use any of the four doors; he has to go out doors to go from one to the other. There is no tender. The water tanks are connected across the frame by six-inch pipes running within a few inches of the track—sure to break off and cause a drought if the engine drops off a switch. Last summer they had this contraption out, and, as might have been expected, she suffered from chills from the start, and was something like five days getting ten cars over a division. But, then, she is "different." The inventor, we believe, is a physician. As an improver of railway motive power he is a failure—not an ordinary, every day failure—but a ripping, howling, sizzling failure.

The employes of the mechanical department of the C. & N. W. have collected $1,500, with which they propose to build a monument to the memory of Geo. W. Tilton, late Supt. of Motive Power. The subscriptions were limited to one dollar each.

Baldwin Compound with Wootten Fire Box.

The engraving shown herewith was made direct from a photograph of a heavy 10-wheeler, compounded on the Vauclain plan and doing service on the Erie road.

This engine has four cylinders, two high-pressure cylinders 14x26 and two low-pressure cylinders 24x26. Steam is admitted to the two high-pressure cylinders by piston valves located back of and between the two cylinders on each side, and the exhaust from the small cylinders passes through ports in the same valve to the two low-pressure cylinders. The back-pressure on the high-pressure pistons is equal to the effective pressure on the low or large pistons, but their areas are so much larger, 3 to 1, that a large percentage of useful work is done.

The boiler pressure carried is 180 pounds per square inch, and steam is admitted to the high pressure cylinders for about two-thirds of the stroke, and then exhausts to the low-pressure cylinder, where it is expanded down pretty low.

The exhausts are hardly perceptible at the stack or on the fire, but the blast is nearly continuous.

This engine is now pulling the Erie's limited train out of New York, although she was built for freight service and has a 62-inch wheel.

The writer recently rode over the division on this machine, and was particularly struck with the speed she was capable of, and the easy riding of the awkward looking craft when running fast. This engine has made over seventy miles per hour for short spurts on favorable track.

Below and between the lower cylinders there are located on each side a combined starting valve and cylinder cock. This valve consists of five small pistons on a rod in a long cylinder which is connected to each end of the low-pressure cylinder, and also by two one-inch pipes to the steam passage in the saddle. When it is desired to move the engine to start, a small lever, corresponding to the usual cylinder cock lever, is moved to a certain location and the valve then admits live steam to the large cylinder and the cylinder cocks are open. Moved a little further the lever causes the valve to close the cylinder cocks and still admit live steam, when a further movement shuts off live steam and the engine is running compound.

The high and low-pressure piston rods, as will be seen, are attached to a common crosshead.

The Baldwin Locomotive Works have built over 100 of this class of compound, many of the earlier ones running in South America, and duplicate orders are now coming in from that country.

The principal dimensions of this engine are as follows:

Cylinders, 14x26" and 24x26".

Piston valves: Travel, 5"; outside lap on high pressure, ¾"; low pressure, ⅝"; lead on high pressure, ¼"; on low pressure ⅜".

Boiler Wootten fire box, 66" at smoke box end; fire box, 114" long and 96" wide; combustion chamber, 49⅝" long; wall of fire brick between grates and combustion chamber, 258 2" tubes, 10' 10" long, total heating surface, 1,672.9 square feet.

The engine has a rigid center truck with journal bearings 5" in diameter and 10" long.

Drivers, six coupled, 56" centers 62" outside diameter, forward pair bald.

The axles have bearings 8" in diameter and 10½" long.

Total wheel base of engine, 22' 10"; driving wheel base, 12'; of engine and tender complete, 50'.

Weight in working order, 182,000 pounds, of which 102,000 are on the drivers. Weight of tender, loaded, 72,000 pounds.

A Heavy Grade in Vermont.

There is a little five-mile road, known as the Barre Railroad, that has a pretty stiff grade, the average being 264 feet per mile. One of the granite quarries that this little road serves is 1,064 feet higher than the town. The engines are Baldwin's, one small four wheel switcher, 15x22 cylinder, and two six-wheeled engines, 16x24, somewhat heavier. The small mill handles four empty cars, and the other two nine empty cars on this grade.

The engines have air brakes, with American driver-brakes, the water-brake, and all modern appliances. The cars have hand brakes. Unlike many, we might say most, private roads, the rolling stock and track are modern, and kept up to date, the line being laid with heavy steel rail, and protected by switchbacks, etc. The Supt. and M. M. of the road, Mr. F. W. Stanyan, keeps things in good shape.

A Good Deal for the Money.

Once in a while—sometimes oftener—a railroad asks far more of its men than the salary paid warrants. They tell a pretty good story about a brakeman who ignored an order to call the names of stations in a "clear tenor voice," and, on being called upon the carpet, asked what grade of a tenor voice they expected for $38 a month.

We recently sat in an office and listened to a civil service examination of a young man who needed to know a good deal, and be a polished gentleman beside, for the privilege of selling tickets for a railroad for the magnificent remuneration of $30 per month.

There are not two railroad managers in the United States that do not expect their master mechanics to know more, do more work, assume as much responsibility, and do twice as much worrying as the engineers under them, and for a third less pay.

Here is a little dog story that is floating around in the papers that fairly illustrates the unreasonable in similar lines:

Fair Customer—"I live in the suburbs, and I want a watch dog."

Dealer—"Yes, mum."

"But of course I don't want one that will keep us awake all night barking at nothing."

"No, mum."

"He must be big, and strong, and fierce, you know."

"Yes, mum."

"Yet as gentle as a lamb with us, you know."

"Yes, mum."

"And he must pounce on every brutal tramp that comes along, and drive him off."

"Yes, mum."

"But he mustn't interfere with any poor but honest man looking for work."

"No, mum."

"If a burglar comes prowling around at night, the dog should make mince meat of him in an instant."

"Yes, mum."

"But he mustn't attack a neighbor who drops in for an evening call."

"No, mum."

"And of course he mustn't molest people who come hurrying in at all hours of the night to call my husband. He's a doctor, you know."

"No, mum. I see what you want. You want a mind-reader dog."

"Yes, I suppose so. Can you send me one?"

"Very sorry, mum, but the only dog I had of that 'ere kind committed suicide yisterday, and I guess the breed is extinct."

Power Dumping Device for Cars.

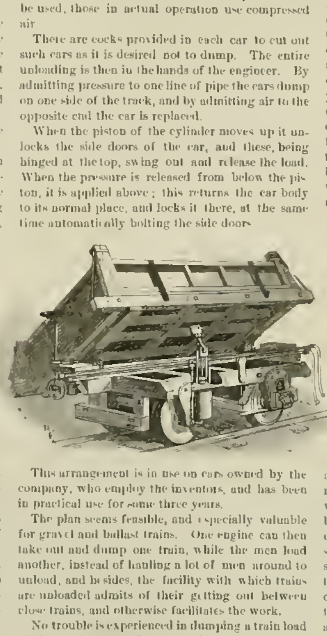
The illustration on this page shows the application of a cylinder for fluid pressure used to dump an ore car.

This arrangement is the invention of Mr. J. H. Gearhart, M. M. of the Arkansas Valley Smelting Co., at Leadville, Col., and W. A. Thatcher, of the same place.

A cylinder is located on the side of the car, and two train pipes and two lines of hose connect it to the locomotive; air, steam or water pressure can be used, those in actual operation use compressed air.

There are cocks provided in each car to cut out such cars as it is desired not to dump. The entire unloading is then in the hands of the engineer. By admitting pressure to one line of pipe the cars dump on one side of the track, and by admitting air to the opposite end the car is replaced.

When the piston of the cylinder moves up it unlocks the side doors of the car, and these, being hinged at the top, swing out and release the load. When the pressure is released from below the piston, it is applied above; this returns the car body to its normal place, and locks it there, at the same time automatically bolting the side doors.



This arrangement is in use on cars owned by the company, who employ the inventors, and has been in practical use for some three years.

The plan seems feasible, and especially valuable for gravel and ballast trains. One engine can then take out and dump one train, while the men load another, instead of hauling a lot of men around to unload, and besides, the facility with which trains are unloaded admits of their getting out between close trains, and otherwise facilitates the work.

No trouble is experienced in dumping a train load while running at moderate speed.

The Illinois Central have put on a special train between St. Louis and Chicago, to be known to fame as the "Diamond Special." Instead of turning over their chair and sleeping cars to the Vandalia at Effingham, Ill., they will run through solid, going into St. Louis on the Vandalia tracks. The Pullman works have recently turned out the cars for this train, and no pains have been spared to make them the most elegant and luxurious cars on wheels. They are named "Felicito," "Delecto," etc. The sleepers are the new design, drawing rooms throughout. As private as English cars.

In Austria there is in use an extensive system of rewards for the discovery of dangerous defects in rolling stock or permanent way. If every track walker got a substantial reward for every broken rail or burned bridge found, and every inspector got a day's pay for every broken wheel found or every cracked side rod that was discovered and recorded, we imagine there would be more thorough inspection and more careful track walking.

The Philadelphia & Reading have ordered twenty Baldwin compounds—the largest order yet given for compounds by one road.

More Electrical Nonsense.

By Fred H. Colvin.

It is little wonder that the engineering fraternity have come to look upon the transmission of power by electricity with considerable distrust. Not that it is not a success in many places, but because of the idiotic claims made by its friends. If these statements were made by men of little experience or knowledge of the business, we might excuse them, on the ground of enthusiasm.

When a man like Frank J. Sprague, who has been connected with the motor business almost from the beginning, gives utterance to such statements as the following, it is time to ask whether they know the truth if they happen—accidentally—to see it.

"Break a single part of the many in a locomotive, and it is helpless," while according to his statement you can break "many of certain parts of an electric motor, and, though crippled, it will still operate." The strange part of the last sentence is the admission that it will even be crippled. Of course we can break many parts of an electric motor and not affect its operation, but let the main conductors be parted, and having no means for repair at hand, you are as "dead" as any locomotive can be with *all* her parts gone. The hundreds of engineers who have come home "on one side" from various causes know well that it takes more than the breakage "of a single part" to make them helpless. Had Mr. Sprague even said vital part, he would not have been absolutely correct, but he did not even so qualify it.

This equals Dr. Louis Bell's statement, that there were sixty-four oil holes under an engine, and "failure to oil any one of these meant accident, and perhaps death to the train."

No one more admires the achievements of electricians than the writer, but achievements to be admired must exist in reality as well as on paper.

No one disputes the advantages that electricity has over steam for many places—the absence of smoke and steam are greatly in its favor; but why not be honest, just for a change.

If Mr. Sprague really believes what he says, we can pity his ignorance, but we must condemn his lack of investigation before making such a statement. If he does know better—and it seems most probable that he does—he must not expect to escape the penalty that follows such willful misstatements—he must not be surprised to have his opinions regarded with distrust. Before the electrical men complain too bitterly about unfair skepticism or a lack of cordiality on the part of the steam engineers, let them be more careful to adhere to facts when showing by comparison the advantages of their mode of transmitting power. The result of the circulation of such statements in the report of a body of men known as the "electrical engineers" cannot fail to work harm to themselves. "You can fool all of the people some of the time, some of the people all of the time, but you can't fool all the people all of the time."

As a locomotive which had been undergoing general repairs was being run out of the Chicago, St. Paul & Kansas City shops at South Park, St. Paul, one day last month, the boiler exploded, fatally injuring three employes of the company, among them being James Dickson, general foreman of the shops, and slightly injuring five others. Examination showed that the crown sheet had given way.

The demand for the M. C. B. type of coupler is growing very rapidly. Within the last sixty days the Janney coupler has been specified for 15,000 cars. The other makes of the same type are largely specified. The Gould is called for by the thousands, the Trojan has just been ordered by the Old Colony, and the Standard by the Central Vermont. The latter order was 250 cars.

The Erie has an old, single pair of drivers, and a tea-kettle, that once upon a time did service upon the six-foot gauge. She is used to move the transfer table and do light switching about the shops. The boys call her "the-fly-up-the-creek."

Sixty Years of Progress.

On the 12th day of November, 1831, Isaac Dripps stepped upon the deck of the "John Bull," at Bordentown, N J, and opened the throttle of the first locomotive in service in the State, and one of the first in the Union On the 12th day of November, 1891—sixty long, eventful years afterward—there assembled at the exact spot where the old "John Bull" stood in '31, a large concourse of people to witness the unveiling of a monument to the memory of the historic occasion.

The old "John Bull"—now resting in the National Museum at Washington—was purchased in England in 1830, by Col. John Stevens of Hoboken. On his way to England, Mr. Stevens whittled out a pattern for a T-headed rail, the first ever made, but had great difficulty in getting them rolled, they were finally rolled in Wales and brought to this country. He also had hook headed spikes made with which to fasten them to the stone blocks used as sleepers—this rail and spike are the standards of the country to-day.

The granite blocks used as sleepers had large holes in them that were plugged with wood, into which the spike was driven

Mr Dripps, the man who set up the locomotive when it came, ran it, and for years afterward was master mechanic of the Camden & Amboy, and superintendent of machinery of the Pennsylvania, still lives at Philadelphia, in the 82d year of his eventful life. Two years ago Mr. Dripps visited Bordentown, and drove a stake at the spot where the monument now stands, and another at the end of the original track, 3,500 feet away. Mr Dripps was, however, unable to attend the unveiling ceremonies, and was represented by his son, Mr. W A Dripps, the well-known mechanical engineer.

The monument is a rough granite block, having a bronze relief of the old "John Bull" and her train as they appeared sixty years ago, with the officials of the State of New Jersey aboard. This picture, from the original tracing, was shown in THE LOCOMOTIVE ENGINEER for March, 1891

The base of the monument is composed of the original stone blocks used as sleepers, and around the monument there is bent one of the original rails held by the original spikes. This rail was 3½ inches high, weighing 42 pounds per yard.

This monument marks an era in the advancement of civilization, and we trust that it may stand for ages, to remind mechanics and engineers how much they are indebted to the men who had no precedents to go by, no examples to follow; but who, groping in the dark, accomplished something of infinite value to mankind, and made precedents and experiments for future generations to stand upon and reach up higher

The Chicago, Milwaukee & St Paul road have ordered twelve heavy ten-wheelers of the Baldwin works, one of which will be a compound. The R. I. works are also building two ten-wheelers for them, one simple and one compound. This plan of the roads, of getting compounds and making comparative tests, not with other compounds, but with simple engines of exactly the same make and capacity, will do a good deal towards proving the economy of the new engines. Tests of efficiency made by George Gibbs, the mechanical engineer of the system, will be accepted by the railroad men of the country as fair, correct and honest.

C Shanks has been appointed master mechanic and master car builder of the Los Angeles Railway, in place of Geo. E. Mosher, resigned. Mr Shanks has heretofore been located at National City, Cal.

The Old Shanghai "Fury."

Some of the gray haired readers of this paper may possibly remember the engine illustrated on this page; she did a lively passenger business in New England over forty years ago

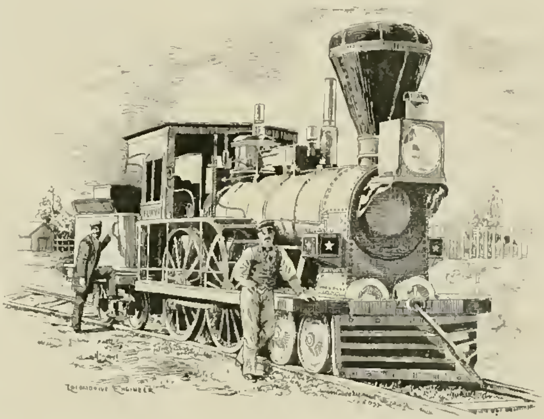
The engraving was copied from an old daguerreotype, the copy being owned by Master Mechanic Wm. H. Taft, of the Boston & Albany

The "Fury" was one of three engines built at South Boston in 1849 by Seth Wilmarth, who afterwards became master mechanic of the U S. Navy yard shops there. The other two are known to fame as the "Falcon" and the "Bee."

The forward man in the picture was the fireman, who has long since passed over to the majority The man at the gangway is Seth H. Ellis, the engineer of the "Fury" forty years ago, who still pulls the throttle on a modern 8 wheeler on the same road Mr. S A Adams, now of Boston, was general foreman of Wilmarth's shop when the "Fury" was built, and afterwards went to be master mechanic of the Boston & Worcester road, the one that owned the "Shanghais," as they were called.

From the memories of these two men we glean something of the peculiarities, the sizes, and the history of the "Fury."

As can be seen from the picture, the "Fury" was an inside connected 8-wheeler, with short front truck, her cylinders were 15x18 inches, driving-wheels 66 inches diameter, her steam ports were 8 inches long and an inch wide. She had the old-fashioned drop-hook motion, and an independent, fixed cut-off, this worked a valve in a separate chest, above the main one, as shown The "Bee" had plain drop hook, and no cut-off, but a longer valve travel.



A SETH WILMARTH SHANGHAI.

The boiler was about 48 inches in diameter, and had 120 inch and three-quarter tubes, 9 feet long. Mr. Ellis does not remember the size of her fire box, but says it looked like a salt box as compared with the one he keeps water over now

These engines all had box tenders; that is, there was no pit; wood was used as fuel, and was piled on top of the water box, a railing being used to keep it on.

Speaking of his service on the "Fury," Mr Ellis said: "I can't remember exactly how long I ran the engine, but it was about fourteen years. I ran all three of them, off and on, and also a freight engine, called the "Bison," also made by Wilmarth, but this was before I took the Saxonville train, which I have pulled continuously for thirty eight years

"Of all the engines I have run in half a century, the 'Fury' was never excelled, for her inches; but I often wonder now how we ever got along without injectors.

"The old 'Fury' was famous for snow, she dived through it as if she liked it. I often had a train of seven to eleven cars on the Auburndale run, and she had no trouble in getting them there with four or five cords of wood

"I have pumped her up by hand many a time in snow or other tight places; sometimes would jack her up so that her drivers would clear the rail, and run her that way to keep her pumped up.

"In snow I have often cut her loose from tender and plowed out a cut alone, and worked the train through one car at a time.

"We had no blowers in those days, but I used to pull her hooks back, and give her light throttle to blow up her fire.

"She had a half-stroke pump connected to crank-pin.

"While I ran her she broke two crank axles; this was the fault of the inside engine design.

"All of the class were very smart, could run like deers, and the 'Fury' had the reputation among the passengers for 'getting there,' especially in winter time."

Long years ago the "Fury," with other faithful slaves of her kind and size, went to the auction block and passed into strangers' hands, and of her final fate none of her old friends seem to know

There recently died at Philadelphia a man who has left his mark on the continent. Moncure Robinson was born at Richmond, Va., in 1802 In early life he became an expert civil engineer, and laid out many of the canals and railroads of Virginia and Pennsylvania. He was one of the first to favor railroads over canals, and laid out many of the original coal roads of Pennsylvania He was at the head of the Beaver Meadow road and was the backer of Eastwick & Harrison, the builders of the "Gowan & Mark," and other famous 8-wheelers of the early days. Mr. Robinson was a man of means, and the moving spirit in many railroad and steamship lines. His greatest work was the establishment of the Philadelphia & Reading road. He secured the money to build it, managed its location and its finances, and his foresight in buying coal lands has given the road the greatest coal-carrying business in the known world. Mr. Robinson has held many positions of trust and responsibility, but for many years has refrained from active work

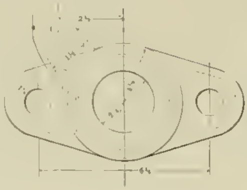
The Pennsylvania Company's Webb compound is in the shop for a new crank shaft This will be fitted with an eccentric to drive the low pressure valve gear. The eccentric is loose on the shaft, and is prevented from turning by a pin that engages stops on a collar fast to the shaft. This eccentric communicates motion to the valve for both forward and backward motion, but has no reverse gear, the high-pressure cylinders move the engine enough to move the low-pressure crank-shaft in the eccentric far enough to cause the second stop to operate the gear for the opposite motion. The engine has been running with the Joy valve motion for some time, and it will be interesting to note if the new gear is an improvement.

Many German engineers prefer masonry to iron for bridges, and they have revived the practice of building masonry bridges with lead joints at the key and points of rupture near the spring lines. The Romans used sheets of lead between cut stone, and in bridges built in England, in 1833, bands of lead were placed in the joints for two thirds of the distance above the springing line. The use of lead is for maintaining the proper interval of joint, and for uniformly distributing the pressures.—*Ex.*

If you want a copy of Phelan's Air-brake Book, at $1, you had best order now.

Some Kinks from the Manhattan Elevated Road.

Once in a while a radical departure from what has before been considered absolutely necessary is made with gratifying success. It has long been considered absolutely essential to success in metallic piston packing that there should be coned rings held into a coned sleeve by a spring, and that the whole should be protected from undue wear by ball joints that would admit of distortion of the rod.



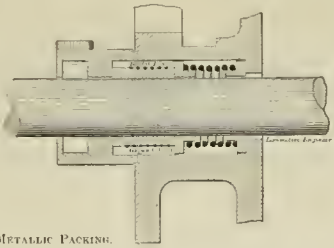
The metallic packing in use on the Elevated Road of New York City is the invention of Mr. B. F. Headley, the general foreman of the shops at Ninety-eighth street.

There are no coned rings and no ball joints. As can be seen by the engraving, the packing rings proper are held against the gland by a strong spiral spring located between the neck ring, and another similar ring sliding loosely on the rod.

Next to the gland there is a heavy babbitt ring (1 5/16" square for a 2¼" rod), and back of this ring there are the three packing rings proper. Each of these rings is in three pieces, as shown in small detail drawing, these rings break joints in their own sections as well as with each other, and when closed on the rod—when new—are left open 1/16 of an inch at each joint; this provides for wear. Each ring is as wide as the diameter of the rod.

When these rings are made they are all fastened upon a mandrel in line, and with a round-nosed tool there is a thread cut upon the outside; the thread just holds half of a No. 11 Bessemer wire. A coil spring of this sized wire is wound with initial tension, that is, so that it requires force to separate the different coils of wire, and this spring is screwed upon the outside of the three segmental rings, this serves to hold the nine pieces of metal together as if they were one piece, prevents their separating and getting out of place, and makes their handling an easy matter.

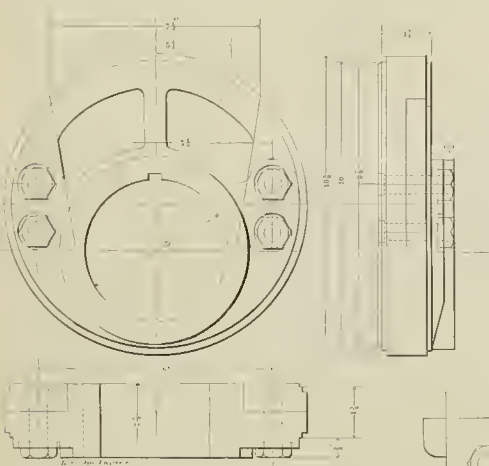
The gland, as will be seen, has an oil cup cast on it, and a large recess is formed below this oil cup, that entirely encircles the rod. A few strands of wicking are passed around the rod and fastened in the oil hole, and this "neck-tie," protected from the dirt and cinders, serves to keep the rod lubricated all around evenly.



HEADLEY'S METALLIC PACKING.

REMOVABLE ECCENTRIC.

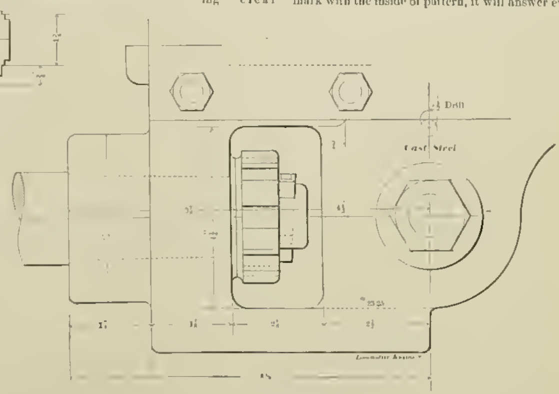
The eccentrics used on this road are small, 10⅝ in diameter on a 5" shaft. They are made in two pieces lapped together and bolted, each half passing beyond the center line of axle. This is made clear in the sketch; this construction is cheap, strong, and not liable to breakage.



ECCENTRIC USED ON ELEVATED.

PISTON ROD FASTENING.

Considerable experience with piston rods broken through the keyway called for a better mode of fastening. Mr. Headley devised the mode of fastening shown. Beam guides are used, and beam guides are noted for doing up pistons, but a cross head was made, with an opening clear through between the end of the piston and the crosshead pin. No keyway is cut, but the rod is threaded back of the taper fit, and a spanner nut is screwed upon it, backed by a strong split key; this leaves the full strength of the metal in the fit, and has reduced the breakages. The piston rods are fastened into the spiders in much the same way.



PISTON ROD FASTENINGS.

Locomotive Cab Construction.

BY WM. NEWTON.

In connection with my duties as pattern maker, I have to see to the building of cabs, and have noticed that to the average carpenter (or rather car builder) cab building seems to be somewhat of a mystery, probably from not having proper confidence in themselves, or not having studied its construction, they are apt to think it requires more skill than they possess. Hoping to give some useful suggestions, I send you results of some of my experience.

In the annexed drawings, Figs. 1, 2 and 3 give general views of an ordinary modern cab, such as is used on large passenger and freight engines, it is known as the closed back type, having doors and sashes as seen at Fig. 3, instead of paneled framing, known as an open back. My experience is confined to a railroad repair shop, where the practice must necessarily differ in some points from that in the locomotive building shops. It will be seen that, instead of the old-fashioned angular roof, it is curved, the only improvement that I can see in the change is it gives a little more space overhead inside. The curved roof cannot shed the rain-water quicker; it takes more material to cover, and also more labor in preparing plates, carlings, etc.

Our first thing will be to make out a bill for the material, which is generally of ash or oak, except the cornice trimmings, water table, etc., which are of pine, and should be got out in numbers and kept in stock. White wood makes good panels, and cherry is often used for sashes, but ash is doing good service for same with us, and it looks nice, simply varnished, in contrast with the framing, painted black.

The mill carpenter will want a template to shape the plates, carlings and tail plate, besides the end facia (see *a*, Fig. 1, *a'*, Fig. 3, and *a''*, Fig. 4); if we make a pattern for the carlings, allowing it a few inches longer than the exact length of carlings, but the same depth and about ⅞" thick, it will answer for all; by marking the outside curve, and then marking off width of tail plate and facia, and then mark with the inside of pattern, it will answer every purpose; this pattern is screwed on to each piece, and used as a guide whilst dressing them on shaper, hence the necessity of its being so thick.

When the framing is ready, the next step will be to "lay it out." Suppose we take the front first, and commencing with the stiles we arrange them in pairs, marking the face and one edge of each, then take a rod previously marked with all the mortises, heights, etc., transfer same to the work, and square across all four, two of which must have tenons to engage mortises in plates; next take one of the muntons and mark the length between shoulders, not forgetting to allow again on the inside the depth of rabbet, as shown in detail, Fig. 9. Where the different pieces are chamfered clear through, a pencil mark run through will be enough, but where stops must be made, as on the stiles, it is well to mark their position at the same time the mortises are located. The thickness of frame being 1⅜" the mortise will be ⅓ of same, equal $\frac{7}{16}$", and as the doors are 1½ thick, one tooth of mortise gauge will answer for rabbet. The same applies to the laying out of back and sides, with the exception of rabbets for sashes; those in sides are arranged for the middle one to slide (see details, Fig. 6). The munton nearest the front measures less than the rest of framing; this will be understood. If we again refer to Fig. 6, also Fig. 8, we shall see an arrow pointing to iron track and brass plate; the track is ⅜" common band-iron screwed to rail, and the brass plate is put on the bottom rail of sliding sash, two plates to each; the part turned up is driven into a saw-kerf made in the end of seeing the mortises will be placed equidistant between shoulders afterward.

If you can conveniently have joint bolt holes bored by machine, do so through stiles and the top plates only, boring the rest, and cutting out mortise by hand. If you notice, the front bolts against the sides, and the back bolts in clear of sides, consequently the bolts must project far enough to engage the front in the former, and the sides in the latter case, which will be two each side of front, and only one each side at back. I use hard wood blocks for the purpose, just the thickness of side when I first "glue up" the work, and by the time everything is ready to put together (the cab) the glue will be set, and the blocks taken off and kept for next time.

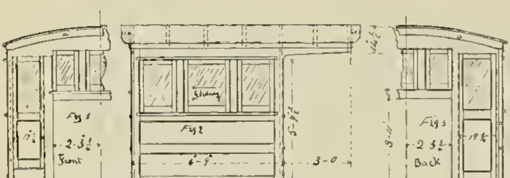
It is best to fit all sashes and hang all doors whilst the frames are lying on the horses. I have plates of iron screwed on the top edge of rail under the front doors, to prevent the wood being worn away.

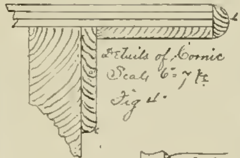
The water table fastened to rail under sashes front should be screwed on without glue, to allow its removal when fitting the "apron sheets," one each side of cab, and bolts passing through same, also through lugs tapped into boiler.

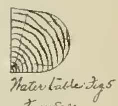
with under edge molded same as *c*, Fig. 4. The circular facia is put on next; then a piece ⅜" thick by 4' wide is bent and well fastened with screws, nails and glue to under side of roofing, and after trimming the ends of roof boards fair with edge of same, and cutting off the corners of roof to receive circular blocks, and mitering with side and end molding, we are ready to complete the cornice by fastening *b* in position, which is a half-round molding steamed or wet with hot water, and well nailed on, bending the same as you nail; care must be taken to let some nails enter both boards of roof, thereby securing the whole.

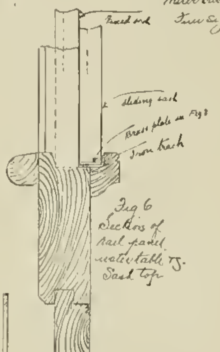
The tail plate is dovetailed, and screwed into the ends of side plates, and of course must be fixed in position before the roof could be put on. Generally we put a quarter round molding around the angles inside, and miter the same to bell-board, which is 10' wide and cut in between back plate and first carling. The details show the panel, also cross-section of sash stop, which is screwed on to frame on top and bottom only.

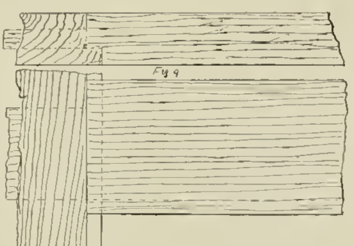
In referring to the method of "gaining" tenons on to the depth of rabbets, as shown at Fig. 9, I was surprised to notice that engines coming from three different builders had square shoulders to











stile about ⅜" in from edge, and the two screws hold it firm. The plate shown in Fig. 7 is used to secure the fixed sashes, two hickory pins are inserted in one stile with holes to match in frame, and the plates are let in across the joint on the other side; it keeps them in place, and is quickly applied.

The doors are hung to open out and against the boiler, whilst those in back open inward. I may remark here that the engineers and firemen do not like this kind of back, as it deprives them of some room which the open kind allows them to use; often their locker is fixed in the back corner, but cannot be with this class.

In laying out the sashes, I find it is best to mark the rabbeted side as face, it gives a better opportunity to gauge for mortises and tenon, it being understood that it is rabbeted and molded before laying out; the rails have a square shoulder, the mold is cut away on stile and mitered at the corners; the side sashes have muntons in them, not shown in our drawing, the mortises for which are laid out after the rails are tenoned, for the reason that only one rail is laid out for tenon; the rest for that size are cut to the length from stops set to the pattern one, therefore less care is exercised

Now, let us suppose that everything is ready to go together, we bolt the four frames together, and after squaring the cab, which may be done by straining a suitable piece diagonally, forcing cab square with a wedge at end of same; then bore all wood screw holes where necessary, and run in screws, after which loosen bolts and screws for one joint, force apart just far enough to glue, then retighten, proceed until each corner is glued and screwed together. I should mention there must be a temporary strip screwed across the back to keep the stiles in position, this same piece should remain until cab is fastened to footboards of engine.

We are now ready for carlings; they should have their ends bored to receive screws, and a half round molding same as we use for cornice *b*, glued and nailed to under edge; this saves the expense of ceiling the cab inside, and strengthens the carlings. I need not dwell on the way they are fixed—they are simply let into side plates, and screwed in position. The roof is made of matched ceiling, planed on the under side only, and extended over ends to give a 5' cornice, it is dressed off true with side plates, and the side cornice molding, which is a piece 1¼' x2' with outer edge molded with same cutter as *b*, next the side facia 2¾' wide by ½' thick,

their cab framing, and stopping all rabbets, leaving short pieces to be soon jarred off, besides making it very inconvenient to work, especially where we have two or three mortises in one piece. If it is found inconvenient to adjust the tenoning heads of machine, then have them cut square, but the depth of rabbet longer, shortening the one shoulder by hand.

The Boston & Albany road has recently been laid with an extra heavy steel rail, and it was at once noticed that engines with well-worn tires were rapidly chewing the corners off the new rail. Orders were at once issued to turn all tires before they had worn $\frac{3}{16}$ of an inch. Most of the driving wheels have already gone through the shop, and you can't find a bad tire on the road. Perhaps if $\frac{3}{16}$ of an inch was the limit of wear on all engines, it would not be so hard to keep up frogs and crossings.

When babbitt starts to dropping silver dollars on the ties, throw out all there is before you stop; if you don't, you will have some fun clearing out the oil hole, etc. As long as a bearing will and can take oil, babbitt will not go.

Tests of Iron and Steel.

The committee appointed by the Railway Master Mechanics Association to investigate the subject of blue shortness of iron and steel have laid out a most comprehensive plan of work. If the tests are carried out as thoroughly as the plans call for there will be material collected for one of the most valuable reports ever submitted to an engineering society. The committee consists of William Smith, chairman; J. N. Barr, A. W. Quackenbush, P. H. Peck, D. L. Barnes.

The following makes of sheet steel, which are those most commonly used by railroad companies, will be tested: Shoenberger, Spang, Park Brothers, Carnegie, Phipps & Co., all of Pittsburgh; Otis Steel & Iron, Cleveland, O., Luken, Centerville, Pa., and Wellman's, Chester, Pa. The work to be done is:

Determine the temperature at which blue shortness manifests itself in a maximum degree.

Determine the tensile strength of iron and steel at this temperature of maximum effect; also, at the same time, elongation and reduction of area.

Determine the effect of bending on samples of the same classes of steel at ordinary temperature.

Determine the effect of bending on samples of the same classes of steel at 30 degrees below zero or more.

Determine the relative endurance of iron and steel stay-bolts after the threads are cut thereon by oft-repeated vibrations inside of the elastic limit, and as nearly as possible with the same degree of bending and conditions that exist in a locomotive fire box.

Determine some means of testing steel rivets to show that, while they have the necessary ductility, they are probably unfitted for boiler work.

Determine some means for detecting laminations in steel boiler plates.

What is the best method of procuring samples of boiler sheets from steel makers in order that there may be no uncertainty regarding their identity? Such samples should not be annealed after being cut from the plates.

What is the best specification for fire box steel?

What is the best specification for shell steel?

What is a good practical test for temperature to be used in a boiler shop to prevent hammering sheets when there is danger of blue shortness?

What is the proper test for steel and iron axles: a small number of large blows, as now used, or a large number of small blows, as is preferred by the Chicago, Milwaukee & St. Paul road?

Can the presence of steel in wrought-iron scrap be detected?

What is a satisfactory test for draw-bar links, and will an old link, which has been used, stand as much as a new link?

What is a satisfactory test for draw-bar pins?

What is the comparative strength of malleable iron, and good cast cylinder iron and cast-steel?

What are the comparative weights of these three metals for equal strength?

Can malleable iron be made more than ⅜ of an inch in thickness?

Is it practicable to etch the ends of all steel crank-pins before they are put in service, in order to determine whether there are longitudinal cracks?

There is a wide difference in the amount of phosphorus and sulphur in fire box sheets by different makers, and it is claimed that there is a vast difference between steels made by the basic and acid process. It is stated that the acid process is vastly superior, as it reduces materially the amount of phosphorus and makes better plates for fire box service. It is stated to be less brittle under a high pressure.

If it is found that fire box plates have a high temperature in service, would it not be well to examine the basic and acid plates to determine their relative values under such heating as is attained in a fire box?

If possible, test the temperature of fire box plates with a heavy fire in progress.

State various curious fractures of iron and steel, and explain reason therefor. The following have been collected:

(*a*) Laminated fire box steel, with a hard and soft structure. C. & N. W. shops.

(*b*) Rivets cracked on inside in bending. C. & N. W. shops.

(*c*) Section of thick piece of malleable iron showing how far the annealing effect penetrates. D. L. B.'s office.

The Telephone Patents.

The basic patents of Bell on the telephone will expire in a couple of years, but the Bell Telephone Co. have enough other patents that "improve" to give them a long term on the monopoly. They have made millions out of it, but they want more. The *Electrical Review* backs them up as follows:

"The fundamental telephone patent will expire in 1893, when the simple method of transmission by magneto currents will be open to the public. The practice of extending the term of patents is one which has fallen into desuetude, and nothing is more improbable than that it would be revived in a case like the telephone. The inventor of the telephone has been enriched for his gift to the public, and deservedly so. With this fact established the chances of extension fall. It must be remembered, however, that the telephone industry of to-day has only attained its present degree of perfection by the coalition of many improvements upon Bell's basic idea. There are hundreds of patented inventions which have been acquired by purchase, which will insure the Bell Telephone Company a firm grip on the business for many years after the fundamental patents expire. First in importance are the microphone patents and the induction coil for raising the tension of feeble microphone currents, and, secondarily, numerous switches, switch-boards and systems which enable the present company to give good service. A competing company can only offer the public magneto transmission minus these improvements, which, of course, will give only inferior results. The bitter tone which characterizes most of the discussions of this subject is unwarranted, and proceeds from a misapprehension of the true position of inventors toward the public. Patent statutes are not purely a benediction of congress on a deserving class of citizens; they are based upon the theory that the public gets a full *quid pro quo*. In order to stimulate progress in the arts an inventor is offered protection of the results of his genius for a period of seventeen years, on condition that he discloses to the public the secret of his invention. The public is the gainer oftener than the inventor, for it frequently happens that an inventor is years ahead of the age, and after securing his patent finds that the times are not ripe for its adoption, so that it lies fallow and comes into use only after the period of protection has expired. In the telephone case, however, the invention at once sprung into general use. Much of this was due to the importance of the invention and much to the energy of the promoters. It is proper that both should have met with financial prosperity. Mr. Bell's success has inspired with enthusiasm thousands of inventors whose efforts have enriched the public. The inventor, as a rule, is poorly rewarded. There are a few cases of distinguished success and we all hear of them; but of the four hundred and odd thousand who have taken out patents, who knows how many have scored failures? Let us rather congratulate those who do succeed than begrudge them an equivalent for services rendered."

To Be the Longest Continuous Railway Line.

The construction of the world's longest railroad is progressing rapidly along the river valleys and across the steppes of Siberia. The western extremity of the road is the mining town of Miask, on the eastern side of the Ural range, and its eastern terminus is at Vladivostok, on the Sea of Japan, making a total length of 4,785 miles, which is nearly twice the length of the Canadian Pacific. Its cost, including surveys, grading, building, stations, rolling stock, and, indeed, everything needed for its construction and equipment, is estimated at $183,825,000—an enormous amount, but profitably invested, and far less than the cost of a useless European war. The country through which the road will run presents no great engineering difficulties, and across the vast plains it will hardly require the grading of a roadbed. It is also for the most part fairly populous, much of it being very fertile and the rest rich in minerals, so that along its entire route the road will open up and develop a country of magnificent resources and of almost inexhaustible agricultural and mineral wealth.—*Exchange.*

Losing a Load.

Once, a long time ago, when the Denver & Rio Grande had just built their first line over the snowy range at Veta Pass, a curious thing happened to a freight train.

Three engines did pretty well to get ten loads on the summit, especially in stormy weather, and twenty empties were enough, and to spare, around the corners and elbows of that steep and winding cow-path.

One night Billy Jamison's train crawled up to the top, and while the helpers got out of the way, and the regular engine got her dose of oil and water, Billy walked ahead through the snow.

When he got to the engine he scratched his head and asked the engineer how the train pulled.

"Hard, you must have had brakes set."

"It's *over*, then," said Billy; "it must be *over*, and standing orders to take empty flats the other way."

"What's that?" asked the driver.

"I've got an empty flat car back there. I don't know where I got it; the boys said they had ten straight loads leaving La Veta."

Bill walked back and counted the cars, and came ahead to the engine again.

"There's only nine loads and an empty. I'll look over my bills."

He climbed up in the gangway, took out his train book, and counted over his bills, calling aloud:

"Coal, coal, merchandise, coal, horses, coal, boiler; one boiler, wt. 29,000 pounds, flat, 16-34; that's the flat, by thunder."

With one of the helpers they crawled slowly down the mountain, hunting one car-load of dead freight that had escaped.

A mile back, at the point of Dump Mountain, there was a twenty-foot swath cut through the snow and brush from the track down the mountain side, that, with the broken stakes on one side of the flat, told the story.

In the spring they hauled the big boiler out of the gulch below with mules, it was little the worse for its roll in the snow and rocks.

Steam-heating men are approaching Mr. James T. Furber, general manager of the Boston & Maine, these days, with bated breath, expecting to hear talk that is more emphatic than refined. They feel drawn to that part of New England where Mr. Furber holds forth, because they know that power greater than their own is making steam heat a living issue even for the Boston & Maine, but the wrestling of the head of the road with the inevitable is said to be fearful to behold. We would say to our steam-heating friends, be of good cheer. The man with the most assurance will get there.

Again we would remind the enthusiasts who are going to accomplish wonders with a long valve travel that they have forgotten one important item, *i. e.*, the steam shovel to fire their improved engines with.

Correspondence

Those Glasses Again.

Editor The Locomotive Engineer:

In your comment on my letter in regard to those worn lubricator glasses, you said that the glasses were worn just where protected by rubber gaskets. Now I think that is a mistake. They are not worn *where the gasket is around* them, but *above* the gasket. The glasses are all cut so that they extend past the gasket from one-quarter to one-half an inch, and it is this part that is worn away. Please examine and see if this is not the case.

Seymour, Ind. SAM'L M. HUFFMAN.

[Why not make the glasses short enough so that there will be no end to cut?]

Why Kalfus' Injector Wouldn't Work.

Editor The Locomotive Engineer:

In answering Mr Kalfus' injector question, would say that if all joints were tight, and injector was in good order, the check valves on boiler had not the proper lift, allowing too much back pressure. EDW. GIBSON.

Wilmington, Del.

That Waste Plug.

Editor The Locomotive Engineer:

Replying to the inquiry of Mr. Paul Synnestvedt, in the October number of THE LOCOMOTIVE ENGINEER, I would say his question is pertinent. Mr. Scott, to whom the matter was referred, states that the bunch of waste was found by unscrewing the union nut from car drain cup, massed in its meshes; that, in his opinion, the air exhausted from rear end of train pipe drew the waste out in the pipe in such a way as to admit of its passage, while if drawn from front end of train line, caused the fiber of the waste to draw into the meshes of drain cup strainer and clog its passage.

Nickerson, Kan. T. PAXTON.

Who Can Explain This?

Editor The Locomotive Engineer:

I have been running a Baldwin motor for some time. They are saddle tank engines. At the engine house there is a water tank, which is supplied with water siphoned into it by steam from the boiler of motor. This water is allowed to get cold before using it, but in two or three hours it becomes so hot that the injectors will not work it. Now, at one end of the line there is a tank which is supplied from springs by a ram. This water never gets so hot that we cannot work it, unless the engine stands under steam several hours. Can you explain the cause? The injectors are No. 3 Monitors, and are in good condition. Understand, the conditions are the same, the engines use a tank of water—making a round trip, which is about seven miles—and make steam as freely with the water of one tank as the other. The cold spring water is impregnated very slightly with lime, the other shows no trace of it. JAMES H. HEVEY.

Rome, Ga.

Taking Chances on His Skin.

Editor The Locomotive Engineer:

We have an engineer here who is running an engine that, according to all known laws, ought to break a rod or a pin and send him to glory and the engine to the scrap heap, but it is not his fault entirely.

His engine broke down recently and got a new main pin; the brasses of the side rod were left very tight between the pins and loose in the straps. This he reported and kicked about, but when the roundhouse gang attempted to line up the rod they could not get the strap bolts out—they were partially sheared, and they broke some of them. Being short of engines, they sent this one out on a fast freight in this condition, and she is going out again.

Should the side rod break, the engineer will probably get ten days for "injudicious use of sand." Don't you consider this careless?

Rotterdam Junction, N. Y. IGNORANCE.

[Should the side rod break, the engineer may be so sure of his future that he won't care for the ten days' lay off. We do not consider the conditions mentioned as "careless"—they are criminal.]

Eccentric Moving.

Editor The Locomotive Engineer:

In reading Brother Hitchcock's article on moving eccentrics, an idea struck me which I will advance and see if any one thinks it worthy of consideration. We will suppose the engine is blind, and I wish to give her ⅛ lead. I would put reverse lever in extreme forward notch, pinch engine ahead and catch front center. Now before moving eccentric would mark it on shaft, then move it forward until I obtained the required lead, and note how much my marks had separated, then mark it on shaft again plainly. Would then loosen set-screws, disconnect eccentric blade from link, and push eccentric out into the middle of shaft. Would then mark and move the back motion eccentric the same distance I had the forward one. I think this would give the exact lead without a second trial. Am I not correct? I thank Brother H. very much for his information. J. W. KALFUS.

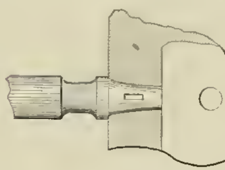
Aspen Junction, Col.

On the Breaking of Piston Rods with Laird Crosshead.

Editor The Locomotive Engineer:

The Laird crosshead was at one time considered the crosshead for locomotives whose design called for one of the driving wheels to be placed inside the guides, which limited the width of crosshead and guides that could be used. But time and use have developed defects in it that are causing it to lose its once popularity. One of the defects is the strain it permits to be put upon the piston rod at the shoulder next the crosshead, causing the rod to break at that point. To remedy this, some roads put a fillet on the rod in place of the square shoulder, and others turn the shoulder off, tapering the rod back for some distance from the crosshead. Either method is superior to the square shoulder, the first is not of as much benefit in preventing breakage as the latter, while if the taper in the crosshead fit of the rod is not sufficient to withstand the compression the loss of the shoulder is apt to cause the piston to work loose in the crosshead.

It is well known that the cause of piston failure with the Laird crosshead is due to the overhung crosshead swing when the piston is on the return stroke. If the line of force between the piston head and crank-pin could be maintained there would be no trouble, but as this is a condition that cannot be maintained in a locomotive in service, it must result in a bending strain on the weakest part of the line, and that is at the shoulder on the rod. The four-bar guide effectually resists the line bending, as also does the top guide in use on some roads with the single bar on top and bottom of the crosshead, putting a fillet at the shoulder strengthens the part but little, and turning it off, beside the evil mentioned, while it distributes the strain over a larger distance, still leaves a sharp point at the crosshead, at which the bending must suddenly cease. The object is to divert the strain from the rod at that point, and to distribute it over as large a portion of the rod as possible, and this can be done by turning the rod down, as shown in the sketch.



There need be no fear of weakening the rod. As the measure of the strength of a body must be its weakest part, and as the piston's weakest part is at the notorious keyway, the rod can be reduced to an area a little above that at the keyway with safety, but it is not necessary to approach that; reducing the rod to a diameter less than that at the crosshead at the shoulder, will divert the strain from that point, and the longer the reduced portion can be made the better it will be.

Albany, N. Y. J. D. C.

What do Water-brake Handlers Think of This Theory?

Editor The Locomotive Engineer:

I do not agree with you in your answer to Question 65, as I hold the water-brake *does* have influence on the injector. T. J. H.'s injector breaks for the following reason, when running in reversed position. The cylinders of a locomotive running in this position serve as two air-pumps, by which compressed air is forced into the boiler through the dry pipe, the mouth of which is located in the same dome that the dry pipe to injector is located. The air thus pumped joins with the current of steam passing down the dry pipe of the injector, causing it to "break," as no condensation takes place. The water brake prevents this, for the following reason: The *jet* of water turned into the exhaust pipes is converted into steam. *This* is forced into the boiler through the dry pipe, and this steam may join with that on its way to the injector, but will not cause it to break, as condensation *will* take place.

Huron, South Dakota. W. W. W.

[How does W. W. W. account for the engines that are let down off mountains with the water-brake with the throttle closed solid? Very few men will use more water in the cylinders than will work out of the cylinder cocks.]

Enginemen Who Missed Their Calling.

Editor The Locomotive Engineer:

I don't know what I said in my article that should offend. I did not say all firemen, only quoted an individual case; but I do say there is a class of men who would never make good engineers if they had a locomotive shoved down their throats, and any observant M. M. will say the same.

The whole path of life is strewn with the wrecks of men who undertook to do something they were not fitted for. The writer was one of a lot of apprentices in a railroad shop; one of the number was the late Wm. Woodcock, Supt. of M. P. of the C. of N. J. He had the five talents and became a master mechanic. Of the rest of us, some had only one, others none, and what was the result? All started out with the same chances. At the close of our four years apprenticeship some of the boys abandoned the business because they were failures in a machine shop. One of them would have made a good lawyer, the others had better remained on the farm. One did his first firing for the writer of this, and at last accounts was pulling passengers in Texas; he was a better engineer than machinist. Under the circumstances I don't know why any one should object to my claiming there are men who will be failures as engineers.

Some time ago the claim was made that railroad companies were getting things down fine, and that the boys would have to keep step; and so they will. The status of the American locomotive engineer is being raised to a higher standard, and it is right it should be so; furthermore, the system of examination, other things being equal, is going to help bring it about.

Who are the men that will be called on to take the throttle of one of our modern flyers? It is not going to be the oldest man in all cases, unless he is up to the standard; it is no place for an old man in his dotage, a young man in his nonage, a nervous, or a reckless man. It requires a clear, cool head, with good judgment and keen sight—a man that can think and act at once, a man of nerve. It takes *sand* to run one of these flyers; in fact, it requires certain elements in the make-up of the man that his examination, or the time card, cannot supply. Mr. Bruce quotes men on the P., C., C. & St. L., who may not know much about petticoats, but who are able to give me some pointers. That is all very true; a man need not know a great deal to tell me lots that I don't know. I said a railroad man would not have to draw very hard on his imagination as to the *result, if that side rod had slipped off the pin.* The collar on the main pin was keeping the forward end of the side rod on, and must have had a tendency to keep the back end on, but that don't alter the desperate risk the engineer took in running a passenger engine with an eight-foot side rod and no collar on the back pin, for over a hundred miles.

In regard to flagmen, I do not condemn them as a class, but if there is a murderer in the sight of God and man, it is the flagman who neglects his duty in times of danger, and causes the death of a score of better people.

Men have died at their posts on railroads, but they did not do it from choice. They stick by their train with the faintest hope that they may get out all right, and try to get out when it is too late.

Corry, Pa. W. DE SANNO.

Same Disease As Other Air-brakes.

Editor The Locomotive Engineer:

On a three-car passenger train on a mountain road they had trouble with the air brake on a sleeper and cut it out.

This is the way she acted. In going down a long hill the engineer would apply the brakes gradually by letting about 8 pounds escape from train pipe, service stop, bringing his handle back "on lap."

The brakes on first two cars would respond, the brake on the sleeper would not commence to set

In perhaps half a minute, or less time, the sleeper brake would apply with a bang through the quick-action principle of triple valve.

The train pipe pressure would reduce about 10 pounds—in applying the sleeper quick-action—and this sudden reduction would apply the brakes on first two cars quick-action, and the train would almost stop before the brakes could be released.

Everything was in normal condition except the sleeper. What was the matter?

Deadwood, So. Dak. BLACK HILLS.

The Air-brake Nut.

Editor The Locomotive Engineer:

In reply to the article in the last issue of THE LOCOMOTIVE ENGINEER, under the caption of "A Nut for Air-brake Manipulators," would say that the trouble was remedied by removing the obstruction in the hose, which partially clogged up the opening.

It is quite evident from the fact that there was sufficient air in the train pipe to set the brakes on the cars at the rear end of the train, that there was an opening through the entire length of the train pipe which permitted the air to flow from the main reservoir to charge up train line and auxiliary reservoirs. The size of the opening through or by this obstruction might have been such that when engineer's brake valve was thrown to the full application position the air could not pass fast enough from behind the second car towards the engine to make a sufficiently quick reduction to move the triple valve pistons enough to close the feed ports, in which event the air as it gradually reduced in the train pipe would also cause a similar reduction to take place in the auxiliary reservoirs by the air returning to the train line through the feed ports provided for charging them. In this case it would be impossible to apply the brakes from the engine behind the two forward cars, but it would be possible to apply the brakes by opening stop-cock at rear of train or uncoupling hose at any intermediate point, and, upon closing this opening, air from the main reservoir would gradually accumulate in the train line until such time as the brakes were all released. K.

Chicago, Ill.

Water-brake Manipulation.

Editor The Locomotive Engineer:

I am glad to hear from the boys on the water-brake question, but cannot agree with Black Hills on certain points. He says: "No water should strike valve or cylinder for water-brake to work successfully. What you want to show at cylinder cocks is steam, not water When an engine's valves have been washed with water the reverse lever will pull you off the seat," etc.

I think there should be sufficient water in cylinders to show at cylinder cocks continually while using the water-brake. In regard to reverse-lever pulling me off the seat, it was caused by cylinders not getting any water, instead of valves being washed with water, for, as long as I had it coming out the cylinder cocks, I had no trouble with the lever, but if the water stopped it would begin to buck. If Brother B H.'s idea of using steam instead of water is correct, why would it not be better to have the valve placed on top of boiler, instead of below the water line? I think the theory advanced by George Shuart is very good, but there is not enough straight track here to give it a fair trial; but the engine I spoke of as handling her water about right, did not throw it out on the stack on the curves or straight track either, but it came out of cylinder cocks as long as I had the water valve open. Of course I could throw it out by giving her more water, but, by being careful, could keep a sufficient supply in cylinders, and not wet the jacket. Had it not been for this engine I should have taken it for granted the water-brake could not be used without drenching the jacket; but if one engine will handle her water in this way, why cannot all be made to do the same?

I often get into an argument with the boys on the water brake question, and most of them are against me, the majority of them think it is very injurious to valves, cylinders, packing, etc. I claim that, if properly handled, it is not. My idea of proper handling is this: On approaching the summit, I open water valve until exhaust sounds like boiler was being overpumped; I then know that water pipe is not corroded or frozen up. As soon as I start down I give the valves a good dose of oil through the cups, open water valve, and wait until I think exhaust cavities are about full, or until I see a spray shoot out the stack. I then reverse engine and start lubricator, and gauge the supply of oil by the way my reverse lever acts. On reaching the foot of the hill I close water valve, and run far enough to get water out of cylinders; then throw lever ahead and churn water out of exhaust passages, then give her another dose of oil through the cups Now I claim that the only way it hurts the valves is, they wear faster by the reverse lever being hooked up coming down hill, than if valves were at full travel. R. B. Reading's answer to my injector question is probably correct; yet the machinist told me he could find nothing wrong. The steam pipe and valves between boiler and injector were all right J. W. KALFUS.

Aspen Junction, Col.

Explanation of Air-brake Tricks.

Editor The Locomotive Engineer:

Having had a little experience with the automatic air-brake, I thought I would dig up my little hammer of knowledge and try to crack "G J. H.'s" air-brake nut, which appeared in your November issue. If I rightly understand him, he says, where pressure on train pipe was reduced through brake valve on engine, brakes were applied on the two head cars only, but when reduction was made through stop-cock at rear of train, brakes were suddenly set on whole train (15 cars). That being the case, I would locate the trouble between the second and third car from engine, possibly some obstruction in hose or train pipe, which prevented sufficient reduction being made back of that point to cause action on triple valves—that is, when the reduction was made from engine, but when made from rear of train the obstruction (if such it was) did not prevent the air from passing freely from train pipe, thereby setting brakes on whole train. My reason for thinking the trouble was as I have stated is, that I once had a like experience myself, and, with your permission, I will relate the circumstance for the benefit of others, as the same thing may happen again.

The action of the brakes in my case was exactly the same as stated by "G. J. H.", when reduction on train pipe was made from engine, the brakes were applied on three head cars only; but when made from rear of train, the brakes were set on whole train (17 cars), and that, too, with a vengeance. After testing the brakes in the manner stated, I came to the conclusion that the trouble was between the third and fourth car from engine, and upon examination I found the difficulty in hose on forward end of fourth car, the hose being an old one, the inside rubber lining was cut or broken where hose was clamped to nipple on train pipe, and loosened up some four or five inches inside; so when pressure was reduced from engine, this loose rubber would roll up in a wad, completely stopping up hose, thereby preventing reduction being made back of that point sufficient to cause triple valves to act; but when stop-cock at rear of train was opened, the force of the air in that direction would cause the loose rubber to straighten out, allowing the air to pass freely from train pipe, setting brakes on the entire train. Defective hose being replaced by a new one, there was no more trouble with the brakes.

With regard to De Sanno's question, I can see no cause for driver brakes to act as he stated without some sudden reduction of pressure from main reservoir or train pipe, perhaps his engine was arranged like some that I have seen: a small pop was placed in end of main reservoir, or train pipe in cab, and set to a certain pressure; when pressure would exceed the limit of pop the air would suddenly escape and blow down to pop limit again. I have seen engine tender brakes fly on from this cause and remain on until pressure was again equalized, which generally required but a few strokes of pump.

I hope some one can explain, as information is what we are all looking for.

Colorado Springs, Col. F. F. D

The "True Inwardness" of Cunningham's Breakdown Puzzle.

Editor The Locomotive Engineer:

I will give you the "true inwardness" of the Cunningham puzzle. In January, 1871, Alex. Cunningham was hauling passenger trains on the Mobile & Ohio R. R. between this city and Columbus, Ky. His engine was a "Danforth & Cooke," built "before de war"; it was a 14'x22" cylinder, and a 5½-foot wheel, and was burning wood.

At this time passengers and baggage were transferred from Columbus to Cairo by the steamboat Geo. Anderson, and the steamboat waited one hour only for the trains from Mobile when late. One day Alex left here on the P. M. train, which got to Columbus after dark. After proceeding some distance from here, he all at once discovered that his engine did not have a full complement of exhausts, and, as a natural consequence, stopped to find out the cause. He looked at his eccentrics, and found them O. K. (which, by the way, were not keyed on). He then formed a natural conclusion, that the yoke on right valve was broken, and did just what any *good engineer should have done, i e.*, he knew his quickest way was to disconnect that side and proceed with the other, and not get behind his hour which the boat waited for him. This he did in a most satisfactory manner to all concerned.

After arriving at Columbus he put his train away and reported, "*Valve yoke broken right side.*" His train was not due to leave until the next afternoon. The next morning the foreman of roundhouse had a machinist take off the right steam chest cover, and when Alex. got there they commenced to "guy" him, as is usual with machinists when they think a "fireman engineer" has made some mistake such as it would be impossible for a "machinist" to do.

Alex. looked at the yoke, and failed to see anything wrong with it He then told them it must be in the cylinder. The foreman insisted that he "just dreamed" that there was something the matter. So he had the engine connected up to show that there was nothing the matter; but Alex. insisted it was in the cylinder, and had them take off the head while they were waiting for steam. The engine stood on front center on right side. When the cylinder head was taken off the piston was apparently O K, and the head was put on by the machinists—who were having lots of fun.

When steam was up, the foreman had Alex. move the engine, to show him that there had not been anything wrong; but the engine started, and it would have done *Puck's* artist good to see the satisfaction there was on that foreman's face; but before one revolution was made the expression changed. Three exhausts was all they could get out of that engine—then the guessing match begun.

Some thought the yoke was cracked, and sprung, etc. The foreman insisted that the eccentrics were out, so he went under engine to see, all hands had ideas of their own. Alex. insisted that it was in the cylinder, and that made the machinist mad to think one could doubt his say so, and he had said, "There is nothing wrong in there." The foreman ordered the chest cover taken off again, and Alex and his fireman took off the cylinder head and found piston same as before, looking O K., and the machinist was more than "jolly" to see that he was right. Alex said he would look at the packing (which was of the Dunbar type), so he put the socket wrench upon a follower bolt, and his fireman took the regulation steel bar to take out the follower bolts. When he pulled down on said bar, behold the piston head turned around in cylinder, and further examination showed the rod had broken off close to the piston head, and had gone far enough ahead to allow the packing rings to drop into the counterbore, which was made with a square shoulder, like all "Cooke" engines, and many others at that time, as it was believed by many engineers that the packing would run much better with such counterbores.

Should you or any of your readers have any doubt about this "railroad story," I will say that Mr. Benj. S Herring was M M. at the shops here, and that James Benson was foreman of engines, or roundhouse, as it was then called, and his brother Samuel was general foreman of the back shop, any of which will give you proof, should you feel like doubting an engineer's story.

Hoping that the Traveling Engineer will get his "puzzle" in better shape next time, and that this one has done some good in causing some thinking to be done by engineers and firemen.

Jackson, Tenn. "ENGINEER."

["Traveling Engineer," after reading the above, says that it must be right and his informant wrong in saying engine made a second trip. T. E. says he has been "guyed" pretty thoroughly, but that he has been pleased to see the way the boys take an interest in practical discussions—especially when they are impractical.]

Danger of Brake Application from Rear Car.

Editor The Locomotive Engineer:

In THE LOCOMOTIVE ENGINEER for November, on page 207, I find a letter from G. J. H., San Bernardino, Cal., asking for an explanation of the following phenomenon:

On a fifteen-car freight train equipped with the Westinghouse quick-acting air-brake, in testing brakes previous to descending a grade of over 200 feet, after exhausting thirty-five pounds of air from the train pipe through the engineer's brake valve, it was found that only the brakes on the two first cars next to the engine had been applied. At the same time an emergency application was obtained by exhausting the air from the train pipe through stop-cock at rear end of caboose. The cause of the above was undoubtedly an obstruction between the triple valves of the second and third cars, said obstruction very likely being at air strainer of the third car. On page 167 of THE LOCOMOTIVE ENGINEER for September is a letter from Mr. T. Paxton, Nickerson, Kan., describing a similar occurrence on the A., T. & S. F. R. R., in which, on a thirty-car train, having twenty-five cars equipped with the Westinghouse brake, the brakes on only the first seven cars could be applied from the engine, while *all* the brakes went on with a "snap" when the rear stop-cock was opened.

Upon examination the cause of the trouble was found (to quote Mr. Paxton's words) to be "a plug of waste in the train pipe behind the strainer, which drew into and stopped it up when the train pipe pressure was reduced from the front end, preventing any reduction back of that point, but when the air was exhausted from the train pipe through the rear stop-cock, the plug was drawn away from the strainer, allowing a uniform reduction to be made the full length of the train pipe, and the consequent application of the brakes."

The above two cases occurring in practice should be taken as warnings against the very dangerous custom, prevalent in some quarters, of testing the air-brakes from the rear of the train; for, under conditions similar to the foregoing, this test may apparently indicate that the brakes are in working order, whereas, in reality, such is not the case.

New York. EDW. L. COSTER.

Good Advice from the Far West.

Editor The Locomotive Engineer:

A great deal is said nowadays about practice and practical men.

This is all very well, I am an advocate of practice and practical men, but there is a point in regard to getting this practice that I want to make.

Men do not make the best use of their own experience, and very few make any use of the experience of others.

Angus Sinclair says: "A belief prevails among men who labor principally with their hands, that laziness is exclusively physical. This is a mistake. It is a psychological fact, well known to metaphysicians, that mental laziness is prevalent enough to dwarf the minds of half the human race."

As the readers of THE LOCOMOTIVE ENGINEER cannot be accused of mental laziness, from the fact that they read it, so what is said here is for those "other fellows" who do not read anything pertaining to their business.

Make the best use of your own experience. If you have a breakdown, know the *why* for everything you do in disconnecting. If one of your air-brake cars won't work, or acts peculiarly, study out what the trouble is, and how to fix it. Don't let the same thing occur day after day, and "cut 'er out" when a little work with your brain will tell you what is the matter and how to fix it.

This approaches mental laziness. I once knew an engineer who never would put his brake valve on "lap" when he broke in two with air-brake cars. Finally the air brake school came, and an examination, and in that examination our friend was asked:

"What would you do if you were running along the road, with a train of air-brake cars, and they broke in two?"

He scratched his head, stammered, and said, "I know, but I can't just exactly tell it, somehow," and the question went to the next who said he would put his brake-valve "on lap," and he also explained how that would hold his main reservoir pressure, so when the stop-cock was shut off behind the last car broken off, he could release all the brakes on cars attached to his engine, back up, couple up and go ahead. Our friend's face lit up; the molecules of his brain had commenced to vibrate, and he realized for the first time in his life the importance of saving his main reservoir pressure in case of bursted hose or break in two.

That same afternoon our friend was called for an extra, all air, he coupled onto the train with the examination fresh in mind. He pumped up and charged his train, tried the air, and with his brake valve in running position, securing his twenty pounds over pressure, he pulled out. He hooked his engine well up, and pulled his throttle well open.

Bill, the fireman, found she was steaming better than usual; he was not using as much coal nor as much water, and everything seemed to be running smoother than usual.

They had not gone far, however, when they struck a low joint, and our friend unconsciously dropped into the same old rut. (These ruts are terrible things. Ask Bill if they are not.) He had forgotten all about his instructions on the expansion of steam, and he hooked her down a couple of notches, and eased off on the throttle as in "ye olden time."

The fire was getting dirty, and Bill was hoping something would happen, so he could get a few extra pounds of steam and a little surplus water, when, bang went the quick-action brakes, and soon the train was standing still, broken in two. What did our friend do? He just sat on his seat, left his brake valve in release position, and lost every pound of air from his main reservoir.

The brakeman had to bleed every car, because the engineer had nothing to release them with till the pump had done a large amount of hard work. They could not wait for the pump to pump them off, for they were making the next station, on short time, ahead of a passenger train. Perhaps if the engineer had to crawl under these cars to bleed them, this bit of experience might have been remembered next time.

Profit by your own experience, and study and profit by other people's experience. Get out of the rut, and what is most important, keep out.

Deadwood, S. D. BLACK HILLS.

Reminiscences of a Government Engineer at the Front.

Editor The Locomotive Engineer:

On page 202 of your November issue I find the following: "On the Western & Atlantic Railroad, famous for its war memories, down below Dalton, Ga., there stands an old car body now used for a tool house, bearing on its weather beaten sides this legend, 'U. S. Military Railroad, Engineering Department.' Ah, what stories that old car could tell."

What has become of the men who could tell you the history of that old car? No doubt many of them are yet in the land of the living. My first acquaintance with it was when three of them came to Chattanooga in the spring of '64. If my memory serves me they were designed and built for the use of the Military Engineering Department for the signal service, several stations of which were located on the line of what was then commonly termed the "State Road," Western & Atlantic.

These stations were located at different elevated points at convenient distances from each other, and a system of flag signaling established between the different army corps; and, in the event of any interruption of telegraphic communication, communication could be carried on through them between Chattanooga and the front. Those cars were designed for the use of this signal corps, and carried the officers, men, and instruments of the corps, as circumstances required.

All engines and cars were marked with the same letters, U. S. M. R. R., with the usual numbers. Engines were numbered from 1 up to, I can recollect, as high as 160. Some of the first numbered engines were second-hand ones from northern roads, widened from 4' 8½" or 4' 10" to 5-foot gauge. I can remember some of them—the Hercules and Jupiter from the Little Miami, 8-wheelers, two 10-wheelers from the 3-C.'s; the Bellefontaine from the B. & I. (Bee Line); the last was a small passenger engine, Taunton build, and is the first one I run after entering the service of the government as a locomotive engineer, in the spring of 1864. Her rates were three loads between Chattanooga and Cleveland, Tenn.

Early in the spring new engines began to arrive, and the small fry were consigned to the "refugee track," in the rear of "Old Tom Webster's shop." All engines were double-crewed except the 44, a Breeze & Kneeland. Our runs were from Chattanooga to Cleveland, on the E. T., V. & G., 26 miles, and to Ringould, on the State road.

The following are the names of the engineers at that time running out of Chattanooga: Geo. Duzenbury, Sam Laird, Chas. Sherman, Ben White, Wm. Freeman, Mose Rogers, Geo. Brown, Pete Thomas, Larry Gaghen, Jas. H. Hevey. Thomas Smith was engine dispatcher. Up to April we had a tough time keeping Uncle Sam's army—which wintered at Cleveland, Graysville and Ringould—fed. After April Col. McGinnis began sending engineers to the front. The army moved, and all engines being double-crewed, they never got cold. In the yard we had Jim Hewitt, Mike Bird, Charley Miller, and Jack Beal to turn them on the Y, get water and wood, and send them out as fast as they came in.

Up to July 16, 1864, we ran by orders something after this style: "Engines Nos. 133, 134 and 135 will meet engines Nos. 126, 128 and 129 at Graysville." There was no superiority, the orders were emphatic, and no trouble ever experienced, rear collisions few. All trains were supplied with a train guard of soldiers, who soon became expert brakemen, so that trains at the slow speed we ran could be stopped very quickly. For fear of becoming tiresome, I will shut off by telling you that myself and Charley Briggs, with Conductors Ostin (Legs) and Jas. Sanderson (Three-fingered Jack), with Baldwin Engine 26, hauled the timber for the historical bridge built by McDonald over the Etowah River, under penalty of being placed in the front ranks with a musket if he did not finish said bridge in a very short specified time. Mc. saved his "bacon," and had about 13 hours to spare. I ran the engine over the bridge that number of hours ahead of Sherman's schedule. I also ran many times over the celebrated pole bridge built by Gen. Rosecrans across the gap on Sand Mountain.

Should this meet the eye of any of the "old time" government locomotive engineers that ran out of Chattanooga in '64 and '65, I would like to hear from them. They can reach me through the columns of THE LOCOMOTIVE ENGINEER, or address Dummy Engineer, J. H. HEVEY.

East Rome, Ga.

[Reminiscences from enginemen who ran at the front for either army will be welcomed to the columns of this paper—the experience of those days reads like novels to us younger men.—ED.]

None of the railroad men in charge of roads doing a suburban business out of New York, believe that the underground road proposed by the rapid transit commissioners will be built, or that its operation is feasible.

Using too much sand on a hill is a pretty sure way to stick; every grain of sand that stays on the rail back of the drivers does hurt, in that it makes the train pull harder. Jet apparatus that deposits a slight sprinkle of sand under the drivers is a grand improvement over the old, free-for-all way of pouring ten times too much sand on the rail. There should be moderation and horse sense used in all things about a locomotive. Water is very essential to the welfare of the boiler, but when its level is raised to the diamond in the stack it becomes a danger.

CONTENTS.

Send for Car Coupler Gauges.

The great loss of life that goes on constantly among men engaged in coupling freight cars, led to a far-reaching agitation in favor of the adoption by railroads of some form of automatic coupler. Most of the interests concerned admitted readily that an automatic coupler was necessary, but there arose great conflict of opinion as to what kind of coupler was best adapted for being made automatic, and for being forced into general use. Railroad managers preferred that their mechanical officers should settle the question as to the most suitable type of coupler; and the battle on this problem was fought year after year in the conventions of the Master Car Builders Association. After years of agitation and discussion, the Master Car Builders Association in 1887 adopted as standard the vertical plane type, whose best known representative was the Janney coupler. That was merely a beginning of the settlement of this question. The adoption of a type of coupler intended to be automatic entailed duties upon railroad mechanical officers that previously were never thought of. With the adoption of a standard type came the necessity for securing uniformity in the essential elements. The association had previously adopted numerous standards, and it was well known that the standard parts made by many roads were not interchangeable with the same standards made by their neighbors. This did not cause very much inconvenience, but to send all over the continent standard couplers that would not couple with other standard couplers was to be a very serious matter. The Master Car Builders Association could not require all railroad companies to purchase the standard coupler from one maker, but it was of the first importance that all couplers of this type, whoever might be the manufacturer, should couple with any other coupler of the same type. The tendency in making patterns is towards diversity. When different pattern makers were left to provide the form of standard bearing wedge by following drawings, they soon produced wedges that would fit only the boxes they were especially made for. If no proper check were put upon them, pattern makers and molders would soon convert the standard couplers into shapes where strange makes coupling together would be the exception rather than the rule.

After giving this subject the most careful consideration, the executive committee of the Master Car Builders Association adopted a gauge that would measure the contour lines of the coupler and establish a limit of variation from the proper form which must not be exceeded. A gauge to control the dimensions of the knuckle in a similar manner was also adopted. In the construction of these gauges, the Executive Committee had again to provide against the difficulty of diversity in the work of different pattern makers, and of free measuring machinists. If every railroad company was to make its own gauges, confusion worse confounded would meet the couplers that were made to pass their test. To provide against this inevitable cause of confusion, the executive committee made arrangements with the Pratt & Whitney Company to manufacture the gauges, and to sell them nearly at cost. The making of such gauges is work of precision, and developed skill that is costly to employ, and the company named agreed to manufacture the gauges at a certain price if at least fifty sets were ordered, and for a lower figure if one hundred sets were ordered. Considering the important interests involved, we supposed that the required number of gauges would be called for within a month, but three months have passed and the secretary of the Master Car Builders Association has sent out notice, that up to date only twelve sets of gauges have been ordered, and that the proposed makers are waiting for more orders before proceeding with the work of manufacture.

This is not an edifying spectacle. The Master Car Builders' coupler is being applied by the thousands. Within three months the Janney is said to have been specified for over fifteen thousand cars. This improvement costs about $25 a car, and numerous railroad companies have cheerfully incurred the great expense, in the hope that it would lead the way to uniformity and safety. It is then melancholy to reflect that, to avoid a trifling outlay, most of these companies are ready to risk losing the utility of their improvement. They are neglecting to supply themselves with accurate gauges, and if they persist in this course it will inevitably result in the standard coupler departing from the proper form so far that the type will have to be abandoned as impracticable. Many other promising things have been made a failure through inferior workmanship.

Asking Something for Nothing.

Men who would not expect for a moment to ask advice of a lawyer or a physician without paying for it, seem to forget that the same law should hold good in mechanical affairs.

Inventors, and men who are about to invest money in inventions, will walk into the office or the home of some mechanical expert and ask questions, get plans and drawings examined, or seek advice, that none but an educated mechanical engineer would be competent to give, without thinking of paying for the service rendered.

A man who graduates from any of our great technical schools spends more money and more time to get his education than a lawyer or a doctor does.

If a competent mechanical engineer was consulted before any machine or device was placed on the market, there would be fewer failures and disappointments, and it would be a good investment to pay well for their services in any case.

Men who want to use the brains and training of these mechanics, without pay, would resent an impeachment of "sponging" on anybody. Yet to the expert making his bread and butter by using his brains and training, they are very despicable dead-beats.

There is another class of men, or a few of the same class, who seem to think that a mechanical newspaper exists for no other purpose than to do their expert designing for them. They will ask questions in mathematics that any fair scholar in their own place could work out in a few minutes. They want you to design engines for certain work, valve gear for certain engines, and boilers for a dozen different purposes, each stating many local peculiarities that materially affect the case, and where the sound judgment of a first-class mechanic is necessary to insure success.

One of this class wrote us not long ago, asking for the required horse-power, sized boiler, sized screw, pitch of screw, etc., necessary to drive a boat 22 feet long eight miles per hour. Now we do know barely enough about locomotives to get along, but what we know about boats is limited—something like our correspondent's information on same subject. We wrote him that if we were in his place we should employ a competent man to work out the problem, and offered to recommend a mechanical engineer, if he knew of none. We received a postal card reply as follows: "The reeson you don't answer wright is becoss you don't know, you editors aint so smart as you pretend."

The information conveyed in the last sentence of the rebuke came as a great shock to us; but, after calmly thinking it over, we decided not to commit suicide, but to struggle along, as we had before, without knowing everything.

This is the age of the specialist. Each man can learn to be an expert at one thing—if it's only opening clams—and by exchanging products we can all get expert service in everything that goes to make up our lives. An expert mechanic will verify your plans or point out their weak points in a few minutes, and perhaps save you thousands of dollars; but don't expect his services for nothing, nor that he will charge by the hour, he has got to have something for the time spent in educating himself.

Last month, by some unexplainable blunder, the types made us say that the Galena Oil Works had brought the car service of the U. P. "*up* from 13 to 50 cents for a hundred miles." The item was written and should have read: "The Galena Oil Works have brought the car service of the U. P. from 50 cents to 13 cents for a hundred miles." Quite a different story.

W. F. Relyea, air pump expert of the N. Y. Central & Hudson River, has been appointed engine dispatcher at Syracuse, N. Y.

This paper completes its fourth year with this issue. The readers have encouraged it in every way from the very start, and to their enthusiasm we owe much of our happiness as we eat our birthday cake. Just what the paper has done in the past the regular readers know, and nobody else cares. With the next issue we will get rid of kilts, and come out in a regular, made-a purpose suit, and we believe that all who have known us before will be glad to see the improvement. The present owners have not only pooled their editorial work, but have secured the services of several writers of national prominence, who will give our readers series of articles on locomotive engineering subjects during the year With the January issue, one of the best—if not the very best—informed steam engineers of America will commence an A B C series on a steam engineering subject that is a mystery to nine out of ten railroad men His articles will make the matter as plain as daylight, and alone will be worth the price of the paper But he is only a starter. We propose making the most *interesting* mechanical paper out. We think we know how to do it, and only ask that you and our other readers will watch us through '92

Mr. George H. Baker, of Chicago, has been appointed editor of the *National Car and Locomotive Builder*, to succeed Angus Sinclair, who will hereafter be identified with this paper Mr. Baker was formerly an engineer on the Wabash road, but left the throttle at the time of the C., B & Q. strike, to become instructor to the new enginemen for that road. After the strike Mr. Baker went to South America for a year, and has been for some months employed as a fuel inspector on the Southern Pacific road. Mr. Baker will make his headquarters in New York

---

A few seem to think that old subscribers will be entitled to the paper next year at the old rates; this is not so. Those whose subscription does not expire until next year will have the new paper after Jan. 1st to the end of their present subscription without extra charge; but all who subscribe or renew after Nov. 1st must pay $2. No more, no less.

Are you on the list for next year? If not, you miss a good thing.

Book Review.

THE PRACTICAL CATECHISM By Robert Grimshaw, M E., Ph D. John Wiley & Sons, Publishers. Price, $1 25

This is a nicely-bound book, and will look well on a library shelf, but seems to be made up of odds and ends from the indefatigable Grimshaw's other "Catechisms" There is something about almost everything in this book lots of it good, but it dodges around from fattening hogs to an untried receipt for weighing the earth. Under the heading of "Locomotives" there are all of three questions asked; they are: "Does the tractive power of a locomotive vary with the speed?" "How can you find the size of rail required for a locomotive?" and "What is a consolidation locomotive?" There may be men in the world who want to know just a little speck about everything, that would appreciate the collection in this work; but to the practical specialist who is trying to be a factor in one branch of usefulness, it will be about as interesting as the unlettered side of a flour sack

CONSTRUCTION AND USE OF MILLING MACHINES is the title of a treatise published by the Brown & Sharpe Manufacturing Company, of Providence, R. I The intention of the book is to give information regarding the machines made by the firm. It performs this purpose in a masterly fashion, and in addition to that it forms an admirable compendium of information on everything relating to milling machines These machines have been largely introduced into railroad shops of late years, and they are rapidly increasing in popularity, but there is still great want of knowledge about them among the mechanics who ought to be thoroughly familiar with every detail of their construction and the means of using them to the best advantage In some shops where the universal milling machine has been introduced, its range of usefulness is greatly curtailed through the men in charge being ignorant of how to use it properly. Those who are in this condition and are anxious to enlighten themselves cannot do better than send for this treatise It will give them valuable information that applies to all makes of milling machines

The first chapters are devoted to describing the construction of the various forms of milling machines, universal and plain The various attachments of the machines are then described and information given about their use. Care and use of milling machines is the next section, and here points are given about placing machines, countershafts, speed, oiling, adjusting, and other facts. A very interesting article from the *American Machinist* on Milling Machines and Skill comes next, and that is followed by quite a treatise on milling cutters. It is hard to select the best part out of a book of this kind, but we think that last mentioned would effect more money-saving reform in tool rooms that we know of than anything else that we have read Use of Milling Machines is a part that treats of how to do work with the machine Numerous particulars are given about the proper methods of doing work, how to run the cutters, speed of cutting for different material, and much more useful information. The book is sold by the publishers Cloth, $1.60; paper, 75 cents.

ASKED & ANSWERED

(73) E. B , Green Bay, Wis., asks:

Why do they split the rim of locomotive driving wheels and then insert pieces? *A.* This is usually done to prevent undue strains being set up in the casting, due to uneven cooling in the mold.

(74) A M B , Banksville, Neb , writes.

There is a boiler of a certain stationary engine working near here, the makers of which said it was tested to 100 pounds cold water pressure, which, they claimed, was equal to 200 steam pressure. Now according to my books this isn't correct. What do you think about it? *A* We think the makers lied

(75) Thos. E. McGinnis, Conneaut, O., asks.

Suppose you break a piece out of a pony truck wheel on a mogul engine; what is the quickest and easiest way to get in? *A.*—It all depends on the kind of track and the distance you must go. If not far, and the track is fairly good, you can block with a tie and slide the truck wheels; if the distance is great you can block over your forward drivers and then chain up the wheels to clear.

(76) Chas. J. Murry, Chicago, Ill., asks:

1. How many square feet of heating surface is there to one square foot of grate surface is the best practice of the present day in the following styles of boilers locomotive, cylinder, return flue tubulars, Scotch flue marine and portable boilers? Please state also how many square feet of heating surface is used to designate one horse-power in locomotive boilers. *A* —1 Locomotive practice varies from the ordinary deep fire box soft coal burners, with an average of 17 square feet of grate for 1,000 square feet of heating surface, to the Wootten fire box, with 80 square feet of grates to 1,250 to 1,400 square feet of heating surface. We cannot give data for other kinds of boilers. 2. The term horse-power is not used in computing size or capacity of locomotive boilers

(77) McG , Galion, O , asks.

Should a tire break on the back driver of an eight wheeler that has bald tires ahead, how can the engine be kept on the track? *A* —Take off the side rods, block up so as to relieve broken tire of weight as much as possible, take out draw-bar between engine and tank, and chain from the end of engine frame on broken side to draw head in tender, keep the tender loaded heavily ahead, and, if necessary, set brake so that the pull of tender, or cars, will have a strong pull to keep the whole flange crowded against the rail. Engines of this kind have been got in by advancing the driving box on the broken side, or bringing the one on good side back; this "slews" the wheels and causes them to crowd to the side; when this is done care should be exercised about clearance, and the main rod lengthened or shortened, to prevent knocking out cylinder heads In usual practice the tank plan is the quickest and best. Run slow.

Special Offer.

Owing to the demand for bound volumes, we have had a large number bound, so that now we can furnish '88, '89, '90 and '91 orders at $2 each. We want to get rid of all back numbers to make room for the new, and make this special offer "To each order for a full set—four volumes—accompanied with the regular price, $8, we will add a full year's subscription to *Locomotive Engineering* **FREE.**" This is $2 clear gain. Of course this can last only as long as we have back numbers, and is only good where the complete four years are taken. The books contain more than 500 illustrations, hundreds of kinks, all of the Progressive Examination Questions and Answers, dozens of John Alexander's stories, and hundreds of answers to puzzling questions. This is your chance.

A correspondent wants to know how to brick up part of a long fire box built for hard coal now used for soft. Perhaps some of our readers have learned something special in experience of this kind, but there seems little else necessary than to thoroughly cover the forward part of the grates as near air tight as possible with fire-brick, being careful to get it tight at flue sheet. A bridge wall at the front, built up twelve or fourteen inches, would aid in keeping fuel off the dead grate, and give benefit, or loss, of a large combustion chamber. Of course, where shaking grates are used, those under the bricks must be disconnected from the shaking mechanism.

Henry M. Sperry, for the past four years signal engineer of the N Y. division of the P. R. R , has been appointed general agent for the Johnson Railroad Signal Co., with headquarters at Chicago.

Work of the Arbitration Committee of the Master Car Builders Association.

Few railroad men, other than the officials most interested, have any idea of the intricate quarrels that arise over the damage and repairs to cars off their home roads.

Perhaps all know that there is a set of rules known as the "Rules of Interchange," that calls for the carding and repairs of defective cars delivered by one road to another road. On the proper inspection and carding depends the fixing of the responsibility and expense of breakages.

As long as men are human there will be disputes, and, where such interests are in conflict, nothing short of angels could always come to an understanding in every case

Where inspectors cannot agree, the case is left to the decision of the Arbitration Committee, which is composed of prominent members of the association, who are also railroad officials in charge of rolling stock

Some of these cases are very interesting, and, for the information of men who know and hear little of this inside business, we publish the work of the committee for its October meeting It may also interest some who think that the pulling out of a draw bar or the smashing in of a car end only represents a delay to them; it costs money to get them back into running order.

CASE No. 88.

The body of Illinois Central car No. 7,607 was destroyed by fire on the Chicago, Burlington & Quincy Railroad. The car was of 50,000 lbs capacity, 40 feet long, and designed and built to carry furniture.

It is claimed that, on account of the increased dimensions of the body, its cost was greater than that of an ordinary box car, and it is therefore billed against the C., B & Q R. R. Co at a figure higher than that fixed in the Rules of Interchange for box cars 34 feet long or over

The C., B. & Q. R. R. Co. expresses a willingness to settle at the figures laid down in the rules, and claims that no more can be charged in accordance with the rules as construed by the Arbitration Committee in Case No. 53.

Both parties to the dispute agree to refer the matter to the Arbitration Committee for decision.

DECISION.

The committee would call the attention of the parties to this dispute to Arbitration Case No. 53, which is a parallel case to that under consideration. The same argument applies, and the opinion of the committee is that the Illinois Central Railroad Co. can only bill in accordance with the figures laid down in Rule No. 23.

(NOTE.—Mr. Rhodes, being interested in this case, was not a party to this decision.)

CASE No. 89.

The Hannibal & St Joseph Railroad Company received from the Gulf, Colorado & Santa Fe Railway Co. C., B. & Q car No. 17,038 with a wrong drawhead. Defect card for the wrong part was issued by the G , C. & S F Ry. Co., and was attached to the car

The H. & St. J. R. R. Co. replaced the wrong draw-bar with another standard to the car, and rendered bill for the cost of replacement against the G , C. & S F Ry. Co.

The bill is disputed by the latter road, on the ground that only the road owning the car can, under the rules, remove the draw-bar, as per Arbitration Case No. 78.

The H. & St. J. R. R. Co. claims that it is a part of the C., B. & Q system, and that, according to the provisions of certain agreements between the roads composing that system, the cars of such roads are repaired at any of the shops on the lines of that system In other words, each of these lines repairs the cars of the others as if they belonged to its own equipment.

Both parties agree to refer the case to the Arbitration Committee for decision.

DECISION.

The Arbitration Committee decided in Arbitration Case No. 78, Texas & Pacific Railway Co. *versus* St. Louis & San Francisco Railroad Co., that a wrong drawhead should be removed only by the company owning the car, unless an intermediate road handling the car deems it necessary to do so, on the ground of safety.

It is not claimed, in the correspondence submitted in the case under consideration, that the removal was deemed necessary on the ground of safety, but that it was made because of an understanding or agreement between the lines composing the C., B & Q. system, of which the H. & St. J. R. R is a part, that the cars of the various lines of that system are to be repaired and maintained at the nearest shop of such lines to which the cars may be The committee has no knowledge of the existence of any such agreements, and, in the absence of such knowledge, can only decide the case under the M C. B. Rules.

The rules provide that a car shall be treated as belonging to the road whose initials it bears. The car in question bore the initials of the C., B. & Q R. R. Co., and this company only is, under the rules, authorized to render a bill upon the authority of such defect card.

In the opinion of the committee there is no ground for a bill from the Hannibal & St. Joseph Railroad Co. against the Gulf, Colorado & Santa Fe Railway Co., but a bill for the repairs in question would be proper if rendered with card by the C., B. & Q. R. R. Co. against the G., C. & S. F. Ry. Co., if there exists such a mutual agreement as is claimed in this case in regard to car repairs on the C., B. & Q. R. R. system, because the H. & St. J. R. R. Co. would then be acting as the duly authorized agent of the C., B. & Q. R. R. Co. in repairing its cars.

As already stated, the committee is of the opinion that, under the rules, the Hannibal & St. Joseph R. R. Co. cannot render a bill against the Gulf, Colorado & Santa Fe R. R. Co. in this case.

(NOTE.—Mr. Rhodes, being interested in this case, was not a party to this decision.)

CASE NO. 88.

July 18, 1890, the Missouri Pacific Railway Co. delivered to the Chicago, St. Paul, Minneapolis & Omaha Railway Co. "O" Refrigerator car No. 8,064, loaded with perishable freight, with pressure-retaining valve missing. The latter road asked for a defect card covering this missing part, which was refused by the inspector of the M. P. Ry. Co. On account of the nature of the freight the car was accepted.

From subsequent correspondence, also submitted, it appears that the C., St. P., M. & O. Ry. Co. requested the M. P. Ry. Co. to furnish a defect card, stating that, under the Rules of Interchange, it is bound to do so. The M. P. Ry. Co. replies that it does not card freight cars for any parts of air-brakes, excepting hose and couplings.

Both parties to the dispute agree to refer the case to the Arbitration Committee for decision.

DECISION.

Rule No. 2 of the Code of Rules states that cars must be delivered in good running order and returned in as good general condition as when received.

In the case in dispute it is not denied by the M. P. Ry. Co. that the car in question was delivered in an improper condition; that is, with the retaining valve missing. The Rules of Interchange do not except this, or any other part of the car, from the operation of the rule cited; the car must be delivered in good order.

Since it is clearly shown, and not disputed, that the car in question was not in the condition contemplated in the rules, the committee is of the opinion that the M. P. Ry. Co. is bound to furnish a defect card for any parts of a car that may be in an improper condition when delivered by it to a connecting line.

CASE NO. 91.

The Chicago & Alton Railroad Co. removed a wrong draw-bar from Mather stock car No. 221, which was applied and carded for by the Cincinnati, New Orleans & Texas Pacific Railway Co. The C. & A. R. R. Co. rendered bill against the C., N. O. & T. P. Ry. Co. for the cost of renewal. The bill is disputed by the latter company, on the ground that, in accordance with decision No. 30 of the Arbitration Committee, the road carding for wrong material is responsible only to the owner of the car. The C. & A. R. R. Co. claims that the Mather Stock Car Company has no repair shops at which these cars can be repaired, and that the railroads operating the cars are expected and authorized by that company to make necessary repairs.

Both parties agree to refer the case to the Arbitration Committee for decision.

DECISION.

There is nothing in the correspondence submitted to show that the C. & A. R. R. Co. removed the wrong draw bar on the ground of safety. If, therefore, the removal had been made solely because the wrong part was carded, the committee would be bound to decide as in cases Nos. 30 and 66, that is, as long as the wrong parts were safe, no one but the owner could remove and bill for them.

The C. & A. R. R. Co. assigns as a reason for doing this work, that the Mather Stock Car Company relies upon the C. & A. R. R. Co. and certain other roads to make necessary repairs to its cars.

This claim is supported by a letter from the Mather Stock Car Company, which is submitted to the committee, and in which it is stated that it has been in the habit of having all roads handling its cars make the necessary repairs.

The C. & A. R. R. Co., therefore, is the authorized agent of the Mather Stock Car Company to repair its cars, and as such, the cost of making such repairs as the road doing the work is not responsible for is a proper charge against the Mather Stock Car Company.

In the case in dispute, the committee is of the opinion that the C. & A. R. R. Co. has no claim against the C., N. O. & T. P. Ry. Co., but its claim is against the company employing it as its agent. If the Mather Stock Car is furnished by the agent repairing its cars with the evidence of the responsibility of another company for the damage to the Mather cars, the Mather Company has its remedy by billing against the proper road in order to reimburse itself for its outlay in paying bills to its agents for repairs to its cars.

In the opinion of the committee, the bill rendered by the Chicago & Alton Railroad Co. against the Cincinnati, New Orleans & Texas Pacific Railway Co. is not in accordance with the rules.

CASE NO. 92.

Pittsburgh, Fort Wayne & Chicago stock car No. 10,011 was delivered to the Louisville & Nashville Railroad, October 14, 1890, and subsequently delivered to the Mobile & Ohio Railroad, which in turn placed it on the tracks of the National Stock Yards Company, at St. Louis, November 3, 1890, loaded with a mixed carload of stock.

March 20, 1891, the P., Ft. W. & C. R. R. Co. learned that the car was still on the stock yards tracks, and in the following damaged condition: One Janney coupler cracked, two Janney knuckles broken, one short brake chain gone. The P., Ft. W. & C. R. R. Co. applied to the M. & O. R. R. Co., and also to the National Stock Yards Company, to return their car, neither of which companies would do so, or assume any responsibility in the case. The M. & O. R. R. Co. claims that it is customary to immediately set back all cars going to the stock yards in bad order, for repairs or to be properly carded, and that as this car was not set back when they delivered it, it is evidence that the car was in good condition. The St. Louis National Stock Yards Company denies all knowledge of the case, and claims it has no means at its disposal of knowing anything about the matter. In order to get the car into service, the P., Ft. W. & C. R. R. Co. requested a neighboring line to receive the car and repair it, and get it into service, which it did, at an expense of $16.70. Both the P., Ft. W. & C. R. R. Co. and the M. & O. R. R. Co. agree to refer the matter in dispute to the Arbitration Committee.

In order to better get at the relations of the St. Louis Stock Yards Company with the railroad companies at East St. Louis, one of the members of the Arbitration Committee visited East St. Louis and learned as follows: The National Stock Yards, including the necessary tracks, are owned by the company of that name. There are also located on the property of that company certain packing houses and tracks leading thereto. A number of the railroad companies centering at East St. Louis have track connection with the Stock Yards tracks, while others reach them by trackage rights over roads having direct connections, or have their work done by one or more of the switching roads. The M. & O. R. R. Co. does not connect directly with these tracks, but reaches them by trackage rights. The National Stock Yards Company owns and uses one engine for its own convenience in cleaning up the yards, switching hay and ice, etc., from one packing house to another. The roads reaching the yards over their own tracks, or by trackage rights, do their own work at the yards proper and at the manufacturing establishments, in consequence of which there may be as many switching engines and crews working there as there are roads. The practical result of this is that each crew has to wait its turn to do its work, which in the case of the work at the manufacturing establishments frequently involves the rehandling of cars just previously handled by another crew. On live stock handled at the yard no trackage charge is paid to the National Stock Yards Company for the use of its track, but for all dead freight handled over its tracks that company receives $1 per car for such use of its tracks. The National Stock Yards Company has never assumed or admitted any responsibility for damage to, or destruction of, cars on the tracks situated on its property. It does not inspect or receive cars from the different railroad companies, and there is no inspection of cars as between railroad companies and the National Stock Yards Company. It is customary for the road which delivers a car at the stock yards to take it out again, but there is no set rule formulated governing the matter, and as so many roads have access to all the tracks, it is possible for a road to take out cars which it did not set in, or to leave cars there that it did set in.

Both parties agree to refer the case in dispute to the Arbitration Committee for decision.

DECISION.

It is clear from the above that the tracks of the St. Louis National Stock Yards Company must be regarded as private tracks, and cars found on them in damaged condition must be governed by M. C. B. Rule No. 28, which reads as follows: "For the mutual advantage of railroad companies interested, the settlement for a car owned or controlled by a railroad company, when damaged or destroyed upon a private track, shall be assumed by the railroad company delivering the car upon such tracks," and railroad companies making use of private tracks can only avoid sustaining loss on account of damage upon such private tracks by specific agreements with the owners of the private tracks to reimburse the railroad companies for the cost of damage sustained while on the private track by cars which the railroad companies deliver thereon.

The committee is of the opinion that the Mobile & Ohio Railroad Company is responsible for the damage, and should pay for the same as prescribed by the rules.

(NOTE.—Mr. Casanave, being interested in this case, was not a party to this decision.)

CASE NO. 93.

The Cleveland, Cincinnati, Chicago & St. Louis Railway Co. destroyed on its line, May 23, 1890, body of Atlantic & Pacific box car No. 316. The trucks were returned to the owner.

The A. & P. R. R. Co. rendered bill against the company destroying the car for the depreciated value of the body, dating from the time it was rebuilt, namely, June 12, 1889.

The C., C., C. & St. L. Ry. Co. objects to the bill, on the ground that the car was only 28 feet long, and that it is probable that the date at which it is claimed the car was rebuilt is an error. It claims that the car must have been much older, and asks that the road rendering bill make necessary correction.

The A. & P. R. R. Co. states in reply that this car was rebuilt at its shops June 12, 1889, and had new posts, braces, belt rail, flooring, siding, roofing, lining, grain doors, brakes and draft timbers, and received other trucks, and it considers this car, when leaving shop at the time mentioned, equal to a new car. The A. & P. R. R. Co. acknowledges, however, that the original car was built July, 1881, at a cost of $580.

Both parties agree to refer the case in dispute to the Arbitration Committee for decision.

DECISION.

Arbitration Case No. 71 is a parallel case to that under consideration.

It is the opinion of the committee that the M. C. B. Rules contemplate that the depreciation shall date from the time the car was actually built.

It is admitted by the A. & P. R. R. Co. that the car in question was only partially rebuilt in 1889, and although the work done was very extensive, yet, when completed, the car was not a new car.

The committee is therefore of the opinion that the depreciation must be computed from the date the car was actually built.

The recent fast run with an experimental train over the New York Central from this city to Buffalo, has satisfied the management that a run nearly as good can be made every day. On Oct. 26 they put on the "Empire State Express," which leaves New York at 9 A. M., and arrives in Buffalo at 5:40, covering the 440 miles in 8 hours and 40 minutes, or at the rate of 52.3 miles per hour. The train will consist of four cars.

The ordinary car builder does not like to make cabs—it's too much like cabinet making. Around every shop there is always kept a handy man who makes cabs, pilots, seat boxes, and, occasionally, works in a fancy tool-chest for one of the boys. The illustrated article on cab building on another page will, no doubt, be appreciated by men who are looking for a good way to do their work.

It is now proposed to paint all electric wires that carry a dangerously high current, red. This may keep people from touching them, but it won't prevent their contact with other wires from sending death and destruction through telephone and messenger calls, clothes lines and house gutters. Bury them.

The *Express Gazette* stole the Old Timer's story about the scared Indian from our columns, and now it's going the rounds credited to the thief. Thus the patient husbandman sows good pumpkin seed with the sweat of his brow, and the middleman gathereth in the fruit and leaves the sweat.

Some of the coal furnished by New England roads to haul passenger trains with, looks and burns more like bran mash than bituminous coal. This wouldn't be so bad if the officials would only refrain from telegraphing for cause of delay.

We have bound volumes for 1888, '89, '90 and '91 on hand, four years, at $2 per volume. You cannot get them in three months from now. Order now.

The Baldwin Locomotive Works have adopted a rule to make all boilers for compound locomotives with a factor of safety of five.

E. Brunton has been made Supt. M. P. & M. of the Florida Central & Peninsular, vice M. J. Rogers, resigned.

The Pittsburgh Locomotive Works are building twenty Forney engines for the Manhattan Elevated Railroad.

The Pennsylvania have recently ordered five Baldwin compounds.

There has been a car famine in the West for the past month.

Improvement in Cutting Tools.

During a recent visit to the Gould & Eberhardt works, at Newark, N. J., we were very much interested in the system of cutting tools in use in the machine shop. The cutting tools for all lathes, planers and all other machine tools are made from small bar steel large enough to give the shape of a cutting face, and this is separate from the holder piece that goes into the tool post. This holder is made of malleable iron and the cutter slips into a hole of the proper size, and is held by two set-screws. The holders are made of such forms that the cutters can be set at the angles required of any tool made in the usual way. The piece of steel that forms the cutter does not require any forging, merely grinding. The system has been developed by Mr. Eberhardt, and has been in use in these works for several years. The firm is now about to put the cutters and holders upon the market.

The advantages of the system are apparent to any mechanic who has paid the least attention to the loss of time that results from waiting for tools to be dressed. Here a workman has merely to keep a few of the cutters ground, and he always has a supply of new tools at hand.

The firm makes the following claims of advantages for the tools :

Economy in grinding; no forging or tempering; tool supported up close; no objectionable projections; no stock of heavy steel on hand; average cutting rake always given; no adjustment of height necessary; time, labor, money and annoyance saved; variety of cutting shapes ground R. and L.; increased speeds and feeds can be obtained; grinding of tools required less frequently; steel will not slip in holder under heavy cuts.

We should strongly advise men in charge of machine shops who are looking for improved methods to apply for full particulars about this system of cutting tools.

At a recent meeting of the Western Railway Club, Mr. Synnestvedt, of the Chicago & Northwestern, in speaking of exhausting all the air out of the pipe in testing brakes, said : "I think the practice of drawing all the air out very valuable for several reasons—the reasons already given here, and one other which I will mention. You can tell it within several cars of the length of the train by the length of the blow-out of the train pipe exhaust. You can tell it also when you are running on the road, while you are making an application. But there is another thing which makes it very important to let all the air out of the train pipe in making the test of brakes; you may have some cars the reservoirs on which are not filled. I have seen an extra car—a sleeper or a diner—attached to a train; they stand a moment, and the brakeman gives the engineer the signal to try the brakes, the car just connected has less air than the others, and its brake does not go on, and I have seen men make three or four, and sometimes more, applications of the brake to satisfy the brakeman that it was all right. All that trouble would have been avoided had the engineer exhausted all the air from the train in trying the brakes. There is a way which I have not heard mentioned, by which an engineer can test the length of the train pipe while running on the road, without making an application of the brakes at all, and by which he can tell within two cars. If the engineer's valve handle stands in the proper position, one gauge pointer will show 20 pounds excess pressure. Now, by pushing the handle to the release position and watching how far the red pointer falls, you can tell very nearly how many cars there are in the train. We find that when there are fifteen cars in the train, it will go down almost exactly a pound to a car; the longer the train the less per car. Suppose a man is running on a dark night and has a meeting point or a crossing to make; he may have a suspicion that all the brakes are not set in. He can tell very easily by slipping the handle around and watching the red pointer, as I say. I have often done this, and guessed the number of cars, and then gone back and counted them, and I never missed by over four cars, even on trains of fifteen or sixteen cars."

The Brooklyn Elevated road have received some more compounds from the Rhode Island works; they are two-cylinder machines.

The makers of steam gauges for locomotives are finding difficulty in keeping their gauges in good working order under the high temperature they are subjected to in the hot cabs to be found on some of our high-pressure locomotives. In talking of this to Chief Henderson, of the Boston Navy Yard, lately, he related a curious experience with a steam gauge. It was correct when tested on the mercury column, but when it was in place its record was of the most erratic character. A careful examination revealed nothing to be wrong with the mechanism of the instrument, and the case was becoming a mystery, when some one loosened the screws that held the gauge to the stand. It registered the correct steam pressure immediately. The trouble was that the gauge mechanism was secured to the back plate, and the pressure of the stand distorted that plate, throwing the register astray. The Ashcroft Manufacturing Company provide against this cause of distortion in their gauges by securing the actuating mechanism to the spring stand itself. This is reported to be an effectual remedy

---

The Leach improved sanding apparatus is meeting with great favor among railroad companies, and those who are using it generally admit that, besides making a supply of sand last from four to ten times as long, its use saves tires and rails from destructive wear. Some railroads noted for slippery rails, caused by the presence of dust having a lubricating tendency, have found that the use of the Leach sander on their locomotives enables them to get along without carrying an extra supply of sand on the engines. One of these sand boxes was placed on a particularly slippery locomotive belonging to the Old Colony Railroad engaged on suburban business, and the regular supply of sand at the right spot effected a great improvement on the engine. The engineer was in the habit of keeping the supply running all the time, and this acted so well as a preventive of wheel sliding that the intention is to apply the sander to all suburban engines, and keep it in use all the time when the trains are in motion.

A peculiarity about the car and locomotive shops of the Delaware & Hudson Canal is the many uses that hydraulic lifts are put to. If manual labor can be economically saved by the introduction of a hydraulic crane or jack, the water pressure is made to do the business. Mr. Blackall is a warm advocate of this means of labor saving, and he keeps down the pay-roll very materially by the practice followed. At present, they are putting into every engine-house a hydraulic elevator which raises an engine and performs the functions usually performed by drop tables. A hydraulic elevator capable of lifting the heaviest engines can be put in at a total expense of $1,200. It is found much more convenient than a drop table, and does the work more quickly

---

The people who buy dummy couplings for air-hose, and then fasten them to the end of the car in such a position that the hose cannot be coupled to them properly, should be clubbed. Sometimes they do couple, but do so at so great a strain as to bend the hook, thus defeating the object of dummy couplings, which is to cover the opening in the hose. The ordinary dummy coupling is of no earthly use unless it prevents dust and cinders from getting into the hose. It's a wonder that some of the brakes on the D., L. & W. passenger trains work at all, and this road is little worse than many others we could name. A couple of links or a swivel between the coupling and the car prevents cramping the hose or placing too much strain on the back hook

---

If any one wants to see discomfort in an advanced stage of decomposition, he wants to get on a locomotive with dirt-burner boiler when the wind blows hard. The grates being above the wheels, the back of the ash-pan is entirely open for about 18 inches deep and 8 feet wide, right under the fireman's nose. Into the immense ash-pan the gentle zephyrs always go by the front damper and air-holes, and, escaping from the back in the shape of an ashen simoom, they make the patient "firesy" look like a chimney-sweep and feel like a tramp bent on murder.

The Central of N. J. will try a compound.

The Best They Can Do in England.

The highest speed ever attained on a railway was accomplished on the Northeastern Railway by one of their new compound single engines. The engine (No. 1,518), with a train of 18 carriages, attained the enormous speed of 86 miles an hour. The total weight of train and engine was 310 tons. —*Ryland's Iron Trade Circular*, London.

The official statistician of the Interstate Commerce Commission gives the following as official on the number of locomotives and cars in this country :

"There are about 30,000 locomotives in the United States, of which one-half are used in hauling freight trains. It is estimated that these iron horses cost $450,000,000 There are 1,100,000 cars of all kinds, of which 26,000 are passenger cars and the remainder freight or service cars. The former cars cost about $250,000,000 and the latter $800,000,000, or an approximated cost of rolling stock of $1,500,000,000.

"To every five miles of railroad in the United States there is a locomotive ; to every mile of road there are six freight cars ; to every five and one-half miles there is a passenger car. Each year a freight engine hauls 35,000 tons of load , each year a passenger engine pulls 60,000 passengers. The railways of the United States employ 725,000 persons. It is estimated that the railway interest provides a living for 3,000,000 in this country, or nearly one-twentieth of the population."

Few persons have an adequate idea of the care required to maintain the electric block signals which make it possible to safely run heavy and fast trains in and out of cities at intervals of a few minutes, regardless of the state of the weather. Batteries, the circuit and its insulation, require careful watching, and the batteries especially demand intelligent care if they are to be kept in the best of condition to insure perfect working signals. G. L. Lang stated to the Association of Railway Telegraph Superintendents that the annual cost per signal for maintenance of double track block signals is not far from $40 per annum, varying somewhat according to the traffic.

It may seem a small matter to adopt an automatic car coupler, said Mr. M N Forney, speaking before the Railroad Commission. It was a small matter to adopt a standard screw thread, yet look at the labor which this involved. Mr. Chanute, on the Erie, was the first to attempt to bring some order out of the chaos that existed. He tried to get the U. S standard threads He sent to the Navy Yard for gauges, but they did not agree, he applied to Pratt & Whitney for them, but they had no tools to make them. At last this firm undertook to make special tools for doing the work, and it was only then that screw threads could be found that were really of uniform size.

Does your headlight wick "crawl up" after you get running, and break chimneys, and smoke up things generally ? When cloth wicks are used this trouble is pretty general, and is caused by the wick sticking in the burner—a home-made wick will stick on the lap side. When you turn the light up, about where you think it ought to stand, you like to have it stay there, but if the wick is fairly loose it will jar up, or the movement of the oil works it up. The trouble is that it is wrinkled and can straighten up. Turn it far too high, and adjust it by turning *down*—it won't work up then.

The Boston & Maine Railroad Company have lately ordered 25 passenger cars from the Laconia Car Company. The cars will have all the latest improvements, including quick-acting air-brakes and steel-tired wheels. This company has lately changed from yellow to the Pullman color for their passenger cars. They have also ordered 500 freight cars.

Get things handy in the cab. We recently rode on a locomotive where the cock for starting the bell-ringer was under the engineer's brake valve, on the right side. Every time we approached a town the "firesy" would go over and reach for it. We thought for some time that he was feeling of the engineer's shin bone to see if it was running hot.

The Lee Composite Mfg. Co., 29 Broadway, N. Y., report a steadily increasing demand for their products. Among the roads using their "Slagphalt" paint on passenger car roofs are the N. Y., S. & W., N. Y., Ont. & W.; D. & H., South Carolina, B. & A.; P. & R., Staten Island Rapid Transit, N. Y., Prov. & Boston, and others. "Slagphalt" prevents cinders from locomotives from cutting the tin, and protects it from the action of acids. Coaches next the engine so treated, after many months' service, it is claimed, show absolutely no evidence of attack from "cinder blasts."

The Old Colony Railroad Company have estimated that it would cost them $198,000 to equip their 265 locomotives and 600 passenger cars with the apparatus required to heat their cars with steam. The management made numerous wry faces over the figures, but they finally said let her go, G—Lauder, and steam heat it is.

The New Haven road have recently bought some new boilers from a builder and made engines for them in their own shop, to take the place of some old ones that have been put on the "scrap heap run." This, and a good many other eastern roads, could keep pretty busy for a few years at this kind of work with profit.

E. J. Desoe, a rising young engineer on the Boston & Albany road, has been selected by the management as air brake instructor for the system. Mr. Desoe can well feel proud of his preferment, as it was made for merit; his work will tell in better service.

Rogers Locomotive Works are building some eight-wheelers for the S. F. & W., ten ten wheelers, with Wootten fire boxes. They also have twenty-five for the C., B. & Q.—they are of the ten-wheel type—for the C., B. & N. Division.

The turnbuckle department of the Central Iron & Steel Co., at Brazil, Ind., was partially burned on Oct. 30th. They were clearing up the wreck before the smoke cleared away, and the plant is again in full operation.

The Finance Committee of the Erie Railroad has decided to recommend the payment of a 3 per cent. dividend on the preferred stock. If such a dividend is paid a non paying record of about fourteen years will be broken.

On the N. Y., N. H. & H. all the bell cords run in on the engineer's side; there is a State law in Connecticut that the engineer must ring the bell. There are no running boards on this company's engines.

H. V. Wilkins, of the Illinois Central, has been promoted to the position of general foreman in charge at Durant, Miss.

The Columbus, Hocking Valley & Toledo are having ten heavy engines built at the Pittsburgh Locomotive Works.

The Big 4 contracts for 40 coaches, 20 engines and large number of freight cars have not yet been given out.

The report that the Seaboard Air Line are in the market for 500 cars is contradicted by reliable authority.

The Lehigh Valley Car Co. have orders for 500 gondolas for the Central of New Jersey.

The Pennsylvania R. R. Co. are letting contracts for 5,000 freight cars.

It is rumored that the Central of N. J. are getting bids on 500 box cars.

The Lehigh Valley are reported to be in the market for 2,000 freight cars.

The N. Y., S. & W. will probably place orders for 200 freights.

The West Shore are getting bids on 500 freight cars.

Model Motive Power.

The Baltimore & Ohio Railroad Company has recently placed in service on its fast trains, between New York, Philadelphia, Baltimore and Washington, six new engines, which are doubtless the finest and fastest ever built in this country. These new flyers have driving wheels six feet six inches high, and cylinders 20 inches by 24. The large cylinders give them tremendous power, and the high drivers protect the machinery from the rack and strain incident to driving smaller engines at great speed. There is practically no limit to the speed to which these new marvels may be driven, and they skim over the rails as smoothly as a swallow over a lake.

Another recent addition to the motive power of the company is a consignment of eight powerful ten-wheel passenger engines, designed for service on the mountain divisions. These are the heaviest ten-wheel engines ever constructed, weighing sixty-seven and one-half tons. They have driving wheels six feet two inches high, and cylinders 21 inches by 26. One of these machines performs the work heretofore requiring two of the ordinary class, and they take the heavy through express trains up the mountain grades quickly and with perfect ease.

The Mt. Clare shops of the company have recently completed an order for ten switch engines of the highest type, and sufficiently powerful to make up a train equal to the full drawing power of a consolidation freight engine. Also three new heavy eight-wheel passenger engines, having driving wheels five feet eight inches, and cylinders twenty inches by twenty-four. These engines are now doing excellent work; they are very powerful, and susceptible of great speed.

In addition to the foregoing, the company has now under construction at its Mt. Clare shops ten powerful ten-wheel engines designed for fast freight service and for heavy passenger trains on occasion, also twelve consolidation freight engines of great power.

PROSPECTUS OF

Locomotive Engineering

FOR 1892.

With the January, 1892, issue, THE LOCOMOTIVE ENGINEER will take the above title, come out with a large 4-column page, and a substantial increase in the number of them—anyway twenty big pages of reading matter.

ANGUS SINCLAIR, for the past six years Editor of the NATIONAL CAR AND LOCOMOTIVE BUILDER, the author of "Locomotive Engine Running and Management," well known as the Secretary of the American Railway Master Mechanics' Association, and JOHN A HILL, Editor of THE LOCOMOTIVE ENGINEER from its birth, have bought out the paper and will devote all their energies to making it the best practical railroad paper in the world.

It is proposed to keep it up to the times and devoted exclusively to subjects interesting to all men in the motive power and rolling stock departments of American railroads.

Old readers of THE LOCOMOTIVE ENGINEER shall not miss a line of Mr. Hill's work, and will in addition secure all the writings of Mr. Sinclair.

The new owners propose to spend a large sum of money next year for engravings to keep up the interest of every engineer, fireman, shop man and officer in the machinery department

The working, every-day engineers, firemen and shop men of our railroads have been slandered by papers containing little of interest to practical men, which have long contended that enginemen would not read a railroad paper, much less pay for one. Four years' experience with THE LOCOMOTIVE ENGINEER has proven the falsity of this claim—16,000 names are now on the list. The men *will* read, and profit by it, if practical matter by practical men is furnished, instead of abstract reasoning and cloudy theories. Both editors of this paper have bent their backs to the coal scoop and taken care of the reverse lever, the throttle and the 3-way cock. "Been there."

Now, this enlarged paper will be worth $2.00—can't furnish it a cent less—all we ask is that you will try it for one year; if you are willing to give it up then we won't say a word. Are you with us?

ABOUT CLUBS.

We pay a cash commission for getting up clubs. If there is no one at work in your field, write us for club rates.

FINALLY.

We do not like to make a lot of promises, blow our own horn and swell up prematurely. We have plenty of new matter laid out, a lot of historical railroad lore as interesting as a novel, some new departments to add, some elementary matter of the right sort, and engravings galore—we propose to lay awake nights scheming to make the paper valuable and interesting to our readers. Our time and abilities shall be all yours. But we would far rather you would tell us how well we have succeeded in a year from now than to blow about it in advance. Will you be on the jury?

LOCOMOTIVE ENGINEERING,
912 TEMPLE COURT, NEW YORK.

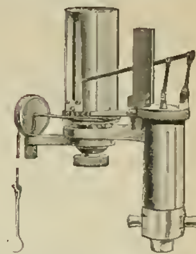
ANGUS SINCLAIR, } *Editors and Proprietors.*
JOHN A. HILL, }

THE ASHCROFT MANUFACTURING COMPANY.

Our double Bourdon Spring Gauge is the only one with actuating mechanism independent of the case. Case, dust and steam-tight. Large figures.

Locomotive Steam Gauge.

The Tabor Indicator has the lightest reciprocating parts, and is the only accurate instrument at excessively high speeds. It has no equal.



Tabor Indicator

OFFICE AND SALESROOM:

111 LIBERTY STREET, NEW YORK.

New Works: BRIDGEPORT, CONN.

Richardson's Patent Safety Valves and Mufflers.

The Muffler is a simple attachment to Richardson's well-known Encased

SAFETY VALVE.

Encased "Pop" Valve.

THESE VALVES HAVE STOOD THE TEST OF YEARS.

The Valve and Muffler have been adopted by many of the largest railroads, and are giving entire satisfaction.

MADE IN THE FOLLOWING SIZES: 2¼ INCH, 2½ INCH, 3 INCH.

Sample Valve and Muffler will be sent on trial, Subject to Approval.

THE CONSOLIDATED SAFETY VALVE CO.,

SOLE OWNERS AND PROPRIETORS,

Salesrooms: 111 LIBERTY ST., N. Y. Works: BRIDGEPORT, CONN.

Muffler.

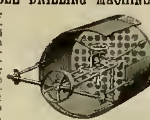
RADIUS

Link Planer Attachment.

For Planing Links, Blocks and Circular Work, on ordinary Planer Quickly Attached. Easily Operated Does Accurate Work

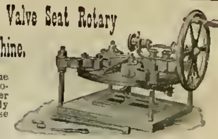
PATENT PORTABLE DRILLING MACHINE.

For fitting new or old cylinders to locomotive boilers. It will drill all the holes in smoke boxes and cylinder flanges necessary to bang one pair of cylinders at one setting of the machine. Quickly set and operated. Driven by hand or belt power.



Patent Portable Valve Seat Rotary Planing Machine.

Will face off the Valve Seats of Locomotives and other Engines perfectly true, without the use of files or scrapers.



Patent Portable Locomotive Cylinder Boring Machine.

Will bore out Locomotive Cylinders in their places by removing one or both heads, as desired, and piston. The end thrust is always in exact line with bar. It is fed with constant feed of cut gears

PEDRICK & AYER,

MANUFACTURERS OF

Special Tools for Railway Repair Shops.

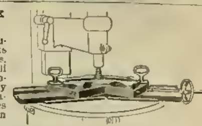
Universal and Plain Milling Machines.

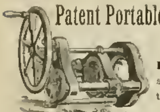
1001 & 1003 Hamilton St.

PHILADELPHIA, PA.

Leed's Patent Link Miller & Slotter.

For rapidly and accurately Milling out Links to any desired radius. Can be used on Drill Press or as an attachment to our Heavy Universal Milling Machine. A link 20 inches long can be finished in four hours.





Patent Portable Crank-Pin Machine.

For turning off Crank-Pins IN POSITION and while wheels are under the Engine, keeping the original centers of the Pin.

JOINTER
—FOR—
Facing Locomotive Brasses.

Will hold any size brass same as held by strap when in use. No more time required to place brass than screw up an ordinary vise. Any desired thickness of cut can be taken, jointing the faces perfectly true. No files required.

Leed's Horizontal and Radial Drilling Machine.

Designed to work on or from a Drill Press. Is useful in drilling ends and diagonal parts of frames. Can also be mounted on the work and driven by a sliding shaft and universal joints. Drilling in all directions can be done.

TOOLS FOR LOCOMOTIVE BOILER WORK.

The Cut shows our

PATENT PLATE BENDING ROLLS,

Specially adapted to this work.

The HILLES & JONES CO., M'f'rs.,
WILMINGTON, DEL.

Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast-iron bed-plate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started stopped or reversed instantly.

THE GENUINE LORD'S BOILER COMPOUND,

Which is acknowledged by authorities and accorded the confidence of the manufacturers throughout the United States and foreign countries, is manufactured exclusively by G. W. Lord, practical chemist and inventor. Attention is called to other parties, who, through the appropriation of G. W. Lord's antiquated patent, have deluded many manufacturers into presenting them with their order for Lord's Boiler Compound. The use of the above formula, patented in 1869 by Mr. G. W. Lord, has been long discontinued by him, owing to his discovery of many new chemicals, which upon critical experiment have demonstrated their superiority. Lord's Boiler Compound, manufactured at the present time, is an article greatly superior to the formulae patented by Mr. G. W. Lord. For decree of court, etc., address G. W. LORD, 320 Union Street, Philadelphia, Pa
