It is further pointed out that the road drag is essentially a maintenance implement, that its use in construction is distinctly secondary, and that roads which are very rocky or very sandy can not be materially improved by its use.

An outfit for boring taprooted stumps for blasting, H. THOMPSON (*U. S. Dept. Agr., Farmers' Bul.* 600 (1914), pp. 5, figs. 4).—This publication gives

detailed information concerning a power outfit for boring taprooted stumps for blasting.

To get the best results when blasting such stumps, the charge must be placed within the taproot. The power outfit consists of one 5-horsepower horizontal gasoline engine, one 3-kilowatt dynamo, two electric drills using 1½-in. augers usually 30 in. in length, and the necessary cables for connecting. The engine and dynamo are mounted upon skids or a wagon and the drills are supplied with current from the dynamo. The total cost for an electric stump boring outfit f. o. b. distribution point is given as \$460.

In a test of such an outfit the dirt was thrown away from one side of the stump to a depth of 12 in. and a hole bored into the stump at least 10 in. below the surface. Of the 100 stumps so blasted 97 were broken off below plow depth while the roots of the remaining 3 were easily cut out low enough to permit cultivation. Slightly less powder was used than where the holes were bored at the surface of the ground and the total average cost for digging, boring, and blasting was 22 cts. per stump. The cost of clearing land with this outfit and the use of nitroglycerin powder will range from \$5 to \$18 per acre provided the wood from the stumps and roots can be sold for enough to pay for their disposal.

Scientific tests of a two-cylinder opposed engine, B. HEEB (*Gas Engine*, 16 (1914), No. 3, pp. 137-141, figs. 6).—Tests of a two-cylinder opposed engine rated at 10 horsepower are reported. In one and two hour tests at full load, the engine had a mechanical efficiency of 82.67 per cent and a thermal efficiency of 23.76 per cent. The heat losses were in the cooling water 47.6, exhaust 11.4, and radiation 17.04 per cent. After a steady 130-hour run at full load the mechanical efficiency was 83.7 per cent and the thermal efficiency 21 per cent.

Use of ball bearings in agricultural machinery, HERMANN (Jahrb. Deut. Landw. Gesell., 28 (1913), No. 4, pp. 868-891, figs. 26).—The author briefly reviews the history of the ball bearing as regards its origin, manufacture, and use in machinery, and points out its advantageous use in a series of more recent development of agricultural machinery.

Competitive tests of tractors and other apparatus for mechanical cultivation, G. D. DE CHASSART ET AL. (*Bul. Agr. Congo Belge*, 4 (1913), No. 4, pp. 799-867, figs. 39).—Tests of a number of steam and internal combustion tractors, motor plows, and motor cultivators are described in detail, and the results reported.

Out of a maximum of 310 points for construction, operation, and tractive power, the winning steam tractor received a rating of 283 points and out of a maximum of 305 points the winning internal combustion tractor received a rating of 266 points, followed closely by a second at 263 points. For construction and operation, the two leading motor plows were rated at 214 and 212.5 points respectively, and the leading motor cultivator at 193 points out of a maximum for all three of 245.

Mechanical cultivation with windlasses and cables, M. RINGELMANN (*Ann. Inst. Nat. Agron.*, 2. ser., 12 (1913), No. 2, pp. 299-343, figs. 12).—The author describes the construction and operation of the roundabout system of windlass and cable plowing, reviews various tests of this system, and reports investigations on the power losses in windlasses, pulleys, and cables, and methods for computing them. By use of computations and test data based on these methods, he compares the roundabout system with the windlass and cable systems using one and two tractors.

The data show that when furnishing a tractive effort of 1,000 kg. the one-tractor, two-tractor, and roundabout systems, have respective mechanical effi-

ciencies of 78, 68.5, and 48.9 per cent, and on the basis that the motor should develop the average maximum power necessary multiplied by 1.75 (E. S. R., 29, p. 185), these systems will require respectively one 30 to 35 horsepower motor, two 35 to 40 horsepower motors, and one 50 horsepower motor.

Motor cultivation, its practical applications, T. BALLU (*La Motoculture, ses Applications Pratiques*. Paris [1913], pp. 290, figs. 79; rev. in *Ann. Sci. Agron.*, 4. ser., 3 (1914), No. 2, pp. 110, 111).—The main purpose of this book is to present the principles underlying the construction in the more recent developments in mechanical cultivating machinery. Their cost and economic application are also treated as prime considerations.

On the history of horseshoeing, J. HORN (*Ueber den ältesten Hufschutz des Pferdes*. Inaug. Diss., Univ. Leipsic, 1912, pp. 83).—A treatise on the history and development of the art of horseshoeing since the earliest recorded history. A list of 84 references is appended.

Test of some joints used in heavy timber framing, H. D. DEWELL (*Engin. News*, 71 (1914), Nos. 12, pp. 593-598, figs. 9; 13, pp. 666-669, figs. 5).—Tests on pin-keyed, lag-screwed, and bolted timber joints and tests of washers are reported.

White oak, Australian hickory, and gas pipe pins were rejected as unsuitable material for pin-keyed joints. Extra heavy wrought steel pipe was practically as efficient as solid metal for pins, but the Hawaiian hard wood Ohia pins gave a higher resistance than either. In lag-screwed joints it is believed that the resistance of the screw is appreciably the same whether it bears against or across the grain of the main timber. "In the case of a metal plate lag-screwed to timber, . . . the strength would be determined by the strength of the screw in shear, or the plate in bearing."

Washer tests, by F. L. Bixby, showed the fallacy of using the ordinary washers with bolts or rods in which considerable tension exists. Other tests showed a great variation in the strength of different washers of the same size. The $\frac{3}{4}$ -in. and $\frac{7}{8}$ -in. washers were less efficient than those of larger diameter.

For permanent work it is recommended that washers be given an area to provide bearing across the fibers of Douglas fir at a stress of 285 lbs. per square inch when the stress in the bolt is 16,000 lbs. per square inch, and that no thickness of metal be less than one-quarter inch.

Anchoring houses in overflow districts, B. YOUNGBLOOD (*Texas Sta. Circ.* 2, n. ser. (1914), pp. 8, figs. 2).—Plans, specifications, and bills of material for two kinds of foundations or piers to be used in anchoring houses in the river bottoms, prepared by A. Mitchell, are given.

Beef cattle and sheep barns, R. S. CURTIS (*North Carolina Sta. Circ.* 2, rev., (1914), pp. 21, figs. 13).—This circular gives several ground plans, accompanied by descriptive information, of beef cattle and sheep barns, and is intended to cover the conditions existing on the various farms in the State where sheep and cattle are maintained.

In planning a cattle or sheep barn it is pointed out that provision should be made for the probable yearly increase in the number of animals, and that the barn should be so arranged that an extension may be conveniently made. The author advocates the construction of a two-story or loft barn as being better adapted to the needs of the general live-stock farmer. For beef fattening cattle he advocates the use of a barn large enough to house the cattle comfortably, thus saving the manure and avoiding the use of an excessive amount of bedding. "Each steer should be provided with at least 50 sq. ft. of space in a closed barn, which with a 10-ft. elevation, allows 500 cu. ft. of air space per animal. In an open barn this provision is not so important, yet it is

necessary to allow ample space for cattle to lie down and rest. . . . Two linear feet of trough space should be provided for each average-sized animal."

If more than a carload of cattle are to be fed it is considered advisable to have the feed passage in the center of the barn, while for carload lots or less, the feed passage may be placed at one side, and the entire number of cattle allowed to run together. In the management of breeding cattle the barns may be made with or without stalls.

The best type of implement shed for Texas farms, B. YOUNGBLOOD (*Texas Sta. Circ. 4, n. ser. (1914), pp. 8, figs. 3*).—This circular, based upon farm experience and observations on the care or neglect of implements on a great number of farms in the Southwest, gives plans and bills of material for implement sheds. "The intention is to embody in these plans some of the best ideas extant among the farmers of the State with those of a competent architect so that the sheds will not only prove satisfactory in point of construction, but will stand as long as the materials of which they are constructed may last." The special implement shed built to itself appears to be the most desirable type.

The Tennessee wooden-hoop silo, C. A. WILLSON (*Tennessee Sta. Bul. 105 (1914), pp. 109-119, figs. 5*).—The planning and construction of the wooden-hoop silo is illustrated and described. It is stated that this type of silo may be constructed at a cost of from \$60 to \$100, and will last from 8 to 12 years when well constructed of good material.

Silo facts, A. J. REED (*North Carolina Sta. Circ. 1 (1913), pp. 8, figs. 6*).—This circular briefly states important facts to be considered in the construction and filling of silos.

The disposal of creamery refuse, A. P. WILSON (*Dept. Agr. and Tech. Instr. Ireland Jour., 14 (1914), No. 2, pp. 241-251*).—Disposal of creamery refuse by irrigation or by septic tank treatment and filtration is discussed.

It is concluded that to discharge safely an effluent into a stream, it must not contain more than 3 parts per 100,000 of suspended matter, and at 65° F. must not take up more than 2 parts per 100,000 of dissolved oxygen in five days. "If the dilution, while not falling below 150 volumes, does not exceed 300, the dissolved oxygen absorption test may be omitted, and the standard for suspended solids fixed at 6 parts per 100,000. . . . If the dilution, while not falling below 300 volumes, does not exceed 500, the standard for suspended solids may be further relaxed to 15 parts per 100,000. . . . With a dilution of over 500 volumes all tests might be dispensed with, and crude sewage discharged."

Sewage disposal in the Tropics, E. WEISSENBORN (*Arch. Schiffs- u. Tropen-Hyg., 17 (1913), Beiheft 3, pp. 47, figs. 20*).—The author discusses methods of sanitation, particularly sewage disposal, such as are practiced in some tropical localities, both municipal and rural, and describes additional sanitary measures which he considers applicable.

Firing house heating boilers for testing, E. R. PIERCE (*Dom. Engin., 67 (1914), No. 1, pp. 2, 3, figs. 1*).—The author discusses the practical benefits of testing a residential heating system to determine its economic operation, referring particularly to the proper use of the chimney check.

RURAL ECONOMICS.

Agricultural surveys, G. F. WARREN (*New York Cornell Sta. Bul. 344 (1914), pp. 419-433*).—The author maintains that the primary object of agricultural surveys is to find out all the facts possible by studying actual conditions in the field. A survey should be limited to one problem only. He discusses the

use and development of statistical agricultural surveys, their accuracy, and methods of carrying on the work and of studying the data.

Value of records in agriculture, M. LAPLAUD (*Ann. Sci. Agron.*, 4. ser., 3 (1914), No. 4, pp. 171-185).—The author discusses the value of records regarding the production of animals, crops, and labor, and concludes that there is no other method by which the maximum net results can be obtained.

Agricultural cooperation, B. H. HIBBARD (*Wisconsin Sta. Bul.* 238 (1914), pp. 3-32, fig. 1).—The author explains the purpose of cooperation, and the condition requisite to its success. The general principle of "one-man-one-vote" is advocated, also the federation of cooperative societies having similar purposes. The management of the organization should rest with a board of directors who should be authorized to employ a competent and trustworthy manager.

In Wisconsin the most common type of cooperation is the butter and cheese factory. The next most important is the farmers' telephone. The text of the Wisconsin law relating to cooperative associations is given, as well as articles of incorporation and a model constitution and by-laws for cooperative cheese producing associations, and a selected list of references on agricultural credit and cooperation.

A Dutch vegetable market (*Co-operation* [London], 8 (1914), No. 5, pp. 95-99, figs. 3).—This article contains a detailed description of the methods used in conducting auctions by the Loosduinen Cooperative Fruit and Vegetable Auction Market, Limited.

Concerning the servant question (*Wiener Landw. Ztg.*, 64 (1914), No. 11, pp. 93, 94).—The author discusses the training of girls for house servants and the relative influence of serving in farm families as against the employment opened to them in cities in training them for future wives and mothers.

The occupying ownership of land, B. TOLLEMACHE (*London*, 1913, pp. XIX+152).—The author believes that occupying ownership is superior to occupying tenancy as a system to be adopted for small holdings. He describes several instances where large tracts have been subdivided successfully, and points out some elements that are essential to success in undertakings of this nature.

Statistics of agricultural population, wages of rural laborers, and the trend of immigration in different countries, A. CARONCINI (*Étude Méthodologique et Statistique sur les Recensements de la Population Agricole, les Salaires de la Main-d'œuvre Rurale, et les Courants D'émigration dans les Différents États*. Rome: Internat. Inst. Agr., 1912, pp. XI+150).—This report notes the publications in which data concerning agricultural population, farm wages, and immigration may be obtained, and discusses the variation in the classification and methods of reporting.

The colonization of rural Britain, J. COLLINGS (*London*, 1914, vols. 1, pp. XXXII+290, pls. 16; 2, pp. 295-607, pl. 1).—The author discusses the various measures that have been proposed to prevent the rural depopulation of England and the causes for the present conditions of agriculture and agricultural laborers, and makes suggestions for their relief.

Report of the Royal Commission on Agriculture, W. H. HAYWARD, A. LUCAS, S. SHANNON, W. DUNCAN, J. J. CAMPBELL, and J. KIDSTON (*Victoria, B. C.: Govt.*, 1914, pt. 1, pp. IX+42).—The commission by means of hearings studied the various conditions affecting the agriculture of British Columbia. The principal part of their report describes conditions connected with the distribution of public lands and with the problems of agricultural labor, credit, and education. The report contains numerous recommendations.

The agriculture of the Cotswolds, R. ANDERSON (*Jour. Roy. Agr. Soc. England*, 74 (1913), pp. 22-36).—In this article are described the soil, climate, systems of cropping, methods of handling live stock, and general agricultural conditions.

Danish agriculture, R. SCHOU (*Mo. Bul. South. Com. Cong.*, 4 (1914), No. 3, pp. 2-5, figs. 3).—The author calls attention to the fact that the number of cattle increased from 1,440,000 to 2,218,000 between 1881 and 1909, and the area devoted to root crops from 225,000 acres to 716,000 between 1888 and 1912, while the area devoted to other crops has remained practically the same.

Although cooperative agricultural societies are the means by which uniformity and high standard of quality in agricultural produce have been maintained, it is due to the close supervision and inspection of the State that they have been able to prevent fraud by those outside of the societies. The Government has exclusive control of the right of export.

Agricultural conditions in Norway, J. FROST (*Ber. Landw. Reichsamte Innern*, No. 31 (1914), pp. VI+249, pl. 1, figs. 76).—This volume contains a detailed description of the climate, soil, means of communication, and of agricultural conditions as they relate to the people, land tenure, system of farming, crops, live stock, markets, and agricultural credit. The work contains a number of statistical tables and illustrations setting forth the facts brought out in the text.

The general agricultural census of Belgium for 1910 (*Statis. Belg. Recense. Gén.*, 1910, *Partie Doc.*, pp. 717).—This volume contains data showing by Provinces, communes, and arrondissements the area devoted to different crops, average yields, total production, and amount of seed used per hectare.

[Agricultural element in the population of Austria], N. HOFMANN (*Statis. Monatschr. [Austria]*, n. ser., 18 (1913), Dec., pp. 983-985).—In Austria, although the total number of males dependent upon agriculture increased from 6,440,405 in 1890 and 6,646,199 in 1900 to 6,667,787 in 1910, they form a decreasing percentage of the total population, viz, 55.1, 51.71, 47.51, respectively. The absolute and relative increase for the 20-year period is even greater among females, the numbers being 6,910,974, 7,063,005, and 7,168,297 and the percentages 56.62, 53.11, and 49.31, respectively.

[Agricultural statistics of the native States of India] (*Agr. Statis. India*, 28 (1907-1912), II, pp. II+1-123).—This annual statement contains statistical data showing for 1907-08 to 1911-12 the total land area classified according to agricultural uses, area irrigated, area in principal crops, and number of live stock for the native States of India, so far as information has been obtained.

[Agriculture in Japan] (*Statis. Rpt. Dept. Agr. and Com. Japan*, 29 [1913], pp. 1-119).—This annual report contains statistical data showing the number of households by form of tenure and by area of cultivated land, the area, production, and average yields of the principal farm crops, number of fruit trees and yield, silk production and trade, number of live stock and poultry, number of animals slaughtered, and number lost by diseases.

[Agriculture of Chosen] (*Statis. Rpt. Dept. Agr. and Com. Japan*, 29 [1913], pp. 781-783).—This report contains statistical data showing the agricultural population, the area of paddy fields and upland farms, area devoted to the principal crops, production of cocoons and raw silk, number of domestic animals and poultry, and number of animals slaughtered.

[Agriculture of Formosa] (*Statis. Rpt. Dept. Agr. and Com. Japan*, 29 [1913], pp. 786-791).—This annual report contains statistical data showing the agricultural population and area devoted to the principal food crops, number

of domestic animals, number of animals slaughtered, and the production of sugar, tea, and indigo.

The native agriculture of Tunis, P. DECKER-DAVID (*L'Agriculture Indigène en Tunisie. Tunis and Auch: Govt., 1912, 2. ed., pp. IX+777, pls. 2, figs. 108.*)—This is the general report of the commission for improving the native agriculture appointed May 13, 1911, and contains a detailed description of the soil, climate, peoples, systems of land proprietorship, irrigation, forestry, breeds and breeding of live stock, plants cultivated, industrial crops, and agricultural societies.

[Economic changes in the Union of South Africa], F. B. SMITH (*Union So. Africa Dept. Agr. Rpt., 1912-13, p. 29.*)—The European population has increased from 1,116,806 in 1904 to 1,276,242 in 1911 and the number of European farmers from 77,926 to 97,381. Of the total land area (143,056,120 morgens or 485,050 square miles), 3,282,971 morgens were under cultivation, 892,929 lying fallow, 89,945,238 used for grazing, and 464,102 under irrigation. The number of cattle has been previously noted (*E. S. R., 30, p. 494*).

[Agriculture in the Commonwealth of Australia, 1903-1912], G. H. KNIBBS (*Commonwealth Bur. Census and Statis. Aust. Prod. Bul. 7 (1914), pp. 1-56, 132-149.*)—This annual statement contains statistical data showing the land settlement; number of agricultural holdings, area, production, and value of agricultural products; imports and exports; and total number of live stock and number by size of holdings. The data relate principally to the crop year 1912-13, but for many items comparative data are given for a series of years.

AGRICULTURAL EDUCATION.

Report of committee on courses of dairy instruction, June 29, 1912, W. J. FRASER (*Proc. Off. Dairy Instrs. Assoc., 5-7 (1910-1912), pp. 105-112.*)—This report considers the question of raising the present standards of instruction in dairying.

The committee thinks that "the ideal course should be so arranged as to distribute the dairy work throughout the four years and yet have time so that a man wishing to specialize in dairy work alone can get it all, or at least the major part, in one year. At least one-fourth of the students' work in the 4-year course should be devoted to technical dairying, as this is the least possible time in which the subject can be properly completed and sufficient training given."

The dairy work in the regular 4-year agricultural course should be arranged primarily to prepare dairy farmers, creamery operators, and city milk-supply men for their life work along practical lines. For college or experiment station work graduate courses should be utilized.

Attention is called to essentials to be considered in outlining the dairy work and to a number of debatable questions as to time to be devoted to various subjects. In the opinion of the committee it is best for students not to specialize too soon. Students insisting upon practical work to bring immediate results should be "specials," and 4-year men should have a good grounding in the fundamental sciences in the first two years in college, in connection with a little of the several different lines of technical agriculture, including dairying. All agricultural students should be required to study the elementary principles involved in the production and handling of milk. This should be from a 3 to a 5-hour course.

A discussion of the report follows.

Physiology in the veterinary curriculum as a factor toward higher veterinary training and education, A. F. SCHALK (*Vet. Alumni Quart. [Ohio State*

Univ., 1 (1914), No. 3, pp. 81-85).—Calling attention to the need of establishing a higher plane of veterinary training and education by raising entrance requirements, lengthening the course, and strengthening the curriculum, the author takes up the subject of physiology as it is usually presented in the various veterinary curricula and attempts to show wherein it is often underestimated, neglected, or very feebly offered as a major integral in the course.

Nature study in the public schools, T. W. TURNER (*South. Workman*, 42 (1913), No. 9, pp. 497-503).—The author enumerates as the advantages of instruction in school gardening and nature study the bringing of the pupil and his parents into closer understanding, the aiding of the preservation of health, its considerable economic importance, in that it enables the pupil to aid the community in increasing its resources and in getting rid of noxious plants and animals, and its value as ethical training.

School gardens in America, V. E. KILPATRICK (*Amer. School Bd. Jour.*, 48 (1914), No. 5, pp. 12, 13, 79, figs. 7).—The author discusses the history, support, forms, management, value, and location of some of the best organized school gardens.

The rural high school as a community center, E. W. GAGE (*Hoard's Dairyman*, 47 (1914), No. 12, pp. 444, 450, figs. 3).—Some of the common forms of community work in practice in agricultural high schools are enumerated, and as an illustration of this type of instruction a description is given of the organization, equipment, and work of the Agricultural High School of Baltimore County at Philopolis, Md.

Agricultural instruction (Min. Agr. Argentina, Mem. Cong. Nac., 1912, pp. 29-36).—An account is given of the organization of the practical and special or technical schools of agriculture and the agricultural extension service in Argentina, which are under the administration of the ministry of agriculture.

[Progress in instruction in agriculture and home economics for farm women in France], COUNTESS DE KERANFLECH-KERNEZNE (*Bul. Soc. Agr. France*, 1914, Apr. 1, Sup., pp. 250-268).—In this address at the convention of the Agricultural Society of France, February 17-21, 1914, the president of the women's section of the society reports on the progress made in agriculture and home economics instruction for farm women in France, including a brief review of the work of the section, an outline of the object and organization of the farm women's institute (*cercle de fermières*) and of the itinerant home economics school, and a description of two typical institutes and an itinerant agricultural home economics school. As a result of 18 months' work, 10 women's sections, 5 itinerant schools, and 25 institutes were established by private initiative under the impetus of the Agricultural Society of France and the Central Union.

The Agricultural Institute of the University of Göttingen (*Das landwirtschaftliche Institut an der Universität Göttingen. Neudamm*, 1914, pp. [19], figs. 8).—An account is given of the organization, equipment, and work of the institute.

An agricultural school in Austria (*Jour. Bd. Agr. [London]*, 20 (1914), No. 10, pp. 898-900).—A description of the curriculum and notes on the organization and finances of the Francisco Josephinum Agricultural School at Mödling are given.

Courses of study in agriculture for the high schools of Illinois (*Agr. Col. Ext. Univ. Ill. [Circ.]*, 1914, Jan., pp. 62).—This circular contains outlines of a course in agriculture for a well equipped 4-year high school and a 1-year agricultural course, as compiled and recommended by the agricultural section of the state high school conference. The general outline of the four agricultural units recommended covers (1) elementary principles of plant life and farm crops,

and (2) horticulture, one-half unit each in the freshman or sophomore year; (3) animal husbandry, one-half or a whole unit in the sophomore or junior year; (4) soils and crop production, one-half unit in the sophomore or junior year; (5) farm mechanics and (6) farm management, one-half unit each in the junior or senior year; (7) special farm problems, poultry raising, home dairying, etc., and (8) plant and animal improvement, one-half unit each in the senior year. An appendix outlines topics under country life interests to which one-half unit may be devoted in the senior year in connection with civics and United States history, suggestions for laboratory equipment, lists of good reference books for secondary agriculture, available Illinois Station bulletins and circulars and Farmers' Bulletins of this Department for school use.

One thousand questions in California agriculture answered, E. J. WICKSON (*San Francisco, 1914, pp. 257*).—These questions, which have actually been asked, and the answers thereto are classified under the subjects of fruit growing, vegetable growing, grain and forage crops, soils, irrigation, and fertilizers, live stock and dairying, feeding animals, diseases of animals, poultry keeping, and pests and diseases of plants.

[Agricultural instruction for the teachers of Porto Rico] (*Agr. Col. Weekly [P. R.]*, 1 (1913), Nos. 35, pp. 181-184; 36, pp. 185-188; 37, pp. 189-192; 38, pp. 193-217; 2 (1913), Nos. 47, pp. 245-248; 48, pp. 249-252; 49, pp. 253-256; 50, pp. 257-260; 51, pp. 261-264; 52, pp. 265-268; 53, pp. 269-272, figs. 3; 54, pp. 273-276; 55, pp. 277-280, fig. 1; 56, pp. 281-288; 57, pp. 289-292; 58, pp. 293-296; 59, pp. 297-300; 60, pp. 301-304; 2 (1914), Nos. 61, pp. 305-308; 62, pp. 309-314, figs. 2; 63, pp. 315-318; 64, pp. 319-322; 65, pp. 323-326; 66, pp. 327-334; 67, pp. 335-338; 68, pp. 339-344; 69, pp. 345-348; 70, pp. 349-352; 71, pp. 353-356).—These articles deal with pineapple culture, irrigation and drainage, the practice and science of feeding farm animals, the instruction offered by the College of Agriculture of Porto Rico, home economics, agricultural instruction in the public schools, Easter week conference for teachers and the scholarship awarded by the agricultural college, physical training, the vegetable garden, the diet of the school child, the conservation of soil moisture, nitrogen, why trained agriculturists are needed in the Tropics, poultry growing in the Tropics, a thesis on foods, and school gardens.

Studies of trees, J. J. LEVISON (*Loose Leaf Field Manual, Wiley Tech. Ser., Exercises T 1-1—T 7-2 (1913), pp. 90, figs. 112*).—These exercises consist of studies of the identification, distribution, soil, location, enemies, planting, commercial values, etc., of various well-known trees, the insects injurious to trees and how to combat them, advice as to what trees to plant and how, pruning, tree diseases, tree repair, structure and requirements of trees, forestry, and care of the woodland.

Apple varieties, M. A. COBB (*Central State Normal School [Mich.], Bul. 19 (1912), No. 4, pp. 12, figs. 8*).—This agricultural bulletin for teachers is designed to arouse an interest in apple varieties and to explain how they are recognized or described. Rules are given for ordering varieties for an orchard.

Dairy laboratory manual and notebook, compiled by E. L. ANTHONY (*Philadelphia and London, 1914, pp. 72, figs. 15*).—This text-book is designed for use in general courses in elementary dairying. Instruction is given in the use of the Babcock tester, lactometer, farm separators, and churns.

Farm management, A. BOSS (*Chicago and New York [1914], pp. 237, figs. 72*).—“This text has been prepared for use in the secondary agricultural schools and in high schools giving courses in agriculture. It is intended to follow the more specialized subjects, such as farm crops, feeding and care of live stock, soils, and other similar courses. The best results will follow its use in the

junior or senior years. Only the large and more general problems in farm management have been discussed."

It is expected that the text, with the exercises, problems, and references to literature appended to each chapter, will make a full semester course.

Syllabus of home economics (*Baltimore, Md., 1913, rev., pp. 69*).—In reprinting this syllabus (*E. S. R., 29, p. 496*), advantage has been taken of the opportunity to make a few textual corrections and to revise and amplify the section on Aims and Results, the concluding subdivision of Household and Institution Management.

School gardens: General recommendations and suggestions for conducting school gardens, A. HOSKING (*West of Scot. Agr. Col. Bul. 61 (1913), pp. 42-79, figs. 11*).—This bulletin contains the code of regulations re school gardens of the Scotch education department, regulations and suggestions proposed by the governors of the West of Scotland Agricultural College, schemes of work, pupils' notebooks, suggestions for autumn and winter work, data on the cost of establishing school gardens, suggested syllabuses of instruction in the elementary principles of horticulture and in the operations and practice of horticulture, a list of common trees and shrubs, and notes on meteorology.

Illinois Arbor and Bird Days, compiled by H. T. SWIFT (*[Dept. Pub. Instr. [Ill.] Circ. 77 (1914), pp. 71, figs. 52*).—This is a compilation of special articles including The Illinois Way of Foundation Planting, by W. Miller and F. A. Aust; What Our Parents Saw on the Prairies; Practical Points About Attracting Birds, by E. H. Forbush; The Jenny Wren Bungalow, by Rebecca H. Kauffman; economic notes on a number of birds, nature poems, and suggestions for the observation of Bird Day.

Arbor and Bird Day manual for West Virginia schools, M. J. ABBEY (*W. Va. School Agr., 4 (1914), No. 3, pp. 58, figs. 28*).—Programs, directions for studying trees and birds, lessons on trees and birds, and general suggestions are given for the observation of Arbor and Bird Day.

Preparation of exhibits for fairs and contests, G. E. THOMPSON (*Kansas Sta. Circ. 36 (1914), pp. 7, figs. 8*).—Suggestions are offered for preparing exhibits of grain, corn, sorghums, grasses, and millets for fairs and contests.

MISCELLANEOUS.

Annual Report of Guam Station, 1913 (*Guam Sta. Rpt. 1913, pp. 24, pls. 4, figs. 6*).—This contains a summary of investigations by the special agent in charge, for the most part abstracted elsewhere in this issue.

Twenty-seventh Annual Report of Nebraska Station, 1913 (*Nebraska Sta. Rpt. 1913, pp. XXIV*).—This contains the organization list, a review of the work and publications of the year, and a financial statement as to the federal funds for the fiscal year ended June 30, 1913, and as to the remaining funds for the fiscal year ended July 31, 1913. The experimental work reported is for the most part abstracted elsewhere in this issue.

The county experiment farm; its function, selection, and management, C. E. THORNE (*Ohio Sta. Circ. 145 (1914), pp. 99-118*).—This contains an account of the work of the station, particularly with reference to its activities through county agents and county experiment farms, an explanation of the methods to be followed in securing a county experiment farm, and the text of the county experiment farm law as amended by the last general assembly.

NOTES.

Alabama College.—A recent number of *The Educational Exchange* announces that Prof. M. T. Fullan will furnish the county high schools, in which agriculture is a required subject of instruction, with a detailed course of study in manual training and farm mechanics in the form of mimeographed sheets pending its publication in book form. The boys' vocational work will consist of woodworking, farm mechanics, and mechanical drawing and the girls' work will include domestic science and art.

Arkansas University and Station.—Dr. R. R. Dinwiddie, pathologist and bacteriologist, who has been connected with the institution since 1887, has resigned with the intention of retiring from active service. Recent appointments include C. D. Stubbs, D. V. M., as assistant veterinarian in the manufacture of hog cholera serum, M. S. Baker, a 1914 graduate of the University, as assistant agronomist for research in the cotton investigation, Earl Kilpatrick as assistant agronomist, Miss Mary E. Metzger as assistant in home economics, and Miss Marcella Arthur for extension work in home economics.

Delaware College.—Dr. Samuel Chiles Mitchell, president of the Medical College of Virginia since 1913, has been appointed president.

Iowa College.—The registration at the summer school for teachers exceeded 600, an increase of over 160 per cent over the previous year. Agriculture and home economics were very largely selected by the teachers for study.

Maryland College.—A foreclosure sale was held September 22 of the half interest in 282 acres of the college property held by private stockholders of the joint stock company formed at the establishment of the college (E. S. R., 25, p. 403). The only bid was that of the state treasurer, thereby transferring title completely to the State of Maryland.

The first country life conference for rural ministers was held at the college in August with an attendance of over 200. It is expected to repeat the conference in 1915 and to hold a short course in agriculture for country ministers in connection with it.

Kansas Station.—Albert Hogan, Ph. D. (Yale, 1914) and E. L. Tague have been appointed assistant chemists. John C. Summers resigned in August as assistant chemist to accept a position with the *Cooperative Miller*.

Massachusetts College.—A department of rural engineering has been established with C. I. Gunness, formerly head of the department of mechanical engineering at the North Dakota College, as associate professor of rural engineering. A. Vincent Osmun has been promoted to the rank of associate professor of botany and F. A. McLaughlin to that of instructor. E. K. Eyerly, associate professor of rural sociology has resigned to become dean of the college of arts and sciences of the University of South Dakota and head of the department of economics and sociology.

Mississippi Station.—C. E. Wilson has succeeded R. N. Lobdell as assistant zoologist and assistant entomologist.

Montana College and Station.—H. E. Murdock of the Irrigation Investigations of this Office has been appointed in charge of the station work just instituted in agricultural engineering, beginning September 1. R. F. Miller, assistant in

animal husbandry in the station, has resigned to take effect October 1 to accept a position with the Texas College and has been succeeded by Russell R. Dodderidge, a graduate of the Kansas College. L. G. Schermerhorn, assistant professor of horticulture and assistant horticulturist, has resigned to accept a position with the New Jersey Stations, to take effect November 1.

Nebraska University and Station.—On September 1, Dean Burnett was appointed head of the department of animal husbandry and C. B. Lee and H. J. Gramlich professors of animal husbandry and associates in the station.

Nevada University and Station.—Archer Wilmot Hendrick, dean of Whitman College, Washington, has been appointed president. Frederick W. Wilson, animal husbandman of the Arizona University and Station, has been appointed in charge of the department of animal husbandry and has entered upon his duties. Other appointments include Dr. Philip A. Lehenbauer as professor of botany and horticulture, Jerome B. Frisbie, instructor in farm mechanics at the Colorado College, as assistant in agronomy, and Miss Norma J. Davis as state leader in home economics in the division of agricultural extension.

New Mexico College and Station.—Despite the loss of many Mexican students and a considerable number of preparatory students through the establishment of additional high schools, the total attendance at the college shows a gain of 15 per cent. Three-day extension courses in agriculture have been offered at many points in southern New Mexico with an aggregate attendance of 1,400.

Among the recent appointments are the following: A. C. Cooley, of Colorado, as director of extension work and farm management; J. M. Mann, instructor in botany at the University of Wyoming, as assistant professor of biology; Miss Lucy T. Boyd, as instructor in household economics; and Robert Latta and James R. Meeks, both graduates of Purdue University, as assistants respectively in dairying and animal husbandry.

Cornell University.—In order to familiarize farmers with the provisions of a new state law on grading and packing apples, demonstrations have been given by the college of agriculture in special cars operated in the fruit growing districts by the New York Central Lines. This special train is the seventh of the present year.

The department of floriculture has recently received two valuable collections of orchids from the Philippine Islands, one being presented by H. Boyle and the other by Dr. A. R. Ward.

North Dakota Station.—W. H. Peters, professor of animal husbandry at the Manitoba Agricultural College, has accepted a position as animal husbandman. He has been succeeded in Manitoba by G. Ward Jones, superintendent of the college extension work.

Pennsylvania Institute of Animal Nutrition.—F. C. Dosé (Pennsylvania State, 1914) has been appointed assistant in animal nutrition vice D. H. Kauffman, resigned, and entered upon his duties September 1.

South Carolina Station.—C. A. McLendon, formerly botanist and plant pathologist of the Georgia Station, has accepted a position as field pathologist, vice L. O. Watson, who has been placed in charge of the cotton wilt studies of the Bureau of Plant Industry of this Department.

Texas College.—C. M. Evans has resigned as superintendent of extension work beginning September 1 to become editor of the *Southern Farm and Dairy Magazine*, published at Bryan, Tex. He has been succeeded by Clarence Ousley as director of the extension service.

Vermont University.—*The New England Homestead* announces that the trustees have allotted \$3,600 per annum to the support of county farm agents beginning July 1. They also have authorized the erection of a stock judging

pavilion 100 by 120 feet, the provision of space for instruction in farm machinery, and a revision of the courses of instruction.

Virginia College and Station.—Lyman Carrier, agronomist since 1907, has accepted a position with the Office of Forage Crop Investigations of this Department, and has been succeeded by T. B. Hutcheson, associate professor in plant breeding in the University of Minnesota and associate in the station. W. K. Brainerd, professor of dairying and dairy husbandman, has accepted a position with the Dairy Division of this Department.

Virginia Truck Station.—The station office building has been doubled in size and a new building for farm implements and storage and a new insectary have been erected.

Washington College and Station.—M. A. McCall has been appointed vice director of the dry-land department vice H. E. Goldsworthy, resigned, and with headquarters at Lind. T. J. Newbill of Portland, Oreg., has been appointed state leader of boys' and girls' club work, and R. N. Miller, farm efficiency agent. In the station A. L. Sherman has been appointed assistant chemist and F. W. Allen assistant horticulturist vice W. J. Young, resigned.

New York Commission on Bovine Tuberculosis.—A commission to study the causes of bovine tuberculosis and its economic and health effects on the State has been authorized by the New York legislature. This commission has been appointed by Governor Glynn as follows: Dr. Theobald Smith, director of the division of animal pathology of the Rockefeller Institute; Dr. Hermann M. Biggs, commissioner of health; Dr. Linsly M. Williams, deputy commissioner of health; Dr. Philip Van Ingen of the New York Milk Commission; Dr. Henry L. K. Shaw, professor of children's diseases, Albany Medical College; Hon. Seth Low, of New York City; and Dean V. A. Moore of the New York State Veterinary College of Cornell University.

Agriculture at the National Education Association.—The program of the National Education Association at St. Paul, Minn., July 4-11, indicates the unusual recognition given to agricultural education at this meeting.

As in former years, the question of the training of teachers for the rural schools brought out much discussion. In a paper before the Department of Rural and Agricultural Education, on The Course in Agriculture for Training Teachers in Normal Training High Schools, A. V. Storm maintained that the rural school is the most important educational factor and the preparation of the rural school-teacher the most important educational task. Inasmuch as the normal schools will not be able to supply the demand for rural teachers for years to come the public high schools must shoulder the burden. A large majority of rural teachers are women, many of whom are reared in town, so they must be taught agriculture from the farmers' point of view and must study rural conditions as well as agricultural text-books. He outlined the work that ought to be done as including (1) a knowledge of some of the underlying principles of education and consequently of teaching, (2) the organization of agricultural subject-matter to be taught in accordance with these principles, which includes the amount, selection, sequence, arrangement, and units to fit the conditions of a rural elementary school, (3) some understanding of the principles, processes, and practices to be followed in the presentation of this subject-matter through the classroom, the home project, and the community work, and (4) actual practice in teaching the subject-matter in this manner.

In another address before the same department on The Rural High School, U. S. Commissioner of Education Claxton emphasized the importance of ascertaining the kind of education that the American farmer needs before attempting to outline a course in agriculture for rural high schools. His address dwelt mainly with the education and training of the farmer and his wife.

The organization of boys' and girls' clubs, as well as adult clubs and similar forms of rural endeavor, was considered this year for the first time. One afternoon devoted to this phase included papers on such topics as What Recognition Should Be Given Vacation and Other School Project Work Done by Pupils, and The Federated Boys' and Girls' Club Work of the United States, and five-minute reports of state and district club-work leaders on projects conducted, membership, club leaders, method of financing, apparent results, recognition given the work in the schools, and prospective club work.

At a meeting of the state and national club leaders, an address was given by E. J. Tobin, county superintendent of schools of Cook County, Ill., on Club Work as an Extension Service of the Public Schools. Mr. Tobin regarded club work, properly conducted, as the best means of tying up the home life of the pupil with the school, as well as of teaching certain subjects. A necessary preliminary to the successful organization of club work, however, is the provision of competent supervisors to follow up the matter during vacation. In Cook County, five country life leaders, one for 25 or 30 schools, are employed the entire year to initiate, carry on, and supervise rural community betterment work. One of their main endeavors is to organize every boy and girl over ten years of age residing in their division into an agricultural club. During the winter months they assist the teachers in giving agricultural instruction in the schools, and during the summer vacation they become itinerant teachers, corresponding to the "Wanderlehrers" in Germany, traveling from one farm to another to visit, inspect, and advise with the boys and girls.

In addition to an afternoon devoted to a conference on School Gardens in Cities, papers were read before the School Garden Association of America on Home Gardens in Indiana, School Gardening on the Prairie, and School Gardening in Los Angeles. Commissioner Claxton also addressed the latter association on Purposeful Occupations for Boys. He maintained that it is impossible to really educate any child who early in life does not engage in some purposeful occupation, that there should be a teacher of gardening in every city school, and that such work would yield considerable financial returns to families and improve the physical, intellectual, and moral condition of the children.

Agricultural Progress in Latin America.—The government of Cundinamarca, Colombia, has contracted with H. Charton, proprietor of vineyards of the municipality of Tocaima, to establish an agricultural institute on his property. The school will begin operations with twelve pupils selected from the municipality. Marcel Berthaul of Paris has been appointed professor of agronomy in the University of Narino. The Colombian Government has also authorized the employment of four instructors of tropical agriculture and two veterinarians.

The Elidoro Villazon National Agronomic and Veterinary Institute at Cochabamba, Bolivia, is now well equipped with experimental grounds, laboratories, library, machinery, and apparatus, and furnishes a 4-year course of theoretical and practical instruction in agronomy and veterinary science. The scholastic year begins in March. A number of scholarships are available to needy students. Pedro Charuli is acting director of the school and a number of the professors are specialists from abroad.

Dr. Moises S. Bertoni, an experienced agronomist and botanist and director of the agricultural station at Asuncion, Paraguay, has been appointed chief of the Bureau of Agriculture of the government of Paraguay. An agricultural school is being established at Ypacarai, with two instructors who have been educated abroad in charge of the several courses.

A three-year theoretical and practical course in agriculture is now being offered in the Peruvian National College of San Luis Gonzaga at Ica. A viticultural experiment station has been in operation in the Moquegua Valley,

under the direction of Julio Solano. A new school is also to be established at Puno, the Peruvian port on Lake Titicaca, for native boys from 6 to 14 years of age. The instruction will be elementary and practical with the aim of developing mining, agriculture, and other industries in this section.

In Uruguay the Paysandu agronomic station, established nearly two years ago, is under the direction of Felix Ruppert and includes 1,360 hectares of land, of which 605 are in flax, wheat, oats, potatoes, and maize. A beginning has been made in the cultivation of olives, oranges, peaches, apples, and pears, and a small forest has been started. The station has a dairy and creamery in operation and is well equipped for raising chickens and other domestic fowls. It also possesses 170 milch cows and 700 ewes, and the breeding of horses and sheep is taught. Both theoretical and practical instruction is given.

The Province of Salta in Argentina has given the subtropical agricultural experiment station at Güemes in the department of Campo Santo 200 hectares of land for experimental work in the cultivation of citrus fruits. The growing of cotton, tobacco, and tropical fruits is being successfully carried on at the station. The eight practical agricultural schools of Argentina had 239 pupils in 1912 and 305 in 1913.

Roseworthy Agricultural College, South Australia.—Principal A. J. Perkins has been appointed to succeed William Lowrie, resigned, as director of agriculture in South Australia. He will be chief technical adviser to the minister of agriculture and will also be responsible for the general experimental work and management of the government farms throughout the State. W. J. Colebatch, superintendent of agriculture in the Southeast and manager of the Kybybolite Experiment Farm, has been appointed principal of Roseworthy College. W. J. Spafford, the lecturer and demonstrator of agriculture and assistant experimentalist at Roseworthy College, has been appointed to the new position of superintendent of agricultural and experimental work and will, under the instructions of the director, supervise the experimental work conducted by the department outside the experiment farms.

Western Australian Farm School.—The Child Emigration Society of England has established a farm school at Pinjarra as an experiment in child emigration. There are 33 boys from England, Scotland, and Wales at the farm, from 7 to 12 years of age. Until 14 years of age the boys are subject to the elementary education of the State, after which they receive two or three years of definite agricultural instruction before they are given positions with reputable farmers. Each boy is given a garden plat and is also taught the elements of pruning fruit trees, packing apples, caring for pigs and poultry, and milking cows. All are employed in turn in house duties. The quarterly cost of supervision, clothing, and maintenance of one boy has been \$126 a year which it is hoped to reduce to \$97.

Miscellaneous.—Ph. van Tieghem, the well-known French botanist and permanent secretary of the Academy of Sciences, Paris, died April 28, 1914, in his seventy-fifth year.

Dr. Jacob Eriksson has resigned the position of chief of the phytopathological experiment station at Stockholm, Sweden.

ABSTRACT NUMBER.

No. 6.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY—AGROTECHNY.

Standardization of potassium permanganate solution by sodium oxalate, R. S. McBRIDE (*U. S. Dept. Com. and Labor, Bur. Standards Bul.*, 8 (1913), No. 4, pp. 611-642).—In view of the numerous methods proposed for the standardization of potassium permanganate solution, the Bureau of Standards has sought a substance which would furnish reasonably correct results. "It was desired, if possible, that the standard selected should serve a threefold purpose, viz, first, as a primary standard of oxidimetry; second, as a working standard for regular use in [our] own laboratories; and third, as a substance which could be distributed by the Bureau with a guaranty both as to its purity and as to its reducing value when used under specified conditions."

Sodium oxalate seemed best to fill the needs, and the results of the investigation showed that the main source of error in the oxidimetric titration is the loss of oxygen. "For this purpose the following detailed method of operation is recommended: In a 400 cc. beaker dissolve 0.25 to 0.3 gm. of sodium oxalate in 200 to 250 cc. of hot water (80 to 90° C.) and add 10 cc. of (1:1) sulphuric acid. Titrate at once with tenth-normal KMnO_4 solution, stirring the liquid vigorously and continuously. The permanganate must not be added more rapidly than 10 to 15 cc. per minute, and the last $\frac{1}{2}$ to 1 cc. must be added dropwise with particular care to allow each drop to be fully decolorized before the next is introduced. The excess of permanganate used to cause an end-point color must be estimated by matching the color in another beaker containing the same bulk of acid and hot water. The solution should not be below 60° by the time the end point is reached; more rapid cooling may be prevented by allowing the beaker to stand on a small asbestos-covered hot plate during the titration. The use of a small thermometer as a stirring rod is most convenient in these titrations, as the variation of temperature is then easily observed."

Benzoic acid as an acidimetric standard, G. W. MOREY (*U. S. Dept. Com. and Labor, Bur. Standards Bul.*, 8 (1913), No. 4, pp. 643-650).—Benzoic acid is considered a satisfactory reagent for standardizing acidimetric solutions. See also a previous note by Phelps and Weed (*E. S. R.*, 21, p. 610).

A new apparatus for quantitative dialysis, A. GOLODETZ (*Chem. Ztg.*, 37 (1913), No. 26, pp. 259, 260, fig. 1).—The construction of the apparatus, which is illustrated, is similar to that of the Soxhlet extractor.

The use of spectrophotometry in analysis, C. FÉRY and E. TASSILLY (*Ann. Falsif.*, 6 (1913), No. 52, pp. 73-78).—The use of an apparatus combining the principles of the colorimeter and spectroscope for measuring the amount of substance yielding a color is recommended in place of the usual colorimeter, which involves many errors. The estimation of iron in water and copper in foods is considered in this regard.

Estimation of alkalis in rocks, H. V. KRISHNAYYA (*Chem. News*, 107 (1913), No. 2779, pp. 100, 101; *abs. in Jour. Chem. Soc. [London]*, 104 (1913), No. 606, II, p. 339).—The method consists in heating a suitable quantity of the powdered rock in a platinum dish with hydrofluoric and sulphuric acids, and after removing the excess of acid, dissolving the residue in boiling dilute hydrochloric acid. If any material remains, the treatment with sulphuric and hydrofluoric acids is repeated. The filtrate obtained is made up to a definite volume "and an aliquot part, representing 1 gm. of the sample, is withdrawn. After evaporating to dryness and igniting the residue, thus rendering the iron and alumina insoluble, the alkali sulphates are extracted with boiling water, and without filtering converted into chlorids by adding barium chlorid solution; some barium hydroxid is also added. After removing the excess of barium with ammonium carbonate, the alkali chlorids are weighed jointly as usual. The potassium is then estimated as platinichlorid in the ordinary manner."

Examination and judgment of water for agricultural and industrial purposes (*Ztschr. Landw. Versuchsw. Österr.*, 15 (1912), No. 11, pp. 1221-1231).—This deals primarily with the criterions for judging water for agricultural purposes, i. e., drinking water for animals, baking, and other domestic purposes, in the dairy, and for watering plants, but also includes the judgment of water for starch manufacture, sugar refining, malting, brewing, alcohol and yeast production, tanning, glue and gelatin manufacture, and silk spinning, and a short chapter on the chemical and biological analysis of water. The methods set forth were adopted by the officials of the Association of Austrian Agricultural Experiment Stations.

Examination and judgment of waste waters (*Ztschr. Landw. Versuchsw. Österr.*, 15 (1912), No. 11, pp. 1232-1237).—These are the methods adopted by the Association of Austrian Agricultural Experiment Stations in regard to the examination of sewage water, especially from the standpoint of stream pollution, etc.

The use of potassium palmitate in water analysis, C. BLACHER, P. GRÜNBERG, and M. KISSA (*Chem. Ztg.*, 37 (1913), No. 6, pp. 56-58).—Potassium palmitate is preferred to potassium stearate for use in Clark's and similar methods for determining the hardness of water. The presence of humates in boiler water does not interfere with the results obtained by the palmitate method, but when soap is used the results are unreliable. In the analysis of waters containing humates the indicator methyl orange can not be employed. When comparing phenolphthalein with anthranilic acidazodimethylanilin it was found that the neutral points were very near one another, and it is proposed to use the latter compound as an indicator in place of methyl orange for the determination of the temporary hardness which has been termed the methyl orange alkalinity. It can also be employed in connection with determining the permanent hardness of water.

Potassium palmitate solution may also be employed for determining the sulphates in water. For estimating the magnesium in water a modification of the Pfeifer method is employed which is described.

Estimation of total nitrogen, E. R. NOYES (*U. S. Naval Med. Bul.*, 7 (1913), No. 3, pp. 394, 395).—The method, while primarily intended for the analysis of urine, is considered of value for other purposes. It is carried out as follows:

"In a test tube (15 by 150 mm.) place 1 cc. of urine and 1 cc. of strong sulphuric acid and boil until frothing ceases, being careful not to allow any of the froth to leave the tube. Cool and add 0.5 gm. potassium sulphate and again boil until solution becomes nearly or quite colorless. Cool and then make up contents of tube to 5 cc. with water. Again allow to cool and then fill the small arm of the Hinds-Doremus ureometer with it, the large arm of the instrument being filled with sodium hypobromite solution. The usual manipulations for a urea estimation are now carried out, allowing, however, 2 cc. of the acid solution to run into the hypobromite. The number of divisions occupied by the evolved gas is observed and then multiplied by 0.373, the result being the number of cubic centimeters of nitrogen. Correct this volume for temperature and pressure and multiply the result by 0.00125, the final result being the weight in grams of total nitrogen in 0.4 cc. of urine."

The time required for the operation should not exceed 30 minutes.

A new volumetric estimation of nitrites and separation of nitrous and nitric acids, W. M. FISCHER and N. STEINBACH (*Ztschr. Anorgan. Chem.*, 78 (1912), No. 1, pp. 134-140; *abs. in Jour. Chem. Soc. [London]*, 102 (1912), No. 601, II, pp. 1093, 1094).—"There is no satisfactory method for the estimation of nitric acid in the presence of nitrous acid. A method is provided by the rapid esterification of nitrous acid in which oxidation to nitric acid does not take place, as is proved by experiments with pure silver nitrite. The solution is placed in a 300 cc. flask, 5 cc. of methyl alcohol is added, and a mixture of tenth-normal hydrochloric acid with a little methyl alcohol is allowed to flow in, while a current of air is drawn through the liquid. After 20 cc. of acid have been run in, the stream of air is continued for five minutes, and the solution is then titrated with sodium hydroxid solution, free from carbonate and phenolphthalein. The reaction is: $\text{NaNO}_2 + \text{HCl} + \text{CH}_3\text{OH} = \text{NaCl} + \text{CH}_3\text{O.NO} + \text{H}_2\text{O}$.

"In the separation of nitric and nitrous acids, a mixture of sulphuric acid and methyl alcohol is placed in the flask, and the solution to be tested, mixed with methyl alcohol, is added drop by drop, air being passed through. The contents of the flask are then washed into a Jena flask, 2.5 to 3 gm. of Devarda's alloy are added, together with 20 gm. of potassium hydroxid, and the ammonia formed is distilled into fourth-normal hydrochloric acid and titrated."

Controls for the Folin method of estimating creatinin, W. H. THOMPSON (*Jour. Physiol.*, 46 (1913), No. 2, pp. I, II).—The control against which the Folin standard solution, i. e., seminormal potassium bichromate solution, is usually tested is a solution of creatinin prepared from creatin by boiling with normal hydrochloric acid for 3 to 4 hours, it being assumed that the transformation is quantitative and completed in this time. The present investigation tends to disprove that this is the case, as the transformation was found to be variable.

In seeking other methods for preparing creatinin from creatin, the Folin autoclave method was tried, but without satisfactory results. A picrate of creatinin was then prepared by the autoclave method and of this substance 0.0757 gm., which corresponded to 0.025 gm. of creatinin, was dissolved in water and made up to 50 cc. Ten cc. portions were then taken and each of them treated with 14 cc. of a 1.2 per cent picric acid solution and 5 cc. of a 10 per cent sodium hydroxid solution, and after standing for 7 minutes the contents of each tube was diluted with water to 250 cc. Readings were then made against an 8 mm. column of a seminormal solution of potassium bichromate. The readings, which were in the neighborhood of eight, were very satisfactory and corresponded to the Folin value.

The double picrate of creatinin and potassium was also prepared from urine in the manner described. The readings obtained with this material were likewise satisfactory. Both salts were found to be very sensitive to the amount of alkali used in the method.

The reaction between metallic salts and the soluble carbonates, and its bearing upon the precipitation of protein, W. N. HEARD (*Jour. Physiol.*, 46 (1913), No. 2, pp. 104-128, figs. 3).—"Since thorough dialysis removes all precipitation of emulsoid protein by salts of the heavy metals, except in concentrated solutions of the latter, precipitation must be intimately associated with some removable constituent. The experiment of adding salts to such dialyzed solutions shows that the production of a body with a very low solubility product is the necessary condition in causing precipitation. The only salt found in the dialyzate which is capable of producing this result is a bicarbonate (except in the case of silver). The reaction of the metals with emulsoid protein closely follows the reaction of these metals with soluble bicarbonates, and it is therefore concluded that the process depends upon this reaction.

"If it be considered to be proved that the presence of soluble bicarbonates is the determining factor in the precipitation of emulsoid protein, it establishes a probability that the precipitation of suspensoid protein is due to a reaction between the metals and soluble carbonates. The reaction between the metals and suspensoid protein follows in degree and also in the shape of the curves produced, the reaction between these metals and soluble carbonates, the general increase of precipitability accompanying the suspensoid state coupled with the partial conversion at any rate of the bicarbonate into carbonate being suggested as the cause of the difference of behavior of the two kinds of protein with the salts of the metals. No dialysis can remove all the salts present and it can easily be shown that a protein solution after sufficient dialysis to make it non-precipitable, as above stated, is distinctly alkaline to alizarin and when converted into the suspensoid state requires a certain definite quantity of acid to neutralize it, the amount being about one-quarter of that which would be needed with it undialyzed.

"Probably the precipitation of bicarbonates and carbonates acts mainly by the removal of the OH ions freed by the hydrolysis of these salts. But the results with AgNO_3 and NaCl suggest that there are other factors."

Quantitative determination of peptic activity, S. VON BOGDÁNDY (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 84 (1913), No. 1, pp. 18-28; *abs. in Chem. Abs.*, 7 (1913), No. 13, p. 2235).—From the Schütz (polarization) and Volhard methods for determining peptic activity a method was evolved which combines some of the salient features of the two. The casein used in the experiments contained 7.3 per cent of water, and the dried material 1.08 per cent of ash and 15.34 per cent of nitrogen.

The solutions required in the test were as follows: A 3.3 per cent solution of casein is prepared by stirring up 17.5 gm. of casein with 250 to 300 cc. of distilled water and then adding 27.5 cc. of normal hydrochloric acid solution; the solution is then poured into a 500 cc. flask and filled up to the mark with water. The solution of the casein is accomplished in the water bath at 40° C. and requires from $\frac{1}{2}$ to 1 hour. As a precipitating reagent for the casein a solution composed of 150 gm. of sodium sulphate, 50 gm. of magnesium sulphate, 100 cc. of alcohol (96 per cent), and water to make 1 liter is employed. If crystals are deposited in the solution they can easily be dissolved by heating the solution to a temperature of from 35 to 40°.

The actual procedure is as follows: In a 100 cc. graduated flask place 60 cc. of the casein solution and the necessary amount of Grüber's pepsin in 0.2 per cent hydrochloric acid, and then place the flask in a water bath kept at 40°.

After the lapse of the proper time add 30 cc. of the precipitating reagent and water to make 100 cc., shake well, and filter through a plated filter. The filtrate is then polarized in a 200 mm. tube with a Schmidt and Haensch triple field polariscope.

A new adulteration of olive oil, A. CUTOLO (*Bol. Soc. Nat. Napoli*, 2. ser., 24 (1910), pp. 117-120).—Olive oil was adulterated with a mineral oil and colored with methyl azodimethylanilin.

Determination of total tartaric acid in wine, P. MALVEZIN (*Ann. Chim. Analyt.*, 18 (1913), No. 1, pp. 19-21; *abs. in Rev. Gén. Chim.*, 16 (1913), No. 15, *Répert.*, p. 260).—Carefully distill 22 cc. of wine until only 2 cc. are left in the flask, and after cooling add 1 cc. of a 10 per cent potassium bromid solution and 40 cc. of an ether-alcohol mixture (equal volumes); then refrigerate for from 15 to 20 minutes and proceed with the precipitate in the usual manner prescribed for the determination of tartaric acid.

The determination of alcohol in wine, G. TOMMASI (*Ann. R. Staz. Chim. Agr. Sper. Roma*, 2. ser., 6 (1913), No. 2, pp. 125-156).—The method used in Italy and the one employed at the port of New York for determining the alcohol content of wine (distilling off the alcohol and determining the percentage of alcohol in the distillate by estimating its specific gravity with either a hydrostatic balance or picnometer) lead to the same results. The differences usually noted, however, are probably due to the different specific gravity tables from which the percentage of alcohol is read off. In the article a correction table is given for estimating the alcohol content found by Windisch's table and that which would be found if the table in the U. S. Internal Revenue Gaugers' Manual were used.

Tables for determining the amount of alcohol from the specific gravity, I, G. TOMMASI (*Ann. R. Staz. Chim. Agr. Sper. Roma*, 2. ser., 6 (1913), No. 2, pp. 157-194).—A table is given with which it is possible to calculate the alcohol content of an alcohol-water mixture to percentage by volume or weight at 15° C. when the temperature at which the specific gravity is taken lies between 10 and 25°.

Contribution to our knowledge of the composition of milk and its serum, W. BREMER, W. GREIFENHAGEN, and K. SAUERWEIN (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 24 (1912), No. 8, pp. 507-512; *abs. in Chem. Ztg.*, 37 (1913), No. 14, *Repert.*, p. 59).—The difference between the highest and lowest amounts of total solids noted in 16 milk sera was much lower than that in the milk from which the sera were prepared. Consequently, the serum can be used for determining the quality of the milk.

The variations in the amount of total ash, calcium, and phosphoric acid in milk and serum were very irregular. The sera of five samples of milk and the skim milk obtained from the whole milk, however, showed a fairly close agreement.

The influence of boiling on the physical-chemical behavior of woman's milk, cow's milk, and buttermilk, P. GROSSER (*Biochem. Ztschr.*, 48 (1913), No. 6, pp. 427-431).—The question as to whether the constituents of various milks are alike from a physical-chemical standpoint has been investigated by Köppe and others, and the conclusion has been drawn that the salts—at least the salts of calcium—are ionized in human milk, while in cow's milk the ions are not present in a free state. It has furthermore been shown that the favorable action of buttermilk in infant feeding is due to its physical-chemical resemblance to human milk.

In this investigation the above problem was studied with Bechhold's ultra-filtration method whereby one can eliminate many of the errors present in the

lesser refined methods which have been used in the older investigations. With the Bechhold method it is not necessary to dilute the milk and consequently any change in the conditions of dissociation which might occur as a result of adding water are prevented. It also allows working with compressed nitrogen for the purpose of preventing decomposition, and, furthermore, a concentrated filtrate is obtained.

It was found that boiling produces no depression of the freezing point in either cow's or human milk. The nitrogen and phosphoric acid content were practically not affected in cow's milk, but in human milk an appreciable reduction in nitrogen and phosphoric acid was produced. The calcium content in the ultrafiltrate of both milks is diminished by long boiling, especially in cow's milk. No changes were noted when buttermilk was boiled.

From the data obtained with unboiled milk it can be seen that in human milk the amount of noncolloidal rest nitrogen (nitrogen not precipitated by phosphotungstic acid) is greater than in cow's milk, and, furthermore, that a larger percentage of phosphoric acid and calcium is present in the free state in human milk than in cow's milk. Buttermilk, so far as calcium and phosphoric acid are concerned, has a greater resemblance to human milk than to cow's milk. The acid fermentation which has taken place in buttermilk results in a scission of phosphoric acid from calcium.

The biologic differentiation of milk proteins, H. KLEINSCHMIDT (*Monatschr. Kinderheilk.*, 10 (1911), pp. 402-419; *abs. in Ztschr. Immunitätsf. u. Expt. Ther.*, II, Ref., 6 (1913), No. 15, p. 1100).—Corresponding to the results obtained with the complement fixation and precipitation reactions, it was also found possible to differentiate milk proteins with the anaphylactic test and guinea pigs; thus serum and milk proteins could be differentiated. The albumin and globulin of whey seem to be the same substance. Casein is markedly differentiated by the reaction.

Animals sensitized with cows' milk albumin were not affected by injections of casein. By a second injection of the homologous antigen, antianaphylactic phenomena were observed. Animals sensitized to globulin became sick on receiving the amount of casein which is lethal to animals sensitized with casein.

Biological method for judging the quality of milk, S. PARASCHTSCHUK (*Milchw. Zentbl.*, 42 (1913), No. 3, pp. 65-69, figs. 9).—In investigations on the biological properties and peculiarities of various strains of lactic acid bacteria it was observed that not every strain gave a good coagulum with milk, and that the souring of milk at times went on very slowly. It often occurred that cultures of equal strength and kind kept under the same conditions would not coagulate certain kinds of milk at all. It was later found that certain strains would not develop in poor milk, and consequently the use of lactic acid bacteria for judging the quality of milk suggested itself.

The milk under examination was poured into a flask and sterilized, and then inoculated with the appropriate strains (1 to 2 per cent) of lactic acid bacteria and incubated at 32 to 36°. Good milk after the lapse of from 5 to 6 hours is coagulated. If the inoculation has been made with a loopful of bacteria, the time required for coagulation is about 12 hours.

For inoculation five separate strains of bacteria were used, as follows: (1) A Danish streptococcus previously used for preparing dry lactic acid cultures and which only grows on fresh milk; (2) a small diplococcus obtained from Jaroslaw, which gives a marked coagulation and is characterized by the fact that it remains virulent for eight months, or twice as long as any other culture; (3) Günther's lactic acid diplococcus, which yields a pleasant sweetish coagulum of not an especially thick consistency (the last two-named strains of organisms require a milk of good quality for development, although they will

develop in milk in which the Danish streptococcus will not grow or die); (4) a Russian lactic acid streptococcus which yields a thick, ropy coagulum and will grow in milk of not especially good quality (the chief microscopical difference between this organism and the Danish strain is the fact that the former has a characteristic size and appears in elongated pairs); and (5) the *Bacillus bulgaricus* (Metchnikoff) which is characterized by developing under abnormal conditions and will grow in milk of poor quality. An addition of a large amount of bicarbonate of sodium will not hinder the development of this organism, and it forms a tenacious coagulum.

If the milk under examination is of very good quality it will, after coagulation, show the following microscopic picture: Numerous Danish streptococci appearing as elongated diplococci and many small lactic acid bacteria (Günther and Jaroslaw diplococci), a few Russian streptococci, and a few *B. bulgaricus*.

Milk of medium quality requires about two hours longer for coagulation than milk of good quality, and in curdled milk the Danish streptococci are practically absent and are displaced by many small cocci, the Russian streptococcus, and the *B. bulgaricus*. In the poor milk the small lactic acid bacteria die, the Russian streptococci develop slowly and die, and only the *B. bulgaricus* survives.

A fresh milk or a milk which has been cooled down to and stored between 6 to 8° C. after drawing are the only ones which will yield satisfactory results with the test.

The value of this method for controlling the milk supply, especially milk which is designed for infant feeding and for butter making is pointed out.

A simple microscopical method for judging the micro-organism content of milk, A. ROSAM (*Milchw. Zentbl.*, 42 (1913), No. 11, pp. 333, 334).—The method consists of spreading a platinum loopful (of a definite size and weight) of milk (previously heated with an equal volume of methylene blue and a little pyridin in a metal spoon) on a microscopic slide, covering it with a cover glass, and counting the number of bacteria per microscopic field. The number of bacteria are calculated from this finding by means of a formula which is stated. The method is a rapid one.

About the detection of boiled and raw milk, A. BALÁZS (*Abs. in Chem. Ztg.*, 37 (1913), No. 54, p. 554).—The test is as follows:

To 5 cc. of milk add 2 cc. of a copper sulphate solution which contains 69.26 gm. of copper sulphate per liter, shake, and filter; then to 5 drops of the clear and transparent filtrate add Adamkiewicz's reagent (1 part sulphuric acid and 2 parts of glacial acetic acid). Warm carefully without boiling, shake, and allow to stand for a while. The serum of boiled milk remains colorless, while raw milk shows a violet red color. Its greatest intensity occurs within 10 to 15 minutes.

Preliminary report in regard to Römer's work on Schardinger's reaction of cow's milk, W. RULLMANN (*Biochem. Ztschr.*, 48 (1913), No. 1-2, pp. 155, 156).—A discussion in regard to Römer's work (*E. S. R.*, 27, p. 810) on the occurrence of Schardinger's reaction in the initial milk of cows. See also a previous note (*E. S. R.*, 27, p. 13).

Alteration of milk preserved with potassium bichromate, G. HINARD (*Ann. Falsif.*, 6 (1913), No. 54, pp. 233-237).—The changes produced in a milk containing 0.098 per cent of potassium bichromate were studied.

In the total solids a loss of 1 gm. per 100 cc. of milk was noted in six months. The figures for fat or ether extract were very discordant owing to the difficulty of obtaining a homogenous sample of milk. The loss in fat-free dry substance was similar to that of the total solids. The lactose figures for the first two months were very variable and in some cases became higher than at the outset, but after a lapse of six months the losses were very rapid and amounted

to 1.4 gm. per 100 cc. Coagulable casein diminished very rapidly and at the end of about six months it was about 0.61 per cent. The acidity calculated as lactic acid at the outset was 0.23 per cent and after six months it was 0.66 per cent.

The author believes that a study of other antiseptics should be made with a view of substituting one of them for potassium bichromate.

The detection of nitrates in milk samples which are treated with potassium bichromate, J. DOS SANTOS (*Rev. Chim. Pura e Appl.*, 8 (1912), pp. 181-184; *abs. in Chem. Ztg.*, 37 (1913), No. 4, p. 41).—Barium chlorid is recommended as a reagent for precipitating the chromate ion. The diphenylamin reaction can then be applied without interference from the chromate.

About the various methods for determining the moisture content of butter fat, F. KÖNIG (*Apoth. Ztg.*, 28 (1913), No. 7, p. 63).—The methods studied were (1) Soxhlet's in a Soxhlet drying oven with a current of air; (2) Soxhlet's in a wine drying oven but without a current of air; (3) the aluminum dish method; and (4) the indirect method, which utilizes the difference between the total solids and 100.

The lowest results were obtained by the second and fourth methods, and the highest with the aluminum dish method. In all probability the high results with the Soxhlet method are due to the removal of volatile fatty acids which may have been present in the butter. While the aluminum dish method is satisfactory for commercial analyses, it is deemed of no value for more exact work. The indirect or difference method is the one preferred by the author.

The detection of preservatives in fats (butter, margarin, lard), E. VOLLHASE (*Chem. Ztg.*, 37 (1913), No. 31, p. 312).—The author points out that the German Imperial Health Department (E. S. R., 28, p. 762) and the books on food analysis prescribe methods which are time consuming and require a large amount of material. To overcome these difficulties he evolved a method as follows: Fifty gm. of fat is placed in boiling water containing 1 to 2 drops of 15 per cent sodium hydroxid solution and 10 gm. of solid paraffin and shaken thoroughly in order to obtain a fairly uniform distribution of the fat. The mixture is allowed to cool, and if necessary ice used to aid the cooling process. The fat cake is then punctured, the infranatant alkaline fluid filtered through paper, and one-third of the filtrate used for formaldehyde and sulphurous acid tests. The remainder is shaken up with aluminum cream, heated to boiling, and after cooling filtered. A slightly opalescent fluid is thus obtained which is tested for the presence of salicylic, boric, and benzoic acids and their salts, fluorin, and chlorates.

Estimation of solid fatty acids by Hehner and Mitchell's method, A. HEIDUSCHKA and A. BURGER (*Ztschr. Öffentl. Chem.*, 19 (1913), No. 5, pp. 87-89; *abs. in Jour. Chem. Soc. [London]*, 104 (1913), No. 606, II, p. 351).—The method, which has been previously noted (E. S. R., 8, p. 861), gives satisfactory results for stearic, palmitic, and myristic acids. When the latter two, however, are to be estimated, they must be dissolved in alcohol to the saturation point. If more than 0.5 gm. of palmitic acid is taken for the estimation, the results are too high. "While the presence of acids which are readily soluble in alcohol does not interfere with the estimation, it is essential that the particular acid under examination should not be mixed with other fatty acids only slightly soluble in alcohol."

About the estimation of solid fatty acids according to Hehner and Mitchell's method, H. SERGER (*Ztschr. Öffentl. Chem.*, 19 (1913), No. 7, pp. 131, 132, fig. 1).—This is said to be an extension of Heiduschka and Burger's statements noted in the abstract above, and it also includes a description of a filtering and cooling apparatus, which is supposed to increase the efficiency of the method.

Examination of fats, oils, and varnish for technical purposes (*Ztschr. Landw. Versuchsw. Österr.*, 15 (1912), No. 7, pp. 767-849, figs. 7).—A detailed description of the methods adopted by the Association of Austrian Agricultural Experiment Stations.

Bromometric determination of formic acid, H. MÄDER (*Apoth. Ztg.*, 27 (1912), No. 76, pp. 746, 747; *abs. in Jour. Soc. Chem. Indus.*, 31 (1912), No. 20, p. 1006).—The method depends upon the quantitative oxidation of formic acid to carbonic acid through the agency of bromin.

Activities of the state chemical laboratory at Göteborg, Sweden, in 1912, J. E. ALÉN (*Årsber. Stadskem. Lab. Göteborg, 1912, pp. 15*).—A description of the activities of this laboratory, which involved the examination of 7,389 samples of miscellaneous substances. These included foods, condiments, waters, chemical and technical products, arsenic, seeds, milk, butter and other fats, canned goods, etc.

Curing meat on the farm, D. T. GRAY (*North Carolina Sta. Circ. 4* (1913), pp. 10, figs. 7).—This circular gives directions for selecting, killing, scalding, and dressing hogs on the farm, and the methods for brining, smoking, and sacking pork.

METEOROLOGY—WATER.

Brief list of meteorological text-books and reference books, C. F. TALMAN (*U. S. Dept. Agr., Weather Bur. Doc. 512* (1913), pp. 22).—This is the third edition of this list, previously noted (*E. S. R.*, 22, p. 117). The list is arranged alphabetically by authors in 17 different classes.

The climatic factor as illustrated in arid America, E. HUNTINGTON ET AL. (*Carnegie Inst. Washington Pub. 192* (1914), pp. VI+341, pls. 14, figs. 90).—Evidence regarding the character and sequence of changes in climate during the last 2,000 or 3,000 years, that is, the period covered by history and man's later development, in the drier portions of America from Guatemala on the south to Idaho on the north is assembled and discussed in this monograph. See also a previous note (*E. S. R.*, 30, p. 416).

The evidence was derived from studies of the influence of the present climatic conditions upon physiography and upon the habits and distribution of plants and animals including man, account being also taken of the relation of the present climatic conditions in the particular region studied to the great climatic zones of the earth as a whole. In connection with the purely physiographic investigations, a study has been made of traces of ancient human occupation in the large number of ruins scattered from the shore of the Gulf of California to the northern limits of New Mexico, as well as in southern Mexico and Yucatan. Data as to climatic changes derived from measurement of sequoias by a method devised by A. E. Douglas, of the University of Arizona, as well as from other tree measurements by the Forest Service of this Department, are also presented.

"A large number of phenomena from the diverse fields of geology, archæology, history, and botany seem to agree in indicating that during the past 3,000 years North America has been subject to pronounced climatic pulsations similar to those which appear to have taken place in Asia and other parts of the Old World. In the temperate portions of the Eastern Hemisphere the climate of the past appears on the whole to have been distinctly moister than that of the present. The change from the past to the present, however, does not seem to have been gradual and regular, but pulsatory or cyclic, so that certain periods have been exceptionally dry, while others have been wet. In America the same appears to be true."

Climatic changes, E. HUNTINGTON (*Geogr. Jour.*, 44 (1914), No. 2, pp. 203-210).—This article deals more particularly with what are known as long-period climatic pulsations and progressive desiccation of the earth. The general conclusion is that it is not possible to say whether the earth as a whole is becoming wetter or drier. Apparently there has been no general change of climate within historic times.

The meteorological conditions of an ice sheet and their bearing on the desiccation of the globe, C. E. P. BROOKS (*Quart. Jour. Roy. Met. Soc. [London]*, 40 (1914), No. 169, pp. 53-70).—The author cites evidence to show that "a well-marked cold period in the north has been associated with increased rainfall over all the more southerly regions for which information is available. . . .

"The regions occupied by extensive ice sheets at the present day, viz, Antarctica and Greenland, are the centers of permanent high-pressure areas, with slight precipitation. We therefore infer that the regions occupied by similar ice sheets in the glacial period were likewise occupied by permanent anticyclones.

"The maximum extent of glaciation occurred at about the same time in different regions of the globe, and also coincided with the maximum of the pluvial period, or period of greater rainfall than the present, in the unglaciated regions. But a general decrease in temperature should lead to a decrease, not an increase, in the amount of evaporation, and hence of precipitation.

"The explanation of the paradox lies in the different distribution of the precipitation. Various causes tended to minimize or reverse the effect of the fall of temperature in decreasing evaporation; thus, while the total precipitation over the globe may have been somewhat less than now, so little of it fell over the ice sheets that the remainder, falling upon the unglaciated areas, rendered these considerably moister than now.

"Since the culmination of the ice age desiccation has progressed with the retreat of the ice. Slight reversals have taken place; an example is the period, cold in the north, moist in the south, from the ninth to the thirteenth centuries."

Recent studies of snow in the United States, J. E. CHURCH, JR. (*Quart. Jour. Roy. Met. Soc. [London]*, 40 (1914), No. 169, pp. 43-52, fig. 1).—This is an account of studies made by the Nevada Experiment Station on Mount Rose and in the vicinity of Lake Tahoe (E. S. R., 28, p. 514; 29, p. 814). It describes the snow sampler and weigher used and discusses especially data secured on the relation of mountains and forests to conservation of snow.

It was found that the forested slope of Mount Rose contained "an average water content one-fifth greater than the unforested but protected slope above it, nearly twice as much water as the cornice at the apex of the mountain, over fourteen times the moisture conserved by the wind-swept slope, and more than twice the average water content of all three areas combined. . . .

"Area for area on mountains of gentler contour (and such mountains are the rule rather than the exception) the talus slopes are less efficient than forests as conservers of snow. . . . It is true that some of the snow above timber-line outlasts the snow in the forest below. This phenomenon is confined, however, to the deeper cornices of limited area. The use of timber screens instead of a forest cover evenly distributed would create drifts but little inferior in size and lasting power to the cornices on the talus slopes. Furthermore, the number of such drifts can be multiplied by planting trees, while the cornices on the rocks not only can not be increased in number, but also place too large an area under contribution if compared with the moisture conserved. Their only virtue is that the water they do furnish is released late."

Effect of snow and ice on the temperature of the air, O. V. JOHANSSON (*Öfvers. Finska Vetensk. Soc. Förhandl.*, 55 (1912-13), *Afd. A, No. 1, Art. 11, pp. 64*).—This article discusses in some detail the effect of melting snow and ice on the diurnal and annual variations in temperature of the air, and it is shown that there is a marked influence in this respect.

A quantitative determination of the radium emanation in the atmosphere and its variation with altitude and meteorological conditions, J. R. WRIGHT and O. F. SMITH (*Philippine Jour. Sci., Sect. A, 9 (1914), No. 1, pp. 51-77, fig. 1*).—This is a detailed account of investigations which have been noted from another source (*E. S. R.*, 31, p. 20).

The rainfall of Rhodesia, E. GOETZ (*Proc. Rhodesia Sci. Assoc.*, 8 (1909), *pt. 3, pp. IV+129, pl. 1, figs. 32; rev. in Cairo Sci. Jour.*, 8 (1914), *No. 90, pp. 72, 73*).—This is a more detailed account of investigations which have already been noted from a briefer paper (*E. S. R.*, 30, p. 211.) The available reliable data are compiled and discussed with reference to variation and distribution (periodic and seasonal) and with relation to pressure.

The origin of the rains is also discussed, the conclusion being that "the Indian Ocean winds are the principal rain-bearing winds." A chapter deals with the relation of the rains of Rhodesia to those of German Southwest Africa and Australia and with the Nile floods. The author presents data which he considers indisputable evidence that the rainfall has been less abundant in Rhodesia during the last 10 or 12 years than prior to that time. He also presents data to show that abnormal rainfall on one part of the earth's surface is followed by the same phenomenon somewhere else.

It is shown that dry and wet seasons are clearly defined in Rhodesia. The former extends from May to September, the latter from November to March.

Rainfall, reservoirs, and water supply, A. R. BINNIE (*New York, 1913, pp. XI+157, pls. 2, figs. 54; rev. in Geogr. Jour.*, 43 (1914), *No. 3, pp. 332, 333*).—The earlier chapters of this book deal with such matters as rainfall, drainage systems, catchment areas, floods, and evaporation, while later chapters take up more technical subjects such as reservoir and aqueduct construction, and water storage and supply to houses, in which water is studied in its mechanical properties. A somewhat elaborate discussion is given on the more practical aspects of rainfall study such as mean annual fall, fluctuations from year to year, and the relation of run-off to amount of rain. Other important information is given upon the influence of geological factors on springs and rivers and on the quality of water to be used for economic purposes.

Water resources, W. H. SHERZER (*Mich. Geol. and Biol. Survey Pub. 12, Geol. Ser. 9 (1913), pp. 222-264, pls. 4, figs. 4*).—The surface and underground water supplies of Wayne County, Mich., are discussed with reference to their occurrence, distribution, and availability for industrial and domestic uses.

Surface water supply of the North Atlantic coast basins, 1912, C. C. BABB, C. C. COVERT, and J. G. MATHERS (*U. S. Geol. Survey, Water Supply Paper 321 (1914), pp. 240, pls. 3*).—This report presents results of measurements of flow made on the St. John, St. Croix, Machias, Union, Penobscot, Kennebec, Androscoggin, Presumpscot, Saco, Merrimac, Blackstone, Connecticut, Housatonic, Hudson, Delaware, Susquehanna, Patuxent, Potomac, and Rappahannock river basins during 1912.

Surface water supply of the Ohio River basin, 1912, A. H. HORTON, W. E. HALL, and H. J. JACKSON (*U. S. Geol. Survey, Water-Supply Paper 323 (1914), pp. 118, pls. 2*).—This paper reports results of measurements of flow made on the Ohio River and its tributaries during 1912. Tables are also included giving gage heights and daily and monthly discharges at each station.

Surface water supply of upper Mississippi River and Hudson Bay basins, 1912, A. H. HORTON, W. G. HOYT, and H. J. JACKSON (*U. S. Geol. Survey, Water-Supply Paper 325 (1914), pp. 193, pls. 2*).—This report presents the results of measurements of flow made on the Hudson Bay drainage area in the United States and the upper Mississippi River drainage basin during 1912. Daily and monthly discharges at each station are given.

Surface water supply of the United States, 1912.—VII, Lower Mississippi River basin, R. FOLLANSBEE (*U. S. Geol. Survey, Water-Supply Paper 327 (1914), pp. 84, pls. 2*).—This paper presents results of measurements of flow made on the Arkansas River, Yazoo River, and Red River basins and their tributaries, during 1912. In addition are given daily gage heights at each station.

Surface water supply of western Gulf of Mexico basins, 1912, W. W. FOLLETT, R. FOLLANSBEE, and G. A. GRAY (*U. S. Geol. Survey, Water-Supply Paper 328 (1914), pp. 121, pls. 2*).—This paper reports measurements of flow made on the Rio Grande, Saguache, San Luis, Kerber, Rio Alamosa, Conejos, Costilla, Rio Colorado, Rio Hondo, Rio Pueblo de Taos, Rio Taos, Rio Lucero, Rio Fernando, Chama, Brazos, Horn, Rio Vallecitos, Rio Puerco, Bluewater, San Jose, Pecos, Devils River, Rio Salado, and Rio San Juan basins and several interior basins of New Mexico. Daily and monthly discharges are given for each station.

Clean water and how to get it, A. HAZEN (*New York and London, 1914, 2. ed. rev. and enl., pp. XII+196, pls. 18; rev. in Engin. Rec., 69 (1914), No. 15, p. 429*).—The second edition of this work (E. S. R., 19, p. 513) contains additional chapters on the so-called redwater troubles and on water sterilization.

The mechanical filtration of moorland water supplies, and the action of water on lead, A. S. DELÉPINE (*Jour. Roy. Sanit. Inst., 35 (1914), No. 3, pp. 117-132*).—In experiments with unpolluted moorland water supplies having a marked action on lead the author found that chemical precipitation combined with mechanical filtration removed all discoloration, reduced more or less the total number of bacteria, and satisfactorily corrected the action on lead.

Sterilization of water by filtration, K. CHARITSCHKOFF (*Chem. Ztg., 38 (1914), No. 20, p. 222; abs. in Gsndhts. Ingen., 37 (1914), No. 12, p. 218*).—The author found that all porous substances form hydrogen peroxid in the presence of water. He points out that the sterilizing effect of ultra-violet light on water depends chiefly on the formation of hydrogen peroxid, and states that the same result can be obtained by filtering water through pumice stone, asbestos, or horizontally through a metal brush.

SOILS—FERTILIZERS.

Field operations of the Bureau of Soils, 1911 (thirteenth report), M. WHITNEY ET AL. (*U. S. Dept. Agr., Field Operations of the Bureau of Soils, 1911, pp. 2356, pls. 27, figs. 61, maps. 50*).—This report contains a general review of the field operations of the Bureau of Soils during 1911 by the chief of the Bureau, together with detailed accounts of the following surveys:

Plymouth County, Mass., by W. E. McLendon and G. B. Jones; Windham County, Conn., by W. E. McLendon; Jefferson County, N. Y., by M. E. Carr et al.; Bedford County, Pa., by C. J. Mann and W. E. Gross; Bradford County, Pa., by P. O. Wood et al.; a reconnaissance soil survey of northeastern Pennsylvania, by C. F. Shaw et al.; the Sussex area, N. J., by H. Jennings et al.; Richmond County, N. C., by R. B. Hardison et al.; Johnston County, N. C., by W. E. Hearn and L. L. Brinkley; Fairfield County, S. C., by M. E. Carr et al.; Georgetown County, S. C., by W. E. McLendon et al.; Chatham County, Ga., by W. J.

Latimer and F. S. Bucher; Glynn County, Ga., by D. D. Long and J. E. Ferguson; Columbia County, Ga., by C. N. Mooney and A. E. Taylor; Chilton County, Ala., by L. Cantrell and W. E. Wilkinson; Elmore County, Ala., by R. A. Winston and A. C. McGehee; Jackson and Marshall counties, Ala., by C. S. Waldrop and N. E. Bell; Madison County, Ala., by R. T. A. Burke and A. M. O'Neal, jr.; Mobile County, Ala., by G. B. Maynadier et al.; Randolph County, Ala., by R. T. A. Burke et al.; Tuscaloosa County, Ala., by R. A. Winston et al.; Forrest County, Miss., by W. E. Tharp and W. M. Spann; Wayne County, Miss., by A. L. Goodman et al.; Lowndes County, Miss., by H. C. Smith and A. L. Goodman; Iberia Parish, La., by C. J. Mann and L. A. Kolbe; reconnaissance soil survey of southwest Texas, by A. E. Kocher et al.; the Huntington area, W. Va., by W. J. Latimer; the Morgantown area, W. Va., by C. N. Mooney and W. J. Latimer; Columbia, Fond du Lac, Juneau, Kewaunee, and La Crosse counties, Wis., by W. J. Geib et al.; Franklin County, Mo., by E. S. Vanatta and H. G. Lewis; Laclede County, Mo., by D. D. Long et al.; Macon County, Mo., by H. Krusekopf and F. S. Bucher; Platte County, Mo., by A. T. Sweet et al.; soil reconnaissance of the Ozark region of Missouri and Arkansas, by C. F. Marbut; reconnaissance survey of western Nebraska, by T. D. Rice et al.; Reno County, Kans., by W. T. Carter, jr., et al.; Shawnee County, Kans., by W. C. Byers and R. I. Throckmorton; reconnaissance survey of southwestern Washington, by A. W. Mangum et al.; Quincy area, Wash., by A. W. Mangum et al.; and Medford area, Oreg., by A. T. Strahorn et al.

During the calendar year 1911, 34,743 square miles, or 22,235,520 acres, were surveyed and mapped in detail on a scale of 1 in. to the mile, making the total area surveyed and mapped up to the end of that year 249,246 square miles, or 159,517,440 acres. There were also conducted reconnaissance surveys covering an area of 131,900 square miles, or 84,416,000 acres.

The white soils of the Bram and Reinhard forests in the colored sandstone regions of the upper Weser River, K. VOGEL VON FALCKENSTEIN (*Internat. Mitt. Bodenk.*, 4 (1914), No. 2-3, pp. 105-137, figs. 4).—The author briefly describes the colored sandstones of middle and southern Germany and discusses the chemical compositions of some of their supposed weathered products, particularly the white soils, chemical analyses of which he compares with those of the colored sandstones and bleached and ortstein soils. The white soils were richer in clay than the sandstone but differed little in regard to the amounts of other mineral constituents present. In contrast to a typical bleached and ortstein soil, the alkali and other salts tended in a measure to concentrate in the upper layer of the white soil, as did also the weathered clay.

It is concluded that the white soils are not related to the bleached and ortstein soils, and that regardless of their greater clay content they are weathered products of the hard colored sandstone. However, the author distinguishes between real and pseudo-white soils, classing as the former those white soils consisting of a loose upper layer and a dense substratum which do not differ widely chemically, and as the latter, soils consisting of a true white soil upper layer and a clay substratum which differ chemically and are of different origin.

See also a previous note (E. S. R., 30, p. 514.)

The origin of the red soils of diluvial times, E. BLANCK (*Jour. Landw.*, 62 (1914), No. 2, pp. 141-147).—A more detailed report on this subject has been previously noted (E. S. R., 29, p. 514).

Rutherglen Experiment Farm—Report on permanent experiment field, season 1913, A. E. V. RICHARDSON (*Jour. Dept. Agr. Victoria*, 12 (1914), No. 3, pp. 142-153, figs. 4).—Chemical analyses of samples of soil from the experimental field in their natural state show the soil to be "deficient in nitrogen, lime, and potash, and extremely deficient in phosphoric acid," as compared with

arbitrary standards of fertility of average European soils. Their mechanical composition also is said to be unfavorable for cultivation.

Methods for soil investigation, R. ALBERT and O. BOGS (*Internat. Mitt. Bodenk.*, 4 (1914), No. 2-3, pp. 181-198).—Comparative tests of methods for determining the humus and water content and specific weight of soils are reported, the object being to determine the simpler and quicker methods which are equally satisfactory for soils of different origin and history.

For humus determination the simplified method of elementary analysis by burning in a stream of oxygen, according to Dennstedt, is concluded to be the most generally satisfactory. As regards water content it is concluded that with sandy soils the determination by drying in an air bath at 105 to 106° C. is sufficiently exact, while for loam, clay, and moor soils Schwalbe's method of distillation with xylol is preferable. For specific weight determination is preferred the simplified method of Wrochem, which is based on the principle that pulverized and absolutely dry substances, such as cement, etc., are easily freed of their air content by immersion in turpentine.

The physical properties of soils, J. KOPECKÝ (*Internat. Mitt. Bodenk.*, 4 (1914), No. 2-3, pp. 138-180, figs. 4).—The author discusses the importance in soil judgment of determining the physical properties of soils, draws attention to the many inaccuracies in several of the commonly used methods, and describes methods and apparatus developed by him for determining the water capacity, apparent and real specific weights, porosity, air capacity, and permeability of soils.

It is concluded that the absolute water capacity of a certain type of soil in nature, excluding all outside influences, may be expressed by the amount retained after 24 hours following saturation, and that the air retained in the remaining pore space serves to indicate the air capacity. On the basis that permeability is that property which permits the soil to retain its absolute capacity of water and allow all excess to escape by percolation, relative permeability is expressed as the quantity of water in cubic centimeters which will percolate through a cross section of 100 sq. cm. of a soil column 10 cm. high in 24 hours.

The absorptive power of soils, P. ROHLAND (*Biochem. Ztschr.*, 63 (1914), No. 1, pp. 87-92).—The author discusses the properties of soil colloids and defends the colorimetric method for determining the absorptive power of soils, particularly kaolin. The absorptive power of kaolin is said to be a measure of its other properties, especially its plasticity.

The nature of drought according to the evidence of the Odessa experiment field, V. G. ROTMISTROV (*Sushchnost Zasukhi po Dannym Odesskago Opytnago Polū. Odessa, Russia, Russian Ed., 1911, pp. 66, figs. 21; English Ed., 1913, pp. 48, figs. 21*).—A continuation of work begun in 1905 is reported and results of previous investigations are summarized. The method of investigation is described and laws of the circulation of water, the root systems of plants in relation to the water of the soil, and methods of combating drought are discussed. The conclusions reached are based upon over 60,000 determinations of water in soils under different conditions of cropping and drought.

The author separates the soil zone in which the roots of plants grow into three layers, which are, beginning at the surface, (1) the periodically humid layer variable in depth, (2) the intermediate dry layer extending to a depth of from 63 to 71 in., and (3) the permanently humid layer below (2). He concludes that water percolating beyond a depth of from 16 to 18 in. does not return to the surface except by means of the roots of plants, and that all water not so utilized goes down into the deeper layers of the soil.

Under normal conditions the network of roots is very uniform throughout the soil layer which they occupy, but in order that this may be true and the

growth of the plants not interfered with, the soil zone occupied by the roots must be uniformly supplied with a sufficient quantity of available water (as a rule more than 10 per cent in the clay soil experimented with).

The depth of the moist layer at seedtime in the spring is of vital importance in relation to subsequent droughts. It was found in the experiments at Odessa, where the useful rainfall is only about 5.85 in., that every year at the end of June or at the beginning of July, and with a dry spring season at the end of May, cereals have consumed all of the reserve water which had accumulated in the root zone in the preceding autumn, winter, and spring, and that with continuous culture of cereals there was a pronounced and complete drying of the soil of the root zone and almost complete cessation therein of formation of soluble plant food.

An elaborate study of the distribution of roots of different kinds of plants in the soil (E. S. R., 20, p. 732) showed wide differences in the depth and extent to which different plants exhausted the soil moisture. Potato and flax roots were found to grow to a depth of approximately $2\frac{1}{2}$ ft., sunflowers and beets about $4\frac{1}{2}$ ft., and most cereals about $3\frac{1}{2}$ ft.

On the basis of his studies of the root systems of plants and their relation to the exhaustion of soil moisture the author recommends very strongly rotations which will alternate short-rooted and dense-rooted crops with those having longer and more scattering root systems.

The conditions conducive to drought are summarized in brief as follows: (1) Uneven distribution of moisture in the soil zone at the time of seeding, (2) persistent and perennial dryness of the intermediate layer of the soil and a deficiency of soluble plant food therein as a result of continuous cropping with the same kind of plants, and (3) great depth of the permanent water table.

Among the measures recommended for lessening or controlling the effects of drought in addition to the rotation of crops of different rooting habits, already referred to, are surface tillage and the destruction of weeds, the latter being considered "the bitterest enemy of . . . field culture and the best friend of drought."

It is pointed out that A. Shishkin about forty years ago formulated quite fully the means of combating drought, anticipating much that is now current practice in dry farming.

Forests and floods, J. AITKEN (*Nature* [London], 93 (1914), No. 2333, p. 506).—Tests with garden soil in pots are reported to show that stirred soil absorbs and retains much more moisture than compact, undisturbed soil, and it is maintained that soils under trees are loosened by the constant growth and expansion of the roots and thus put into condition for absorbing and retaining more rainfall than bare soils.

The chemistry of the soil: The evolution of acid amines, G. CHARDET (*Rev. Gén. Chim.*, 17 (1914), No. 9, pp. 137-144).—This article discusses the theoretical and practical value of the determination of acid amines in soils, reviewing briefly the chemistry of the metabolism of these substances, their evolution, and their transformation into products which are either toxic or fertilizing to plants. Attention is also called to the numerous points of similarity between the nutrition of the plant cell and the animal cell and the relation thereto of nutritive substances and excretory products.

The application of the Sørensen method for the rapid determination of acid amines in the study of soils is discussed and examinations of the nitrogenous compounds of four soils by this means are reported. It was found that the proportion of nitrogen in the form of acid amines varied from 49 per cent of the total nitrogen in peat to 52 per cent in swamp soil, 66 per cent in humus garden soil, and 68 per cent in compost.

Special reference is made to the work of the Bureau of Soils of this Department on the subject.

The effect of soluble humates on nitrogen fixation and plant growth, W. B. BOTTOMLEY (*Rpt. Brit. Assoc. Adv. Sci.*, 1913, pp. 777, 778).—A continuation of previous experiments is reported (*E. S. R.*, 30, p. 323). Data obtained from pot and field experiments with the so-called "bacterized" peat prepared by the author's method are presented to show that this material not only promotes nitrogen fixation in the soil but has a direct effect in increasing the growth of plants, and it is stated that "this is probably due in part to the presence of ammonium humate, which, in addition to being a direct source of nitrogen for plants, stimulates their root development in a remarkable manner."

Nitrification in pasture soils, C. T. GIMINGHAM (*Rpt. Brit. Assoc. Adv. Sci.*, 1913, p. 777; *abs. in Nature [London]*, 92 (1914), No. 2305, p. 516).—A study of nitrification was made in a soil intermediate in character between the true moor and the true fen soil. This soil contained a large amount (30 to 40 per cent) of organic matter and only traces of carbonate, but the soil water was neutral in reaction. The soil was found to be capable of bringing about immediate and rapid nitrification of peptone. Ammonium sulphate was also quickly nitrified, but the soil in this case became slightly acid in reaction.

A note on the use of nitron in the determination of nitrates in the soil is appended.

Investigations on the protozoa of soil, T. GOODEY (*Rpt. Brit. Assoc. Adv. Sci.*, 1913, p. 775; *abs. in Jour. Soc. Chem. Indus.*, 32 (1913), No. 18, p. 919; *Nature [London]*, 92 (1914), No. 2305, p. 516).—A rapid method for obtaining protozoa from a hay-infusion culture of soil was devised. The organisms first obtained by this method were ciliated protozoa, chiefly Colpoda. The indications were that these protozoa were present in soil only in an encysted condition and, therefore, could not inhibit bacterial activity.

Partial sterilization by means of volatile antiseptics had no effect on the rate of development of bacteria in a soil which had been kept in bottles since 1846 and contained no protozoa, but a soil kept since 1870 which contained a few protozoa (amoeba and flagellates) was improved in bacterial activity by partial sterilization.

Improvement of swamp land in Finland by addition of sand, A. RINDELL (*Finska Mosskulturför. Årsbok*, 16 (1912), No. 2, pp. 181-188; *abs. in Jour. Soc. Chem. Indus.*, 33 (1914), No. 8, p. 432).—"Experiments with oats extending over two years showed that loam is much superior to sand as an addition to unmanured marshy land. The addition of sand did not produce any improvement unless more than 400 cubic meters per hectare (about 5,700 cu. ft. per acre) was added. If the land was otherwise provided with phosphates and potash, the difference in effect between sand and loam was not appreciable."

Greater profits from land, A. L. DRYSDALE (*Edinburgh, London, and Leipsic*, 1914, pp. VIII+187, pls. 7).—This is primarily a summary of results of agricultural investigations carried on at the Dalmeny Experiment Station in Scotland during eight years beginning in 1895, with an introductory chapter discussing some features of recent progress in agricultural science and tables showing how the unexhausted value of applications of manure and fertilizers may be estimated.

New views on fertilization (*Mitt. Deut. Landw. Gesell.*, 29 (1914), Nos. 10, pp. 145-147; 11, pp. 154-156; 12, pp. 171-173; 13, pp. 181-183; 14, pp. 196, 197; 15, pp. 207, 208; 16, pp. 216-218; 17, pp. 230, 231; 19, pp. 259, 260; 21, pp. 292, 293; 23, p. 337).—This is a symposium on this subject contributed by a number of the more prominent investigators in the field of soil fertility and fertilization.

Fertilizers, fungicides, and insecticides, C. PLUVINAGE (*Industrie et Commerce des Engrais et des Anticryptogamiques et Insecticides. Paris, 1912, pp. XII+543, figs. 269*).—This is one of the volumes of the *Encyclopédie Agricole* published under the direction of G. Wery. It deals quite fully with the sources, nature, production, manufacture, and consumption of the principal fertilizing materials, namely, sodium and other nitrates, ammonium sulphate, synthetic nitrogenous compounds, phosphates, and potash salts. It also discusses the nature and use as fertilizer of garbage, poudrette, oil cakes, dried blood, tankage, horn, leather, and wool refuse, guanos, so-called humic fertilizers, and mixed fertilizers. Under the head of fungicides and insecticides sections are devoted to copper and iron sulphates, sulphur, carbon disulphid, and sulphocyanates.

The sections relating to sodium nitrate, ammonium sulphate, and the phosphates are especially complete.

A short bibliography is given but no index, a detailed table of contents taking the place of the latter.

Chemical fertilizers in the Canary Islands, H. BRETT (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 95, pp. 443-445*).—Statistics of consumption of fertilizers in these islands during the years 1910-1912, inclusive, are briefly summarized.

In 1912 the fertilizer imports amounted to 14,177 metric tons, over one-half coming from England.

Identification of commercial fertilizer materials, W. H. FRY (*U. S. Dept. Agr. Bul. 97 (1914), pp. 13*).—The methods and equipment required for the microscopic identification of the principal fertilizing materials are described and optical constants for the materials are given. It is stated that the methods described are those of the simplest and most accessible nature and that with their aid and a little practice anyone should soon be able to determine many of the materials ordinarily used in the manufacture of fertilizers.

Experiments in fertilizing with stable manure, A. VON LIEBENBERG (*Wiener Landw. Ztg., 64 (1914), No. 13-14, pp. 120-122*).—The results of a large number of experiments are summarized in this article, a conclusion of general interest being that it is profitable in many cases to use comparatively small applications of manure.

Guano and national agriculture, J. A. DE LAVALLE Y GARCIA (*El Guano y la Agricultura Nacional. [Lima, 1913], pp. 111*).—This is a series of papers dealing with the guano deposits of Peru and their relation to the national welfare, including also information regarding the extent, exploitation, and protection of these deposits.

Peruvian output of guano (Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 175, p. 559).—It is stated that the output of high-grade guano by the company administering the guano deposits of Peru was 31,486 tons in 1913-14 as compared with 24,350 tons the previous year. The corresponding outputs of low-grade guano containing less than 3 per cent nitrogen were 7,301 and 12,242 tons.

The seaweed industry of France, J. B. OSBORNE (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 152, pp. 1988-1990*).—The use of seaweed as fertilizer, which is stated to be quite general all along the French coast, is discussed.

New sources of nitrogen, D. A. GILCHRIST (*County Northumb. Ed. Com. Bul. 21 (1914), pp. 89, 90*).—Comparative tests of sodium nitrate, calcium nitrate, calcium cyanamid, and ammonium sulphate at Cockle Park during several years are reported, but no conclusions are drawn from the data reported except that

while calcium cyanamid is a useful nitrogenous fertilizer it should not be applied as a top-dressing but spread evenly and worked into the surface soil at least ten days before the crop is sown.

Synthetic ammonia by the Serpek method, HERRE (*Chem. Ztg.*, 38 (1914), Nos. 29, pp. 317, 318; 31, pp. 341-344, fig. 1).—The development and industrial value of this method is discussed. A short bibliography of the subject is given.

Experiments with nitrogenous fertilizers, E. HASELHOFF (*Landw. Vers. Stat.*, 84 (1914), No. 1-2, pp. 1-55).—Five years' field experiments with different crops and soils were made to determine the relative fertilizing value of lime nitrogen, nitrogen lime, urea and guanadin and their nitrates, calcium nitrate with and without free lime, sodium nitrate, potassium nitrate, ammonium nitrate, sodium nitrite, ammonium sulphate, Burkheiser salt, and galalith waste are reported.

The effect of the different fertilizing substances varied with the time and method of application, the season, and the kind of crop. In general, sodium nitrate and ammonium sulphate were about equal in effect, better results being obtained on loam soil than on sand, and from deep and fall applications rather than from surface and spring applications. Calcium nitrate was equal to and sometimes superior to sodium nitrate and gave better results on sand than on loam. Adding salt increased the beneficial effect of the calcium nitrate. Potassium nitrate and ammonium nitrate were as effective as sodium nitrate. Sodium nitrite was not equal to the nitrate in fertilizing effect, but it was so little inferior to the latter that it is thought that the small amount of nitrite sometimes occurring in calcium nitrate is likely to have a negligible effect upon the fertilizing value of the latter. Lime nitrogen in deep applications in the fall gave as good results as sodium nitrate, but was much less effective when applied as a top-dressing in the spring. Urea and guanadin and their nitrates were inferior to sodium nitrate. Burkheiser salt (containing cyanids in addition to ammonium sulphate) was inferior in fertilizing effect to ammonium sulphate. The waste in the manufacture of articles from galalith (indurated casein) was decidedly inferior to the nitrate, especially when used in coarse form on sandy soils.

The utilization of the nitrogen of these different substances by crops is discussed in detail in the article.

Comparative results with different phosphatic manures, D. A. GILCHRIST (*County Northumb. Ed. Com. Bul.* 21 (1914), pp. 35-43).—Summarizing the results of several years experiments with different crops at the Cockle Park Experiment Station it is stated that high citric acid solubility in case of phosphatic slags is not a sure index of greater fertilizing efficiency. While somewhat contradictory, the results indicate that high lime content in slags is advantageous and that high iron content is not disadvantageous. Both Tunisian and Belgian phosphates gave quite satisfactory results, the latter especially when it had been calcined. The indications were that the same amount of phosphate applied as a mixture of basic slag and superphosphate may give better results than when all the phosphate is applied as slag.

The fertilizing action of the phosphoric acid of steamed bone meal, T. ALEXANDER (*Monatsh. Landw.*, 7 (1914), Nos. 1-2, pp. 20-24; 3-4, pp. 67-73).—In experiments on grass lands it was found that the phosphoric acid of steamed bone meal was in no case inferior but in a few cases superior to that of Thomas slag, and this was true even in case of soils well supplied with lime.

The reserve supply of phosphate rock in the United States, W. H. WAGGAMAN (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 6, pp. 464, 465).—Including all rock containing from 58 to 78 per cent of "bone phosphate of lime," it is estimated that the total reserve supply of phosphate in the United States is

equivalent to 10,519,875,000 tons of high-grade rock. This is stated to be distributed as follows: Utah, Idaho, Wyoming, and Montana—high grade 2,500,000,000, high-grade equivalent of all grades, 7,500,000,000 tons; Florida—high-grade equivalent of all grades, 354,300,000, high-grade equivalent of wash heaps, 20,000,000 tons; Tennessee—high-grade equivalent of all grades, 115,075,000 tons; South Carolina—high-grade equivalent of all grades, 10,000,000 tons; Arkansas—high-grade equivalent of all grades, 20,000,000 tons; and Kentucky—high-grade equivalent of all grades, 500,000 tons.

The composition of the Wittelsheimer potash salts and their use in agriculture, P. KULISCH (*Ztschr. Angew. Chem.*, 27 (1914), No. 53, *Referatenteil*, p. 413).—From numerous analyses it is shown that the potash salts of the Alsatian deposits are mainly a mixture of potassium chlorid, 25 to 30 per cent, and sodium chlorid, 55 to 65 per cent. Therefore, the salts should not be used on crops injuriously affected by chlorin. They also contain a considerable percentage of calcareous clay and are, therefore, not suitable for use in fertilizer mixtures.

The importance and value of phonolite as a fertilizer, O. LEMMERMANN (*Arb. Landw. Kammer Prov. Brandenburg*, No. 35 [1914], pp. 39).—Reviewing the results of experiments with this material, it is concluded that, while phonolite has a certain value as a potash fertilizer, it does not compare in cheapness and efficiency with the ordinary potash salts.

Kelp production in United Kingdom, J. L. GRIFFITHS (*Daily Cons. and Trade Rpts.* [U. S.], 17 (1914), No. 134, pp. 1402-1405).—Brief accounts are given of the collection and use of kelp in various parts of the United Kingdom.

Extensive use is made of kelp as a fertilizer in the island of Jersey, particularly in connection with the potato crop. In the Scilly Islands, on account of the lightness of the soil, as much as 50 long tons of seaweed are frequently applied per acre for early potatoes, nearly as much for mangolds and other root crops, and somewhat less for grain crops. The use of seaweed ash for the manufacture of iodine has been largely superseded by the preparation of this substance from Chilean nitrate, although iodine is still manufactured to some extent from seaweed ash in Scotland. Lately, however, a process for obtaining the iodine directly from the seaweed by distillation with superheated steam has been proposed.

Methods of burning seaweed and the species best suited to kelp making are discussed.

The partial sterilization of the soil by means of caustic lime, H. B. HUTCHINSON and K. MACLENNAN (*Rpt. Brit. Assoc. Adv. Sci.*, 1913, pp. 774, 775).—The investigations of which this is a brief account have been noted from another source (*E. S. R.*, 29, p. 730).

Carbonic acid as a fertilizer, G. QUARRIE (*Commercial Fert.*, 8 (1914), No. 6, p. 26c).—Garden experiments in which one plat of soil was treated with carbon dioxide forced into it through underground pipes and another was untreated with gas but abundantly supplied with stable manure are reported.

The crops grown were potatoes, cabbages, Brussels sprouts, and privet. The treated plat yielded a little over one-third more potatoes than that which received only manure, and the potatoes were of better quality. The effect of the treatment was pronounced in the case of all of the other crops.

AGRICULTURAL BOTANY.

Formation of chlorophyll in plants, II, N. MONTÉVERDÉ and W. LUBIMENKO (*Izv. Imp. Akad. Nauk (Bul. Acad. Imp. Sci. St. Pétersb.)*, 6. ser., No. 9 (1912), pp. 609-630; *abs. in Jour. Chem. Soc. [London]*, 102 (1912), No. 598, II, pp. 800,

801).—Previous investigations of the authors (E. S. R., 21, p. 726) have shown that formation of chlorophyll in green plants proceeds by definite stages and that the phenomena are very complicated from a chemical point of view.

In the present paper they give the results of investigations in the formation of chlorophyll in green plants. It is stated that this involves two stages. The first includes the reactions by which the colorless leucophyll is converted into colored chlorophyllogen without the direct action of light. The second stage consists of chemical or photochemical transformations by which chlorophyllogen is converted into chlorophyll itself. With the conifers and other plants which become green in the dark the chlorophyllogen is acted on by unknown chemical reagents, but with most green plants the energy required for the transformation of chlorophyllogen into chlorophyll is supplied by light.

The part played by light has been found a complicated one. The maximal accumulation of chlorophyll corresponds with an optimal light intensity, the value of which varies with different species of plants. With excessive intensity of light both etiolated and nonetiolated plants were found to turn green more slowly, and the latter exhibited a kind of adaptation to strong light which showed itself in accelerated accumulation of chlorophyll during the development of the young plants. Chlorophyll accumulated by leaves developed in daylight was found to possess considerable resistance to strong light. Brief exposure of etiolated plants to strong sunlight retarded their subsequent greening under the influence of diffused light. A well-defined relation was found to exist between chlorophyll and the yellow pigments accompanying it, and in general the accumulation of each is influenced by the same factors. The pigments are not combined chemically with chlorophyll, so that the destruction of the latter in autumn leaves does not affect the yellow pigment.

Formation of chlorophyll in plants, III, N. A. MONTÉVERDÉ and V. N. LUBIMENKO (*Izv. Imp. Akad. Nauk (Bul. Acad. Imp. Sci. St. Pétersb.)*, 6. ser., No. 17 (1913), pp. 1007–1028, fig. 1; *abs. in Jour. Chem. Soc. [London]*, 106 (1914), No. 616, I, pp. 240, 241).—A description is given of an improved apparatus for carrying out the spectro-colorimetric estimation of chlorophyll, xanthophyll, and carotin as described in a previous publication (E. S. R., 24, p. 718). By means of the apparatus the amounts of the above pigments were determined in fresh leaves of a considerable number of plants representing quite a range of plant families.

The authors also report investigations on the influence of various constituents of the ash of plants on the extent to which the leaves turn green, this being measured by the proportion of chlorophyll present. Two series of experiments were made, one with etiolated *Luffa* seedlings and the other with etiolated wheat seedlings. With the first all the potassium salts used caused marked increases in the amount of chlorophyll formed, while magnesium sulphate produced a slight increase. Calcium or magnesium nitrate brought about a considerable decrease in chlorophyll formation, while sodium nitrate gave a small decrease. The presence of sodium dihydrogen phosphate resulted in a large increase. In the experiments with wheat seedlings magnesium sulphate, potassium permanganate, or dihydrogen phosphate had no effect on the amount of chlorophyll formed, while potassium nitrate had but a slight positive influence.

Hydrocyanic acid in plants.—II, Its occurrence in the grasses of New South Wales, J. M. PETRIE (*Proc. Linn. Soc. N. S. Wales*, 38 (1913), pt. 4, pp. 624–638).—In continuation of a previous paper (E. S. R., 28, p. 36) the author reports on the occurrence of hydrocyanic acid in plants of New South Wales.

The present paper is confined to a study of grasses. In addition to its occurrence in species that are naturalized or cultivated in New South Wales, the

author adds 17 species which are recorded for the first time as containing a cyanogenetic glucosid and the correlated enzym.

The influence of increased carbon dioxid content of the air on green plants, H. FISCHER (*Jahresber. Ver. Angew. Bot.*, 11 (1913), pt. 1, pp. 1-8).—Studies with plants under glass subjected to an increased density of carbon dioxid in the surrounding atmosphere are said to have produced, in almost all experiments, a notable increase in body growth by the plant; earlier and more abundant flowering and fruit in several cultivated species; fruit bearing by ordinarily sterile hybrids; and greater resistance to parasites.

The controlling influence of carbon dioxid in the maturation, dormancy, and germination of seeds, I. F. KIDD (*Proc. Roy. Soc. [London]*, Ser. B, 87 (1914), No. B 597, pp. 408-421, fig. 1; abs. in *Gard. Chron.*, 3. ser., 56 (1914). No. 1437, p. 34).—Experiments described are claimed to show that a high content of carbon dioxid in the atmosphere retards or inhibits germination of seeds without injury thereto. The seeds may germinate at once after removal of the carbon dioxid, as in case of beans, cabbage, barley, peas, and onions, or inhibition may continue indefinitely after removal of the inhibitory carbon dioxid pressures. In some cases described it was terminated only by complete drying and rewetting, or by removal of the testa. In such cases a lowering of the permeability of the testa to gases is thought to occur, reducing the admission of oxygen to the embryo and raising relatively the actual carbon dioxid pressure in the embryo tissues. The production of carbon dioxid in nature by decay of vegetable matter may, it is thought, play a part analogous to that noted in these experiments.

The growth of potatoes in a medium containing but little humidity and very little light, H. HUA (*Bul. Soc. Bot. France*, 60 (1913), No. 7, pp. 621-623).—A description is given of the growth of three potato tubers left by accident in a cave during the summer. Long, thin, etiolated shoots appeared and from near their bases short branches were put out which bore tubers at their extremities. No roots were observed to be formed, but in the absence of absorption from the soil and assimilation through aerial organs about 50 tubers were formed that weighed from 4 to 30 gms. each. The original weight of the tubers was unknown.

Decalcification of soils by smoke and effect thereof on plants, A. WIELER (*Jahresber. Ver. Angew. Bot.*, 10 (1912), pp. 58-74, figs. 6).—The effects of smoke gases on the development of lupine, vetch, pine, oak, and beech are shown and discussed. It is claimed that acids contained in the fumes may injure forest trees, not alone directly, by their action on the foliage, but indirectly, by forming soluble compounds with bases in the soil, thus permitting valuable constituents to be carried away in the drainage. Calcium was found to be notably deficient in soils examined which were unable to support forest growth.

The relative abundance of bacteria in forest soils and the influence of soil characters on their development, A. RÄUBER (*Forstw. Centbl.*, n. ser., 36 (1914), No. 4, pp. 195-208).—A study of bacterial flora of different soils at varying depths in 1913 is said to show that the bacterial content of limy forest soils in the upper layers is from ten to twenty times as high as in sandy soils, and varies considerably with the depth. The relative smallness of the number at or very near the surface is attributed to the development of humus acids there, as noted by Migula (*E. S. R.*, 29, p. 325). The importance of the influence of soil bacteria as regards decomposition varies greatly with local and temporal circumstances.

The rôle of winter temperatures in determining the distribution of plants, F. SHREVE (*Amer. Jour. Bot.*, 1 (1914), No. 4, pp. 194-202, fig. 1).—The author has carried out some preliminary investigations on the importance of the temperature phases of the past season in determining the distinct distributional limits of some subtropical desert plants.

Studies previously noted (E. S. R., 25, p. 732) with succulent plants native to various altitudes in southern Arizona, indicate, it is claimed, that within the limits of the species tested the number of hours that they are exposed to temperatures below freezing determines their survival or death without regard to the absolute minimum reached during the freezing period (although minima below 18° F. were not used). It is stated also that the succulents which have the lowest vertical limit of distribution are unable to resist freezing for more than 19 to 22 hours in duration, while species of higher limits are progressively able to withstand longer periods of freezing, up to about 66 hours, but that *Opuntia missouriensis* withstood 375 consecutive hours of freezing at Havre, Mont., in 1910-11. It is suggested that further studies in this direction may furnish a knowledge of the underlying causes of the phenomena of distribution.

The wilting coefficient of the soil, V. H. BLACKMAN (*Jour. Ecology*, 2 (1914), No. 1, pp. 43-50).—This is mainly a review of some recent contributions dealing with soil moisture in relation to plant needs as affected by the various factors involved, in particular an article by Briggs and Shantz (E. S. R., 26, p. 628).

Changes produced in the sap by the heating of branches, H. H. DIXON (*Sci. Proc. Roy. Dublin Soc., n. ser.*, 14 (1914), No. 15, pp. 224-228).—Comparisons were made of the sap of branches killed by heating with steam in the case of beech, poplar, and Ilex, and it was found that the steaming brought about a change in the depression of the freezing point, a decided increase in conductivity, a marked increase in acidity, a change in color, and the destruction of oxidase. The sap of steamed branches from a number of different species of plants was centrifugally extracted and tested on the leaves of *Elodea canadensis*, comparisons being made with fresh sap. In nearly every instance destructive changes were brought about in the leaves within two or three days.

The evidence drawn from these experiments indicates that leaves above a steamed branch perish not because they are cut off from their water supply, but because profound changes have been produced in the sap, resulting in the production of poisonous substances. The drying of the poisoned leaves is believed to be caused by the partial or complete plugging of the water channels by colloids exuded from the heated cells or coagulated in the sap.

The rôle of glycerin in causing anomalous structures in *Pisum sativum*, J. LAURENT (*Bul. Soc. Bot. France*, 60 (1913), No. 7, pp. 592-601, pls. 3).—The author describes certain anomalous structures of peas grown in culture solutions to which glycerin was added. In studying peas grown in such solutions it is said to be difficult to recognize asparagin, as that substance is transformed into albuminoid material as rapidly as formed. With plants having a less abundant nitrogen reserve than the Leguminosæ, and grown in cultures containing glycerin and asparagin or glycerin and peptone, these substances offer material for the synthesis of albuminoids, and some not only favor growth, but often produce a multiplication of cells and other unforeseen anomalies.

The spur shoot of the pines, R. B. THOMSON (*Bot. Gaz.*, 57 (1914), No. 5, pp. 362-385, pls. 4, figs. 2).—Giving an account of studies by himself as well as some views held by other authors on the deciduous spur shoot of the genus *Pinus*, the author considers the facts as noted on a study of both fossil and living pines as practically conclusive evidence regarding the specialized character of this structure. The spur, as it stands to-day, is considered a special-

ized branch which is of limited growth and bears a limited number of specialized and cyclically arranged leaves, its progenitor probably having been an ordinary branch.

A bibliography is appended.

On the relationship between the number of ovules formed and the number of seeds developing in *Cercis*, J. A. HARRIS (*Bul. Torrey Bot. Club*, 41 (1914), No. 4, pp. 243-256, figs. 3).—Continuing the plan of treatment outlined in a paper previously noted (E. S. R., 29, p. 829) but employing in the later studies *Cercis canadensis*, the author gives the results of studies carried out with nearly 35,000 pods. The results are indicated in tabular and graphical form. It is stated that the correlations for number of ovules formed and number of seeds developed per pod were found to be positive and of a moderate, considerable, or high degree of intensity.

Reversion in prickly pears, D. GRIFFITHS (*Jour. Heredity*, 5 (1914), No. 5, pp. 222-225, figs. 2).—This is a brief account of a supposedly spineless *Opuntia* from the island of Malta, which, since being planted at Chico, Cal., has developed spines on a part of the plant, also on plants developed from that part. This is thought to be possibly a case of reversion showing that the original ancestor of the *Opuntias* was spiny.

The probable origin of *Oenothera lamarckiana*, H. DE VRIES (*Bot. Gaz.*, 57 (1914), No. 5, pp. 345-361, pls. 3).—Summing up the results of this historical investigation, the author states that *O. lamarckiana*, as represented by specimens studied a century or more ago and still preserved, remains entirely unchanged at the present time, being now a well established component of the flora of the eastern United States and of England. It is thought that the strain which is now in cultivation, having been introduced into the trade about 1850, was probably derived from some wild English stock which may itself have come from the introduction into Europe of seeds collected by some botanists of the earlier period of study referred to.

An analytical and phytogeographical study of Leguminosæ, L. CAPITAINE (*Étude Analytique et Phytogéographique du Groupe des Légumineuses*. Paris, 1912, pp. 500, pls. 24).—The author presents analytical keys to the tribes and genera of leguminous plants, after which the geographic distribution of the species is discussed at length.

The seed of the Leguminosæ, L. CAPITAINE (*Les Graines des Légumineuses*. Paris, 1912, pp. XII+455, pls. 26, figs. 692).—The results are given of a study of the external morphological characters of seeds of a large number of species of leguminous plants. The author claims that the seeds of leguminous plants have characteristics by which the species may be generally recognized, and that numerous characters of convergence indicate adaptations which should be considered in a study of the seed and of the geographic distribution of the species producing it.

The culture of Leguminosæ with particular reference to nitrogen assimilation, B. HEINZE (*Jahresber. Ver. Angew. Bot.*, 10 (1912), pp. 75-114).—Reporting a continuation of work previously noted (E. S. R., 26, p. 37), the author shows that serradella on ground previously used for clover showed a distinct gain in green and in dry weight, also in percentage of nitrogen, after being inoculated with bacteria from soil in which serradella had been grown. Both lupines and serradella on land previously used for the latter gave a greater increase of nitrogen content than did either after potatoes, oats, peas, or vetches. The effects of several cultures offered on the market are also discussed.

FIELD CROPS.

[Field crop experiments] (*Rpt. Dept. Agr. Barbados, 1912-13, pp. 2-27*).—This reports and discusses results of manurial and variety tests with sugar cane and cotton, variety tests with cassava, caladiums, various legumes, and yams, and cultural trials with sour grass, guinea grass, and *Andropogon annulatus*.

The results of 20 years' experimenting with barnyard manure, superphosphate of lime, sulphate of potash, sulphate of ammonia, nitrate of soda, and dried blood have shown that the highest yields obtained with sugar cane were when 60 lbs. of nitrogen as dried blood was applied, 15 lbs. in January and 45 lbs. in June, in addition to other fertilizers. The best monetary results, however, were obtained when 40 lbs. of nitrogen as sulphate of ammonia was applied, 15 lbs. in January and 25 lbs. in June.

The addition of phosphatic manures showed losses. The best results obtained by the addition of potash were where 80 lbs. as sulphate of potash was applied in January.

Experiments with calcium cyanamid, H. LIPSCHÜTZ (*Illus. Landw. Ztg., 34 (1914), No. 25, p. 247, figs. 6*).—This article gives results of experiments in various localities in which calcium cyanamid, used at rates varying from about 100 to 125 kg. per hectare and applied as a top dressing to oats, potatoes, stock beets, and cabbage, not only destroyed the wild mustard growing in the crop but increased the yields materially.

The application of nodule bacteria for legumes, G. KÖCK (*Monatsh. Landw., 7 (1914), No. 1-2, pp. 24-27, fig. 1*).—It is here noted that soil condition is an important factor for successful inoculation. The results obtained with lupines and serradella showed the method of inoculation with nodule bacteria to be entirely satisfactory and productive of results equivalent to those with pure culture preparations.

Some minor farm crops, J. V. EYRE, A. W. ASHBY, G. F. WHITMORE, and A. J. BRANDON (*Jour. Roy. Agr. Soc. England, 74 (1913), pp. 127-172*).—This article discusses the general cultural and industrial conditions, and gives statistics in regard to flax, hemp, tobacco, teasels, and the production of seed of farm roots, vegetables, flowers, cereals, and grass.

Seeding grass with or without a nurse crop, A. RINDELL (*Finska Moorkultur För., 1913, pp. 241-255; abs. in Zentbl. Agr. Chem., 43 (1914), No. 3, pp. 176-177*).—The results here reported of several trials from 1906-1909 show heavier yields of hay obtained without a nurse crop of oats than with such a crop.

Investigations on the influence of water on the yield of meadows and pastures, LUEDECKE (*Kulturtechniker, 17 (1914), Nos. 1, pp. 23-37, pl. 1; 2, pp. 101-121, pls. 7*).—Some observations on recent investigations relating to the influence of water upon the development of grass and forage plants are given.

Phosphorus-containing substances in meadow hay, M. C. DUSERRE ET AL. (*Arch. Sci. Phys. et Nat. [Geneva], 36 (1913), No. 12, pp. 578-581; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, pp. 350, 351*).—In this study the quantity of (1) phosphatids, (2) phosphates, and (3) nucleo-proteids in various samples of hay is given. The application of phosphatic manures seems, from the data given, to have increased the phosphorus content of the hay, more especially that part present in the form of phosphates and phytin.

The composition of alfalfa, P. LAVENIR (*Bol. Min. Agr. [Buenos Aires], 16 (1913), Nos. 5-6, pp. 581-596*).—Results of analyses of several hundred samples of alfalfa from numerous localities in Argentina are given and discussed.

A many-eared variety of maize obtained by selection in Hungary, E. GRABNER (*Gaz. Lapok, No. 51 (1913), p. 850; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, pp. 352-354*).—As high as 12 ears are noted as being secured on a single stalk, but there seemed to be no regularity in the transmission of this character.

Cultural experiment with American and African horse-tooth corn, WACKER (*Fühling's Landw. Ztg., 63 (1914), No. 3, pp. 73-75*).—In comparative tests between Virginia and Natal corn, grown at Hohenheim, Germany, in 1912, the American corn made the best growth, as has also been noted in results of earlier tests (E. S. R., 28, p. 534).

Acidity as a factor in determining the degree of soundness of corn, H. J. BESLEY and G. H. BASTON (*U. S. Dept. Agr. Bul. 102 (1914), pp. 45, pl. 1, figs. 33*).—This bulletin describes the acid test (E. S. R., 24, p. 409) and shows how it may be used in the commercial grading of corn, and states the following facts that have been established by the corn acidity investigations:

“All corn, unless in a state of putrefaction, contains acid-reacting substances which impart to the corn a certain degree of acidity. There is a great variation in the degree of acidity of corn, ranging from 9 to 10 cc. to over 100 cc. The degree of acidity can be determined by the acid test to within 0.5 cc. The source of corn acidity is mostly in the germ. The source of increase in the degree of acidity is almost entirely in the germ. All corn judged damaged by the eye is higher in degree of acidity than corn judged sound by the eye. In a general way the degree of acidity of corn varies inversely with the germinative power. The degree of acidity of corn increases directly with the percentage of damaged kernels as determined by mechanical analyses. The degree of acidity of corn is greatly increased by the action of fermentation and high temperature. Throughout the year, from harvest to harvest, there is a gradual increase in the degree of acidity and a corresponding decrease in the percentage of germination of corn arriving at terminal markets.

“With respect to quality and soundness, the degree of acidity of corn is commensurate with the commercial grading at terminal markets. The degree of acidity of corn is a criterion of soundness and quality. From the standpoint of commercial grading, corn with a degree of acidity less than 22 cc. is normally sound and of good commercial quality; corn with a degree of acidity between 22 and 26 cc. is somewhat inferior in quality and soundness, due to deterioration of the germ; corn with a degree of acidity between 26 and 30 cc. evidences marked deterioration and is unsound, and corn with a degree of acidity greater than 30 cc. is badly damaged and should be considered from a commercial standpoint as sample-grade corn.”

A preliminary report of this work has already been noted (E. S. R., 30, p. 734).

Cotton, H. HEIZMANN (*Die Baumwolle. Zurich and Leipsic, 1913 vol. 1, pp. VIII+355*).—A treatise, of which this volume seems to be the first part, covering the cultural, ancient and modern history, and industrial aspects of cotton.

Experimental work with cotton, W. ROBSON (*Imp. Dept. Agr. West Indies, Rpts. Bot. Sta. Montserrat, 1912-13, pp. 2-7*).—This paper reports results of variety tests and of hybridization. In crossing native Montserrat cotton with Sea Island varieties a type was obtained that in the F_2 generation yielded lint ranging from 35 to 50 mm. in length.

Mutation in Egyptian cotton, T. H. KEARNEY (*U. S. Dept. Agr., Jour. Agr. Research, 2 (1914), No. 4, pp. 287-302, pls. 9*).—In this article the author discusses the origin of the Egyptian varieties, origin of new varieties in Arizona, mutability of Egyptian cotton, and the theories of mutations of De Vries, Heribert-Nilsson, and others. The varieties Yuma, Pima, and Gila are

described, and their origin as mutations from the Egyptian variety Mit Afifi is noted.

Plant breeding work in Arizona, which began 12 years ago with imported seed of the Mit Afifi variety, has through "persistent selection of the best plants caused some improvement in earliness and productiveness and in the quality of the fiber, but the progress was not very substantial prior to 1908, in which year two types very different from the Mit Afifi were recognized and isolated."

"If the tendency to produce mutants is a result of remote or complex hybridization, the mutability of Egyptian cotton might be accounted for upon either of the following grounds: (1) The supposed hybrid origin of the type as a whole, or (2) later crossing with other types of cotton. Ever since mutation became recognized as a factor in the breeding of Egyptian cotton the following methods have been followed in Arizona: (1) Recognition and isolation of desirable mutants; (2) selection and comparison on the progeny-row basis of those individuals among their progeny which express most fully the desirable characters of the new type; (3) elimination from the seed-increase fields, preferably before blossoming begins, of the aberrant and otherwise undesirable individuals."

A bibliography of 21 titles is appended.

The deterioration of Egyptian cotton, K. SNELL (*Jahresber. Ver. Angew. Bot.*, 11 (1913), pt. 1, pp. 9-13).—Methods of cultivation and crossing with the Hindu cotton are given as causes for the deterioration noted.

Studies in Indian cottons.—I, The vegetative characters, H. M. LEAKE and R. PRASAD (*Mem. Dept. Agr. India, Bot. Ser.*, 6 (1914), No. 4, pp. 115-141, pls. 22).—This discusses studies on the vegetative characters of Indian cotton, and includes monopodial and sympodial types, pollination, color of the corolla, eye of the petal, red coloring matter in the sap, leaf factor, type of branching, and length of vegetative period in their relation to field culture and commercial value of the crop. Many of the data are reported in tabular form.

Fibers from various sources (*Bul. Imp. Inst. [So. Kensington]*, 12 (1914), No. 1, pp. 32-45).—Results of tests are reported of fibers of jute, *Malachra capitata*, *Urena lobata*, Sida, Rama, sisal, aloe, and "Crowa" from India, Nigeria, Federated Malay States, Bechuanaland, and British Guiana, and of paper-making material made from the Nipa palm and *Scilla rigidifolia* from the Federated Malay States and South Africa.

Experiments in Hungary with hemp seed from Asia Minor and from Italy, K. GASZNER (*Köztelek [Budapest]*, 24 (1914), No. 4, p. 84; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, p. 360).—This notes the superiority of Asiatic hemp over Italian in yield and length in a 3-year test.

Sexual inequality in hemp, O. F. COOK (*Jour. Heredity*, 5 (1914), No. 5, pp. 203-206, figs. 2).—This notes the appearance at the Virginia Truck Station near Norfolk of a great inequality in oil-seed hemp plants. The male plants die while the females grow vigorously under the same conditions.

"Another peculiarity of the oil-seed hemp is that the lateral fruit-bearing branches have extremely short internodes, analogous to those of the so-called cluster varieties of cotton. The shortening of the fruiting branches may also be connected with the earliness and productiveness of the crop, from which high yields of seed are obtained."

Investigations on hops, J. SCHMIDT (*Compt. Rend. Lab. Carlsberg*, 10 (1913), Nos. 2, pp. 233-251, figs. 4; 3, pp. 267-283, pls. 2, figs. 2; *abs. in Nature [London]*, 93 (1914), No. 2321, pp. 199, 200).—This paper consists of two parts.

Part 1 gives results of a study, continued during 1911-12, to ascertain "if the improved sorts of cultivated hops from southern regions have a different rate of growth in our northern climate from our wild-growing plants, which possibly are better suited to the climate."

Measurements of the hop stems were also taken at 6-hour periods for several days, and it was "found that the growth in length of hop stems under natural conditions has a very distinct diurnal period, the rate of growth being smallest during the night, greatest during the day. This periodicity is determined by outer factors, among which the temperature has such a predominant influence that under natural conditions it determines the rate of growth."

Part 2 gives the results of observations made in 1913 by which it is shown that "in experiments with vigorous 3-year-old hop plants, which were firmly rooted in an open glass (cold) house, the stems were found to show during May and June a rotational movement amounting on an average for 1 to 2 weeks' observations to about 120° per hour or one-third of the rate of the minute hand of the clock.

"On closer study the rotational movement proved, like the growth in length, to have a very distinct daily periodicity, the rate being greatest during the day, least at night. Further, the experiments showed that this daily periodicity is determined by external factors, among which the temperature is of such dominating importance that its variation under natural conditions is determinative for the rate of rotation. A graphic comparison of the fluctuations in the rate of rotation and degree of humidity shows that there is no connection between them under the natural conditions prevailing when the observations were carried out.

"From laboratory experiments in June with pot plants, which were placed alternately in the light and dark, under otherwise uniform external conditions as far as possible, it appeared that the rotational movement is not different, at any rate not essentially different, in the dark and in scattered daylight. Experiments carried out in a cellar with constant low temperature showed that the minimum temperature for the rotational movement, just as for the growth in length, lies in the neighborhood of 4°.

"An endeavor has been made with the minimum temperature as starting point to obtain an expression of the relative quantities of heat which were of importance for the rate of rotation under the main experiment. The numbers obtained, which are called 'active quantities of heat', show that there is a very complete agreement between fluctuations in these and in the rate of rotation, the fluctuations showing a perfect synchronization under the conditions observed.

"A comparative experiment with twining bean plants showed that quite a similar daily periodicity in the growth in length and rate of rotation of the stem can also be seen in them and is also determined here by the temperature. It is probable that the growth movements in many plants living under climatic conditions such as ours, where great temperature fluctuations occur in a diurnal period, have a diurnal periodicity which follows that of the temperature."

Fertilizer experiments by the German Hop Culture Association with phonolite meal and 40 per cent potash salt in 1913, F. WAGNER (*Prakt. Bl. Pflanzenbau u. Schutz, n. ser., 12 (1914, Nos. 1, pp. 9-12; 2, pp. 22, 23)*).—This paper reports a continuation of work previously noted (*E. S. R., 30, p. 527*), and gives results that show superiority of the potash salt over phonolite meal, both by direct application and in its after effect.

Tests of selections from hybrids and commercial varieties of oats, C. W. WARBURTON, L. C. BURNETT, and H. H. LOVE (*U. S. Dept. Agr. Bul. 99 (1914), pp. 25, figs. 6*).—Results of comparative yield tests are reported between numer-

ous pure-line selections from commercial varieties of oats and hybrids secured in crossing some of these pure-line selections, under the various climatic and soil conditions found at McLean, Ill., the Iowa, New York Cornell, Pennsylvania, Virginia, Ohio, Indiana, Kentucky, Tennessee, and Minnesota experiment stations, and the Arlington, Va., Experimental Farm.

The system of numbering and methods of testing and of making the selections are described. From these results it seems that hybrids resulting from the use of varieties Welcome, Sixty-Day, Probsteyer, Burt, Danish Island, Asia Minor Rustproof, and Silvermine have proved among the most valuable, but none of the hybrids yielded persistently higher than the pure-line selections at any location.

It is noted that at Cornell Station, and similarly at other places, "the variation in results and in the relative yields of the different strains from year to year has been considerable. This is well shown by the yields of the best ten hybrids and selections for each year. In certain years the earlier strains represented by the Burt and Sixty-Day types are the best yielders, while in other years the later types represented by the Silvermine or Welcome yield best. This place variation operates to make one-year varietal tests inconclusive, [as] unusual conditions affecting the results may arise in any season."

Nitrogenous fertilizers with spring oats, J. B. MARTIN (*Vie Agr. et Rurale*, 3 (1914), No. 21, pp. 575-577).—More satisfactory results are reported in several experiments by the use of 160 kg. nitrate of soda, one-half applied at seeding time and one-half 15 days later, than with 120 kg. sulphate of ammonia, 60 kg. sulphate of ammonia and 80 kg. nitrate of soda, or 160 kg. nitrate of soda in one application.

Influence of nitrates on the germinative period of oats, F. PLATE (*Atti R. Accad. Lincei, Rend. Cl. Sci. Fis., Mat. e Nat., 5. ser., 23* (1914), I, Nos. 3, pp. 161-164; 7, pp. 506-512).—These articles continue previous work (E. S. R., 31, p. 231), in which the nitrates of many cations were used, in water solutions of varying concentrations, to fertilize the germinating seeds. The influence of these cations is discussed and results given in terms of weight of entire seedlings, length of radicle, and length of culm.

Aluminum seemed to act favorably on the young plants, tin and lead with an increase of dilution, while cerium and thorium caused the plants to die.

Chromium and manganese had a similar and depressing effect on the growth. Nitrate of uranium killed all of the plants. Iron, cobalt, and nickel nitrates gave negative results. The development correlation of other nitrates is given as follows: Rb > Sr > K > Ca > Na > Li > Mg > [Mn > Cr] > Zn > Al

Information on peanuts, A. C. TONNELIER (*Bol. Min. Agr. [Buenos Aires]*, 16 (1913), No. 5-6, pp. 636-641, fig. 1).—This paper continues work previously noted (E. S. R., 31, p. 231), and notes further the advantage of shelling the peanuts before planting as a means of reducing the cost of seeding without a proportional reduction in yield. Chemical analyses are included.

Varieties of potatoes, A. C. TONNELIER (*Variedades de Papas. Buenos Aires: Min. Agr., 1913, pp. 147, figs. 155*).—This article gives cultural notes and methods used for several hundred varieties of potatoes studied experimentally at Córdoba from 1910-1912.

Potato growing in New York State (N. Y. Dept. Agr. Bul. 57 (1914), pp. 1051-1173, figs. 43).—This bulletin consists of 18 papers by different authors, touching upon the history, cultural methods, breeding methods, diseases and insect enemies, marketing, and food value of the potato.

Crosses between summer rape and turnip, E. BAUR (*Jahresber. Ver. Angew. Bot., 11* (1913), pt. 1, pp. 117, 118).—It is noted that the F₁ generation of this

cross was similar and intermediate between the parents, while the F_2 generation was composed of individuals of every degree of characteristics between the original parents.

On the physiology of germination of *Oryza sativa*, M. AKÈMINE (*Fühling's Landw. Ztg.*, 63 (1914), No. 3, pp. 78-93).—From the results of experiments conducted at Sapporo, Japan, since 1909, the author announces the following conclusions in regard to the germination of rice:

The maximum, optimum, and minimum germinating temperatures are 40°, 30 to 35°, and 10 to 13° C., respectively. Light had no influence, light rays of different refrangibility having the same value. Rice seed germinated as well in water as in air, whether hulled or unhulled, or whether or not the water had the oxygen expelled by boiling. The plumule, radicle, and crown roots appeared quicker when the seed was germinated in air than when germinated in water. The elongation of the plumule proceeded more rapidly in water than in air, while the reverse was true for the radicle and crown roots. Frequently changing the water and the depth of water over the seeds within the limits of 3 to 20 cm. had no influence upon hastening the germination of the seeds. The most favorable degree of moisture for the seed ranged from 60 to 95 per cent of the water-holding power of the germinating medium. Rice kernels absorb 25 to 30 per cent of their air-dry weight of water, but may be brought to germination after they have taken up 25 per cent of their air-dry weight. The loss in weight of the unhulled seed during the swelling period of 20 days, with the temperature ranging from 10 to 15°, was 1.5 per cent of their weight.

New varieties of rice from Japan, P. POLI (*Gior. Riscolt.*, 4 (1914), Nos. 6, pp. 82-87, figs. 8; 7, pp. 100-102, figs. 4).—These articles describe six varieties of rice imported into Italy in 1913.

Rice cultivation and milling in Burma, M. K. MOORHEAD (*Daily Cons. and Trade Rpts.* [U. S.], 17 (1914), No. 109, pp. 768-774).—Industrial conditions and methods of cultivation, including implements used and values of rice in several Provinces of Burma, are described.

Nitrogenous fertilizer for rye, V. RYGULA (*Ztschr. Landw. Kammer Schlesien*, 18 (1914), No. 15, pp. 686-688, figs. 2).—This gives results of experiments which indicate that rye following oats requires a nitrogenous fertilizer, that part may be applied in the fall in the form of sulphate of ammonia, and that the spring application may either be nitrate of soda or sulphate of ammonia.

Tubers of *Solanum commersonii*, L. WITTMACK (*Jahresber. Ver. Angew. Bot.*, 11 (1913), pt. 1, p. 119).—This notes a tuber about 5 by 6 cm. produced on a plant of *S. commersonii*, and also an aerial tuber on the ordinary potato plant.

Analyses of soy beans from Tonkin (*Agron. Colon.*, 1 (1913), No. 9, p. 87).—Analyses of two new white varieties of soy beans show a range in fat content from 16.4 to 18.42 per cent and in protein from 38.1 to 42.5 per cent.

Variability in chemical composition of the offspring of a single mother beet in the first generation, K. ANDRLÍK and J. URBAN (*Ztschr. Zuckerindus. Böhmen*, 38 (1914), No. 7-8, pp. 339-355, figs. 7).—This reports results of analyses of about 100 representative individual plants taken from a plat that had been planted to seeds of a single mother beet in order to determine the ranges of variability in the composition of individuals of a single generation.

The range of sugar content was from 15 to 18.55 per cent. The ranges of variability of the different determinations, in terms of the average content, are given as follows: Of dry matter in the roots 33.4 per cent, dry matter in the tops 71.9, ash in the roots 64.7, ash in the tops 81.8, nitrogen in the roots 88.2, nitrogen in the tops 67.1, green weight of the roots 193, green weight of the tops 189 per cent, and sugar content 28.5 per cent.

Work at the several fields of the experiment stations for the Java sugar industry, 1912, J. SCHUIT (*Meded. Proefstat. Java-Suikerindus.*, 4 (1914), No. 20, pp. 317-412; *Arch. Suikerindus. Nederland. Indië*, 22 (1914), No. 7, pp. 213-308).—Results are here given in tabular form and discussed regarding yields and soil analyses of about 100 experimental fields.

Experiments in thinning out sugar cane rows, A. H. ROSENFELD (*Internat. Sugar Jour.*, 16 (1914), No. 185, pp. 220, 221).—Data obtained from thinned and unthinned plats of sugar cane show that there was nothing gained by thinning sugar cane, for it is stated that a "considerable amount of cane is lost, apart altogether from the expenses of the thinning operations themselves. From the very slight difference in the average weight per stalk in the two lots, it will be seen that in the first year at least the thinning out has not increased the size of the stalks left growing. Fifty kg. more cane per row were obtained from the lot not thinned out; that is, a difference in favor of this lot of more than 3 tons per hectare. This difference is slight in itself, but it certainly serves to indicate that it is not advantageous to thin out the rows."

The shipment of seed cane specimens, J. A. HALL, JR. (*La. Planter*, 50 (1913), No. 23, p. 366, fig. 1).—This article notes a method of shipping seed cane in tin cans 18 in. long by 3 in. in diameter, in which the pieces of cane are packed in loose, dampened charcoal.

A rational system of payment for cane, L. G. CAMP (*La. Planter*, 50 (1913), No. 23, pp. 363, 364, fig. 1).—This article describes and discusses methods by which the producer in Cuba and other parts of the West Indies is generally paid for the sugar value of his cane on the basis of the average selling price of sugar during the fortnight in which the cane was delivered. In Cuba the average is about 6 per cent in sugar on the weight of cane.

Tobacco growing in Ireland (*Dept. Agr. and Tech. Instr. Ireland Jour.*, 14 (1914), No. 2, pp. 320-337; *abs. in Jour. Bd. Agr. [London]*, 21 (1914), No. 1, p. 58).—Results of experiments embracing 108 acres, by 20 growers, showed the cost of pipe tobacco to be 10.9d. (22 cts.) per pound and £27 1s. (\$131.64) per acre, and of cigarette tobacco 11.2d per pound and £40 5s. 2d. per acre.

A Ruakura experiment, P. McCONNELL (*Jour. Agr. [New Zeal.]*, 7 (1913), No. 3, pp. 252-259, figs. 3).—In a fertilizer experiment with Swedish turnips it is noted that in general phosphatic manures showed better results than any other fertilizer, but in conjunction with kainit lower yields were obtained than when superphosphate was used alone. "This may to some extent be accounted for by the fact that when the seeds and manures were sown there was not sufficient moisture in the soil to dissolve the injurious salts in the kainit, resulting in an injury to the germination; and it is a well-known fact that potassic manures are better applied some time previous to the sowing of the seed. It will also be noticed that the basic superphosphate and sulphur and the basic slag and sulphur plats have given a greater yield than the basic slag and kainit or basic slag and basic superphosphate plats. The addition of sulphur has, however, considerably increased the cost, and it seems strange that sulphur should be so dear in a country where it is so plentiful."

On the physiology of germination in connection with internal factors in wheat, H. NILSSON-EHLE (*Ztschr. Pflanzenzücht.*, 2 (1914), No. 2, pp. 153-187, pl. 1).—Based upon the assumption that the red and white color factors of the wheat kernels were coupled with the germinative resistance of new wheat, the author announces the following conclusions from results of several years of experimenting:

The ability of a wheat to germinate quickly or slowly after maturity (germination resistance to weather conditions) was found to be a variety characteristic, segregating in the customary manner in hybrids. This physiological

character is determined by other internal factors which are essentially independent of the physiological characters hardiness and earliness, as shown in comparisons of different varieties and lines as well as in hybrid segregations. It is deemed possible to combine to a greater or lesser degree the germination resistance with hardiness and earliness.

The relative differences in the germinating conditions of wheat varieties are qualified by several internal inherited factors. Among these inherited factors the red factor, which produces the red color of the seed coat, plays a greater part than the inhibiting factor during the early stage after maturity. The white varieties, which do not contain the red factor, germinate easiest, the single red factor variety next, and the many-factored red variety the slowest. The specific germinative conditions of different varieties will be only partly influenced by the red factors, other internal factors also operating. At the same time the seed maturity and the specific seed maturation period of different varieties are essentially independent of the red factor and of other internal factors; the red factors work, however, as the inhibiting factors in the same direction as does faulty seed maturity.

The determined facts elucidate, from a new viewpoint, the important germinative physiological rôle which the seed coat plays, especially the cork layer in which the influence of the red factors is localized. The white- and single-factor red variety investigated showed somewhat more rapid absorption of water than did the multi-factored red variety. The germination inhibiting effect of the red factors is traceable, in part at least, to the fact that these factors not only influence the color, but also the structure of the seed coat.

The claim that the true seed coat of the ripe wheat kernel consists of only two cell layers, to the inner of which the integument belongs, is held to be in error. The author states that the seed coat always consists of two completely free skins, insoluble in concentrated sulphuric acid. Each of these in the red variety consists of two cell layers, and in the white variety the inner one in mature kernels is entirely structureless.

A bibliography of 32 titles is attached.

A case of repulsion in wheat, F. L. ENGLEBOW (*Proc. Cambridge Phil. Soc.*, 17 (1914), No. 5, pp. 433-435).—Results are here given of a cross between Smooth Black and Rough Chaff wheat. The 213 plants of F₂ generation segregated rough black 120, rough white 43, smooth black 47, and smooth white 3, which corresponded closely with the theoretical expectation of 109.8:49.9:49.9:3.3. The application of methods of determining the best coupling and repulsion series for these observations are discussed.

Studies on the stems of wheat, L. BLARINGHEM and E. MIÈGE (*Compt. Rend. Acad. Sci. [Paris]*, 157 (1913), No. 25, pp. 1457-1460).—This notes some results in crossing pure lines of *Triticum vulgare*, *T. dicoccum*, and *T. turgidum* which, the author states, indicate the mosaic in the anatomical characters.

On the production of hybrids between wild and cultivated wheats, BLARINGHEM (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 5, pp. 346-349, fig. 1).—The author notes in the results of this cross the dominance of flinty albumin and triangular shape to amylaceous albumin and rounded shape and wrinkled.

Increase of the productivity of Hungarian wheat by means of selection, E. GRABNER (*Köztelek [Budapest]*, 23 (1913), No. 99, pp. 3331-3333; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, p. 352).—This notes the improvement of some Hungarian wheats by selection to increase the number of kernels per spikelet.

Characters of the grain in varieties of Hungarian pedigree wheat and their hereditary transmission, E. OBERMAYER (*Köztelek [Budapest]*, 23 (1913),

No. 93, pp. 3133, 3134; abs. in *Internat. Inst. Agr.* [Rome], *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, pp. 351, 352.—It is noted that the selected forms of Hungarian wheat from the same variety differ not only in their development and in the morphological peculiarities of the plants, but also in the character of the kernels, and that these characters breed true.

Seeding wheat in Oklahoma, A. H. WRIGHT (*Oklahoma Sta. Circ.* 32 (1914), pp. 3-8).—Cultural methods are here described for producing wheat under Oklahoma conditions.

Results of seed inspection, 1913, J. P. HELYAR (*New Jersey Stas. Bul.* 266 (1914), pp. 3-39).—This bulletin gives results of the inspection of seeds for 1913, with comments and some directions for sampling and sending samples of seeds to be inspected, and gives the text of the New Jersey seed law.

Combating weeds, with special reference to calcium cyanamid and kainit, OPITZ (*Ztschr. Landw. Kammer Schlesien*, 18 (1914), No. 14, pp. 617-622).—Results here noted show iron sulphate, sulphuric acid solution, and some proprietary preparations to have been satisfactory. Those obtained with calcium cyanamid and kainit, used at the rate of 100 and 600 kg. per hectare, respectively, were unsatisfactory.

Weeds, R. H. BIFFEN (*Jour. Roy. Agr. Soc. England*, 74 (1913), pp. 376-379).—Notes on and methods of eradication of the following weeds are here presented: *Spergula arvensis*, *Polygonum persicaria*, *Orobanche minor*, and dodder.

HORTICULTURE.

Manual of horticulture, G. BASSOTTI (*Vademecum do Horticultor. Sao Paulo, Brazil*, 1913, pp. XII+556, figs. 267).—Part 1 of this manual deals with the general principles of horticulture. Part 2 takes up in alphabetical arrangement the botany, culture, and uses of all of the more important vegetables, pot herbs, etc. A similar brief treatment of the pineapple is appended.

Everyman's garden every week, C. A. SELDEN (*New York*, 1914, pp. XIV+338).—A popular treatise on kitchen and ornamental gardening. Aside from the general considerations relative to preparation of the soil, fertilizing, protection against pests, etc., the chapters of the book are placed in chronological order with reference to the various garden operations for the year. These operations are arranged for the most part under the weeks in which they best may be done.

The gardener's pocket manual, F. F. ROCKWELL (*New York*, 1914, pp. 90, figs. 33).—A manual of information and data covering various operations in connection with the flower garden, the vegetable garden, and the home grounds in general.

The carbon nutrition of horticultural plants, H. FISCHER (*Gartenflora*, 63 (1914), No. 6, pp. 125-132).—In continuation of previous investigations relative to the value of carbonic acid gas as a plant nutrient (E. S. R., 28, p. 837), the author here describes experiments conducted in a greenhouse with various horticultural plants. Although working conditions were at times unfavorable, the results as a whole tend to confirm the author's previous conclusion that the development of both foliage and flowers is stimulated by an excess of carbonic acid in the air. The yield of tomatoes was practically doubled by the carbonic acid treatment, and the yield of cucumbers was increased about 12.5 per cent. In the case of treated and untreated cuttings of fuchsia plants, practically no difference was noted in the time of rooting, but the treated plants came into bloom quicker, and the blooming period was prolonged for several weeks. A number of other plans gave more or less successful results when grown with an excess of carbonic acid in the air.

The general conclusion is reached that the question of carbon nutrition is of great importance in plant culture and should be widely investigated. From his investigations as a whole, the author is of the opinion that the increased flower development under carbonic acid treatment is due to a certain excess of carbohydrates over the soil nutrients. The fact that 0.03 per cent of carbonic acid has usually been considered as sufficient for plant growth is attributed to the failure to conduct investigations in the presence of a sufficient amount of light for the greater utilization of carbonic acid.

Another hypothesis to account for Dr. Swingle's experiments with citrus, A. C. and A. L. HAGEDOORN (*Amer. Nat.*, 48 (1914), No. 571, pp. 446-448).—The authors advance the hypothesis that *Citrus trifoliata*, the lemon, orange, and other citrus fruits used in Swingle's cross-breeding experiments (E. S. R., 29, p. 839) are self-sterile and that the seeds, normally produced, are produced asexually with a resulting trueness to type. Likewise, although the plants secured from a first cross differ exceedingly among themselves, these new forms reproduce only their own kind because they normally produce seed asexually.

The authors have begun an experiment with squashes to find out whether it is possible that a plant impure for a number of genes produces a variable F_2 generation of only completely homozygous plants. Certain hybrid plants in which the female buds have been carefully sealed have produced no fruit; others have produced plenty of empty fruit; and still others have produced several fruits full of viable seed. These seeds are to be grown with a view to studying the F_2 generation.

Fertilizer experiments with muskmelons, J. W. LLOYD (*Illinois Sta. Bul.* 155, Abs. (1912), pp. 4, figs. 2).—A summarized account of experiments previously noted (E. S. R., 28, p. 46).

Onion culture on muck lands, C. P. HALLIGAN (*Michigan Sta. Spec. Bul.* 67 (1914), pp. 3-18, figs. 12).—A practical treatise on onion culture with special reference to muck lands. It discusses the drainage and preparation of soils, various cultural operations, harvesting, storing, and varieties.

Spray and practice outline for 1914, H. J. EUSTACE and R. H. PETTIT (*Michigan Sta. Spec. Bul.* 69 (1914), pp. 24, figs. 7).—This bulletin contains general spraying directions for the treatment of orchard and small fruits and of vegetables.

The relation of ventilation to the keeping qualities of fruits and vegetables, G. R. HILL, JR. (*Wash. Univ. [St. Louis] Studies*, 1 (1913), I, No. 1, pp. 46-64).—A report on the author's experimental studies on the respiration of fruits and growing plant tissues, the substance of which has been largely noted from another source (E. S. R., 29, p. 538). In addition to the work with fruits, the present paper contains some additional data on the keeping qualities of lettuce with good ventilation, and with no ventilation in air, in nitrogen, and in carbon dioxide.

Methods of heating commercial greenhouses, C. PYNAERT (*Jour. Soc. Nat. Hort. France*, 4. ser., 15 (1914), May, pp. 336-348, pl. 1).—A descriptive account of various greenhouse heating systems, including the results obtained the first winter from a steam plant installed in a greenhouse establishment in Ghent.

The status of fruit culture in Tunis and Algeria, L. GUILLOCHON (*Bul. Dir. Gén. Agr. Com. et Colon. Tunis*, 18 (1914), Nos. 74, pp. 87-103; 76, pp. 219-241).—This embraces the results of a general survey of the fruit industry in various parts of Tunis and Algeria.

The blooming time of fruit trees, J. P. M. CAMMAN (*Maandbl. Nederland. Pomol. Ver.*, 4 (1914), No. 5, pp. 94-99).—Data for the beginning and end of the blooming period are given for numerous varieties of apples and pears growing

in the Zeeland Horticultural Gardens. The data given cover the period 1905 to 1913, inclusive.

The pollination of apples and pears, G. H. WEST (*Trans. Kans. State Hort. Soc.*, 32 (1912-13), pp. 38-50).—This is largely a review of the American literature on the subject.

The influence of chemical fertilizers on the ripening time of pears, G. RIVIÈRE and G. BAILHACHE (*Jour. Soc. Nat. Hort. France*, 4. ser., 15 (1914), June, pp. 435-438).—The results of the authors' experiments with pear trees as determined for the first season indicate that a complete fertilizer may retard rather than hasten the ripening period of pears.

Olive culture in Tunis, C. CAMPBELL (*Bul. Dir. Gén. Agr. Com. et Colon. Tunis*, 18 (1914), No. 78, pp. 375-388).—A brief survey of the olive industry in Tunis with special reference to cultural conditions and types of olives grown there.

Study of the influence of various grape stocks on the quality and quantity of the harvest, H. FAES and F. PORCHET (*Terre Vaud.*, 6 (1914), Nos. 15, pp. 179-181, fig. 1; 16, pp. 187, 188, fig. 1; 17, pp. 197-199, fig. 1; 23, pp. 255-257, figs. 4; 24, pp. 265, 266, figs. 2; 25, pp. 275-277, fig. 1).—In continuation of the previous report (E. S. R., 30, p. 43) data are given for 1913 relative to the adaptability of a number of pure American, American hybrid, and French-American hybrid grape stocks for the Chasselas grape.

On the cultural effects of the time of pruning grapes and their relation to the physiological effects, J. L. VIDAL (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 17, pp. 1192-1194).—Pruning experiments conducted during the 3 years 1911-1913 led the author to conclude, in general, that other conditions being equal the time of pruning modifies only slightly the number of bunches of grapes which are borne.

With extreme late pruning the bunches are more vigorous and the proportion of imperfect bunches and aborted flowers is less. The individual berries are larger, heavier, and more numerous. The growth is more rapid for late pruned vines and continues for a longer time. The vegetation is at times diminished and at times increased by spring pruning just as in winter pruning. These positive or negative variations in vegetation progress or retrogress in more or less regular order with the progression of the time of pruning. The data here considered deal with pruning operations conducted at intervals from the first of January to about the middle of April. With vines pruned after the middle of February, the later the pruning the greater the retarding effect on bud swelling and the flowering season.

The cultural results here noted are attributed to a disturbance either in one direction or the other of the stored-up food supply and the recently assimilated material. This phase of the subject is here briefly discussed.

Spraying in relation to the flowering season, L. LEBRUN (*Prog. Agr. et Vit. (Ed. l'Est-Centre)*, 35 (1914), No. 23, pp. 711, 712).—Experiments and observations conducted by the author in 1913 and here briefly noted indicate that solutions of copper applied for the control of grape mildew during the blooming period are more or less injurious to the blooms and newly-set fruit and may result in a short crop. The application of copper salts in dust form during the flowering period does not appear to cause such serious results.

Strawberries, J. VERCIER (*Jour. Soc. Nat. Hort. France*, 4. ser., 15 (1914), May, pp. 349-375, fig. 1).—This comprises the results of an investigation with special reference to conditions in France relative to the influence of soil and fertilizers on the yield, chemical composition, size, and edible qualities of strawberries.

The general conclusion is reached that although strawberries will grow on various types of soils they will thrive best on a deep mellow soil, rich in iron salts. Analyses of the strawberries grown on different soils and treated with various fertilizers indicate that the fertilizer treatment should vary with the type of soil in question in order to produce the best fruit. A number of general fertilizer formulas for different types of soil are suggested.

Application of cold in the agricultural industry.—The conservation of strawberries, I. MAURO (*Agr. Mod. [Milan]*, 19 (1913), No. 23, pp. 270, 271, figs. 3).—A general discussion of the application of cold storage to the preservation of agricultural products, including some data on cold storage experiments with strawberries conducted at Breganze in cooperation with A. Cogo. A bibliography of literature on the conservation of food supplies is included.

New varieties of roselle, P. J. WESTER (*Philippine Agr. Rev. [English Ed.]*, 7 (1914), No. 6, pp. 266-269, pls. 3).—The author here describes and names the following varieties of roselle (*Hibiscus sabdariffa*): The Temprano, which originated at the Lamao Experiment Station; the Archer, which was introduced from the British West Indies; and the Altissima, which was introduced from the Gold Coast, West Africa.

Parthenocarpy and seed formation in bananas, A. D'ANGREMOND (*Ber. Deut. Bot. Gesell.*, 30 (1912), No. 10, pp. 686-691, pl. 1; *Flora, n. ser.*, 7 (1914), No. 1, pp. 57-110, pls. 8, figs. 14).—In the first part of this paper the author gives the principal results secured from his observations and pollination experiments with bananas conducted in Surinam from 1909-1911. The second part of the paper describes studies of fixed material conducted at the Zürich Institute for General Botany in 1911-1913. The subject matter is discussed under the following general headings: Morphological and experimental studies on the fruit formation in seed-containing and seedless bananas in Surinam; the historical and cytological development in seed-forming and seedless bananas from Surinam; and hypothesis on the origin of edible bananas. The literature dealing with parthenocarpy in fruits is briefly reviewed and a bibliography is appended.

The investigation as a whole shows in brief that our common edible bananas are naturally parthenocarpic. Their own pollen is practically sterile and the fruit is not improved by cross-pollination. In addition to practically sterile pollen, there is a more or less complete degeneration of the embryo sacks, particularly in the Jamaica variety commonly shipped to the United States.

The changes occurring in the ripening coconut, B. M. GONZALEZ Y SIOCO (*Philippine Agr. and Forester*, 3 (1914), No. 2, pp. 25-31).—This comprises a preliminary study of the ripening coconut with reference to the changes in size, weight, and color of the nut and the chemical changes in the milk and solid endosperm.

From the data thus far secured the ripening of a coconut is divided into three periods, during the first of which there is an accumulation of invert sugar and amino acids in the milk or watery portion; the meat is still absent, the shell and husk are soft and watery, and the nut as a whole has its greatest diameter along the main axis. During the second period water is lost from the coconut though its total weight continues to increase. Sucrose appears in the milk and the specific gravity of the latter is high. During this period the nut begins to acquire its greatest diameter in a direction at right angles to the main axis. During the third period of ripening there is a sudden rise in the content of oil in the endosperm and the specific gravity of the milk falls owing to the transfer of nutrient materials or to respiration. During this period the shell becomes impervious and the drying out of the husk results in loss in weight, thus overbalancing the gain in weight due to other changes.

The macapuno coconut, B. M. GONZALEZ Y SIOCO (*Philippine Agr. and Forester*, 3 (1914), No. 2, pp. 31, 32).—A brief descriptive account is given of the macapuno, a sport fruit of the coconut which instead of containing water is nearly or quite full of a viscous, white, translucent jelly whose texture next to the shell more or less closely approaches the firmness of ordinary coconut meat. This type of fruit occurs only in small quantities on trees bearing normal coconuts. Thus far no way is known of distinguishing normal fruit from macapuno fruit, except by shaking the fruit. It has been observed, however, that the trees which bear macapuno nuts will continue to do so from year to year.

The sex of date palm seedlings (*Roy. Bot. Gard. Kew, Bul. Misc. Inform.*, No. 4 (1914), pp. 159-162).—From the information thus far secured as a result of an investigation of the reputed ability of Arabs to change the sex of date palms, it is concluded that there is no authentic record of such changes ever having been made.

The jaboticaba, W. POPENOE (*Jour. Heredity*, 5 (1914), No. 7, pp. 309-326, figs. 6).—A descriptive account with illustrations is given of the jaboticaba (*Myrciaria* spp.), a grapelike tree fruit collected by the author on a recent trip of agricultural exploration in Brazil.

Cultural directions for the papaya, P. J. WESTER (*Philippine Agr. Rev. [English Ed.]*, 7 (1914), No. 6, pp. 251-257, pl. 1, figs. 3).—A brief popular treatise on the propagation, culture, and care of the papaya, including notes on the rejuvenation of old plants and seed selection.

Cultural experiments with medicinal plants in Korneuburg in 1913, E. SENFT (*Ztschr. Landw. Versuchsw. Österr.*, 17 (1914), No. 3-4, pp. 129-182).—Results of cultural tests of a large number of medicinal plants are reported, and some general considerations are given relative to the culture of medicinal plants in Austria.

The National Rose Society's official catalogue of roses (*Berkhamsted, England, 1914*, pp. 132).—This comprises a descriptive catalogue of roses compiled under the direction of the National Rose Society of England. In addition to the general descriptive catalogue, a descriptive list is given of the newer roses for the period of 1910 to 1913, together with lists of roses arranged according to the classes to which they belong and selections of roses for various purposes.

The practical book of garden architecture, PHEBE W. HUMPHREYS (*Philadelphia and London, 1914*, pp. XV+330, pls. 83).—A practical treatise on garden architecture, combining several of the author's articles on this subject which have appeared in different publications with considerable new matter. The work embodies many suggestions gleaned from an intimate study of beautiful home surroundings in the form of garden architecture during extensive travels in various European countries and throughout the United States. The text is fully illustrated.

Rock gardens, how to make and maintain them, L. B. MEREDITH (*New York, 1914*, 2. ed., pp. XXII+390, pls. 21, figs. 6).—In the present edition of this work (E. S. R., 26, p. 139) the list of plants suitable for rock gardening has been increased by the inclusion of desirable forms which have recently been put on the market.

Trees for street and yard planting and their care, C. A. SCOTT (*Trans. Kans. State Hort. Soc.*, 32 (1912-13), pp. 25-32).—Lists are given of trees for street and yard planting in different districts of Kansas, together with suggestions dealing with the care of shade trees.

Hardy shrubs for Kansas, E. F. A. REINISCH (*Trans. Kans. State Hort. Soc.*, 32 (1912-13), pp. 32-35).—The author here presents a list of some 36

kinds of trees, shrubs, and vines with ornamental fruit which have proved to be hardy and otherwise desirable for planting in Kansas.

FORESTRY.

Connecticut's forest taxation law (*Connecticut Sta. Spec. Bul. (Forestry Pub. 9), 1913, pp. 8, fig. 1*).—A special bulletin containing the text of a law providing a new plan of taxation of woodland which was enacted by the Connecticut General Assembly of 1913, and a brief discussion of its more important features.

Administration report of the forest circles in the Bombay Presidency, including Sind, for the year 1912-13 (*Admin. Rpt. Forest Circles Bombay, 1912-13, pp. 166+5*).—This is the customary report relative to the administration of the state forests in the Northern, Central, and Southern Circles of the Bombay Presidency, and of Sind, including a financial statement for the year 1912-13. All important data relative to alterations in forest areas, forest surveys, preparation of working plans, forest protection, silvicultural operations, exploitation, yields, revenues, etc., are appended in tabular form.

Annual progress report on forest administration in the Province of Bihar and Orissa for the year 1912-13, H. CARTER (*Ann. Rpt. Forest Admin. Bihar and Orissa, 1912-13, pp. 6+18+XXXVII+5*).—A report similar to the above relative to the administration and management of the state forests in the Province of Bihar and Orissa for the year 1912-13.

Progress report of forest administration in the Punjab for the year 1912-13, W. MAYES (*Rpt. Forest Admin. Punjab, 1912-13, pp. 10+20+LI*).—A report similar to the above on the administration and management of the state forests in Punjab for the year 1912-13.

Observations on the edge of the forest in the Kodiak region of Alaska, R. F. GRIGGS (*Bul. Torrey Bot. Club., 41 (1914), No. 7, pp. 381-385, fig. 1*).—A brief study of the natural extension of the forest boundaries in the Kodiak region of Alaska.

The conversion of coppice-with-standards into high forest in France, R. S. TROUP (*Quart. Jour. Forestry, 8 (1914), No. 3, pp. 208-212, pls. 3*).—A brief descriptive account of the systems employed in France in the conversion of coppice-with-standards into high forests.

On natural and artificial regeneration in the forests of north Sweden, E. WIBECK (*Meddel. Stat. Skogsförsöksanst. (Mitt. Forstl. Vers. Anst. Schwedens), No. 10 (1913), pp. 91-138, XI-XVI, figs. 13*).—Results are given of both natural and artificial regeneration studies with pine and spruce in north Sweden, including results to date of forest planting work in that region.

Three thinning areas in the Skagersholm state forest, G. SCHOTTE (*Meddel. Stat. Skogsförsöksanst. (Mitt. Forstl. Vers. Anst. Schwedens), No. 10 (1913), pp. 181-210, XXIII-XXVII, pls. 2, figs. 13*).—Thinning experiments in mixed coniferous forests conducted under the direction of the Swedish Forestry Experiment Station are here reported.

Recent ecological investigations, H. DE FOREST (*Proc. Soc. Amer. Foresters, 9 (1914), No. 2, pp. 161-176*).—A brief review of some of the recent developments in ecological investigations, including a bibliography of cited literature.

The determination of site qualities for even-aged stands by means of a site factor, E. J. HÄNZLIK (*Proc. Soc. Amer. Foresters, 9 (1914), No. 2, pp. 229-234*).—A comparative analysis of the cubic volume and formula methods of determining site qualities for even-aged stands, as applied chiefly to Douglas fir stands in Washington and Oregon.

Yield in uneven-aged stands, B. MOORE (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 2, pp. 216-228).—In this paper the author analyzes the fundamental difficulties met with in the application of existing methods of determining yields in uneven-aged stands and offers suggestions relative to new methods or modifications of already existing methods.

Determination of stocking in uneven-aged stands, W. W. ASHE (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 2, pp. 204-206, figs. 2).—The author briefly describes a method of determining the proportion of stocking in uneven-aged stands. This method, it is believed, is applicable for use in connection with any species which occasionally forms pure even-aged groups.

The measurement of increment on all-aged stands, H. H. CHAPMAN (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 2, pp. 189-203, fig. 1).—A similar paper by the author has been noted from another source (*E. S. R.*, 27, p. 647).

The use of yield tables in predicting growth, E. E. CARTER (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 2, pp. 177-188).—A discussion of the nature and use of yield tables as applied chiefly to pure, unthinned stands of New England white pine.

Experiments on eccentric growth of ash, SOMERVILLE and A. G. HARPER (*Quart. Jour. Forestry*, 8 (1914), No. 3, pp. 218-229, pl. 1).—The authors here report data on the eccentric growth of some 5-year-old ashes which were bent over permanently or intermittently in one or more different directions.

The hardwoods, F. W. NEGER (*Die Laubhölzer. Berlin and Leipsic, 1914*, pp. 160, figs. 74).—This comprises brief descriptions of the native trees and shrubs of central Europe, including the more important cultivated forms.

Accretion in the lower part of the stems of both pine and spruce, A. MAASS (*Meddel. Stat. Skogsförsöksanst. (Mitt. Forstl. Vers. Anst. Schwedens)*, No. 10 (1913), pp. 45-58, V. VI, figs. 2).—The author here reports a statistical study of accretion in the stems of pine and spruce between the base of the tree and breast high (1.3 meters) from the ground.

In the case of pines there appears to be no definite relation between the measurement at 1.3 meters and the diameter accretion either above or below this measurement. In spruce there appears to be no definite relation between the diameter at breast height and diameters above this measurement, but there is a relation between breast-high measurements and the lower part of the trunk.

The stem height in normal pine stands, A. MAASS (*Meddel. Stat. Skogsförsöksanst. (Mitt. Forstl. Vers. Anst. Schwedens)*, No. 10 (1913), pp. 59-66, VII, VIII, figs. 5).—With yield data secured from 79 pine stands in different parts of Sweden as a basis, the author has plotted height and diameter curves for pine trees belonging to different locality classes.

On some transverse tests of Australian and foreign timbers, J. NANGLE (*Jour. and Proc. Roy. Soc. N. S. Wales*, 47 (1913), pt. 2, pp. 165-173).—A paper on this subject read before the Royal Society of New South Wales, October 1, 1913, in which are presented tabulated results of tests of a large number of commercial timbers. The data given show the breaking load in pounds, modulus of rupture and of elasticity in pounds per square inch, and rate of load in pounds per minute.

Fire damage in mature timber, J. A. MITCHELL (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 2, pp. 239-244).—The author here presents data dealing with the susceptibility to damage and the power of recovery of various species as observed on the Klamath and Shasta National Forests during the two years 1910 and 1911.

Preservative treatment of timber for estate purposes, J. F. ANNAND (*Quart. Jour. Forestry*, 8 (1914), No. 3, pp. 169-186).—The results are given

of experiments with saponified creosote and naphthalin by the open-tank method of treating timber.

The data given are for Scots pine and spruce timber, a small quantity of unseasoned larch timber having been used for comparison. From the results thus far secured the following deductions are made:

The addition of 0.25 per cent or less of caustic soda in pure creosote improves penetration in the case of timbers which take the preservative with difficulty. Saponification of the creosote makes it possible to dilute the preservative by the addition of water and thus cheapens the creosoting process. Saponified diluted creosote may be claimed as a cheap effective substitute for the "Reuping" process of professional creosoters. Average creosote may be diluted to as much as half its full strength with good results. Naphthalin proved to be an excellent preservative and discolored the timber less than creosote. Large quantities of naphthalin are taken up by most timbers, hence its cost as a preservative is practically the same as creosote. Green timber can be treated with naphthalin quite as effectively as air-dried timber.

DISEASES OF PLANTS.

Diseases and parasites of the principal cultivated plants, A. CANEVARI (*Malattie e Parassiti delle Principali Piante Coltivate e loro Rimedii. Catania, Italy, 1913, pp. 374, figs. 101*).—Descriptions are given of the principal fungus and insect pests as well as the diseases due to malnutrition and other physiological disturbances, and where known, suggestions are offered for their control.

The diseases and injuries of cultivated plants in 1911 (*Ber. Landw. Reichsamte Innern, No. 30 (1914), pp. VIII+339, fig. 1*).—After reviewing the weather conditions in Germany in 1911 a description is given of the influence of diseases and other injuries on the yields of some of the more important crops. Following this, reviews are given of the literature relating to the more important injuries to cultivated plants and of recent publications relative to apparatus and materials used in plant protection. The publication concludes with a review of six years' work, 1906–1911, on plant protection work undertaken by the Imperial Biological Institute of Agriculture and Forestry.

[Report on plant protection in Baden, 1912], C. VON WAHL and K. MÜLLER (*Ber. Grossh. Bad. Landw. Vers. Anst. Augustenb., 1912, pp. 89, fig. 1*).—This report deals comprehensively with the diseases and insect enemies of grapes, fruits, berries, grains, tubers, forage plants, vegetables, etc., and the remedies tried or proposed. The influence of the dry hot summer season of 1911 is also discussed. Publications issued by the station or other related contributions appearing in 1912 are listed.

Division of plant pathology and mycology, I. B. P. EVANS (*Union So. Africa Dept. Agr. Rpt. 1912–13, pp. 169–183, pls. 19*).—After a brief description of the new laboratory for plant pathology and mycology, the author describes the most conspicuous diseases observed during 1912–13. Among the fungus diseases of economic importance reported from South Africa for the first time are apple tree disease (*Cytospora leucostoma*), apricot and nectarine tree disease (*Calospharia princeps*), fescue grass ergot (*Claviceps purpurea*), lemon scab (*Cladosporium citri*), orange fruit scab (*Sporodesmium* sp.), onion scab (*Vermicularia circinans* and *Mystrosporium alliorum*), orange leaf blotch (*Pleospora disrupta*), peach mold (*Fusarium putaminum*), pomegranate rot (*Sterigmato-cystis* sp.), potato stalk or sclerotium disease (*Sclerotinia sclerotiorum*), sugar cane diseases due to a species of Sphaeronema and a species of Phoma, and a bacterial disease of tobacco similar to that known as the Granville tobacco wilt in the United States.

[Reports from Dutch East Indies on plant diseases], KNISCHEWSKY (*Ztschr. Pflanzenkrankh.*, 23 (1913), No. 6, pp. 338-345).—Brief notes are given regarding attacks, injuries, and diseases affecting economic plants in the Dutch East Indies, particularly tobacco, coffee, rubber, and cacao, with citations to some articles published reporting investigations thereon.

Culture experiments with rust fungi, H. KLEBAHN (*Ztschr. Pflanzenkrankh.*, 24 (1914), No. 1, pp. 1-32, figs. 23).—Reporting work done in 1912 and 1913 in continuance of that previously noted (E. S. R., 28, p. 242), the author deals in considerable detail with the various factors affecting viability and germination of the teleutospores and the duration of germinability by uredospores, some new hosts of *Cronartium asclepiadeum* and of *Coleosporium* spp., and some studies on *Puccinia malvacearum*.

Experiments with *Puccinia* spp. show that repeated soaking with fresh water, preferably alternating with fairly complete drying out, is a large factor in determining duration of viability in teleutospores. The air content of the water is perhaps also influential in this regard. Winter cold is thought to be neither essential nor influential as regards viability of teleutospores. Uredospores obtained early in August and later placed on germinating wheat showed a decrease of germinability with age, scarcely any germinating when sown after being kept dry for 2½ months.

Influence of the host on the morphological characters of *Puccinia ellisiana* and *P. andropogonis*, W. H. LONG (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 4, pp. 303-319).—In continuation of a previous note on the possibility of *P. ellisiana* having its æcial stage on Pentstemon and species of *Viola* (E. S. R., 28, p. 551), the author has continued his investigations and presents the results of cultural data, in which numerous inoculations were made, showing that *P. ellisiana* has two widely separated æcial hosts, *Viola* and *Pentstemon*.

The infection of *Pentstemon* is vigorous and abundant and the characters of the fungus are completely changed after passing through *Pentstemon* assuming in every essential feature those belonging to the *Pentstemon* rust, *P. andropogonis*. The characters of the rust obtained by inoculating species of *Viola* with *P. andropogonis* are identical with those of the regular *Viola* rust. The transfer of *P. ellisiana* from *Pentstemon* back to the *Viola* is more difficult than from *Viola* to *Pentstemon*. It is believed that *P. andropogonis* may easily have originated in nature from *P. ellisiana*.

Witches' broom, E. LEMÉE (*Jour. Soc. Nat. Hort. France*, 4. ser., 15 (1914), Apr., pp. 229-246, figs. 15).—The author illustrates and describes the witches' brooms produced by the various rusts on fir trees and red currants; species of *Exoascus* on birch, hornbeam, cherry, pear, apple, plum, and elm; those on a number of trees caused by various insects; effect of mistletoe on junipers; and witches' brooms on junipers, spruce, and pine, due to causes unknown.

The parasitism of smut fungi, W. LANG (*Jahresber. Ver. Angew. Bot.*, 10 (1912), pp. 172-180).—A brief historical discussion is followed by an account of the author's study of grain plants affected with smut in regard to the localization and mode of invasion and the vegetative life of the parasite within the host. It is stated that while mycelium arising from spores dusted on the stigma develops abundantly between cells which show lessened turgor, neighboring tissue retaining high turgidity is generally not invaded. Only in very dry seasons is the mycelium checked in development before leaving the young seed, where it enters the resting stage. The subsequent development of the parasite is described.

An extension of the studies is contemplated.

A dangerous genus (*Phytophthora*), A. A. L. RUTGERS (*Teysmannia*, 24 (1913), No. 10, pp. 626-632).—Discussing briefly the genus *Phytophthora*, the author compiles in brief form the dates of discovery of 14 species and one variety, naming hosts in connection therewith.

Investigations on the control of disease in plants, R. H. BIFFEN (*Jour. Roy. Hort. Soc. [London]*, 39 (1913), No. 2, pp. 313-320).—This paper, besides giving a general discussion of plant diseases and their control, refers more particularly to the work of Biffen (*E. S. R.*, 23, p. 147), Spinks (*E. S. R.*, 29, p. 844), and Orton (*E. S. R.*, 30, p. 331), dealing with immunity or susceptibility as related to manuring and to heredity.

The preparation and composition of lime-sulphur sprays, A. A. RAMSAY (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 194-201).—The author reports a chemical study of lime-sulphur sprays in which an attempt was made to determine the exact composition of the material as well as the most satisfactory proportions of lime and sulphur.

From his experiments it is claimed that the ratio of lime to sulphur should be between 1:2 and 1:1.9, the exact ratio being, probably, 1:1.95. The solution of lime sulphur is said to consist of calcium hydroxyhydrosulphid, calcium thiosulphate, and calcium sulphate, with sulphur held in solution.

The preparation and use of lime-sulphur mixture, L. SAVASTANO (*Prog. Agr. et Vit. (Ed. l'Est-Centre)*, 35 (1914), No. 4, pp. 109-113; *R. Staz. Sper. Agrum. e Frutticol. Acireale, Bol.* 2 (1912), pp. 6).—It is claimed that a spray mixture composed of lime, sulphur, and water in the proportions by weight of 1:2:10, prepared according to the process here recommended and described in detail, gives satisfactory results when used as either insecticide or fungicide, being relatively inexpensive in comparison with Bordeaux mixture as ordinarily employed.

Further observations on the fungicidal action of Bordeaux mixtures, B. T. P. BARKER and C. T. GIMINGHAM (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 220-232).—In continuation of a previous report on Bordeaux mixture (*E. S. R.*, 25, p. 458) the authors review their work and reply to criticisms of Pickering (*E. S. R.*, 26, p. 853). They claim that subsequent investigations more strongly confirm their previous opinion than before.

From a study of seedlings and foliage in relation to Bordeaux mixture the authors have come to the conclusion that living cells with readily permeable walls of the unchanged cellulose type or its equivalent are able to produce and absorb soluble copper from insoluble compounds, such as the basic sulphates. The area over which a single cell can exert the solvent action is limited by the size of the cell or by the quantity of the solvent diffusing from it. Groups of cells acting together may cause action over a wider area than isolated cells acting singly. The fate of the organism is held to depend upon the relation between the amount of soluble copper produced and absorbed and the rate of growth of the organism. This is held to be a significant point in connection with practical spraying, since it explains why at times there is little check to the growth of a parasitic fungus after spraying. Cells with impermeable walls possess no power of solvent action upon insoluble copper compounds. It is held that under changed conditions cells with normally impermeable walls may become permeable and capable of action upon insoluble copper compounds. This, it is believed, will explain the difference in behavior of summer and autumn apple foliage.

Studies of mechanical frost injuries, P. SOBUEB (*Ztschr. Pflanzenkrankh.*, 24 (1914), No. 2, pp. 65-76, pls. 3).—The author reports on further studies (*E. S. R.*, 30, p. 541) carried out with cereals as affected by cold and parasitic fungi. Supporting conclusions by Voges (*E. S. R.*, 29, p. 244), he states

that natural or artificial cold may produce in winter cereal plants alterations and discolorations of the membranes and vessels, which may be followed by parasitic attack in the weakened portions. Anatomical changes are described and illustrated.

Partial frost injury of winter cereals confused with animal injuries H. ZIMMERMANN (*Ztschr. Pflanzenkrank.*, 23 (1913), No. 6, pp. 332-334, pls. 3).—Frost injury of winter cereals resembling in its last stages that from gnawing animals is described and illustrated. The resemblance to animal injury is completed by attacks of semiparasitic fungi, resulting in blunt abscission of the weakened portions.

Ophiobolus herpotrichus and stem rot of cereals, E. VOGES (*Ztschr. Gärungsphysiol.*, 3 (1913), No. 1, pp. 43-83, figs. 5).—This is a more extended account of studies previously noted (*E. S. R.*, 28, p. 445.)

It is stated that *O. herpotrichus* is not the specific or exclusive cause of stalk disease or foot rot of cereals (this fungus not being able to attack the plants under normal conditions), and that the disease may be found as a secondary phenomenon in association with one or more of several organisms (*Cladosporium herbarum*, *Mucor racemosus*, and, more particularly, *Fusarium rubiginosum*) discussed in this connection, being favored also by unseasonable weather conditions and attacks of nematodes.

Two Michigan bean diseases, J. H. MUNCIE (*Michigan Sta. Spec. Bul.* 68 (1914), pp. 12, pl. 1, figs. 2).—Popular descriptions are given of the bean anthracnose due to *Glomerella (Colletotrichum) lindemuthiana* and bean blight caused by *Bacterium phaseoli*. The characteristics of these diseases are contrasted, and suggestions are given for their control.

For the anthracnose the selection of seed from pods showing no diseased spots is recommended, while for the bean blight disinfection of pods and selection will partially, though not completely, control the disease. In connection with these diseases, particularly the blight, the growing of resistant varieties is recommended.

A bacterial rot of celery, W. WORMALD (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 203-219, pl. 1).—The author states that during the month of February, 1913, an examination was made of celery plants that were thought to be damaged by the parasitic fungus *Septoria petroselinii apii*. Some of the plants were found to be in an advanced stage of decay, showing every evidence of a soft brown rot. An examination of the tissues showed the presence of active motile bacteria. These were isolated, and inoculation experiments showed that the organism was capable of producing the disease in question.

A technical description is given of the organism described as *Bacillus apiovorus* n. sp. It is said that little is known concerning the conditions inducing and favoring the development of the disease or of remedies for its prevention, but that proper sanitary precautions, the destruction of all decayed plants, and the holding in check of biting insects, slugs, and snails would probably aid in controlling the disease.

A brief bibliography is appended.

A fungus disease of peppers (Capsicum spp.), C. K. BANCROFF and R. L. HUNTE (*Jour. Bd. Agr. Brit. Guiana*, 7 (1914), No. 3, pp. 139, 140).—The authors report considerable injury to peppers grown in experimental tracts at the botanic gardens during 1913. The pods were affected and in a number of instances the crop was practically worthless. A study of the cause of the trouble showed that it was due to the fungus *Colletotrichum nigrum*. Some varieties, such as the Long White and Long Red, appeared very susceptible to the disease, while others were less subject to attack. Red Chili and Long Bird were unaffected.

Experiments for the control of the disease indicated that spraying with Bordeaux mixture would keep it in check.

Further observations on *Phytophthora erythroseptica* and on the disease produced by it in the potato plant, G. H. PETHYBRIDGE (*Sci. Proc. Roy. Dublin Soc., n. ser., 14 (1914), No. 10, pp. 179-193, pl. 1, figs. 2*).—This paper contains further observations on *P. erythroseptica* which has been previously shown to be the cause of a pink rot of the potato (*E. S. R., 29, p. 550*).

The author states that the reproductive organs of the fungus have been found in all of the underground parts of the plant, including in one case a tuber. Plants affected with this fungus exhibit symptoms of disease in their subaerial organs which are of the wilt type. On account of this character he suggests that the disease be known as pink rot wilt. The disease is considered contracted from the soil and is of serious consequence only in land which has been continuously in potatoes for several seasons.

Potato leaf roll, L. von BEKE (*Jahresber. Ver. Angew. Bot., 10 (1912), pp. 145-155*).—In a brief preliminary report of studies on potato leaf roll the author states that the disorder is thought to be hereditary and infectious. The trouble does not seem usually to spread from a center. Three different forms or degrees of development are described. Field experiments continued for three years in different parts of Hungary on infected and uninfected soils showed the hereditary character of the disorder and the increase of intensity in case of infected seed tubers when planted on infected soil, plants grown from healthy seed on noninfected soil showing no trace of the trouble. Differences in violence of the attack appeared more closely related usually to weather, soil, etc., than to variety used, although two varieties used were severely attacked. The influence of soils, elevation, climate, culture, and rotation are briefly discussed.

In laboratory studies mycelium of each of four fungi, *Fusarium solani*, *F. discolor*, *F. gibbosum*, and *F. subulatum* was used, the infection being accomplished by spraying or dipping on April 29. Disease symptoms appeared late in August and on September 5 only 14 out of 120 plants tested were free from symptoms resembling those of leaf roll.

Decisive results have not yet been obtained from field tests in which the plants were sprayed with liquid containing spores, spraying with mycelium appearing to cause infection more readily.

Microscopic investigation of the tissue failed to show invariable correspondence between the disease and the presence of mycelium. The latter was more frequently noted in the lower third of the aerial portion and in the roots near the surface. It was found only once in the vascular bundles of the leaves, but commonly in the vascular bundles of the tubers near their point of attachment. Young sprouts from diseased tubers showed no mycelium.

The potato diseases of Michigan, G. H. COONS (*Michigan Sta. Spec. Bul. 66 (1914), pp. 31, figs. 13*).—Popular descriptions are given of the late blight, early blight, scab, *Rhizoctonia*, dry rot, wet rot, deep scab, and *Fusarium* wilt, all of which are reported as being present in Michigan, and in addition brief accounts are given by E. A. Bessey of the wart disease, curly dwarf disease, leaf roll, blackleg, and powdery scab, none of which have yet been reported as occurring in that State. In connection with the different diseases control measures are discussed at length.

Diseases of sugar beets, O. FALLADA (*Österr. Ungar. Ztschr. Zuckerindus. u. Landw., 43 (1914), No. 1, pp. 23-28, fig. 1*).—This is part of the 1913 report by the author on the enemies and diseases of sugar beets, and includes brief general notes on root rot, heart and dry rot, and scab, and also on some diseases affecting the leaves.

Identification of species of *Fusarium* occurring on the sweet potato, *Ipomœa batatas*, H. W. WOLLENWEBER (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 4, pp. 251-286, pls. 5).—The author describes 13 species and varieties of *Fusarium* found occurring on the sweet potato, only a few of which are actively parasitic. The species and varieties described are *F. radicicola* n. sp., *F. incarnatum*, *F. culmorum*, *F. caudatum* n. sp., *F. caudatum volutum* n. var., *F. orthoceras*, *F. orthoceras triseptatum* n. var., *F. batatatis* n. sp., *F. oxysporum*, *F. hyperoxysporum* n. sp., *F. acuminatum*, *Hypomyces ipomœæ*, and *Gibberella saubinetii*.

A bibliography of cited literature is appended.

A disease resembling gummosis, J. A. HONING (*Meded. Deli-Proefstat. Medan*, 7 (1913), No. 10, pp. 465-468).—Cases are discussed in which symptoms (in particular the stripes near the leaf bases) closely conforming to those considered as characteristic of gummosis in tobacco, due to *Bacillus solanacearum*, are claimed to have been associated with an organism differing therefrom in some important characters. The stripes also are said to show on close inspection a greater breadth than those due to the bacteria which cause gummosis.

Cicinnobolus parasitic on apple mildew (*Oidium farinosum*), O. OBERSTEIN (*Ztschr. Pflanzenkrankh.*, 23 (1913), No. 7, pp. 394-396).—The author, noting that *Cicinnobolus*, previously reported by him as parasitic on *Sphærotheca mors-uvæ*, has been found on oak mildew (*O. quercinum*) by Vuillemin (*E. S. R.*, 24, p. 352), also possibly on other fungi, states that he has recently been able to confirm De Bary's listing of *Cicinnobolus* sp. as parasitic on *O. farinosum*.

Contribution to the life history and physiology of *Cylindrosporium* on stone fruits, B. B. HIGGINS (*Amer. Jour. Bot.*, 1 (1914), No. 4, pp. 145-173, pls. 4).—This contribution, which in its present form contains a bibliography, has already been noted from another source (*E. S. R.*, 30, p. 750).

Peach yellows investigations, H. S. REED (*Rpt. State Ent. and Plant Path. Va.*, 9 (1912-13), p. 20).—A brief account is given of a cooperative experiment begun between the State Crop Pest Commission and the department of plant pathology of the Virginia Station for the purpose of making investigations on the nature and control of peach yellows. In this experiment a number of trees from the western part of the State, where the disease was very prevalent, have been planted in the eastern part of the State, where the disease is unknown. These will be kept under observation and an attempt made to discover the nature of the trouble.

Contributions on the pathology of grape stocks, J. BERNATSKY (*Jahresber. Ver. Angew. Bot.*, 10 (1912), pp. 31-57).—Discussing disorders of grapevines and crops as related to climate, maturity and degree of improvement in stocks, weather and smoke, elevation and slope of land, qualities of soil and fertilizers used, cryptogamic diseases, etc., the author mentions among injurious parasites noted, *Botrytis* and *Dematophora glomerata*. The latter fungus thrives at temperatures above 7° C., inflicting much injury. It is found to be too deep seated to be controlled by spraying, and to require employment of such physiological factors as protection against strong sunlight, etc.

Control of chlorosis by acidification of soils is said to be ordinarily too expensive to be practical, thus requiring the selection of varieties less sensitive to lime.

Combating downy mildew of grape in 1913, L. SAURET (*Prog. Agr. et Vit. (Ed. l'Est-Centre)*, 35 (1914), No. 19, pp. 582-587).—In continuation of previous work (*E. S. R.*, 29, p. 50) the author gives an account of experiments conducted in Narbonne in 1913 for the control of the downy mildew of grape.

Different treatments were given vines, and it was found that liquid fungicides containing 2 kg. of copper sulphate to 1 of lime or carbonate of soda were sufficient in 1913, as in 1912, to protect completely both the leaves and the grapes. Powdered fungicides containing copper may be successfully used, but in most cases it was found advisable to supplement these treatments with liquid applications. The efficiency of the treatment was greatest the more nearly it was applied at the time of susceptibility and the nearer to rains accompanied by conditions for infection. There was found to be little choice in the use of fungicides whether they were acid or basic, and pronounced basic solutions gave very efficient results.

In conclusion the author states that if the fungicide is well made, abundantly applied, and followed by the use of a powder, it is possible to protect vines against mildew for 15 days after each application.

A preliminary report on raspberry curl or yellows, L. E. MELCHERS (*Ohio Nat.*, 14 (1914), No. 6, pp. 281-288, figs. 5).—This disease is said to be one of the most serious to which the raspberry is subject. It has been attributed to various causes, but it is considered by the author as identical with that described by Detmers (*E. S. R.*, 3, p. 411), where the disease is attributed to bacteria. The raspberry curl is said to occur mainly on Cuthbert, Marlboro, Golden Queen, Early King, and Herbert, the varieties being susceptible in the order named. It generally makes its appearance the second year after planting, although sometimes not until the third year does it become sufficiently abundant to attract attention. After it becomes established in a plant it reappears to a greater or less extent as long as that plant lives. One of the more striking symptoms of the disease is said to be the stunted appearance of the plant. The canes are short and bushy, the plants flower prematurely, the leaf blades are arched upward, and the berries mature from ten days to two weeks earlier than the normal crop. Where berries are ripened they are small, deformed, light in color, and have a disagreeable flavor.

For the control of this disease the author recommends planting of red raspberries from regions where the raspberry curl is not known to be present and the growing of varieties which are not known to be especially subject to the disease. The plants should be set in rather light or medium heavy soil provided with adequate drainage and well manured in order to produce vigorous growth. All plants showing the presence of the disease should be removed and destroyed.

American gooseberry mildew, F. J. CHITTENDEN (*Jour. Roy. Hort. Soc. [London]*, 39 (1913), No. 2, pp. 373-378).—The progress of *Sphaerotheca mors-uvæ* attacking gooseberries at Wisley since 1910 is noted in connection with measures for its control. Pruning was successful in 1911, but not in 1912. Spraying with potassium sulphid in 1913 did not check the disease very effectively, but did cause a considerable loss of foliage in some cases. No variety seemed to escape the disease completely.

Observations on the perithecial stage of the American gooseberry mildew, E. S. SALMON (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 187-193, figs. 11).—The author has reported some observations on the winter stages of the gooseberry mildew (*Sphaerotheca mors-uvæ*).

In 1913 the winter stage was found to be developing as early as May 26, and by June 6 the perithecia were found in abundance. This indicated that the winter stage may be formed almost at the beginning of an attack, the process of inoculation, incubation, and development of both summer and winter stages occupying only 11 days. Specimens of the winter stage exposed on the bush throughout the winter did not in February show any mature asci in the perithecia.

Investigations are in progress to determine under what conditions, if any, such perithecia may mature.

Notes on a new treatment for American gooseberry mildew, G. DOROGIN (*Ztschr. Pflanzenkrank.*, 23 (1913), No. 6, pp. 334, 335).—The author reports some preliminary experiments.

The complete treatment as recommended for American gooseberry mildew includes the removal and destruction in autumn of all suspected parts of the plants, followed immediately and again in early spring by spraying plants and earth with 1 to 3 per cent iron sulphate, and spraying the young foliage every 10 days with 0.5 per cent soda, 0.25 per cent soda and potash, or 0.25 per cent potash.

Disease of Veronicas, IVY MASSEE (*Gard. Chron.*, 3. ser., 55 (1914), No. 1429, p. 335, fig. 1).—The author reports that among specimens of diseased plants sent in for examination, one of *V. hulkeana* was found to be attacked by *Peronospora grisea*, heretofore thought to be restricted to wild species of Veronica. The young leaves dry and wither, the under surface showing a dingy white mildew, proving to be the fungus named. Growth in case of attack of *V. hulkeana* is checked by death of the young leaves and shoots, while some other species of Veronica are little affected by its presence.

The diseases of nut trees, M. B. WAITE (*North. Nut Growers Assoc. Proc.*, 4 (1913), pp. 50-59).—In this paper the author gives a brief account of the principal diseases of the hickory, pecan, and walnut, calling attention to the fact that the native parasites attack the introduced species to a very considerable extent, while the attack on the native species is of comparatively little consequence.

Present state of the chestnut blight, J. F. COLLINS (*North. Nut Growers Assoc. Proc.*, 4 (1913), pp. 25-29).—The author has given a popular summary of the present state of information relating to the chestnut blight in this country, and called attention to the discovery in China of a disease which is supposed to be identical with the chestnut disease in this country (E. S. R., 29, p. 753).

The question of resistance of varieties to chestnut blight is discussed at considerable length. In noting its distribution the author states that it is known to occur in Maine, New Hampshire, Vermont, New York east of the Catskills and as far north as Lake George, and generally as far south as northern Virginia. One nursery has been reported in North Carolina as infected, and chestnut trees in British Columbia are also reported as having the disease.

The chestnut blight in Virginia, F. GRAVATT (*Rpt. State Ent. and Plant Path. Va.*, 9 (1912-13), pp. 21-25).—The author states that chestnut blight is established in 19 counties in northern Virginia and that the chief work carried on in connection with this disease in Virginia has been the general inspection of the State and the destruction of trees showing the disease in advance isolated localities.

Warty roots of *Gymnocladus canadensis*, A. SPERLICH (*Ztschr. Pflanzenkrank.*, 23 (1913), No. 6, pp. 321-331, figs. 7).—Illustrations and descriptions are given of tumorous swellings on roots of *G. canadensis* and other abnormalities noted in connection therewith. It is stated that the abundant deposit of material in the tumorous regions interferes with the normal movement of nutritive or elaborated materials, some of the growths showing internally some characters of branches.

Some observations on plant diseases caused by parasitic fungi, P. MAGNUS (*Jahresber. Ver. Angew. Bot.*, 11 (1913), pt. 1, pp. 14-18, fig. 1).—Noting the progress of *Oidium quercinum* in northern France, the author states that this fungus, said to be of American origin and to attack ordinarily the American

species *Quercus rubra* and *Q. palustris* less severely than the European species *Q. tozza*, *Q. pedunculata*, and *Q. cerris*, has recently shown increased activity on *Q. rubra*. It is said also to have been noted recently as attacking *Colutea arborescens* in several places.

It is also stated that *Dædalea unicolor*, usually mentioned as saprophytic on live trees, has been noted as parasitic on *Æsculus hippocastanum*, *Fagus sylvatica*, *Robinia pseudacacia*, *Betula*, *Acer rubrum*, and *A. platanoides*.

The fight against dry rot of pine and fir trees, A. MÖLLER (*Ztschr. Forst u. Jagdw.*, 46 (1914), No. 4, pp. 193–208).—In extension of work previously reported (E. S. R., 23, p. 653), the author states that results of his recent studies involving infection of pine and fir with *Trametes pini* support the claim of Hartig (E. S. R., 7, p. 512) to the effect that the dry rots of these conifers are due to the same fungus, *T. pini*.

Studies on dry rot attacking wood, C. WEHMEB (*Jahresber. Ver. Angew. Bot.*, 11 (1913), pt. 1, pp. 106–116, figs. 5).—This article refers to work previously reported (E. S. R., 31, p. 248). *Merulius lacrymans* attacked wood only when the mycelium grew out from an old infection.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

A review of the spread of the chief injurious animals in Russia during 1912, I. A. PORTCHINSKY (*Ezheg. Dept. Zeml. [Russia]*, 1912, pp. 351–361, pls. 3; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 3, pp. 197–199).—A general discussion of the subject.

The mongoose in Trinidad and methods of destroying it, F. W. URICH (*Bd. Agr. Trinidad and Tobago Circ. 12* (1914), pp. 16, pls. 2; *Bul. Dept. Agr. Trinidad and Tobago*, 13 (1914), No. 81, pp. 196–208, pls. 2).—The mongoose (*Herpestes mungo*), which was introduced into Trinidad about 1870 by a sugar estate in the Naparimas for the purpose of controlling rats which were pests in that district, has since become a pest of considerable importance.

Birds of town and country, H. W. HENSHAW (*Nat. Geogr. Mag.*, 25 (1914), No. 5, pp. 494–531, figs. 66).—A pictorial description in colors is given of 64 of the common birds in addition to the 50 considered in the work previously noted (E. S. R., 28, p. 853).

The food of birds, LAURA FLORENCE (*Trans. Highland and Agr. Soc. Scot.*, 5. ser., 26 (1914), pp. 1–74).—This report, in continuation of that previously noted (E. S. R., 27, p. 550), presents results of examinations of the crop contents of 1,390 birds. The majority of these birds are said to have been shot while feeding on agricultural land and to have been obtained chiefly in the northeastern counties of Scotland.

Some further observations on the dispersal of weed seeds by wild birds, W. E. COLLINGE (*Jour. Econ. Biol.*, 9 (1914), No. 2, pp. 69–71).—A brief statement of the work carried on in continuation of that previously noted (E. S. R., 30, p. 248).

Insect pests and fungoid diseases [in Barbados, 1912–13], J. R. BOVELL and W. NOWELL (*Rpt. Dept. Agr. Barbados, 1912–13*, pp. 33–43; *abs. in Agr. News [Barbados]*, 13 (1914), Nos. 315, pp. 170, 171; 316, p. 186).—A brief review of the occurrence of the more important insect enemies of the year.

Insect pests in British Guiana, G. E. BODKIN (*Rpt. Dept. Sci. and Agr. Brit. Guiana, 1912–13*; *abs. in Agr. News [Barbados]*, 13 (1914), No. 318, pp. 218, 219).—This report deals with the insect pests under the headings of the principal crops of the colony.

Report of the chief entomologist to the zemstvo on injurious insects and diseases of plants in the Government of Taurida during the year 1912,

S. A. MOKRZECKI (*Abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 361-364).—Among the more important insects discussed are the pear psylla, the gipsy moth, *Phlyctænodes sticticalis*, the codling moth, *Ino ampelophaga*, euonymus scale, the pear thrips which was found on pear trees in Alushta, etc.

Report of the assistant entomologist to the zemstvo on injurious insects and diseases of plants in the Government of Taurida during the year 1912, I. M. SHTCHEGOLEV (*Abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 357-359).—A detailed report of the occurrence of the more important insect pests of the year.

Division of entomology, annual report, 1912-13, C. P. LOUNSBURY (*Union So. Africa Dept. Agr. Rpt.*, 1912-13, pp. 271-296, pls. 5).—This presents details of the work for the period from January 1, 1912, to March 31, 1913, and reports on the occurrence of the more important pests, control measures, plant inspection, etc. A supplementary report of the Cape Province entomologist, C. W. Mally, is appended.

Insect enemies of corn, F. SHERMAN, JR. (*Bul. N. C. Dept. Agr.*, 35 (1914), No. 5, pp. 56, figs. 21).—A popular account of the more important insect enemies of corn with remedial measures therefor.

The insect enemies of cotton in German East Africa, H. MORSTATT (*Pflanzer*, 10 (1914), Beiheft 1, pp. X+49, pls. 3).—This is a brief discussion of the more important insect enemies of cotton and control measures therefor. A work on the insect enemies of the cotton plant in the German colonies by Aulmann has previously been noted (*E. S. R.*, 29, p. 653).

The entomology of Helianthus, T. D. A. COCKERELL (*Entomologist*, 47 (1914), No. 614, pp. 191-196).—A report of observations of the insect fauna of the sunflower.

Experiments on fighting the pests of winter rape (*Prel. Rpt. Bio-Ent. Sta. Bessarabia*, 1913, pp. 5; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 395, 396).—The cultivation of winter rape is said to have decreased greatly in Bessarabia, owing chiefly to the damage done to it by insect pests, the most serious of which are the larvæ of the sawfly *Athalia spinarum*, which feeds usually on grasses, and *Entomoscelis adonidis*.

Insect pests of sugar cane in British Guiana, H. W. B. MOORE (*Abs. in Agr. News [Barbados]*, 13 (1914), No. 319, pp. 234, 235).—A discussion of the more important enemies of sugar cane.

Insect damage to the cones and seeds of Pacific coast conifers, J. M. MILLER (*U. S. Dept. Agr. Bul.* 95 (1914), pp. 7, pls. 3).—This bulletin gives information regarding the character and extent of insect damage to the cones and seed of coniferous forests of the Pacific slope, thus supplementing the information on the subject, previously noted (*E. S. R.*, 16, p. 175; 18, p. 255; 28, p. 657). It also furnishes preliminary information on the more important groups of insects causing this damage, and their habits. The names of none of the insects causing the injury have been mentioned since it is intended that a special bulletin on the subject will be issued.

Spraying apple trees in blossom with tobacco extract, S. GLAZENAP (*Trudy Bûuro Prikl. Bot. (Bul. Angew. Bot.)*, 6 (1913), No. 4, pp. 243-250; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 370, 371).—In combating the apple psyllid the author has met with success in the application while the apples are in bloom of tobacco extract, prepared by boiling 1 lb. of *Nicotiana rustica* for 15 minutes in 3 gal. of water, and then diluting with 6 gal. of water. It is stated that the spraying, which was done while the trees were in full bloom, did not affect the bees, and was sufficient to destroy *Psylla mali*, young caterpillars of *Cheimatobia brumata*, Tortricidæ, and similar pests.

The use of lime and sulphur solution on citrus trees, W. W. YOTHERS (*Fla. Grower*, 10 (1914), No. 16, pp. 10, 11).—The author presents a brief report of results obtained from the application of lime-sulphur in the control of mites on citrus in Florida.

Applications of lime-sulphur for the control of the rust mite on July 18, when there were many eggs and adults present, indicate that it is unnecessary to use dilutions stronger than 1:75 since this kills all adults and eggs. Dilutions of 1:75 are said to kill also eggs and adults of both the 6-spotted mite (*Tetranychus sexmaculatus*) and the purple mite (*T. mytilaspidis*).

While lime-sulphur was not so effective as oil sprays in killing the purple scale, experiments show it to be suitable for this purpose. Fruit sprayed three times with a dilution of 1:25 had only about one-fourth as many scales per orange as were found on unsprayed fruit. It is stated that the white flies are not affected by lime-sulphur, in several experiments dilutions of 1:9 having no appreciable effect upon the pupa. The author mentions having observed that lime-sulphur has some stimulating effect upon the growth of the foliage. Attention is called to the fact that it should not be used on ripe fruit at dilutions stronger than 1:40 or 1:45.

The use of carbon bisulphid in emulsion at Martinique and Guadeloupe, G. BORDAZ (*Abs. in Agr. News [Barbados]*, 13 (1914), No. 317, pp. 202, 203).—Applications of carbon bisulphid in kerosene emulsion have been found of value in destroying white grubs, eelworms, and a root disease, probably a Rosellinia disease. The most efficacious method in cacao and coffee plantations is to pour the emulsion around the foot of each tree.

The locust pest, C. R. JONES and D. B. MACKIE (*Philippine Agr. Rev. [English Ed.]*, 6 (1913), No. 9, pp. 8, pls. 2; *Philippine Bur. Agr. Circ.* 23 (1913), pp. 8, pls. 2).—These data have been substantially noted from another source (*E. S. R.*, 28, p. 753).

Thrips as pollinators of beet flowers, H. B. SHAW (*U. S. Dept. Agr. Bul.* 104 (1914), pp. 12, pls. 3, figs. 5).—During the course of studies of the rôle of thrips in the pollination of sugar beets several species were collected from beet flowers at Garland, Utah, including *Heliothrips fasciatus*, *Frankliniella fusca*, and *F. tritici*. It is stated that *Thrips tabaci* was the species most abundant in Ogden, Utah, during the seasons of 1911 and 1912.

The investigations show that thrips are active agents in pollination, being very numerous among beet flowers and effecting both close pollination and cross-pollination. After taking into account the various forms of injury which they cause, however, the author considers it doubtful whether the balance remains in their favor in regard even to beets. "Under ordinary conditions, in fields of commercial seed beets, it is believed that on the whole their work is beneficial; but should they become excessively numerous, they sustain their reputation as one of our really destructive pests. To the horticulturist and plant breeder they are pests of the worst type, necessitating constant watchfulness and a refined technique in all pollination work.

"The suggestion is ventured that certain supposed mutations may really have been the result of unsuspected cross-pollination by means of one or another species of thrips, whether in cereals supposedly not susceptible to cross-pollination without the intervention of man or in flowers which were thought to have been isolated against cross-pollination."

New genera and species of Thysanoptera, with notes on distribution and food plants, A. C. MORGAN (*Proc. U. S. Nat. Mus.*, 46 (1914), pp. 1-55, figs. 79).—Three genera and 19 species are described as new to science, among which are *Euthrips floridensis*, taken on *Asclepias variegata* and in blossoms of *Catalpa catalpa*, at Quincy, Fla.; *E. hawaiiensis* from cotton at Honolulu;

E. gossypii collected from the tips of the leaves of cotton at Yuma, Ariz.; *Rhipiphorothrips pulchellus* n. g. and n. sp., from the banyan tree, Philippine Islands; *Microthrips piercei* n. g. and n. sp., collected from cotton and Vernonia at Dallas, Tex., and from papaw at Clarksville, Tenn.; *Horistothrips australie* n. g. and n. sp., collected under dead scales of Eriococcus on Eucalyptus at Swan River, Australia; etc.

New locality and food plant records for certain Thysanoptera are appended.

Attempts to find disease germs in the European bedbug (*Cimex lectularius*) after feeding experiments in various diseases, leprosy, lymphadenoma, carcinoma, etc., D. THOMSON (*Ann. Trop. Med. and Par.*, 8 (1914), No. 1, pp. 19-28).—"Four hundred and fifty-five bedbugs were employed in this research; of these 184 were used as controls. Insufficient research has been carried on with regard to the possibility of the transmission of disease in temperate climates by bloodsucking insects occurring in these climates. Protozoal parasites do not appear to exist normally in the European bedbug. No acid-fast bacilli were found in 105 bedbugs fed on lepers, nor in 35 bedbugs caught on the bed mattresses of leper patients. In the few experiments conducted nothing abnormal was found in bugs fed on cases of lymphadenoma, chronic lymphatic leukemia, sarcoma, carcinoma, and malaria. Forty bedbugs fed on a case of spleno-medullary leukemia all developed numerous Charcot-Leyden crystals in their intestines."

An egg parasite of the tarnished plant bug (*Lygus pratensis*), C. R. CROSBY and M. D. LEONARD (*Canad. Ent.*, 46 (1914), No. 5, pp. 181, 182, figs. 2).—Under the name *Anagrus oviventatus* the authors describe a new parasite reared from eggs of *L. pratensis* in October, 1913, at Ithaca, N. Y.

A contribution toward a monograph of the homopterous insects of the family Delphacidae of North and South America, D. L. CRAWFORD (*Proc. U. S. Nat. Mus.*, 46 (1914), pp. 557-640, pls. 6).—This is a synopsis of a family closely related to the Fulgoridae.

On the susceptibility and immunity of vines to the attacks of phylloxera, C. BÖRNER (*Biol. Centbl.*, 34 (1914), No. 1, pp. 1-8; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 3, pp. 156, 157).—A report is given of experiments carried on by the author in Villers l'Orme, near Metz, by Brichon in Pagny-sur-Moselle, and by Autelin in Nancy, on the resistance of different vines to attacks of phylloxera. The most important result of the experiments is to show that the effect produced upon vines by the Lorraine phylloxera is quite different from that produced by the south of France form. The author concludes that there are two species of phylloxera and designates the Lorraine form as *Phylloxera percastatrix*.

The fumigation of citrus trees, L. GOUGH (*Agr. Jour. Egypt*, 4 (1914), No. 1, pp. 17-29).—This paper gives a brief account of the habits of the Coccidae which infest citrus trees in Egypt and means of combating them.

Sweet potato sphinx, J. C. FAURE (*Agr. Jour. Union So. Africa*, 7 (1914), No. 4, pp. 515-519, fig. 1).—The sweet potato sphinx moth (? *Herse convolvuli*) is said to cause serious damage to the sweet potato in Natal, reducing the crop from 25 to 50 per cent, and perhaps more.

Oak pests.—The carpenter worm (*Prionoxystus robiniae*), L. CHILDS (*Mo. Bul. Com. Hort. Cal.*, 3 (1914), No. 7, pp. 259-264, figs. 6).—It is stated that California live oaks, as well as poplars, willows, locusts, and elms, are in many localities attacked and greatly damaged by this pest through the larva feeding in the trunks and larger limbs.

Phlyctænodes sticticalis, its life history and methods of fighting it, S. A. MOKRZECKI (*Abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 359-361).—This pyralid moth is said to occur everywhere in European Russia, as well as

in Siberia and Russian Turkestan, and to have been imported to the United States, where it was first found in 1869 and where it caused considerable damage to the beet crops in 1909 and 1910. A detailed report of its life history and remedial measures is given.

Serious outbreak of *Phlyctænodes sticticalis* near Poltava, N. V. KURDJUMOV (*Khutorianin*, No. 26 (1913), pp. 697, 698; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, p. 394).—A brief discussion of outbreaks of this pest with recommendations as to remedial treatment. A detailed account of this pest is given in the article above.

The codling moth in Uruguay, E. LAHILLE (*Rev. Asoc. Rural Uruguay*, 42 (1913), No. 8-9, pp. 645-648; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 3, p. 162).—The author states that in Uruguay adult codling moths are destroyed by bonfires lit in the evening around pear and apple trees when in blossom.

A small manual on malaria, L. M. PARROT (*Petit Manuel du Paludisme. Paris, 1914, pp. 32, figs. 11*).—This work, which is intended for the use of schools in North Africa, gives information on the nature of the malarial parasite and of the mosquito and its rôle in the transmission of the parasite and means of combat.

Mosquitoes and malaria, J. C. FAURE (*Agr. Jour. Union So. Africa*, 7 (1914), No. 2, pp. 223-242, figs. 13).—This is a general discussion of the subject.

A synopsis of the described North American species of the dipterous genus *Tipula*, W. G. DIETZ (*Ann. Ent. Soc. Amer.*, 6 (1913), No. 4, pp. 461-484).—The synopsis here presented is in tabular form. A list with habitat and bibliography of the North American species described since the publication of Aldrich's Catalogue of North American Diptera is appended.

Heredity of bristles in the common greenbottle fly, *Lucilia sericata*.—A study of factors governing distribution, P. W. WHITING (*Amer. Nat.*, 48 (1914), No. 570, pp. 339-355, fig. 1).—"Taking a general summation of all the bred material of *L. sericata*, we find that reduction affects the males while addition affects the females. Of the 5,367 flies bred, 2,708 are males and 2,659 are females, giving practical equality. Reduction in the males is 748.5 bristles, while in the females it is only 455.5 bristles. As has been noted before, the degree of reduction in the females is increased by the later generations of strain 1913-A, by reason of the fact that reduction rarely goes beyond the loss of two bristles in a single fly. Thus when most of the flies of a population become reduced to this extent it is evident that reduction in the males would be but slightly in advance of that in the females.

"There are 210 bristles added in the males, while there are 343 added in the females. Thus addition affects the females more than the males. These figures for bristles added represent number of bristles, and thus no distinction is made between bristles of large and bristles of small size."

The skin maggot of man, C. FULLER (*Agr. Jour. Union So. Africa*, 7 (1914), No. 6, pp. 866-874, fig. 1).—This paper relates to *Cordylobia anthropophaga*.

An attempt to transmit poliomyelitis by the bite of *Lyperosia irritans*, E. FRANCIS (*Jour. Infect. Diseases*, 15 (1914), No. 1, pp. 1-5, figs. 2).—In several experiments conducted flies (*L. irritans*) that had sucked the blood of infected rhesus monkeys twice daily for periods of four and six days from the time of their inoculation with poliomyelitis virus to their death and were allowed to feed on healthy rhesus monkeys twice daily during the same periods and two or three times daily during periods ranging from six to eight days following, failed to transmit the disease.

Flies in relation to disease.—Nonbloodsucking flies, G. S. GRAHAM-SMITH (*Rev. in Science, n. ser.*, 39 (1914), No. 1013, pp. 787-789).—A review by L. O. Howard of the work previously noted (*E. S. R.*, 30, p. 552).

A synopsis of the genera of *Agromyzidæ*, with descriptions of new genera and species, J. R. MALLOCH (*Proc. U. S. Nat. Mus.*, 46 (1914), pp. 127-154, pls. 3).—A synopsis of a dipterous family of considerable economic importance.

An account of the bionomics and the structure of dipterous larvæ occurring in human foods with particular reference to those which have been recorded as accidental parasites of man.—I, The cheese skipper (*Piophilæ casei*), D. C. MOTE (*Ohio Nat.*, 14 (1914), No. 7, pp. 309-316, figs. 16).—"The cheese skipper because of its ravages on cheeses and smoked meats and its possible relation to myiasis is of considerable economic importance. The fly deposits its eggs upon bacon, cheeses, smoked ham, slightly putrid beefsteak. Duration of egg stage, 23 to 54 hours. Larvæ feed upon bacon, cheese, ham, beef, oleomargarine. This insect gets its common name from the peculiar leaping or skipping habit of the larva. Duration of larval instar, 14 days. Pupation occurs in drier places than those in which the larvæ feed. Duration of pupal stage, 12 days. The flies in an experiment seemed to prefer beefsteak with a slightly putrid odor in preference to ham, bacon, or cheese for egg deposition. The adult flies lived longer, and the larvæ fed and matured more readily on the beefsteak than on the other substances."

Biological notes concerning *Drosophila ampelophila*, F. E. LUTZ (*Jour. N. Y. Ent. Soc.*, 22 (1914), No. 2, pp. 134-138).—Data are presented on the development of the different stages of the pomace fly, based on observations of some 400 individuals.

The biology of *Ceratophyllus fasciatus*, the common rat flea of Great Britain, C. STRICKLAND (*Ann. Rpt. Local Govt. Bd. [Gt. Brit.]*, 42 (1912-13), *Sup. Rpt. Med. Off.*, pp. 401-412; *Jour. Hyg. [Cambridge]*, 14 (1914), No. 2, pp. 129-142).—The results of life history studies of this flea have been summarized as follows:

"The duration of the various stages is very variable, even under the same conditions. Temperature and humidity are the two conditions which have most influence. . . . On an average, the egg hatches out in 5 to 14 days, an increase of humidity having a retarding, and a moderately high temperature a slight accelerating effect. The larva is soon killed by a high temperature (70° F.) combined with a low degree of humidity (40 per cent). However, under these conditions, the larvæ will live longer if rubbish is present, for they are then able to bury themselves in it and thus obtain a certain amount of moisture. The pupal stage is much prolonged by cold, but this is partly due to the nonemergence of the imago, even when it is fully formed. The imago, at least when unfed, dies off much more rapidly in summer than in winter. Eggs are laid by the imago even at comparatively low temperatures (50°).

"The larvæ and imagines like to bury themselves in rubbish, and under these circumstances their duration of life is much prolonged, even when other external conditions are somewhat severe. When copulating, the imago frequently lives at least two months, but it will not copulate unless it is fed on rat's blood. It feeds readily on man and many other animals, but will not copulate after feeding on these facultative hosts, even though at least one of them—man—seems to be more attractive to it than its normal host, the rat. Oviposition invariably takes place within 24 hours of copulation, even when the insect has only been fed once after being starved for a period of many weeks. The rat's blood, therefore, probably contains some substance that possesses a stimulating effect on the flea's sexual organs. When starved, the imago will live for a very long time—at least 17 months—but only in the presence of rubbish in which it can bury itself. In the absence of rubbish the flea will only live for about a month, even under the most favorable conditions of temperature and humidity.

"From the foregoing observations it is clear that the presence of rubbish containing organic matter is essential for the development of the flea."

Buprestids collected in the Philippine Islands, C. KERREMANS (*Philippine Jour. Sci., Sect. D, 9 (1914), No. 1, pp. 83-90, fig. 1*).—Twenty-eight species are here listed, of which 12 are described as new to science.

Notes on *Rhabdocnemis obscurus* in Australia, A. A. GIRAULT (*Canad. Ent., 46 (1914), No. 5, pp. 174-179*).—The author presents notes on the biology of this borer, which has been the source of injury to sugar cane in north Queensland.

The Tenebrionidæ of the Philippines, H. GEBIEN (*Philippine Jour. Sci., Sect. D, 8 (1913), Nos. 5, pp. 373-400; 6, pp. 401-433*).—This paper records 88 forms, of which 4 genera and 41 species are described as new to science.

The cowpea weevil (*Pachymerus chinensis*), J. A. KRALL (*Oklahoma Sta. Circ. 31 (1914), pp. 8*).—In an introduction to this circular C. E. Sanborn summarizes the measures which have been the most satisfactory in controlling the cowpea weevil, which has caused an almost total destruction in the bin of seed peas in Oklahoma. Notes on controlling the cowpea weevil follow.

In cold storage experiments cowpeas kept at temperatures as low as from 26 to 31° F. for periods ranging from 58 to 184 days gave a germination of 86 to 95 per cent and varied but little from the checks kept. The observations show that when any of the stages in the life cycle of this weevil are subjected to a temperature of 32° or below they will not mature. Notes on hot water, dry heat, carbon bisulphid, and kerosene treatments follow. The remedies recommended include immersion of the seeds in water at a temperature of 130° for 1 minute and after 2 minutes' interval a submersion for another minute; heating of the seed in a steady temperature of 130° for a period of 2 to 4 hours; use of 1 lb. of carbon bisulphid to 40 bu. of seed in an air tight bin; and spraying peas, thinly and evenly spread on a canvas or floor, with kerosene at the rate of 1 pint to 10 bu. or 600 lbs. of peas. In the kerosene treatment an atomizer, hand spray pump, or very fine sprinkler should be used, after which the peas should be shoveled so as to bring the treated and untreated seed together until all have an equal coating of the kerosene.

The temperature of the bee colony, B. N. GATES (*U. S. Dept. Agr. Bul. 96 (1914), pp. 29, figs. 8*).—This paper is based upon work conducted during the period extending from October 22, 1907, to September 26, 1908, during which time over 2,576 observations and 20,000 separate readings were made. It describes the apparatus made use of, the arrangement of the thermometers, methods of observation and recording, the consumption of stores in winter, general phenomena of the cluster in winter, the temperature below frames in relation to the outside air, comparisons of temperatures of the center of the cluster and of the outside air, effects of manipulation on the cluster, behavior of the cluster in winter, temperature accompanying the laying of the first eggs, transition from winter to summer conditions, general phenomena of the summer temperature, the effect of "orientation" or "play flights," effects of cluster heat on the temperature below the frames, the effects of storm, and the effects of transportation on the temperature of the colony.

A paper relating to the subject from the same Bureau has been recently noted (*E. S. R., 31, p. 254*).

Bee diseases and bee enemies, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scot., 5. ser., 26 (1914), pp. 150-169, figs. 2*).—This general account of the subject summarizes the main results of recent work.

Foul brood, F. E. MILLEN (*Michigan Sta. Spec. Bul. 64 (1914), pp. 8*).—This bulletin, which is supplementary to one recently noted (*E. S. R., 28, p. 456*),

deals with sacbrood and also gives the text of the state law relative to bee inspection in Michigan.

Annual report of the Bee-Keepers' Association of the Province of Ontario, 1913 (*Ann. Rpt. Bee-Keepers' Assoc. Ontario, 1913, pp. 72*).—The proceedings of the annual meeting are here presented.

The relation of the honeybee to other insects in cross pollination of the apple blossom, J. W. MCCOLLOCH (*Trans. Kans. State Hort. Soc., 32 (1912-13), pp. 85-88, fig. 1*).—The author presents a chart which shows the number of different insects that visited apple blossoms at the Kansas Experiment Station, with the comparative number of honeybees. During the course of observations made to determine the number of blossoms a honeybee would visit on a trip, a bee which already carried some pollen on its legs was followed while it visited 61 blossoms, and was then lost sight of in the top of the tree. Another was watched while it visited 53 blossoms and several were followed while they visited from 25 to 40 blossoms.

A pine pest (*Lophyrus pini*), P. NIKOLAEV (*Khutorianin, No. 25 (1913), pp. 676, 677; abs. in Rev. Appl. Ent., 1 (1913), Ser. A, No. 10, p. 395*).—The larvæ of a sawfly (*L. pini*) are said to have appeared in southwestern Russia and to have been the source of great injury to pine forests, especially to young trees. There are two annual broods, the first ovipositing in May and the second appearing early in August.

Descriptions of new Hymenoptera, VIII, J. C. CRAWFORD (*Proc. U. S. Nat. Mus., 46 (1914), pp. 343-352, figs. 8*).—Among the species here described that are of economic importance are *Trissolcus trinidadensis* reared from the eggs of *Sphyrocoris obliquus* on cotton, *Perilampidea syrphi* n. g. and n. sp. from the larva of a syrphid preying on *Dactylopius citri* on cacao, *Ooencyrtus chrysopæ* from the eggs of *Chrysopa* sp., *Signiphora giraulti* from *D. citri*, and *Gonatocerus anomocerus* from the eggs of *Horiola arcuata*, all in Trinidad; and *Derostenus fullowayi* reared from *Agromyza diminuta* at Honolulu, Hawaii.

Descriptions of twenty-three new genera and thirty-one new species of ichneumon flies, H. L. VIERECK (*Proc. U. S. Nat. Mus., 46 (1914), pp. 359-386*).—*Meteorus mamestræ*, reared from *Mamestra trifolii*, at Rocky Ford, Colo., is among the species here described as new to science.

Descriptions of two new genera of parasitic Hymenoptera, S. A. ROHWER (*Psyche, 21 (1914), No. 2, pp. 79-81, figs. 2*).—Two parasites, here described as representing new genera and species, have proved to be of economic importance in relation to the chestnut, namely, *Anomopterus fasciipennis*, a primary parasite of *Ectædemia phlæophaga*, at Falls Church, Va.; and *Centistidea ectædemie*, a primary parasite of *E. castanæ*, at Ballston, Va.

A new scelionid parasite of locust eggs from the Northern Territory of Australia, A. A. GIRAULT (*Entomologist, 47 (1914), No. 614, p. 197*).—The parasite here described as new; namely, *Scelio semisanguineus*, was captured over acridid egg beds on sandy soil, at Port Darwin, Northern Territory.

FOODS—HUMAN NUTRITION.

The problem of the food supply as to breadstuffs and kindred articles (*Chamber Com. U. S. A., Gen. Ser., Bul. 84 (1914), pp. 220-223, figs. 2*).—Statistical data are brought together in this article which combats the opinion that a widespread shortage of food supplies is to be expected in the future.

Making, examining, and judging bouillon cubes, H. SERGER (*Ztschr. Öffentl. Chem., 20 (1914), Nos. 5, pp. 81-88; 6, pp. 101-109*).—Analytical and other data are summarized and discussed.

Concerning the fat of the European coot (*Fulica atra*), S. BLAHA (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 89 (1914), No. 6, pp. 456-464).—The European coot is little used as a game bird owing to the fact that the flesh has a decidedly unpleasant odor and taste. This is not noticeable if the skin is removed before cooking and the bird carefully cooked. The results obtained in a study of the fat show that the peculiar odor and taste should not be attributed to it. On the other hand, the author succeeded in isolating from the flesh a base which possessed all the characteristics of methylamin, and he attributes the odor and flavor observed to the presence of monomethylamin.

Canned salmon—cheaper than meats, and why (*U. S. Dept. Com., Bur. Fisheries Econ. Circ. 11* (1914), pp. 11).—A number of recipes are given for dishes made with canned salmon, the importance of this foodstuff is pointed out, and its nutritive value in comparison with other foods is discussed.

Studies of the effects of corn as a food—utilization of corn protein by man, S. BAGLIONI (*Atti R. Accad. Lincei, Rend. Cl. Sci. Fis., Mat. e Nat.*, 5. ser., 22 (1913), II, No. 11, pp. 608-615).—The results are reported of experiments in which the relative food values of corn polenta (mush), a wheat polenta, and bread and meat were compared.

In the subjects of these experiments during the periods of exclusive vegetable diet undernutrition was observed with loss of nitrogen and a decrease in body weight of about 1 kg. A greater quantity of nitrogen was introduced with the diet of corn polenta, but relatively less was absorbed than in the case of the wheat polenta.

The conclusion is drawn from these experiments that an exclusive diet of corn is inferior to one of wheat and that both are inferior to a mixed diet of bread and meat.

Unpolished rice and the prevention of beri-beri, H. FRASER and A. T. STANTON (*Lancet [London]*, 1914, I, No. 2, pp. 96-98, fig. 1).—The authors report additional data regarding the use of unpolished rice as a cause of beri-beri, which apparently indicates that polished rice can be used safely provided it has a phosphorus content of not less than 0.4 per cent. The belief is expressed that the use of a polished rice of this standard would tend in a great measure to prevent the spread of beri-beri. See also earlier work (E. S. R., 28, p. 168.)

Toxic brans, MARCHADIER and GOUJON (*Ann. Falsif.*, 7 (1914), No. 64, pp. 77-81).—From a digest of the data regarding the toxic effects of bran, the authors make the following recommendations: Bran showing an acidity less than 0.15 per cent should be regarded as normal; that having an acidity between 0.15 and 0.3 per cent should be regarded as being in a state of transformation not yet dangerous but liable to rapid decomposition; that showing an acidity greater than 0.3 per cent should be regarded as unfit for food.

Contribution to the study of baker's yeasts, E. KAYSER (*Ann. Inst. Nat. Agron.*, 2. ser., 12 (1913), No. 2, pp. 345-377, figs. 13).—From the experimental data here reported, the author concludes that baker's yeasts should be studied with a view to determining the optimum temperature and rate of action, in order to ascertain which yeast is best suited for a particular use. It is stated that yeasts contaminated with mycoderma may be used in bread making, but, although they are more active, they produce a less satisfactory product. Trials and microscopic examinations of the different yeasts are recommended as giving the best index of their relative efficiency.

Food poisoning due to cream cakes, CHANTEMESSE and RODRIGUEZ (*Bul. Acad. Méd. [Paris]*, 71 (1914), No. 7, pp. 245-259; rev. in *Jour. Amer. Med. Assoc.*, 62 (1914), No. 12, pp. 939, 940).—An account is given of poisoning due

to eating cream cakes, and specifically to the meringue which covered them. The interior portion of the meringue, it was found, contained a peculiarly toxic paratyphoid bacillus. It is pointed out that when the surface of the meringue was browned, the heat did not penetrate the interior and sterilize it, and that the egg white furnished a favorable medium for the development of the contaminating organism. Similar cases of illness were traced to the same bakery, and it was discovered that the cook was a paratyphoid carrier.

Molasses (*Maine Sta. Off. Insp. 59 (1914), pp. 33-40*).—The nature of molasses is discussed. Maine standards and definitions are quoted and data given regarding the inspection, with analyses of a large number of samples.

Ice cream (*Maine Sta. Off. Insp. 57 (1914), pp. 13-20*).—Data are given regarding the examination of a large number of samples of ice cream and determinations reported of the milk fat present in cream used in the manufacture of ice cream.

Alum in foods (*U. S. Dept. Agr. Bul. 103 (1914), pp. 7*).—The results of the experimental studies carried on with healthy young men by R. H. Chittenden, A. E. Taylor, and J. H. Long, of the Referee Board of Consulting Scientific Experts, with respect to the use of alum in foods are briefly summarized. The aluminum was given in various forms and in some cases up to and exceeding 1 gm. per man per day.

The board report as follows:

“Aluminum compounds when used in the form of baking powders in foods have not been found to affect injuriously the nutritive value of such foods.

“Aluminum compounds when added to foods in the form of baking powders, in small quantities, have not been found to contribute any poisonous or other deleterious effect which may render the said food injurious to health. The same holds true for the amount of aluminum which may be included in the ordinary consumption of aluminum baking powders furnishing up to 150 mg. (2.31 grains) of aluminum daily.

“Aluminum compounds when added to foods in the form of baking powders, in large quantities, up to 200 mg. or more per day, may provoke mild catharsis. Very large quantities of aluminum taken with foods in the form of baking powders usually provoke catharsis. This action of aluminum baking powders is due to the sodium sulphate which results from the reaction.

“The aluminum itself has not been found to exert any deleterious action injurious to health, beyond the production of occasional colic when very large amounts have been ingested.

“When aluminum compounds are mixed or packed with a food, the quality or strength of said food has not been found to be thereby reduced, lowered, or injuriously affected.”

Briefly stated, the decision reached by the board is that alum baking powders are no more harmful than any other baking powders, but that it is wise to be moderate in the use of foods that are leavened with baking powder.

In discussing the general question, A. E. Taylor states:

“We must not, however, be oblivious to the fact that a saline cathartic residue results from the reaction of every form of known baking powder now commonly employed. The use of cream of tartar or tartaric-acid baking powder leaves in the alimentary tract a residue of tartrates which exhibit the action of a saline cathartic and of diuresis as well. The so-called phosphate baking powder leaves as a residue of reaction sodium phosphate, again a saline cathartic. And aluminum baking powder leaves as a residue of reaction sodium sulphate, a saline cathartic. Apparently therefore, at present at least, the use of baking powder is associated with the introduction into the alimentary tract of a certain

amount of saline cathartic, the salt differing with the use of the particular type of baking powder.'"

Is the use of saccharin and other artificial sweetening substances to be regarded as a sophistication or adulteration of foodstuffs? F. W. DAFERT (*Arch. Chem. u. Mikros.*, 7 (1913), No. 2, pp. 43-48).—A summary and discussion of data.

The examination of miscellaneous foodstuffs, J. HECKMANN and H. KUTTENKEULER (*Ber. Chem. Untersuch. Amt. Elberfeld*, 1912; *abs. in Hyg. Rundschau*, 24 (1914), No. 7, pp. 402, 403).—Data are given regarding the examination of miscellaneous foods, condiments, and beverages, including among others chopped meat and sandwiches.

Household tests for the detection of adulterations in common foods, J. O. HALVERSON (1911, pp. 28).—In this pamphlet, issued by the Missouri State Department of Food and Drug Inspection, a number of simple methods for detecting adulterants are given.

A history of dietetics, LICHTENFELT (*Die Geschichte der Ernährung. Berlin*, 1913, pp. XVII+365; *rev. in Zentbl. Expt. Med.*, 5 (1914), No. 4, pp. 157, 158).—As the reviewer points out, this volume contains a large amount of data regarding diet in prehistoric and in historic times. It also summarizes much data for and against a high protein diet.

Diet charts, J. C. TAYLOR (*London*, 1911, pt. 1, 2 ed., charts 5; 1913, pt. 2, charts 5).—This collection of diet schedules, designed for physicians' use, contains detachable charts which present classified lists of different types of foods. The physician can check those which he wishes to prescribe. Both sets of charts have to do particularly with diet in disease. In addition, the first set contains diet charts for nursing mothers and for infant feeding, and the second set charts for the feeding of school children.

The effects of school life upon the nutritive processes, health, and the composition of the blood, L. M. TERMAN (*Pop. Sci. Mo.*, 84 (1914), No. 3, pp. 257-264).—A summary and digest of data.

The influence of nutrition and the influence of education in mental development, F. W. MOTT (*Sci. Prog. Twentieth Cent.*, 8 (1914), No. 31, pp. 460-481, pls. 2).—The author discusses infant feeding, stimulus in relation to development of the brain, and other similar questions.

School breakfasts (*Mo. Bul. Ind. Bd. Health*, 17 (1914), No. 2, p. 20).—A brief statement is given regarding the character of breakfasts of 37 pupils in a public school in Indiana.

Notes on food and diet in Katanga, E. POPPE (*Bul. Soc. Chim. Belg.*, 27 (1913), No. 1, pp. 33-36).—Typical food products are described and data given regarding the food habits and diet of Belgian Kongo natives.

The usual ration of laborers consists of 1 kg. bolted corn (maize) meal, 1.4 kg. unground corn, 0.14 kg. meat, and 14 gm. salt per day. The ordinary evening meal is composed of meat used for making soup and corn meal cooked in water. The cooking is very simple. The morning and midday meals consist of corn boiled or parched.

Analyses are reported of corn meal in common use and of a fermented beverage made from corn. Information is also given regarding food legislation and the nature and origin of food products imported.

Dishes and beverages of the old South, MARTHA McCULLOCH-WILLIAMS (*New York*, 1913, pp. 318).—In this discussion of food and its preparation, directions for preparing many dishes are included, as well as data regarding kitchen equipment, living conditions, available food supply, and similar topics.

The art of home candy making (*Canton, Ohio, 1913, 3. rev. ed., pp. 110, figs. 24*).—Detailed directions are given for making candy at home, in most cases the sorts usually thought of as commercial candies.

Electric cooking, W. H. ALABASTER (*Elect. Rev., 73 (1913), pp. 451-454; abs. in Sci. Abs., Sect. B—Elect. Engin., 16 (1913), No. 192, p. 590*).—The author discusses and summarizes in tabular form data regarding the amount of energy required with electrical ovens of different makes to secure a temperature of 400° F. and maintain it for 1½ hours, and regarding the comparative efficiency of different sorts of hot plates when used to raise the temperature of 3 pints of water to boiling, as well as the weekly cost of cooking for a family of two adults and two children when different cooking devices are used.

Retail prices, 1890 to October, 1913, F. C. CROXTON (*U. S. Dept. Labor, Bur. Labor Statist. Bul. 138 (1914), pp. 160*).—This publication, which is No. 12 of the Retail Prices and Cost of Living Series, and a continuation of earlier work (E. S. R., 30, p. 364), contains a summary of data regarding the retail prices of food, coal, and gas, and the scaling weight of bread.

Further notes on dietetics, A. KAKOWSKI (*Ther. Monatsh., 27 (1913), No. 4, pp. 285-297; abs. in Hyg. Rundschau, 24 (1914), No. 4, p. 237*).—According to the author's experiments, eating fungi (*Boletus edulis*), even wholesome ones, has a harmful effect in parenchymatous nephritis.

The vitamins of food (*Nature [London], 93 (1914), No. 2315, pp. 41, 42*).—A summary of data included in a lecture entitled a Grain of Wheat, delivered by T. Johnson at the National Museum, Dublin, February 24, 1914. Rather sweeping deductions are drawn from recently published work regarding the occurrence of vitamins in foodstuffs.

Amino acids in nutrition and growth, T. B. OSBORNE, L. B. MENDEL, ET AL. (*Jour. Biol. Chem., 17 (1914), No. 3, pp. 325-349, figs. 8*).—In their introduction to the report of their experimental work the authors point out the necessity for adding to and systematizing knowledge regarding the protein "building stones" formed by the complete hydrolysis of the protein molecule. From theoretical considerations and experimental data they discuss the necessity for adding the lacking "building stones" to a deficient protein, which the body can not synthesize except from its own tissue.

Distinction is made between maintenance and growth from a theoretical as well as from an experimental standpoint. The necessity for a certain amount of maintenance protein to make good wear and tear is discussed and other theoretical considerations suggested. The body may maintain itself, as the authors point out, on a kind of protein on which it can not make growth. Therefore, growth, which involves the actual formation of protein substance, makes a different kind of demand from maintenance only. For instance, the authors have found gliadin sufficient to supply the nitrogenous material required for maintenance over long periods of growth (E. S. R., 28, p. 864). However, gliadin would not suffice, as the sole protein, for growth, this and other experiments being facilitated by the addition to the diet of butter fat (E. S. R., 30, p. 560). In more recent work with laboratory animals (rats) the authors have succeeded in promoting growth at a normal rate when a maintenance ration containing gliadin as the sole protein was supplemented with lysin.

The authors believe that their feeding trials, in conjunction with their "demonstration of the almost complete cessation of growth on diets containing only lysin-free proteins, furnish the first and only conclusive demonstration that lysin is indispensable for the functions of growth. They are supplemented by further evidence of the same sort in which the necessity for the same amino acid is brought out in connection with the zein of maize [see below], a protein likewise devoid of lysin. . . .

“The facts here established make it clear that, at least in so far as nutrition in growth is concerned, the normal construction of new tissues is limited by the factor of the supply of lysin. In the light of this, little is gained by emphasizing the quantitative aspects of the protein needs in growth . . . , unless the qualitative character of the protein available is kept clearly in mind. No amount of energy or protein, however abundant, has induced growth of our animals in the absence of lysin. The animal organism apparently can not synthesize lysin, which is evidently not essential for maintenance in the sense of preservation of body weight, though it is, of course, impossible to say that when this amino acid is missing all functions are normally carried out. That the tissues either form a typical protoplasmic product, or none at all, now seems to be axiomatic in physiology. We may therefore reasonably assume that the growth of rats on our gliadin+lysin food represents the construction of typical tissue substance. It is obvious, furthermore, that the possibility of growth must be limited, among other things, by the amount of lysin available.”

The following data are brought together regarding the percentage of lysin in proteins of different sorts, both animal and vegetable: Lactalbumin 8.10, halibut muscle 7.45, ox muscle 7.59, casein (cow's milk) 7.61, vitellin (egg yolk) 4.81, crystallized albumin (hen's egg) 3.76, legumin (pea) 4.98, phaseolin (kidney bean) 4.58, glutelin (maize) 2.93, glutenin (wheat) 1.92, edestin (hemp seed) 1.65, amandin (almond) 0.72, gliadin (wheat) 0.16, and hordein (barley) and zein (maize) none.

“It is a teleologically interesting fact brought out by the foregoing figures that those proteins, like casein, lactalbumin, and egg vitellin, which are in nature concerned with the growth of animals, all show a relatively high content of lysin.”

In further proof of their contention that lysin is indispensable, the authors cite experiments with zein, which, like gliadin, is devoid of lysin as well as glycocoll and tryptophan. Their experiments have shown that when zein is the sole protein fed to both adult and growing rats, a decline is always noted. When a tryptophan or a tryptophan-yielding protein is supplied, maintenance is possible for a long period.

“The relative efficiency of different proteins in preventing the failure with zein apparently depends to a dominant degree, in so far as maintenance is concerned, on their comparative yield of tryptophan.

“Where growth is involved in addition to maintenance, the lysin factor as well as others not yet more accurately ascertained must also be taken into account. Here, then, is evidence of the relative economy of different proteins in maintenance, based upon the content of one or more of the amino acids essential for the proper functioning of the organism (in so-called maintenance) or for new tissue construction (in growth). Obviously the relative values of the different proteins in nutrition are based upon their content of those special amino acids which can not be synthesized in the animal body and which are indispensable for certain distinct, as yet not clearly defined processes, which we express as maintenance or repair. . . .

“With the indispensability of tryptophan for maintenance, and of lysin for growth, thus emphasized, we may expect that the addition of both of these amino acids to zein food will result in growth. This expectation has been fulfilled by the experiments planned. . . . The respective parts played by the two amino acids are here clearly brought out. These are, we believe, the first successful attempts to grow animals on a diet in which zein forms the sole protein.” When comparison is made with results of the experiments showing the relative effect of replacing one-fourth of the zein with lactalbumin,

casein, and edestin, respectively, it will be seen that "this small addition of lactalbumin has furnished all the factors required for normal growth. This protein mixture therefore undoubtedly contains sufficient tryptophan and lysin to satisfy the normal requirements of the growing animal. Since casein yields nearly as much lysin as does lactalbumin, we assumed that the failure of an equal addition of casein was due to a relative deficiency in tryptophan." That this assumption was true was shown by experimental evidence. "Similarly we assumed that the failure to grow on the comparable zein+edestin food was caused by the relatively small amount of lysin yielded by edestin."

Here, too, the experimental evidence showed the correctness of the assumption. "These experiments are further of chemical interest in indicating, as the result of this biological test, that edestin is richer in tryptophan than casein—a fact hitherto unappreciated.

"The growth of rats on a food of zein+lysin+tryptophan has not always been as rapid and prolonged as we might expect. We are by no means prepared to maintain that the final solution of the proportion of amino acids requisite for the growth of rats has been determined. Newer trials may indicate the desirability of increasing the proportion of arginin present in zein foods; and still other adjustments may be required to promote ideal growth in this or different species. The way to successful investigation has been opened."

The influence of cod liver oil and some other fats on growth, T. B. OSBORNE, L. B. MENDEL, ET AL. (*Jour. Biol. Chem.*, 17 (1914), No. 3, pp. 401-408, figs. 4).—The inability of laboratory animals (young albino rats) to complete their growth on a diet consisting of isolated proteins, starch, protein-free milk, and commercial lard, called attention to the need for supplying some other substances in order that growth might proceed to its normal limits.

As was pointed out in earlier experiments (E. S. R., 30, p. 560), the lacking factor was found in the fat component of milk, a conclusion substantiated by later investigations. A ration consisting of 18 per cent purified protein, 26 per cent starch, 28 per cent protein-free milk, 10 per cent commercial lard, and 18 per cent butter fat, the authors state, appears to be in every way adequate for the continued nutritive needs of the species experimented with. Some other fats have been found to behave like butter fat in this respect—for instance, egg yolk fat (E. S. R., 29, p. 664). The authors state that they have likewise obtained uniform success when cod liver oil was substituted for a portion of the lard in the standard diets. On the other hand, it was observed that almond oil uniformly failed to restore growth when it had ceased on the usual lard-food mixtures.

"We have already pointed out that it seems improbable that the triglycerids of the fatty acids ordinarily present in foods are responsible for the favorable effects noted. If they were, there is no apparent reason why such fats as commercial lard and almond oil should be ineffective. Experiments as yet incompleting have made it clear that the growth-promoting substance is not present in the more solid fractions of butter fat which constitute about one-half of it and are at least soluble in alcohol at low temperatures.

"It is perhaps more than a mere coincidence that cod liver oil has so long enjoyed a reputation for nutritive virtues which can scarcely be attributed to its fat content per se. At one time its therapeutic value was ascribed to the small proportion of iodine which it is known to contain. This explanation has, of late, been replaced by the suggestion that the special potency of cod liver oil resides in the peculiar fatty acids which it contains. . . .

"Perhaps experiences such as have been reported in this paper will pave the way for a clearer understanding of the physiological potency of natural

products like butter, egg yolk, and cod liver oil, which have long enjoyed a popular, yet inexplicable, reputation for unique nutritive potency."

The cleavage of fatty acids in the animal body, M. KOPPEL (*Über den Abbau der Fettsäuren im Tierkörper. Inaug. Diss., Univ. Strassburg, 1913, pp. 42; abs. in Zentbl. Biochem. u. Biophys., 16 (1914), No. 11-12, p. 366*).—The author has studied the cleavage of saturated, aliphatic acids of the acetic acid series with a view to determining the first step in the oxidation of fatty acids.

Influence of phytin on the elimination of nitrogenous compounds in normal individuals, F. VENTURI and V. MASSELLA (*Arch. Farmacol. Sper. e Sci. Aff., 16 (1913), No. 3, pp. 97-118*).—Experimental data are given which demonstrate that the ingestion of from 1.5 to 2 gm. of phytin per day results in a marked decrease in the elimination of urea, creatinin, hippuric acid, and other unidentified nitrogen compounds in the urine, as well as in a decrease in the loss of nitrogen in the feces. Little or no effect was observed upon the elimination of uric acid and ammonia. At the end of the period during which phytin was ingested a nitrogen balance four or five times greater than that observed during the preliminary period was noted.

Minimum requirement of alimentary carbohydrates, R. LAUFER (*Bul. Gén. Thé. Méd. et Chirurg., 165 (1913), No. 5, pp. 176-183; Zentbl. Biochem. u. Biophys., 15 (1913), No. 4-5, p. 149*).—The results are reported of experiments carried out at 16° C. with two subjects who were given a daily carbohydrate ration of from 290 to 300 gm.

In the opinion of the author, these results show that there is a certain minimum amount of carbohydrate which the body requires. Unless this minimum amount is supplied the carbohydrate can not be replaced by its equivalent isothermal value of protein or fat. For example, in the absence of this minimum requirement in the diet 1 gm. of fat would develop only 6.8 calories instead of 9.1 calories. It is pointed out that in pathological conditions this minimum requirement of carbohydrate should be supplied in the diet both to prevent a loss of heat value and to prevent the overworking of the organs.

From a study of the data here given, the author concludes that with a diet containing not less than 219 gm. of carbohydrate per day the body weight does not decrease. For a 70 kg. subject at rest the minimum daily requirement of carbohydrate is probably that which would furnish from 900 to 1,000 calories. [This must, of course, presuppose an adequate supply of nitrogen in the diet also.]

Experiments on the carbon dioxid excretion with different kinds of muscular work, G. BECKER and J. W. HÄMÄLÄINEN (*Skand. Arch. Physiol., 31 (1914), No. 1-3, pp. 198-240, fig. 1*).—In these experiments, which were made with men and women engaged in different kinds of labor, the Tigerstedt respiration apparatus was used.

The work periods were of two hours' duration, and in every case were compared with similar periods in which the subjects were at rest. The men were engaged in shoemaking, tailoring, bookbinding, metal working, painting, carpentry, stone masonry, or wood sawing, and the women in hand sewing, machine sewing, laundering, domestic service (cleaning windows and floors and washing and polishing dishes, etc.), or bookbinding.

From the excretion of carbon dioxid the respiratory carbon output was calculated and found to vary between 6.68 and 10.12 gm. per hour for the men, and 5.50 and 6.83 gm. for the women in the rest periods, and between 11.23 and 45.5 gm. per hour in the case of the men, and between 7.5 and 25.91 gm. per hour in the case of the women in the work periods.

The authors conclude that work may be called light or moderate when the respiratory excretion of carbon is not greater than 16 gm. per hour. This would be the case with the work of tailors, bookbinders, and shoemakers. When the respiratory carbon excretion is from 16 to 30 gm. per hour the work is designated as severe. To this group would belong metal workers, painters, or carpenters. When the respiratory carbon excretion exceeds 30 gm. per hour the work is called very severe. To this group would belong stone masons and wood sawyers. In the case of the women sewing either by hand (7.5 to 8 gm. carbon per hour) or by machine (9.35 to 10.78 gm. carbon per hour) is regarded as relatively light work, much the same as that of a bookbinder (8.88 to 11.5 gm. carbon in respiratory products per hour). The authors are of the opinion that women's work can be called light when it does not cause a respiratory excretion of more than 20 gm. per hour. The respiratory excretion in the case of the laundresses was 16.91 and 25.91 gm. per hour on an average. In the case of the two subjects engaged in housework it was 13.01 and 20.7 gm. per hour on an average.

From the amounts of respiratory carbon excreted per hour and the energy required by the body for maintenance, the authors compute the energy expenditures for the work alone in the different experiments. These are found to range from 44 calories per hour with the tailors to 406 calories per hour with the wood sawyer, and in the case of the women from 4 calories per hour with one of the women engaged in sewing by hand to 214 calories in the case of the woman engaged in laundry work. The computed amount of work in an 8-hour day ranged from 29,920 kgm. with the tailors to 276,080 kgm. with one of the subjects sawing wood, and in the case of the women from 16,320 kgm. in the case of one of the women working with a sewing machine to 106,760 kgm. with one of the women engaged in housework. The seamstresses engaged in handwork were not included in this calculation, but would differ little from those who worked with the machine.

The general deduction is that men engaged in light or moderate muscular work produce up to 60,000 kgm.; in severe work up to 160,000 kgm.; and in very severe work up to 280,000 kgm. and more. In the case of women, the expenditure in light or moderate work is up to 40,000 kgm.; in severe work up to 100,000 kgm.; and in very severe work up to 145,000 kgm. and more. The total energy production per day as calculated, ranging from 2,600 to 6,000 calories, was very much the same as the energy supplied in the diet (2,300 to 6,300 calories). The authors note that the energy supplied in the experimental diet was somewhat smaller than it should have been in the case of shoemakers, tailors, and metal workers, but they are of the opinion that rather more work was done in the calorimeter chamber than would be under ordinary circumstances. In the case of the carpenter and the wood sawyer the energy supplied in the experimental diet was very close to the energy production.

Since the energy supplied in the diet in these experiments was in accord with the requirements as expressed by the usual dietary standards, they believe that these are reasonable with respect to the energy which should be provided for persons engaged in muscular work.

The relation between gaseous exchange and surface area at extreme temperatures, E. GÖTSCH (*Über die Beziehungen des Respiratorischen Stoffwechsels zur Körperoberfläche bei Extremen Aussentemperaturen. Inaug. Diss., Univ. Leipsic, 1912, pp. 42, figs. 3; Arch. Anat. u. Physiol., Physiol. Abt., No. 5-6 (1912), pp. 421-459, figs. 3*).—A small respiration apparatus was used for these experiments with laboratory animals (guinea pigs).

According to the author's conclusion, Rubner's rule that the carbon dioxide production at constant temperature is proportionate to the surface area has a

limited application in the case of extreme temperatures. In general, the heat regulation is less efficient with small animals at low temperature than with large animals at high temperature.

An increased rectal temperature in childhood, E. MORO (*Monatsschr. Kinderheilk.*, 11 (1913), No. 9, pp. 430-438; *abs. in Zentbl. Physiol.*, 27 (1913), No. 22, p. 1185).—The author found that even in normal children the rectal body temperature was usually increased after exercise with the legs and lower part of the body. As shown by measurements, the axilla temperature would not be so raised. If the work was done with the arms and upper part of the body, the increased temperature was noted in the axilla and not in the rectum.

The effects of light upon metabolism, L. PINCUSOHN (*Berlin. Klin. Wchschr.*, 50 (1913), No. 22, pp. 1008, 1009; *abs. in Zentbl. Physiol.*, 27 (1913), No. 24, p. 1309).—In experiments with laboratory animals (white dogs) it was found that in the light period (arc light, 500 candlepower) the excretion of allantoin was much diminished, while the urea excretion remained unchanged. Oxalic acid excretion was increased.

ANIMAL PRODUCTION.

Principles of feeding, O. KELLNER (*Grundzüge der Fütterungslehre. Berlin, 1912, 4. ed., rev. and enl., pp. VII+231*).—This edition of this book treats of the general principles involved in the feeding of farm animals, the composition, digestibility, and value of feeding stuffs, the characteristics of various feeding stuffs, and their preparation, conservation, and economical use.

The nutritive values of organic and inorganic phosphorus, E. B. FORBES (*Proc. Soc. Prom. Agr. Sci.*, 34 (1913), pp. 23-32).—This paper treats of the nutritive limitations imposed by the differences in the chemical relationships of phosphoric acid in feeds. It is the purpose to determine whether organic and inorganic phosphorus compounds can serve equally well all of the requirements of the body for phosphorus under all conditions of life.

After citing the results of previous investigators and of work conducted by the author, it is concluded that "the character of the evidence does not warrant final conclusions in regard to this problem. We are unable to say whether the lack of harmony in results with dogs, rats, and mice is due to differences in the nutritive processes of these animals or to differences in the purity of the organic phosphorus compounds used, or to ill-considered or incomplete experimental methods. . . . The problem now seems to take the form of a question as to whether we shall regard organic phosphorus compounds as of superior nutritive value because of the chemical relationship of their phosphoric acid or because of the presence of other unknown substances of value associated with them in natural feeds."

A bibliography of 36 references is appended.

Fish meal, E. HASELHOFF (*Fühling's Landw. Ztg.*, 63 (1914), No. 4, pp. 137-143).—Experiments conducted at the experiment station at Harleshausen indicate that, providing it is of good quality, fish meal forms a desirable supplementary feeding stuff for farm animals, especially for pigs. Fish meal is produced from fish offal and condemned whole fish. Owing to the varied nature of its raw material and its methods of preparation, fish meal varies very widely in its composition as shown by the following analyses: Water from 5.9 to 18.91 per cent, crude protein 38.83 to 58.96, digestible protein 30.43 to 54.52, fat 1.55 to 14.03, phosphate of lime 7.8 to 36.16, salt 0.7 to 20.1, ash 20.53 to 45.07, and sand 0.1 to 6.05 per cent.

It is said that if fed in too large quantities or containing too high a percentage of oil the meal is liable to give a fishy taste to the meat product, but

meal containing from 2 to 4 per cent of oil may be safely fed. Salt should not exceed 3 per cent. The phosphate of lime found in fish meal is deemed a valuable adjunct in feeding animals.

It is suggested that the following amounts may be given daily if the meal is of good quality: Cattle 2 lbs. for every 1,000 lbs. live weight, pigs from $\frac{1}{4}$ to $\frac{1}{2}$ lb. per head according to weight, and sheep from $\frac{1}{16}$ to $\frac{1}{8}$ lb. for every 100 lbs. live weight.

[Feeding stuffs] (*Maine Sta. Off. Insp. 60 (1914)*, pp. 41-88).—Analyses are reported of the following feeding stuffs: Cotton-seed meal and feed, gluten meal and feed, linseed meal, distillers' grains, red dog flour, wheat middlings, bran, and offals, and various mixed and proprietary feeds.

Origin of our important domestic animals, H. W. BEHM (*Zool. Beob.*, 55 (1914), Nos. 2, pp. 33-40, figs. 2; 3, pp. 65-71, figs. 5).—This is a general article treating of the origin and distribution of our common breeds of cattle, sheep, goats, horses, and swine.

Effects of inbreeding, H. KRAEMER (*Jour. Heredity*, 5 (1914), No. 5, pp. 226-234).—In this article the author reviews the theories advanced by Darwin and others with regard to the effects of inbreeding in animals and points out the wide diversity of opinion held by these investigators. He concludes that "continued inbreeding always must result in weakened constitution, through its own influence."

The determination of sex, P. J. WESTER (*Jour. Heredity*, 5 (1914), No. 5, pp. 207, 208).—The author reviews the investigations of T. Ciesielski in Lemburg with plants and animals on the determination of sex. Numerous experiments were conducted with rabbits, dogs, horses, and cattle, a large number of which, it is stated, served to verify previous studies with plants. It is concluded that the sex of the progeny is governed by the condition of fecundation and that sex in animals is determined by the age of the spermatozoa at the time they unite with the ova.

An editorial note appended calls attention to the fact that it is now believed by many investigators that the determination of sex depends on the inheritance of a Mendelian factor differentiating the sexes, and that microscopical studies of the cell indicate that the presence of an accessory or "x" chromosome in the sperm or egg (usually the latter) is the deciding factor in some species.

The problem of the meat supply (*Chamber Com. U. S. A., Gen. Ser., Bul. 88 (1914)*, pp. 230-237, figs. 6).—This relates to the present situation with regard to meat supply in the United States, causes of decrease, import and export statistics, domestic and foreign sources, and suggestions as to the problem of adjustment of conditions in the near future.

Australia and New Zealand as sources of meat supply, A. W. PEARSE (*Proc. Amer. Warehousemen's Assoc.*, 23 (1913), pp. 213-219).—Data are given on the relative importance of these countries in supplying frozen meat to the United States and other countries.

The amount of bone in animals for the slaughterhouse, TRIDON (*Hyg. Viande et Lait*, 8 (1914), No. 1, pp. 18-22; *abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, pp. 404-406).—Investigations made on calves and sheep indicate that the proportion of bone to the total weight of the animal varies inversely with the age, the quality, and the weight of the animal. The proportion of bone was found to be very variable and the weight of bone reaches and sometimes exceeds one-third of the total weight of the animal.

A comparison between the fat stock and the carcasses exhibited at Smithfield Show, J. LONG (*Jour. Bd. Agr. [London]*, 21 (1914), No. 1, pp.

1-12).—Results obtained with cattle, sheep, and hogs at the Smithfield Show indicated that there is a difference of but 409 lbs. in live weight and 266 lbs. in carcass weight between 2 and 3 year old fat steers. This suggests that it can not pay the feeder to retain a steer for the additional year involved, since the actual weight of beef produced would barely exceed 5 lbs. a week. In the classes for heifers similar results were obtained, showing the economical value of early maturity. Likewise with sheep and hogs it is seen that in the open classes these are fattened too much without any corresponding advantage, while those which are fitted for the carcass competition realize higher prices.

It is concluded from these observations that breeders and feeders will obtain better results by finishing their fattening cattle as early as possible and by avoiding excessive fatness in general.

The cattle industry in Britain, R. WALLACE and J. A. S. WATSON (*Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, pp. 306-312, figs. 2*).—The authors trace the development of the cattle industry in Britain since 1878. It is shown that whereas the number of "cows or heifers in milk or in calf" has remained fairly constant, varying between 35.7 and 37.3 per cent, the number of "other cattle two years old or over" has fairly steadily decreased from 24 per cent in 1893 to just under 20 per cent in 1912, with a corresponding increase in the proportion of yearling cattle and calves. There appears to have been a long-continued tendency to market cattle for slaughter at a diminishing age. With regard to available supplies of feed for cattle, there has been a considerable decrease in the root crop in the past 35 years, and an increase in the total area of pasture and hay up till about 10 years ago, since when it has shown a decrease and a very great increase in imports of cakes and meals, etc.

During the five years, 1906-1910, inclusive, the annual exportation of pedigreed breeding cattle from Great Britain averaged 3,097 head and the average value about £60. The United States took about 32 per cent and Argentina and Uruguay about 30 per cent of the total exports. The Shorthorn breed is most numerously represented in the exports. It is stated that at the present time one of the main features of the cattle industry of Britain is the scarcity of feeder cattle, with consequent high price for such stock and a diminution in the profits of feeding.

Attention is called to the increased importance of the dairy industry. British methods of feeding and fattening are discussed.

The cattle of the valleys of Saint-Girons and Aure, A. GUY (*Vie Agr. et Rurale, 3 (1914), No. 20, pp. 545-549, figs. 5*).—An account of the breed characteristics, utility value, and improvement of the local breeds of cattle of the valleys of Saint-Girons and Aure.

Cattle of Ruanda, K. SOMMERFELD (*Tropenpflanzer, 18 (1914), No. 4, pp. 177-201, figs. 5*).—This article treats of the weights, measurements, and breed characteristics of several types of cattle in Ruanda, German East Africa.

Variation in the tongue color of Jersey cattle, R. PEARL (*Proc. Soc. Prom. Agr. Sci., 34 (1913), pp. 49-57*).—The results of studies made of the recorded tongue color of 6,917 registered Jersey cattle in the herd register for 1893 and of 7,450 cattle in that of 1913 indicate that at the present time something over 75 per cent of registered Jersey cattle have black tongues; that in the last 20 years the proportion of black-tongued individuals has increased slightly, in males about 1 per cent and in females nearly 4 per cent; and that a higher proportion of males than of females have black tongues, though the difference was somewhat larger 20 years ago than now. The cause of these relations between the sexes is attributed to the influence of "fashion" in tongue color in the Jersey breed. It is thought that "more pigmented tongues are actually

being produced now, fundamentally for the reason that there are more black-tongue genes in the general Jersey population than there were then [1893]."

Distributing the very small percentage (0.6 per cent) of spotted-tongue individuals found in the 1893 studies equally between the two classes, pigmented and unpigmented, it was found that the ratio of the one to the other was very close to 3:1, which suggests a "simple case of Mendelian inheritance, in which pigmented tongue is the dominant character and nonpigmented the recessive." Further studies indicate that "tongue color hereditarily depends upon two separate factors which show partial coupling on a 3:1:1:3 basis." It is stated that a detailed discussion of the data regarding inheritance of the characters will be published later.

Calf-rearing experiment, J. A. VOELCKER (*Roy. Agr. Soc. England, Rpt. Calf-Rearing Expt., 1912-13, pp. 7*).—Five lots of four Shorthorn bull calves each, three weeks old, were fed for nine weeks as follows: Lot 1, cod liver oil and separated milk; lot 2, a proprietary "calf meal" and whole and separated milk; lot 3, gruel (linseed and oatmeal) with separated milk; lot 4, whole milk; and lot 5, crushed oats and separated milk. Lot 1 gained 9.66 lbs. per calf per week at a cost of 3.33d. per pound gain in live weight; lot 2, 8.66 lbs. at 2.77d.; lot 3, 8.33 lbs. at 3.45d.; lot 4, 12.83 lbs. at 5.39d.; and lot 5, 13.3 lbs. at 2.52d.

This experiment was followed with further grain and pasture feeding for seven months in which all calves were fed alike. Those calves which had received crushed oats and separated milk continued to gain faster than the other lots. It is concluded from this that the influence of early feeding of calves has an important bearing on their after development and that a good start is very essential. The next best results were obtained from the whole-milk fed calves, which lot had the most "bloom" of any of the lots. The poorest of all was the calf-meal lot.

The domestic buffalo, L. GRANATO (*Bol. Agr. [Sao Paulo], 14. ser., 1913, Nos. 8, pp. 471-514, figs. 13; 9, pp. 559-625, figs. 20*).—This is a study of the morphological characteristics of the domestic buffalo and a comparison with those of domestic cattle. Items included are cranium measurements, character of tongue, dental system, capacity and character of stomach, duration of digestive process, respiratory, circulatory, urinary, and genital systems, and body characteristics.

Other subjects discussed are the relation of dental system to age, growth and character of horns in relation to age, geographical distribution, milk and meat production, and the physical and chemical characteristics of buffalo milk.

Crossing bison and cattle, M. M. BOYD (*Jour. Heredity, 5 (1914), No. 5, pp. 189-197, figs. 6*).—The author's experience in crossing bison and cattle indicates that the bison furring characteristics are retained equally well in the one-half, three-eighth, and one-quarter cattalo. It is thought that the one-quarter cattalo has somewhat the best coat of the three. From these observations it is believed that later generations having 10 per cent or less of bison blood will have as good fur as is now seen on the one-half and three-quarter buffaloes. The opportunities for improving the beef carcass through this cross are also pointed out.

It is stated that the most remarkable and most disastrous feature of the first cross was the abnormal secretion of the amniotic fluid which was excited without exception in every cow, and which proved fatal in a large percentage of cases. However, no trouble has been experienced in the second and third crossings.

It is concluded that "it does not seem unreasonable, therefore, to suggest that the fur of the bison and his great back may be carried by means of selec-

tion without any diminution through succeeding generations of diminishing bison blood until the coat and hump have been practically taken from the bison and placed upon the back of the domestic ox."

My experience with bison hybrids, C. GOODNIGHT (*Jour. Heredity*, 5 (1914), No. 5, pp. 197-199, fig. 1).—The author summarizes his experience in crossing Texas buffaloes with native cattle.

It is stated that no male calves have been born from the cross; cows conceiving them either suffer abortion or die. The heifer hybrids breed readily to either the buffalo or the cattle. When bred to the buffalo, the males, which are three-quarter, are not fertile. The females are perfectly fertile and will breed to either race. They are then bred back to the polled Angus stock from which they came, with resulting males which are fertile and are half-breeds.

Advantages claimed for these hybrids, or cattaloes, are immunity from diseases, especially Texas blackleg and Texas fever. The cattaloes are much "greater in weight, eat much less, and hold their flesh better under more adverse conditions. They will easily cut about 70 per cent net of their gross weight. They have a better meat, clear of fiber, and it never gets tough like beef. They have long and deep backs, enabling them to cut at least 150 lbs. more meat than other cattle. More of them can be grazed on a given area. They do not run from heel flies nor drift in storms, but, like the buffalo, face the blizzards. They rise on their fore feet instead of their hind feet. This enables them to rise when in a weakened condition. They never lie down with their backs downhill, so they are able to rise quickly and easily. This habit is reversed in cattle. . . .

"The buffaloes have fourteen ribs, giving them a longer and deeper lion. As we get them higher and deeper in the buffalo we get the extra rib on the 'cattalo.' They can exist on less feed or salt than cattle. . . . They could do without water much longer than cattle, without inconvenience. They are docile, easily broken, and never fight. They put on flesh faster than any cattle and will live and appear to do well where cattle will perish."

Domestic breeds of sheep in America, E. L. SHAW and L. L. HELLER (*U. S. Dept. Agr. Bul.* 94 (1914), pp. 59, pls. 28, fig. 1).—This bulletin gives detailed information as to the origin, adaptability, distribution, and distinguishing characteristics of the various domestic breeds of sheep. Tables showing the probable origin of the breeds of sheep in America, and giving the breeding of grand champions, reserve champions, and winners in the carcass contests at the International Live Stock Exposition, and a short bibliography are appended.

Caracul sheep farming, M. KARPOV (*Agr. Jour. Union So. Africa*, 6 (1913), Nos. 5, pp. 760-766; 6, pp. 939-944; 7 (1914), Nos. 1, pp. 93-95; 2, pp. 199-206; 3, pp. 398-407).—This article, which is translated from the Russian, relates to the environments, breed characteristics, and management of this breed of sheep, and to the grades and quality of caracul fur.

Heredity studies with swine, G. FRÖLICH (*Jour. Landw.*, 61 (1913), No. 3, pp. 217-235, pls. 2).—In reviewing observations made in Germany and the United States on the heredity of coat color in swine, the author concludes that in the F₁ generation of crosses the following are dominant: White of improved German swine over white and black of Hanoverians, black of Berkshires, grayish-black of European wild pigs and of Cornwalls, red of Tamworths, or black of Caucasian wild pigs; grayish-black of European wild pigs over red of Tamworths; and black and white or Hampshire over red of Tamworths.

Carcass tests conducted on Lincoln and Mangalica pigs in Hungary, O. WELLMANN (*Köztelek [Budapest]*, 23 (1913), No. 97, pp. 3272-3275; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, p. 382).—With the purpose of improving the curly coated Mangalica

pigs of Hungary in prolificacy and early maturity the breed was crossed with the English Lincoln curly coated breed. Among pigs fattened for five months the dead weight of Lincoln×Mangalicza pigs at 14 months was the same as that of the pure-bred Mangalicza pigs at 26 months. The dead weight of all the animals amounted to from 82 to 88 per cent of the live weight.

Pig feeding, F. C. GRACE (*Jour. Dept. Agr. Victoria*, 12 (1914), No. 1, pp. 44-50; *abs. in Jour. Bd. Agr. [London]*, 21 (1914), No. 1, pp. 59, 60).—General conclusions drawn from pig feeding experiments conducted in Victoria are that "the younger the pig, the cheaper is the gain per pound; that pollards and milk, with a little bran, is one of the cheapest rations to feed to pigs of all ages; that rape pasture is likely materially to reduce the cost of production; that with well-bred pigs, properly fed and cared for, first grade pork and bacon can be produced in Victoria for about 1½d. per pound live weight or under 2¼d. per pound dressed weight; and that an average weekly gain of about 8 lbs. should be expected, and the pig put on the market at from 180 to 200 lbs. live weight within 6 months."

Alfalfa and hogs, C. A. NORCROSS (*Nev. Bur. Indus., Agr. and Irrig. Bul.* 7 (1912), pp. 74, figs. 18).—This is a popular treatise on the feeding, care, and management of hogs in Nevada, with special reference to the feeding of alfalfa pasture and hay.

A pork production contest, T. P. COOPER (*Breeder's Gaz.*, 65 (1914), No. 10, pp. 523, 524).—This reports a pork production contest conducted under the management of the Better Farming Association of North Dakota. The first prize was awarded to the owner of a large Yorkshire sow which produced a litter of pigs weighing 2,903 lbs. after 203 days at a feed cost of 2.87 cts. per pound. The profit on the cost of feed with pork at 6 cts. was \$91.06 for the litter. A Poland China sow produced a litter weighing 2,098 lbs. in 218 days at a cost of 1.7 cts. per pound.

In this contest house slops constituted a portion of the feed but were not considered in the cost of production. The average number of pigs born in the litter was 8.2 and the average number saved and raised, 7.5 pigs per litter. In general more economical gains were made with pure-bred stock than with crossbred.

Experiments on pig fattening in Prussia with automatic feeder or common trough, DE LA BARRE (*Landbote [Prenzlau]*, 34 (1913), *Beilage: Tierzuchtnachrichten*, 6 (1913), No. 8, pp. 114-117; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 4 (1913), No. 11, pp. 1751-1753).—The results of experiments conducted with 8-weeks-old pigs for 22 weeks indicated that from an economic point of view there is not much difference between the use of the automatic feeder and that of the common trough.

Our domestic birds, J. H. ROBINSON (*New York, Chicago, and London*, 1913, pp. X+317, pl. 1, figs. 236).—This is a general text-book treating of the feed, care, and management of poultry and domestic fowls.

Poultry management, C. K. McCLELLAND (*Hawaii Sta. Press Bul.* 46 (1914), pp. 54, figs. 4).—This deals with the housing, breeding, feed, care, and management of poultry and poultry diseases and pests, with especial reference to Hawaiian conditions, and replaces Bulletin 1 (E. S. R., 13, p. 898).

The Garonnaise breed of chickens, J. GIRARD (*Vie Agr. et Rurale*, 3 (1914), No. 20, pp. 550-553, figs. 4).—An account of the habitat, breed characteristics, and utility value of the Garonnaise breed of chickens.

The ash and protein factor in poultry feeding, H. R. LEWIS (*New Jersey Stas. Bul.* 265 (1913), pp. 5-76, figs. 37).—Three extensive series of experiments carried on at the station as to the relation of ash and protein to broiler pro-

duction, rearing of pullets, and egg production, are summarized by the author, as follows:

Protein from a vegetable source, even when accompanied by a high phosphoric acid content in the ration, is not an efficient method of providing protein when feeding growing chickens or laying flocks. The addition of animal protein in the form of meat scrap materially increases the efficiency of a ration relatively high in vegetable protein, both for egg production and for flesh growth. An increased consumption of nitrogen, occasioned by the addition of meat scrap, does not cause increased loss of nitrogen in the droppings, the reverse, however, being true.

Phosphoric acid from an organic source (animal bone) is much more efficient than phosphoric acid from an inorganic source, as phosphate rock. Lime in itself has little or no effect upon increasing assimilation of nitrogen. Lime from bone is not as easily assimilated as lime from phosphate rock. This was verified in every instance, and the difference was very pronounced. From the standpoint of broiler production, from the standpoint of maturity, and from the standpoint of egg production, meat scrap is a necessary adjunct to any ration. Dry granulated bone was found to be a cheaper source of phosphoric acid and protein than a prepared commercial product, and was more efficient in poultry feeding.

Laying hens fed a ration deficient in protein not only give a low production but the eggs which are produced are small and undersized. A dry mash containing considerable variety and having 20 per cent by weight of beef scrap, is an efficient foundation for a laying ration. For growing chicks a dry mash, having for its base wheat bran and containing by weight at least 10 per cent of meat scrap and 10 per cent of granulated bone, is an efficient ration.

Analyses of the foods used are reported, and a number of practical working rations are appended.

The breeding of egg-laying poultry, J. WILSON (*Dept. Agr. and Tech. Instr. Ireland Jour.*, 14 (1914), No. 2, pp. 231-240).—The author reviews the studies of Pearl on the inheritance of egg laying in poultry (*E. S. R.*, 28, p. 576).

In addition, data are given on the results of an egg-laying competition at the Munster Institute, Cork, 1912-13, when it was found that a hen's total yield for the year could be predicted approximately from her yield a few weeks after she had begun to lay. The record of 24 hens is given, 8 very good, 8 medium, and 8 poor layers. It is pointed out that the good layers have blanks of only 1 day at a time, as a rule, and that this rate is kept up for 8 or 10 weeks at least; that the medium layers have blanks of several days at a time, or if not, lay for a few weeks only; and that poor layers lay no eggs at all, or only a very few. It is stated that "the great value of the observation lies in this, that the breeder knows before the setting season begins the grades to which his pullets belong and he can infer therefrom the parents' grades in some cases."

Factors influencing the size, shape, and physical constitution of the egg of the domestic fowl, MAYNIE R. CURTIS (*Maine Sta. Bul.* 228 (1914), pp. 105-136).—This paper is an analysis of the normal variations in the size, shape, and physical constitution of the eggs of the domestic fowl as determined by observations made of all of the eggs laid by 22 Barred Plymouth Rock birds during their first two laying years.

With regard to the individuality of the eggs of the same bird it was found that the "individuality of a bird is expressed in each physical character of her eggs. This individuality is more pronounced in respect to the size than the

shape of eggs and also in respect to the weight of albumin and shell than weight of yolk. There is a tendency for the several egg characters to be related to each other in such a way that when the eggs of an individual are large they are both long and broad and each of the parts is large; but the hens which lay large eggs lay eggs with a smaller proportion of yolk than hens which lay small eggs. Also individuals may show a decided tendency to vary from the flock type in quite different degrees in different characters.

"The eggs of an individual tend to be either uniform or variable in all the egg characters, but certain individuals may be variable in certain egg characters and uniform in others. An individual is in general less variable than the race in respect to egg characters; but certain individuals may show a variation in an egg character which is relatively as great as the variation in the race. Also certain egg characters (particularly yolk weight) show a decided tendency to approach the race variation in several individuals. The factors which bring about the individuality in respect to egg characters are too complex for analysis from the data at hand."

With regard to the correlation of egg character it was determined that "each egg character is related to every other egg character, but different pairs of characters show a decidedly different degree of correlation. There is a general tendency for a given pair of characters to be similarly related in the eggs of the several individuals, but different individuals may show significantly different degrees of correlation in any pair of characters. Length and breadth are significantly but not highly correlated. Both length and breadth are significantly correlated with the weight of the whole egg and of each of the egg parts. Breadth is as a rule more highly correlated with these weight characters than is length. The shape of the egg as measured by the length-breadth index is negatively correlated with the weight of the egg and with the weight of each of the egg parts. The weight of each part of the egg is positively correlated with the weight of both the other parts."

It was noted that with respect to intraindividual variation "the variation among the eggs of the same bird is shown to be related to certain other changes in the bird. The egg weight and the weight of the egg parts, especially the weight of the yolk, increases as the bird matures. The rate of this gain in weight decreases with the successive months. Each part of the egg shows a seasonal fluctuation in weight which is apparently related to the general seasonal fluctuation in the physiological activities of the bird, expressed also in the curves for food consumption and egg production. The state of health also may affect the size of the egg. The size of the egg is related to the rate of production as it expresses itself in the laying of litters. As a rule the first and last eggs of a litter are smaller than the intermediate ones. When eggs are produced on successive days they tend to decrease in weight, while the egg laid on a day after one on which no egg is produced is larger than the last egg of the preceding series."

A biometrical study of egg production in the domestic fowl.—IV. Factors influencing the size, shape, and physical constitution of eggs, MAYNIE R. CURTIS (*Arch. Entwickl. Mech. Organ.*, 39 (1914), pt. 2-3, pp. 217-327, figs. 18).—This paper reports in more extended and detailed form the data noted above.

A bacteriological and chemical study of commercial eggs in the producing districts of the Central West, MARY E. PENNINGTON ET AL. (*U. S. Dept. Agr. Bul.* 51 (1914), pp. 77, pls. 8, figs. 2).—This bulletin deals with the subject of the quality of eggs which go to the egg-breaking establishments of the egg-producing sections of the Central West.

It has been found that when the egg is laid it is of a fairly constant chemical composition and contains but few bacteria or molds. However, in the process

of marketing, eggs in shell undergo a variety of changes referable, almost exclusively, to the mode of handling. From former investigations (E. S. R., 22, p. 762) there was found an average of 2 organisms per gram in the white and 6 per gram in the yolk of perfectly fresh eggs when the incubation temperature was 37° C., and 7 organisms per gram in the white and 9 per gram in the yolk when the incubation was at 20°. The character of the organisms present was widely diversified. *Bacillus coli* is practically never present. As regards chemical composition of fresh eggs, whole eggs gave an average percentage of ammoniacal nitrogen of 0.0013. The moisture content is thought to be indicative of the egg's resistance to decay. In August and September, when the quality of the eggs is lowest, the maximum quantity of water is found in both white and yolk. In the early spring when eggs are of highest quality the water content is lowest, and in the cool days of autumn it occupies a medium position. An examination of what are termed "market-fresh" eggs showed that bacterially these eggs do not differ from strictly fresh eggs.

A study made of the relation between bacterial multiplication and chemical changes indicates that "for certain substances, at least, the number of organisms must approach the 100,000,000 per gram mark before the analytical methods for the detection of substances indicative of bacterial life can be applied satisfactorily."

Summarizing the bacteriological results of individual eggs opened aseptically in the laboratory, it was found that the greatest percentage of second-grade food eggs examined, the medium stale eggs, hatch-spot eggs, heavy rollers, dirty eggs, cracked eggs, and eggs with yolk partially mixed with albumin contained less than 1,000 bacteria per gram. *B. coli* was not present in the whole-shelled second-grade eggs and in only 5.9 per cent of the cracked-shelled eggs. In 26.5 per cent of the eggs with adherent yolks, 50 per cent of the eggs with dead embryos, 75.9 per cent of the moldy eggs, 66.7 per cent of the white rots, and 100 per cent of the black rots, over 1,000 organisms per gram were to be found. With the exception of the white and black rots, *B. coli* was present in but few of the eggs.

Conclusions reached from bacteriological and chemical examinations of composite sample of eggs opened commercially in the packing house are as follows: "The samples of July and August firsts contained very few organisms, and in many cases no bacteria of the *B. coli* group. The majority of the samples of clean-shelled seconds had a comparatively low bacterial content, only 8.3 per cent of them containing over 1,000,000 organisms per gram. The number of *B. coli* varied in different specimens from none to 100,000 per gram. The percentage of bacterial counts over 1,000,000 per gram in samples of dirties, checks, and eggs with yolk partially mixed with albumin was 16.6, 18.8, and 20 per cent, respectively. No greater number of *B. coli* was found in these samples than in samples of seconds.

"The samples of blood rings contained comparatively few organisms. The large blood rings in most instances showed more infection than did the small rings. Most of the specimens contained less than 10 *B. coli* per gram. The amount of protein decomposition as shown by the ammoniacal nitrogen in the preceding six types of eggs was greater, as would be expected, than that found in strictly fresh eggs, but was no greater than that found in some grocery eggs. Although a cracked or dirty shell may be a factor in facilitating infection and subsequent decomposition, the data obtained show that checks and dirties in the producing section are as well preserved as the clean whole-shelled seconds or the July and August firsts. The eggs constituting the samples of July and August firsts, seconds, dirties, and checks would be used without compunction by the housewife, baker, or confectioner.

"The majority of the samples of white rots, eggs with yolk lightly adherent to the shell, and all of the samples of sour eggs, black rots, eggs with a green albumin, and eggs with yolk heavily adherent to the shell, were infested with bacteria. *B. coli* was present in most of these samples, forming the predominating organism in the samples of sour eggs. The eggs with the yolk lightly adherent to the shell were, chemically, slightly lower in quality than were the second-grade food eggs, whereas the sour eggs, white rots, eggs with a green white, and eggs with yolk heavily adherent to the shell showed much more deterioration. Black rots had five times as much ammoniacal nitrogen as any of these types of eggs. With the exception, possibly, of the eggs with yolks lightly stuck to the shell, none of the eggs in these samples would be used by the housewife or reputable baker or confectioner."

An explanation of the technique used for the bacteriological and chemical examination of eggs is included.

Development of spurs and growth of the crest among females of the Gallinaceæ, A. PÉZARD (*Compt. Rend. Acad. Sci. [Paris], 158 (1914), No. 7, pp. 513-516, figs. 3*).—This reports successful operations of ovariectomy on pullets, with a resulting development of secondary male sex characters.

Studies on inheritance in pigeons.—I, Hereditary relations of the principal colors, L. J. COLE (*Rhode Island Sta. Bul. 158 (1914), pp. 311-380, pls. 4, fig. 1*).—A synopsis of the principal color characteristics of pigeons is presented, and the results of a study of the inheritance of certain colors of Tumbler pigeons and some of their modifications are summarized as follows:

"Only two kinds of pigment are concerned—red and black. Red (*R*) is potentially present in all the birds, but shows only when not inhibited, and when black (*B*) is absent, since black is epistatic to red.

"For the full development of intensity of red and black the presence of an intensity factor (*I*) is necessary. In the absence of this factor these colors remain in the dilute condition, red appearing yellow and black as dun. Another factor necessary for the full expression of black is one (*S*) which is presumed to cause the pigment to spread throughout the barbules of the feather instead of remaining clumped in the central part of the old barbule cells. When *S* is absent and the pigment is clumped as described, the appearance known as blue results. The dilute condition of blue is silver. The factor *S* affects only black pigmentation and does not produce any difference in the appearance of red, at any rate that has as yet been identified.

"White in the plumage of pigeons is due to an indefinite number of factors (W_1, W_2 , etc.) which inhibit the production of pigment in the areas which they influence. Definite patterns may result from the approach of a homozygous condition for *W* factors which act on particular definite regions of the plumage. 'Reversion' to the wild blue Rock Pigeon type in domesticated pigeons is due simply to a recurrence of the particular combination of factors which are present in *Columba livia*. An extensive experiment on the inheritance of black and red showed an overproduction of red birds in F_2 , the ratio being practically 2:1 instead of 3:1. This is not due to the absence of the homozygous dominant class as in yellow mice. Possible explanations are offered but no definite conclusion is reached.

"Different strains or family lines appear to have different tendencies as to the ratios of blacks and reds they produce in F_2 . Lumping all of the results shows still a slight excess of reds. The ratios of intense to dilute birds from heterozygotes bred to other heterozygotes or to dilutes closely approximate Mendelian expectation, that is 3:1 and 1:1, respectively. Various matings of the different colors give the results expected according to theory. A considerable number of illustrative matings are presented. Illustrations are given of

matings of white to white, white to splash, white to self, splash to splash, and splash to self. In general, the offspring tend to be grouped around the parental mean with respect to amount of color in the plumage. The evidence supports the conclusion that a number of factors are concerned in the production of white and splashed birds."

A list of references is appended.

DAIRY FARMING—DAIRYING.

Dairying, J. A. FOORD, E. B. FITTS, J. B. LINDSEY, H. O. DANIELS, A. J. PIERPONT, P. H. SMITH, W. P. B. LOCKWOOD, and P. M. HARWOOD (*Mass. Bd. Agr. Bul. 6 (1914), pp. 147, pls. 11, figs. 5*).—This bulletin is a compilation of articles treating of general dairy topics, including barn building, breeding, care, feeding, and management of dairy cattle, use of silage, production of market milk, and related subjects.

Cassava meal in feeding dairy cattle, MALLÈVEE (*Bul. Soc. Nat. Agr. France, 74 (1914), No. 6, pp. 638-644*).—In experiments in which cassava meal was substituted for gluten meal in a regular ration of wheat bran, beets, chopped straw, and alfalfa hay for dairy cattle no material gain was secured either in quantity or quality of milk.

Cost of milk production, O. ERF (*Cream. and Milk Plant Mo., 2 (1914), No. 10, p. 11*).—The average cost of keeping a cow per year as determined from data secured by the Ohio Experiment Station is estimated to be \$73.68. After crediting her with the by-products, the estimated cost of milk produced is for a 3,000 lb. cow 21.1 cts. per gallon, for a 4,000 lb. cow 15.8, 5,000 lb. cow 12.7, 6,000 lb. cow 10.6, and 7,000 lb. cow 9.05 cts.

Relation of conformation and mammary system to milk and butter fat production, V. F. DOLCINI (*Univ. Cal. Jour. Agr., 1 (1914), No. 9, pp. 9-11*).—Studies made of the conformation of a number of cows lead the author to conclude that there is a positive correlation in most cases between the different points of conformation and production and also a correlation between all points of the mammary system and production. The important points seem to be circumference of barrel, width and depth of chest, open frame work, and rump conformation. It was found that a pound of milk fat can be produced more cheaply in a high producing animal than in a low producing one.

The specific heat of milk and milk derivatives, A. R. JOHNSON and B. W. HAMMER (*Jour. Indus. and Engin. Chem., 6 (1914), No. 7, pp. 569-573, figs. 4*).—The experimental technique is fully described and data are reported showing the variation with the temperature of the specific heat of milk and a number of milk products, including whey, skim milk, cream, and butter.

Studies on the ash of colostrum milk with particular reference to its quantity and composition several days after calving, M. SATO (*Trans. Sapporo Nat. Hist. Soc., 5 (1914), No. 2, pp. 96-110*).—This reports analyses made of the colostrum milk of six mature cows immediately after and 24 hours after calving. The average specific gravity of the former was 1.0656, of the latter 1.0385; the fat content 4.8 and 3.6 per cent; the ash content 1.03 and 0.899 per cent; and the reaction, amphoteric in both cases.

The ratio of potassium oxid to sodium in the ash colostrum milk immediately after calving was 1.9:1, of milk 24 hours after calving 21:1. The calcium oxid, phosphoric acid, and sulphuric acid content were quite variable. The chlorine content is about the same as for normal milk.

Cow's milk for infants in Saxony, E. W. THOMPSON (*Cream. and Milk Plant Mo., 2 (1914), No. 11, pp. 25-27*).—This is an account of the production in Saxony of what is known as "Kindermilch." The text of the ordinance of

the city of Dresden, relating to the production and sale of this milk, is given. The health of the cow, the feed, surroundings, and operation of milking are all under strict control. Great importance is attached to giving dry feed as distinguished from all kinds of sloppy feeds, such as distillery waste, silage, and beet tops. The usual sources of carbohydrates are dry hay, wheat bran, rye bran, and small amounts of green fodder cut and taken to the stall. The protein content is brought up to the desired ratio with cotton-seed meal, peanut meal, copra meal, coconut meal, or linseed meal.

Results secured at the Racknitz Dairy show that when milk is produced under certain rigid conditions the bacterial content may be kept within safe limits without the necessity of sterilizing by heat. It is stated that the dairy has records showing a count of from zero to 250 bacteria per cubic centimeter against 220,000 in good commercial milk. It is shown that in the eight years since the consumption of this milk has begun, infant mortality has decreased from 21.7 to 12.5 per cent in Dresden, and from 17.8 to 5.5 per cent in suburbs of Dresden.

Comparison of the plating and microscopic methods in the bacteriological examination of milk, G. W. GOODRICH (*Jour. Infect. Diseases*, 14 (1914), No. 3, pp. 512-519).—In comparing the relative value of the plate and microscopic methods in the bacteriological examination of milk the author concludes that there is a marked correlation between the two counts; that the factor 20,000 which is used to reduce the microscopic counts to terms of the plate count is satisfactory; and that the microscopic count from a single slide can be depended upon as being within the limits of one-third as great to three times as great as the plate count, but can not be depended upon as being within 10,000 of the plate count. The microscopic count from a single slide is not sufficiently reliable to warrant the condemnation of market milk, especially when the standard for passing is a low count. Any milk which is "passed" on the microscopic count from a single slide where the passing standard is a low count is not likely to have a dangerously high count by the plate method.

A bacteriological index for dirt in milk, J. J. KINYOUN (*U. S. Naval Med. Bul.*, 8 (1914), No. 3, pp. 435-442).—In discussing the relative importance of a bacteriological index for dirt in milk the author concludes after an examination of about 3,000 samples of milk that in good milks there is present on a general average 1 colon bacillus to 50,000 bacteria in the milk; in dirty milk, 1 colon bacillus to 555. He is of the opinion that cleanliness in the production is the most important of all factors entering into the milk problem. The employment of a standardized Endo medium, as described in this article, is recommended for isolating the colon group.

Ability of streptococci to survive pasteurization, S. H. AYERS and W. T. JOHNSON, JR. (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 4, pp. 321-330, figs. 3).—The authors of this paper summarize their investigations as follows:

"The thermal death points of 139 cultures of streptococci isolated from cow feces, from the udder and the mouth of the cow, and from milk and cream showed a wide variation when the heating was performed in milk for 30 minutes under conditions similar to pasteurization. At 60° C. (140° F.), the lowest pasteurizing temperature, 89 cultures, or 64.03 per cent, survived; at 62.8°, the usual temperature for pasteurizing, 46, or 33.07 per cent, survived; and at 71.1° 2.58 per cent of the cultures survived; all were destroyed at 73.9°.

The streptococci from the udder were, on the whole, less resistant and those from milk and cream more resistant to heat than those from the mouth of the cow and from cow feces. When heated to 60° all of the 18 cultures from milk and cream survived; at 62.9° 17, or 94.44 per cent survived; at 68.3° 9 cultures,

or 50 per cent, withstood the heating process. All the streptococci from milk and cream were destroyed by heating to 73.9° for 30 minutes.

“Among the 139 cultures of streptococci there were 22 that formed long chains, which, for the purpose of this paper, were considered as typical streptococci. The others were considered atypical. The typical streptococci were much less resistant to heat than were the atypical. Of the 22 typical streptococci 12, or 54.54 per cent, survived heating for 30 minutes at 57.2°; at 60° 9, or 40.91 per cent, survived; at 62.8° only 1 culture, or 4.54 per cent, withstood the heating. All of the typical streptococci were destroyed by heating for 30 minutes at 65.6°. The 117 atypical streptococci were more resistant; at 60° 68.37 per cent survived; at 62.8° 38.46 per cent survived; and at 71.7° 2.56 per cent survived; all were destroyed at 73.9°.

“Two classes of streptococci seem to survive pasteurization: (a) Streptococci which have a low majority thermal death point but among which a few cells are able to survive the pasteurizing temperature. This ability of a few bacteria to withstand the pasteurizing temperature may be due to certain resistant characteristics peculiar to a few cells or may be due to some protective influence in the milk. (b) Streptococci which have a high majority thermal death point. When such is the case, the bacteria survive because the majority thermal death point is above the temperature used in pasteurization. This ability to resist destruction by heating is a permanent characteristic of certain strains of streptococci. The thermal death point determinations in this work were made in milk in such a manner as to represent actual conditions of pasteurization by the holder process; therefore the results show what may be expected in commercial pasteurization, and it is evident that some streptococci may survive the process. However, different results might have been obtained if a larger number of cultures had been studied and if other methods and media had been used for determining the thermal death points.”

The application of refrigeration to the handling of milk, J. T. BOWEN (*U. S. Dept. Agr. Bul. 98 (1914), pp. 88, figs. 37*).—This bulletin discusses the application of refrigeration in the operation of the modern milk plant and describes the various forms of mechanical and other systems of cooling.

After treating of the physical changes, including specific heat, cohesion, viscosity, and coefficient of expansion and freezing, and the bacteriological changes of milk and cream the author takes up a discussion of the principles involved in cooling by means of salt and ice mixtures. Curves are given showing the approximate temperature obtained with different proportions of salt, the refrigeration available with different percentages of salt, and the specific heat of common salt brine with different percentages of salt. The ice bunker, gravity brine, compression and vapor absorption systems of refrigeration are treated, together with their installation and operation. Methods of utilizing refrigeration described are the direct expansion, brine circulating, brine storage, congealing tank, and air-circulating systems.

Other subjects discussed are insulation, size and cost of plants, and cooling milk on the farm, during transportation, and at the receiving stations, bottling plants, and creameries.

A study of the market butter of Boston, M. J. ROSENAU, W. D. FROST, and RUTH BRYANT (*Jour. Med. Research, 30 (1914), No. 1, pp. 69-85*).—Twenty-five samples of butter, representing the market supply of Boston and scoring from 80 to 98, were studied.

There appeared to be no definite relation between score and price. Attempts were made, without success, to devise a practical dirt test for butter.

The average number of bacteria per gram was determined by emulsifying the butter in warm water. The average number for the 25 samples was

5,700,000 per gram; the lowest number was 8,600 and the highest 41,000,000. There was no particular relation between the number of bacteria and any other constituent determined, such as salt reaction, moisture, etc. The number of bacteria diminished markedly with age, in one sample 85.8 per cent in 2 weeks, in another 93.7 per cent in 4 weeks, and in another 95.6 per cent in 6 weeks. The number of bacteria may therefore be used as an index to the age of the butter.

Bacillus coli was found in only 6 of the 25 samples and then only in small numbers. It seems that *B. coli* soon dies out in butter. Streptococci were found in 14 samples, but no special relation between their presence and virulence as tested upon guinea pigs could be made out. *Bacterium welchii* was not found in any of the samples. Tubercle bacilli were demonstrated in 2 of the 21 samples tested for these organisms and from butter of apparently first quality. Pasteurization of cream intended for butter is recommended.

Butter (*Maine Sta. Off. Insp.* 58 (1914), pp. 21-32).—This reports official inspections made of the weight and chemical analyses of samples of package butter in different parts of the State.

Inquiry into the factors which control the texture of Cheddar cheese, I, A. GEAKE (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 169-178, figs. 3).—This investigation was undertaken with the view of ascertaining the influence of acidity on curd, caseinogen, and casein. In the course of the investigation the following acids were used: Fatty acids; formic, acetic, propionic, butyric, isobutyric, valerianic, and isovalerianic acids; oxyacids; and glycollic, lactic, α -oxybutyric, β -oxybutyric, and oxyisobutyric acids.

It was shown that in the presence of weak organic acids, caseinogen and casein swell and finally dissolve to a greater or lesser extent. The presence of lactic or acetic acids hindered the solution of rennet curd. This is explained as being due to the acids hindering the action of the enzymes, since these solutions did not become putrid so readily as those in pure water. The acid curd, in which the presence of large amounts of enzymes was excluded, was much more readily dissolved by the acids than by water and by the stronger than by the weaker lactic acid solutions. It was found that the addition of sodium chlorid to lactic acid solutions of caseinogen lessens the solubility of the caseinogen and if sufficient salt is added the protein is more or less completely salted out. It was noted that there is a "very rapid change in the percentage of caseinogen precipitated by concentrations of sodium chlorid between about 0.1 N and 0.17 N. At the former concentration the amount of caseinogen precipitated is less than 10 per cent, and at the latter is more than 90 per cent. This illustrates the value of the method of separating proteins by fractional salting out from solution."

VETERINARY MEDICINE.

Atlas and text-book of the more important animal parasites and their means of transmission, R. O. NEUMANN and M. MAYER (*Atlas und Lehrbuch wichtiger tierischer Parasiten und ihrer Überträger mit besonderer Berücksichtigung der Tropenpathologie*. Munich, 1914, vol. 11, pp. VI+580+93, pls. 49, figs. 260; rev. in *Science*, n. ser., 40 (1914), No. 1023, pp. 210-212).—This work, which deals with the more important animal parasites, includes 45 colored plates.

Vaccination for infectious diseases, R. M. STALEY (*Proc. Penn. State Vet. Med. Assoc.*, 30 (1913), I, pp. 64-69; *Amer. Vet. Rev.*, 43 (1913), No. 6, pp. 611-617).—This deals especially with the methods as carried out by the Com-

monwealth of Pennsylvania, with particular reference to anthrax, blackleg, and hog cholera.

The lecithin content of different tissues, J. CRUICKSHANK (*Abs. in Jour. Path. and Bact.*, 18 (1913), No. 1, pp. 134-136).—The amount of lecithin in different tissues was determined, the procedure used consisting in brief in extracting the tissues with alcohol or ether and treating the residue from the evaporated extract with hot acetic ether. "On cooling this solution a precipitate results. After purification by repeated solution in, and precipitation from, hot acetic ether the precipitate is dissolved in ether (any material insoluble in ether is removed by rapidly centrifugalizing), and the solution is precipitated with excess of acetone. Solution in ether and precipitation with acetone is repeated a number of times till the precipitate is completely soluble in ether. Finally, the acetone precipitate is shaken with cold alcohol. The fraction soluble in cold alcohol constitutes the 'lecithin.' The amount of lecithin present has been estimated by evaporating to dryness a known volume of the alcoholic solution and weighing the residue."

The amount of lecithin found in 100 gm. of wet tissue was as follows: Ox's heart, kidney, spleen, lungs, testicles, thyroid, pancreas, and submaxillary gland, 0.36, 0.48, 0.14, 0.4, 0.62, 0.3, 0.68, and 0.3 gm., respectively; sheep's liver and red corpuscles, 1.6 and 0.12 gm., respectively; ox's red corpuscles 2.5 gm.; and human brain 0.6 gm.

"A number of these tissues have also been fixed in formalin, dried to constant weight, and extracted with ether in place of alcohol. The amount of lecithin obtained by this method has in all cases been small, generally about one-tenth of the amount obtained by extracting a corresponding amount of the same dried tissue with alcohol. It has been found that the yield of lecithin from certain dried tissues by extraction with alcohol may be considerably less than that obtained from the corresponding amount of the same tissue extracted in the wet state. This difference occurs more particularly with tissues (brain, blood) which in the dried condition are difficult to reduce to a fine powder, and is probably attributable to want of proper penetration of the tissue by the extracting fluid.

"In estimating the amount of lecithin, it is inconvenient to work with very large amounts of acetone precipitate, as it is difficult, without the use of sand or other material by which the precipitate may be triturated, to extract the whole of the lecithin. Further, the amount of lecithin in any precipitate can only be estimated by thorough extraction of the precipitate with cold alcohol, as it has been found that the proportion of lecithin in acetone precipitates varies considerably."

A comparative study of the chemical and biochemical properties of lipid substances as extracted from pig's liver and egg yolk, F. P. WILSON (*Jour. Path. and Bact.*, 18 (1913), No. 1, pp. 60-63).—"The best anticomplementary property is shown, as in the case of the liver, by the acetone-insoluble fraction of the ether extract. The figure obtained is very low compared with the liver, and is practically equalled by the other acetone-insoluble fractions. The hemolytic property is absent in all fractions, and in this connection it may be noted that the saponification values are much the same as in the liver, but the iodine values are higher. In both liver and egg yolk a high iodine value is accompanied by an increased anticomplementary action, but in the case of the liver the converse does not hold good.

"No relation appears to exist between the anticomplementary property and the percentage of nitrogen and phosphorus, nor apparently is there anything in the ratio of N:P. It is noteworthy that the acetone-soluble portion of the

hot alcohol extract contains the highest percentage of phosphorus, the next highest figure being found in the acetone-insoluble fraction of the same extract. In the case of the liver the phosphorus was practically all in the acetone-insoluble fractions, and especially in that of the ether extract. In short, it is apparent that the lipoids of egg yolk differ widely in certain chemical and biochemical properties from those obtained from a mixture of several pigs' livers."

An attempt to preserve hemolytic complement in a permanent form, H. R. DEAN (*Abs. in Jour. Path. and Bact.*, 18 (1913), No. 1, pp. 118, 119).—"The main object of these experiments was to obtain hemolytic complement in a state in which it could be preserved and used in place of fresh serum. This object was not attained. The method employed was such as to effect a separation of the lipid and protein constituents of serum, and it is possibly of interest to note that the separated protein was rich in mid-piece fraction, but contained traces only of end-piece."

Two important western poisonous plants, H. G. KNIGHT (*Proc. Soc. Prom. Agr. Sci.*, 33 (1912), pp. 51-58).—The data here presented relating to the woody aster and death camas have been previously noted (E. S. R., 28, p. 197). See also a subsequent note (E. S. R., 29, p. 77).

Studies in the toxicity of cotton-seed meal, W. A. WITHERS and B. J. RAY (*Proc. Soc. Prom. Agr. Sci.*, 33 (1912), pp. 19-21).—Previously noted (E. S. R., 28, p. 197).

A remedy for cotton-seed meal poisoning, W. A. WITHERS (*North Carolina Sta. Circ.* 5 (1913), pp. 3).—The data here presented relating to experiments with rabbits have previously been noted from another source (E. S. R., 29, p. 477). In addition, brief mention is made of preliminary tests with swine.

Twelve pigs, weighing an average of 50 lbs., were fed daily 0.5 lb. of cotton-seed meal and 1.5 lbs. of corn meal, the ration being increased as the pigs grew. In addition, a solution of copperas was given to 6 of the pigs. At the time of writing, or thirteen weeks after the experiments were commenced, 4 of the 6 pigs receiving the cotton-seed meal without the iron salt had died and the remaining 2 had a very unthrifty appearance and had made an average gain of but 35 lbs. The 6 which had received an iron salt had gained an average of 54 lbs. "Based upon these results, iron salt appears to be of value in diminishing, if not entirely preventing, the harmful effects to swine of cotton-seed meal feeding, provided that feeding is not in excess of the rate of 1 lb. of meal daily to each 100 lbs. of live weight."

The directions given for the preparation and use of the iron solution are as follows: "Dissolve 1 lb. of copperas (ferrous sulphate) in a barrel (about 50 gal.) of water. For each pound of cotton-seed meal take 1 gal. of the solution, mix thoroughly daily for each 100-lb. pig. If the pig weighs only 50 lbs., use half the amount of cotton-seed meal and one-half of the copperas solution."

The diagnosis of anthrax according to Ascoli's and Schütz-Pfeiler's methods, F. FISCHÖEDER (*Ztschr. Infektionskrank. u. Hyg. Haustiere*, 13 (1913), No. 6, pp. 317-322).—Continuing previous work (E. S. R., 28, p. 477), the author reports tests made with the Schütz-Pfeiler precipitating serum. In all cases where anthrax bacilli, whether living or dead, were present in the material examined, anthrax could be diagnosed by the Schütz-Pfeiler method.

A diagnosis of anthrax sepsis with the lumbar puncture, L. POLLAK (*Wiener Klin. Wchnschr.*, 25 (1912), No. 43, pp. 1702-1704, fig. 1; *abs. in Centbl. Bakt. [etc.]*, 1. Abt., Ref., 56 (1913), No. 12, p. 355).—A minute description of cases in which it was possible to detect the causative organism in the cerebrospinal fluid. The fluid was centrifuged, and in the sediment the *Bacillus anthracis* was noted by the usual method.

Infectious bulbar paralysis, pseudo-rabies or Aujeszky's disease, L. PANISSET (*Rev. Gén. Méd. Vét.*, 23 (1914), No. 275, pp. 601-618, figs. 4; *abs. in Jour. Compar. Path. and Ther.*, 27 (1914), No. 2, pp. 179-182).—A summarized account of the disease with references to the literature.

A contribution on the cultivation, isolation, and disinfection of the blackleg bacillus, E. HÖLZEL (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 71 (1913), No. 2-3, pp. 147-165).—A report of the results of investigations of *Bacillus gangrænæ emphysematosæ* at the Pathological Institute of the Veterinary High School at Munich.

A contribution to the knowledge of *Bacillus mallei*, M. CARPANO (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 71 (1913), No. 4, pp. 267-285, pls. 3).—This paper deals with the morphology and biology of the glanders bacillus.

Observations on the clinical diagnosis of glanders, C. H. SCHULTZ (*Philippine Agr. Rev. [English Ed.]*, 6 (1913), No. 8, pp. 380-385, pl. 1).—After reviewing the literature in regard to the value of the various tests for diagnosing glanders, the author points out that he has been able to verify de Blicck's findings (*E. S. R.*, 26, p. 376) in regard to the value of the conjunctival reaction when using crude mallein in the eye. "During an investigation of an outbreak of contagious disease among native ponies at Calamba . . . its application gave negative results. *Streptococcus equi* was subsequently isolated from the afflicted animals, thus identifying the disease as strangles."

The vitality of the hemorrhagic septicemia organism outside the body, J. D. E. HOLMES (*Mem. Dept. Agr. India, Vet. Ser.*, 2 (1914), No. 4, pp. 105-118).—This paper consists of three parts, the first dealing with the effect of exposure of the virus to direct sunlight, the second with the vitality of the virus when protected from direct sunlight, and the third with tests on cattle.

It was found that exposure to direct sunlight for one day kills the virus both in broth cultures and in sterile dry earth. When exposed to direct sunlight in agar slant cultures the virus is killed in five days. Agar and broth cultures when kept in the shade at air temperature maintain their virulence for guinea pigs for six weeks or longer, and broth cultures mixed with sterilized moist earth keep their virulence for guinea pigs for a similar period. In surface water protected from direct sunlight the virus maintains its vitality for about three weeks. Broth cultures mixed with unsterilized mud and protected from sunlight maintain their virulence for three months and longer.

In experiments with cattle it was found that the virulence of the organism is reduced after it has remained for some time in mud, but is still fatal for more susceptible animals. After passage through cattle the original virulence is recovered. Bovines in normal health can resist large amounts of virulent broth cultures when ingested. The ingestion of virus confers an immunity against a lethal dose of culture inoculated subcutaneously three weeks after the ingestion. Bovines whose resistance has become lowered from fatigue, poor condition, exposure, and other like causes, are very susceptible to the ingestion of the virus when ingested.

Contribution to the cultivation of the parasite of rabies, H. NOGUCHI (*Jour. Expt. Med.*, 18 (1913), No. 3, pp. 314-316, pl. 1).—In the experiments about 50 series of cultivations were made with the brain or medulla removed aseptically from rabbits, guinea pigs, and dogs infected with street virus, passage virus, or fixed virus. The method of cultivation was the same as that used for the spirochetes of relapsing fever. In the culture minute chromatoid bodies arise which on subsequent transplantation reappear in the new cultures throughout many generations. The bodies from all the viruses seemed to be alike. The smallest of these could just be seen with a Zeiss apochromatic 2-mm. lens.

In four different instances in cultures from the passage and fixed virus nucleated round or oval bodies, surrounded with a membrane totally different from the minute bodies mentioned above, were noted.

"By inoculating cultures containing the granular, pleomorphic, or nucleated bodies, rabies has been reproduced in dogs, rabbits, and guinea pigs, as shown by the typical symptoms and positive animal inoculations, while the film preparations from the brain of the animals contained always the granular and sometimes the nucleated bodies in large numbers."

Contribution to the study of the filtrate of the rabies virus, NEUMANN and T. MIRONESCO (*Compt. Rend. Soc. Biol. [Paris]*, 74 (1913), No. 12, pp. 712, 713).—The filtrate from the rabies virus has been found to be very variable as regards strength. In order to see if a homogeneous virus could be obtained, the brain of a rabbit which died of the disease was rubbed up in a mortar with 100 cc. of a normal serum, and the emulsion obtained was shaken up in a bottle containing glass beads for about one hour. The emulsion was then filtered through a sterile gauze, and at this juncture there was added an emulsion made from two 24-hour agar cultures of the *Bacillus pyocyaneus* and emulsified with normal serum. The entire mixture was then diluted with 300 cc. of normal serum, mixed well, and filtered through a Berkefeld V filter under a pressure of from two to five atmospheres.

Some rabbits were then inoculated with the filtrate and others with the unfiltered virus. The rabbits receiving the filtrate died in the same time as those receiving the unfiltered virus. The brains of the rabbits dying as a result of the injection of the filtrate were infectious for other rabbits.

The diagnosis of rabies, H. KOENIGSFELD (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 70 (1913), No. 1-2, pp. 85-98; *abs. in Ztschr. Fleisch u. Milchhyg.*, 24 (1913), No. 3, p. 64).—In this work it was possible to verify the findings of others that the rabies virus can penetrate the skin or mucous membrane through superficial wounds and cause the disease. The corneal and cutaneous methods will in many cases determine the presence of the disease even though putrefied material is used for the tests. The incubation periods, etc., are often lengthened when putrefied material is used in the experiments.

The treatment of tetanus, J. SCHMIDT (*Ber. K. Tierärztl. Hochschule Dresden, n. ser.*, 7 (1912), p. 151; *abs. in Vet. Rec.*, 26 (1913), No. 1324, p. 326).—A comparison of nine cases of tetanus in the horse. Two of the animals were treated with morphin and chloral hydrate alone and the other seven with tetanus antitoxin only. The two first-mentioned horses were slaughtered, being incurable, one after 12 hours and the other 3½ days after treatment. Of the other seven, four recovered, two died, and one was slaughtered. The antitoxin was given intravenously.

Double infection with the human and bovine types of *Bacillus tuberculosis*, P. A. LEWIS (*Jour. Amer. Med. Assoc.*, 60 (1913), No. 3, pp. 202, 203).—A description of a case in a man, by occupation a butcher, in which the lungs were affected by the human type of organism, and the thumb (tuberculosis verrucosa cutis) by the bovine type of organism.

Investigations in regard to the isolation of the human and bovine types of tubercle bacilli from cultures of atypical virulence (Schroeder-Mietzsch strain) and from artificially mixed cultures, E. A. LINDEMANN (*Arch. K. Gsndhtsamts.*, 45 (1913), No. 2, pp. 197-225).—The Schroeder-Mietzsch culture is an atypical culture isolated from a 20-year old woman affected with pulmonary tuberculosis. It grows like the bovine type in bouillon, but lacks the virulence of this type of organism. Thinking that it might be a mixed culture, although investigations by others have proved the contrary, the author made tests with it on rabbits, guinea pigs, and chickens, and in bouillon. The results

were negative, but he is not inclined to believe that it can be classified with the human type of organism. The gallinaceous type is not present in the culture.

Some tests with artificially mixed human and bovine type cultures were then made for the purpose of determining to what degree such cultures, which have been artificially cultivated for a long time, may be separated. Nine out of ten cultures prepared from the two types could be isolated and identified. Even though one of the types was present in a dilution of 1:50 with the other type, it could be detected. In the tenth mixture of types only the human kind could be isolated. The test showed in an indirect way the constancy of the various types.

In regard to the etiology and serodiagnosis of human, bovine, and avian tuberculosis, G. RONCAGLIO (*Rapporti Etiologici e Sierodiagnostici fra Tubercolosi Umana, Bovina, Aviaria. Parma, Italy, 1912, pp. 199; abs. in Ztschr. Immunitätsf. u. Expt. Ther., II, Ref., 6 (1913), No. 14, p. 995*).—In this work the etiological, clinical, and serodiagnostic relations which exist between human, bovine, and avian tuberculosis were studied. The first part of the work is mainly historical in nature and gives a good perspective of the present status of this problem. The biological methods used were the complement fixation test, meiotagmin reaction, and passive anaphylaxis. The tests made were too few and did not allow a definite conclusion as to the types of bacilli present. The meiotagmin reaction, however, gave the best results.

The occurrence of avian tuberculosis in man, E. LÖWENSTEIN (*Wiener Klin. Wchnschr., 26 (1913), No. 20, pp. 785-787*).—The author states that avian tuberculosis occurs more frequently in man than is usually supposed, and may be due to eating eggs from tuberculous hens. The cases can be definitely classified from the bacteriological and clinical findings, but a much simpler method is to employ the avian tuberculin test. Artificially infected eggs when soft-boiled showed living organisms. In all cases where acid-fast bacilli are found which are not pathogenic for guinea pigs, tests must be made with rabbits and hens.

Studies in avian tuberculosis, L. R. HIMMELBERGER (*Centbl. Bakt. [etc.], 1. Abt., Orig., 73 (1914), No. 1, pp. 1-11, pls. 2*).—In this contribution from the Michigan Experiment Station, after reviewing some of the literature relative to avian tuberculosis, the results of cultural, transmission, and agglutination tests are reported.

It was found possible to cultivate the avian tubercle bacillus on sterile bananas and glycerinated slants of carrots, turnips, and garden beets. The results suggest that the media tried may eventually be used as a means of differentiation.

Transmission experiments were made with tuberculous chickens and white rats, guinea pigs, rabbits, and calves. The attempts to infect rats by cohabitation with tuberculous hens and two guinea pigs, one rabbit, and two rats, by injecting a broth culture of the avian tubercle bacillus subcutaneously, resulted negatively. One rabbit, however, showed an abscess at the site of injection which was found to contain the tubercle bacillus. Three other rabbits, which received an intravenous injection of a suspension of macerated tubercular material from a diseased hen and were killed two months later, showed no evidences of infection.

The results with twin calves one week old from a nontubercular herd, which were fed with milk and the macerated organs of a tubercular hen as previously noted by Giltner (*E. S. R., 28, p. 476*), showed in one case a reaction with avian tuberculin but none with mammalian tuberculin as applied some months later. About five months afterward it again reacted to avian tuberculin, and

on autopsy was found to have lesions in the abdominal viscera, although the bacilli could not be isolated from the lesions. Another calf, which was injected with a suspension of tubercular lymph nodes and tested five months later with avian tuberculin, gave a decided reaction, but no lesions were found on autopsy.

A fourth calf, which was fed with the macerated organs of tubercular hens, gave positive tests to both avian and bovine tuberculin. Fifteen days elapsed between the application of the tuberculins. The results support the view "that avian tuberculin will not immunize an animal against the anaphylactic action of ordinary tuberculin or vice versa. The response to this test with ordinary tuberculin weakens the supposition advanced previously that a difference exists in the avian and ordinary tuberculins. This calf was killed and examined post-mortem with the following findings: Liver presented many yellowish, white spots $\frac{1}{2}$ cm. in diameter, smears from which showed presence of tubercle bacilli. Hepatic lymph glands were normal, however. Mesenteric lymph nodes opposite union of jejunum and ileum enlarged and tubercular. No lesions were found in the intestines."

Agglutination tests with normal and diseased fowls are reported upon, and the results, while encouraging, do not warrant the drawing of positive conclusions because the number of birds examined was too few. The possibility of using the precipitin, agglutination, and complement-fixation tests as diagnostic agents is emphasized.

Avian tuberculosis, L. VAN ES and A. F. SCHALK (*North Dakota Sta. Bul.* 108 (1914), pp. 3-94, pls. 3, fig. 1).—This discusses the history, geographic distribution, economic importance, etiology, modes of transmission and pathogenesis, lesions, symptoms, and diagnosis of avian tuberculosis, with special reference to its occurrence in fowls, and reports experiments in applying the tuberculin test to the diagnosis of tuberculosis in fowls. An extensive bibliography is appended.

"Owing to the negative results obtained by previous investigators when the subcutaneous, ophthalmic, or cutaneous method of application was used, the writers experimented almost exclusively with the intracutaneous method of tuberculin application introduced by Moussu and Mantoux [*E. S. R.*, 21, p. 582]." A portion of the experiments (320 birds) has been reported from another source (*E. S. R.*, 30, p. 381), but in all 601 tests were made. The number of fowls given autopsy was 277, the number of birds found to have lesions was 125, and those showing typical reactions were 90 in number. The reacting fowls with lesions were 88, or 97.77 per cent. The number of non-reacting fowls was 130, of which 120, or 91.53 per cent, were without lesions. There were 57 fowls with doubtful reactions, and of these 27, or 47.36 per cent, had lesions. In many of the cases the lesions were confined to a single organ.

A tuberculin reaction in chickens is considered an almost certain indication of tuberculous infection. "While nothing less than a great amount of practical experience obtained under all kinds of conditions will be necessary to establish the usefulness of the intradermal tuberculin test in the eradication of tuberculosis from farm poultry, the results obtained in experiments are strongly suggestive of its value."

As tuberculosis is considered a chronic, essentially progressive disease, and the treatment of avian tuberculosis is impracticable, prophylaxis as a means of eradication of tuberculosis from a flock is suggested. "The owners of a healthy flock should be careful in the introduction of new stock, and when the latter is procured from unknown or questionable sources, it would be advisable to subject the fowls to a tuberculin test before they are permitted to mingle with the healthy birds."

The data presented show that more of the older fowls in a flock are usually diseased, and as such constitute the greatest factor in the distribution of avian tuberculosis. "After the elimination of the older birds the remainder of the flock may be tuberculin tested in the manner indicated, and all fowls reacting either typically or doubtfully should share the same fate as the older birds. . . . Certain phases of the management of poultry must be given consideration in connection with tuberculosis. Clean, airy, well-lighted [roomy] quarters are less apt to promote the spread of the disease than when the opposite is the case. . . . To what extent the disease is transmitted by means of eggs can not be said at this time, but even if the danger from this source is probably a slight one, common prudence should cause one to avoid the use of eggs from tuberculous birds for setting purposes.

As an indication of what may be accomplished in the eradication of tuberculosis from a rather heavily infected flock of chickens, the authors relate that in the beginning of 1913 a flock of 249 chickens was found by tuberculin test and autopsy to be tuberculous to the extent of 43.37 per cent. Eliminating all reacting and undesirable birds 56 nonreacting fowls were retained, to which were added 47 new purchases which did not react to the test. During the summer one more bird died with tuberculosis, and is regarded as a case which failed to react on account of very extensive lesions. A year later the flock had again increased to 249 fowls, and the test revealed only 2.41 per cent of tuberculosis. "All those cases showed very slight lesions, probably incipient, and may be attributed to infection by the missed case which died during the summer."

In discussing the relation of avian to mammalian tuberculosis it is concluded that "with the possible exception of swine the danger to mammals from avian infection sources is probably very slight and negligible," but as we have no knowledge how soon an avian organism in a mammal may become adapted to its new surroundings and become capable of producing mammalian disease, "it is apparent that prudence demands that fowl tuberculosis be so controlled as to prevent its transmission to other farm stock."

Prophylaxis with attenuated tubercle bacilli, M. RABINOWITSCH (*Berlin. Klin. Wehnschr.*, 50 (1913), No. 3, pp. 114, 115; *abs. in Jour. Amer. Med. Assoc.*, 60 (1913), No. 9, pp. 703, 704).—A method is described with which it is possible to reduce or enhance the virulence of the tubercle bacillus at will. It is done by allowing vapors of formaldehyde to act on the culture, and then transferring the culture to a fresh serum medium. A strain derived from the blood of a tubercular subject and highly virulent for both rabbits and guinea pigs became avirulent by this treatment.

"Two guinea pigs inoculated subcutaneously with 0.002 gm. of the culture showed no signs of infection when killed six weeks later, while others inoculated in the same way and then, after two months, inoculated with the same amount of a highly virulent culture, human and bovine, showed no signs of infection when killed six weeks later. The controls developed tuberculosis in a very severe form."

Studies on the biochemistry and chemotherapy of tuberculosis.—VII, Report of some experimental work on the use of methylene blue and allied dyes in the treatment of tuberculosis, LYDIA M. DE WITT (*Jour. Infect. Diseases*, 13 (1913), No. 3, pp. 378-403, figs. 2).—"Methylene blue will penetrate the tubercle, stain the living tubercle bacillus, and in some cases kill the bacillus in vitro and in others lessen its virulence. When added to the culture media, a relatively small percentage of methylene blue will inhibit the growth of the human tubercle bacillus. Methylene blue iodid is no less irritant than the

chlorid and has less bactericidal power and no greater therapeutic value. The new methylene blues are various modifications of the methylene blue molecule and have in the main no advantage over methylene blue. New methylene blue GG, however, showed some effect in the one case in which it was used therapeutically, and it, with other oxygen derivatives of methylene blue, will be given further tests.

"Selenium blue and tellurium blue are new blue dyes in which the sulphur of the methylene blue molecule is replaced by selenium and by tellurium. They are weaker and less stable dyes than methylene blue and more toxic and less bactericidal than that dye. They penetrate the tubercle, and are reduced in it, and can be reoxidized; they stain the living tubercle bacillus, but more faintly than does methylene blue. In fact they behave in all respects as weaker editions of methylene blue and have no advantage over it.

"Neither methylene blue nor any of the allied dyes tested by me may be said to have much therapeutic influence over experimental tuberculosis of the guinea pig. While methylene blue seems for many reasons a favorable starting point for tuberculosis chemotherapy, other modifications of it, and probably many others, must be tried before a claim to have found a specific for this disease [can be made]."

Acid-fast bacilli in milk, J. M. BEATTIE and F. C. LEWIS (*Abs. in Jour. Path. and Bact.*, 18 (1913), No. 1, pp. 122, 123).—Special stress is laid on the fact that acid-fast bacilli occur in milk which are totally different from tubercle bacilli. These organisms, however, grow very well in milk at ordinary temperatures. The bacillus is Gram-positive, nonmotile, nonliquefying, and in morphology is rather thick and stains more uniformly than the tubercle bacillus. When grown in milk many of the rods isolated from inoculated animals closely resemble the human and bovine types of tubercle bacilli.

The authors believe that the microscopic method for examining milk for the presence of the tubercle bacillus should not be substituted for the inoculation method.

Investigations in regard to the experimental diagnosis of contagious pleuro-pneumonia of bovines, K. POPPE (*Arb. K. Gsndhtsamts.*, 45 (1913), No. 2, pp. 238-268, pls. 3, figs. 4).—In localities where many cases of this disease occur the diagnosis is easily made, but in those where the cases are few, especially when the first ones occur, it is more difficult. The uncertainty of the anatomical method of diagnosis made it desirable to look for a means which rests on accurate experimental principles, consequently filtration, inoculation, and serum diagnostic tests were made in this direction.

The findings of Nocard and Dujardin and Beaumetz in regard to the filtration method for isolating the contagious pleuro-pneumonia virus were verified. In the study, tissues from other diseases such as tuberculous broncho-pneumonia, emphysema of the lungs, and normal lung tissue were included for comparison with the lung tissue and exudates from authentic cases of lung plague. The exudates, etc., were diluted with Martin's peptone bouillon.

With normal tissue or the tissue from cases in which the etiologic factor of lung plague was not present, the results of the filtration test showed the absence of the characteristic opalescent clouding of the filtrate (culture) and no minute strongly refracting granules. Where material containing a considerable amount of blood, or material in a putrefying condition was used, a light opalescence was noted, but it was never so pronounced as that from the specific material. Culture tests with filtered exudates, etc., accompanied by inoculation tests with calves and smaller experimental animals supported the diagnosis of this disease. The complement fixation test did not give satisfactory results, but the

precipitation test in most cases was satisfactory, although the number of tests made were too few to draw a final conclusion.

On the basis of the results obtained the following criterions are considered of value for diagnosing the presence of lung plague in an animal: (1) The filtered lung—or thoracic—cavity exudates of the suspected animals must give the characteristic opalescent turbidity in Martin's peptone bouillon at 37° C. after five to seven days; (2) the virus obtained with the necessary precautions, when inoculated subcutaneously in the lower lip of calves, must show after four to five days a typical swelling at the site of injection accompanied by a rise in temperature (the fastigium is reached after the tenth to twelfth day); (3) the culture obtained from the filtered subcutaneous exudate from the inoculated calf must show the characteristic opalescent clouding; and (4) smaller experimental animals, treated with the lung—or thoracic—fluid or with the edematous fluid from inoculated calves must succumb to the infection.

Immünization of cattle against East Coast fever, A. THEILER (*Rpt. Dir. Vet. Research, Union So. Africa*, 2 (1912), pp. 266-314; *abs. in Jour. Compar. Path. and Ther.*, 26 (1913), No. 3, pp. 261-265).—"The experience in the field indicates that the inoculation can be safely undertaken in respect of either clean or infected cattle with the prospect of conferring immunity on 56 to 60 per cent. The best results in the field may be expected from the injection of 5 cc. of spleen or gland pulp (medium, half-coarse, or coarse grain) mixed with aleuronat or peptone, such animals to be kept on clean veldt for 14 or 15 days before they are exposed to natural infection. The immunity conferred by the injection may not be absolute, inasmuch as twelve breakdowns were noted among the experimental animals, or 1 per cent. The animal which supplies the spleen or gland pulp for the inoculation has apparently an influence on the results, as the variation in the mortality from the injection can not be considered to be due to any other factor.

"As a possible improvement to the present method of immunizing cattle against East Coast fever, the saturation of the pulp in a solution of quinin hydrochlorid is suggested, the strength of the solution to be between 0.6 and 0.7 per cent."

Immünization of imported cattle against Northern Rhodesia piroplasmosis and anaplasmosis, F. CHAMBERS (*Jour. Compar. Path. and Ther.*, 26 (1913), No. 3, pp. 249-253).—An account of two Ayrshire bulls affected with Northern Rhodesia piroplasmosis and anaplasmosis. Both were treated with Northern Rhodesia blood and various medicaments which included sodium sulphate, ammonium carbonate, citrate of iron and quinin, and sweet spirits of niter. One of the animals received 120 cc. of a 1 per cent solution of trypan blue. Both animals recovered.

The susceptibility of the pig to blackleg, S. von RÁTZ (*Ztschr. Infektionskrank. u. Hyg. Haustiere*, 14 (1913), No. 1, pp. 1-8; *abs. in Jour. Compar. Path. and Ther.*, 27 (1914), No. 2, pp. 175, 176).—The author's experiments show that the pig does not possess an absolute immunity.

Hog cholera and preventive treatment, W. S. ROBBINS (*Michigan Sta. Spec. Bul.* 65 (1914), pp. 5-22, figs. 11).—This is a descriptive account of hog cholera and the manner of immunizing hogs against it.

Roaring in the horse, H. A. VERMEULEN (*Das Kehlkopf Pfeifen beim Pferde. Utrecht*, 1914, pp. 97, pls. 6, figs. 17; *rev. in Jour. Compar. Path. and Ther.*, 27 (1914), No. 2, pp. 173, 174).—The author considers this affection to be a symptom of a widespread disease affecting the motor nerves and their centers and not one localized in the larynx. The condition is considered as a poisoning, the poison being sometimes of mineral or vegetable origin but in most cases a bacterial toxin or an autotoxin, the last mentioned having its origin in dis-

turbance of the function of the thyroid gland. The author has attempted to treat the condition in horses through the administration of dried and powdered thyroid gland. Of 15 horses treated two are said to have been cured and four recognizably improved. Of the nine horses in which treatment failed four are said to have been very old.

Parasites and parasitic diseases of the dog and cat, L. G. NEUMANN (*Parasites et Maladies Parasitaires du Chien et du Chat. Paris, 1914, pp. X+348, figs. 156*).—The several chapters of this work deal with parasites of the skin, connective tissue and muscles, digestive system, serous membranes, respiratory system, circulatory system, brain and organs of sense, and genito-urinary organs.

Brief mention of parasites of the ferret is made in an appendix (pp. 337-340). A subject index is included.

Investigations of spirochetosis of fowls from Tunis and of *Argas persicus*, which transmits the disease, III, B. GALLI-VALERIO (*Centbl. Bakt. [etc.], 1. Abt., Orig., 72 (1914), No. 6-7, pp. 526-528*).—In this third memoir (E. S. R., 20, p. 1154; 22, p. 392) the author reports finding *A. persicus* which became infected with *Spirochata anserina* to be free therefrom in from nine to ten months. *A. persicus* from Humt-Suk, island of Jerba, caused a fatal chronic disease in fowls, six months after arrival at Lausanne. This tick is very resistant to high and low temperatures and can survive without food for 21 months.

The blood of the fowl in experimental spirochetosis, L. LAUNOY and M. L. BRUHL (*Ann. Inst. Pasteur, 28 (1914), No. 5, pp. 517-539, pl. 1, figs. 6*).—The infection of the adult fowl with *Spirochata gallinarum* causes a rapid and marked anemia in which the erythrocytes are reduced in number by one-half in five days.

Investigations in regard to the blood cells of healthy and sick fowls and pigeons, E. HEDFELD (*Abs. in Deut. Tierärztl. Wchnschr., 21 (1913), No. 17, pp. 266, 267*).—The following kinds of white blood cells were noted: Eosinophil leucocytes with rod-like granulations, eosinophil leucocytes with grain-like granulations, large lymphocytes, small lymphocytes, and basophil leucocytes. The blood was taken from a wing vein. It was noted that in the birds hemato-blasts occur, but the amount is greater under pathologic conditions. Neutrophil cells were never noted.

The absolute number of blood cells per cubic millimeter for erythrocytes was 4,000,000 and for leucocytes 24,000. The differential leucocyte count was as follows: Eosinophils with grain-like granulations, 26 to 30 per cent; eosinophils with rod-like granulations, 10 to 20; large lymphocytes, 12 to 13; small lymphocytes, 42 to 49; and basophil cells, 3 per cent. By treating the birds with either fowl cholera or erysipelas cultures the following blood picture was noted: Hypoleucocytosis followed by a hyperleucocytosis which went up to 101,000, and a rise in eosinophils up to 74 per cent. The birds were also fed with the heart muscle of a goose which died from fowl cholera. After infestation with round worms (*Ascaris megaloccephala* and *A. suis*) the number of white cells was 125,000 and the eosinophils 74 per cent.

RURAL ENGINEERING.

A treatise on the law of irrigation and water rights, C. S. KINNEY (*San Francisco, 1912, 2. ed. rev. and enl., vols. 1, pp. XXXII+1097; 2, pp. XXVIII+1098-2194; 3, pp. XXV+2195-3146; 4, pp. XXI+3147-4558*).—It is the author's aim in this work to cover completely and exhaustively every phase of irriga-

tion and water-right law, and to make it, by way of comparison, world wide in its application. It is presented in four volumes and consists of 14 distinct divisions, which are as follows: Economic questions relating to irrigation and waters; ancient and modern irrigation; classification, definitions, and the nature of waters; rights of the public in waters and water courses; acquisition and disposal of lands and waters by the United States; the common law governing waters; the civil law governing waters; the appropriation of water for beneficial uses; the nature, extent, and character of rights acquired to water by appropriation, rights of way, and the pollution of waters; subterranean waters and rights acquired thereto; international, interstate, federal, state, district, and municipal control; control by private water companies; adjudication and protection of rights—injuries to rights and remedies therefor; and special features and statutory laws of the arid and semiarid States.

Elements of western water law, A. E. CHANDLER (*San Francisco, 1913, pp. 150*).—This book, intended for advanced students in agricultural or civil engineering, contains chapters on the following topics: Early development of the doctrine of appropriation, riparian rights in the Western States, the law of underground waters, the doctrine of appropriation, loss of water rights, water right legislation, water rights on interstate streams, rights of way over public lands for ditches and reservoirs, commercial irrigation enterprises, the desert land act and the Carey act, the reclamation act, irrigation ditches, and the desideratum in legislation regarding the public waters.

Water laws of the State of Oregon (*Salem, Oreg., 1913, pp. 195*).—The text of the state laws pertaining to irrigation, drainage, water-power development, and water supplies is given.

Hydraulics, E. H. SPRAGUE (*London, 1914, pp. 184, figs. 89; rev. in Engin. Rec., 69 (1914), No. 18, p. 514*).—This is a text-book for students and engineers containing chapters on the principles of fluid pressure; liquids in motion; discharge through orifices, weirs, etc.; flow in pipes and channels; and the pressure of water and its application to motors and pumps.

Station of rural engineering and agricultural hydraulics: [Report of tests], R. GAGEY (*Bul. Dir. Gén. Agr. Com. et Colon. Tunis, 17 (1913), No. 71, Sup., pp. 53–87*).—Tests at the station extending from 1898 to 1912 on a large number of agricultural machines and motors, including animal power, and experiments in soils and agricultural hydraulics are briefly reported.

Report of state engineer, Colorado, 1911–12, C. W. COMSTOCK (*Bien. Rpt. State Engin. Colo., 16 (1911–12), pp. 363, pls. 10*).—This report gives information on water appropriation and distribution and includes hydrographic and flood data and data on pumping for irrigation, particularly from wells.

Drainage and irrigation: The duty of water, L. SCHMEER (*Engin. and Contract., 41 (1914), No. 16, pp. 478–481, fig. 1*).—The author defines the duty of water, and discusses it under the heads of net duty, influence of methods of irrigation on net duty, methods of estimating net duty, percolation, gross duty, and method of estimating gross duty. Tables and formulas are included.

Measurement of flowing streams, R. R. LYMAN (*Utah Engin. Expt. Sta. Bul. 5 (1912), pp. 18, pls. 2, figs. 3*).—This bulletin presents in popular language a simple method for using the weir, and is designed for the use of irrigators and others concerned in the measurement of flowing water. Tables of discharges in second-feet per foot of weir and of weir dimensions and discharge diagrams are appended.

An investigation of the use and rating of the current meter, C. P. RUMPF (*Engin. News, 71 (1914), No. 20, pp. 1083, 1084, figs. 4*).—Rating curves from tests of screw and cup current meters under ordinary conditions of movement

parallel with the stream flow, and also to show the effect of cross-currents at angles with the stream flow, are given.

A comparative rating curve of the two meters shows that both give practically a straight line, but the results from the screw type are slightly more consistent. When turned at angles varying from 0 to 90° by increments of 10° with the stream flow, the revolutions of the screw meter were decreased almost proportionately to the number of degrees turned, while the revolutions of the cup meter were increased when turned with its head to the left and decreased when turned to the right. Both meters followed their regular rating curves in all ordinary depths, but when brought nearer the surface than 1 ft., measuring from the center of the wheel, the revolutions of both were decreased, and when brought nearer the bottom than 6 in. the revolutions of the cup meter were decreased and those of the screw meter increased.

The revolutions of the cup meter were increased if the open part of the cups was near the side of the tank as the meter advanced, but were decreased if the point of the cups was near the side. The side swaying of the rating car decreased the revolutions of the screw meter and increased those of the cup meter. Rating the screw meter backwards decreased its revolutions. When the meters were only partially covered, as in very shallow water, the curves were very eccentric. Curves for the cup meter were the same whether or not the tail was attached.

See also a previous note by Scobey (E. S. R., 31, p. 288).

Methods of finding center cut for economic locations of banked irrigation ditches, F. C. SNOW (*Engin. and Contract.*, 41 (1914), No. 16, pp. 481, 482, figs. 3).—Formulas and methods for computing diagrams for determining the center are given, with a sample diagram.

Centrifugal pumps for irrigation, C. F. BRAUN (*West. Engin.*, 3 (1913), No. 2, pp. 124-138, figs. 14).—It is the purpose of this article "to point out a few features, which, if carefully regarded, make the centrifugal pump a highly efficient, very reliable unit, capable of delivering water at surprisingly low cost, and of competing with gravity canal systems."

The author deals with the design of both turbine and volute pumps, discussing multi-stage pumps, centrifugal pump limitations, multi-impeller pumps, mechanical details, clearance bushing rings, hydraulic-balance, thrust-bearing, materials of construction, pump characteristics, methods of drive and installation, and cost.

Irrigation, J. L. COULTER and R. P. TEELE (*Thirteenth Census U. S.*, 5 (1910), pp. 827-876, pl. 1, figs. 15).—This is a more extensive report of work previously noted (E. S. R., 28, p. 888).

Irrigation pumping in Nevada, C. A. NOBCROSS (*Nev. Bur. Indus., Agr., and Irrig. Bul.* 8 (1913), pp. 78, figs. 35).—It is the purpose of this bulletin to show the practical outlook for irrigation pumping in Nevada within lifts of 50 ft. In dealing with the underground water supply the general principles governing surface and artesian water are discussed from the standpoint of pumping. Methods of computation of the cost of pumping water are described, and tables are given of the cost per irrigated acre with different kinds of power and at pumping lifts up to 50 ft. In dealing with pumping efficiency and types of pumps the several kinds of pumps adapted to low-lift irrigation pumping are discussed. A final section dealing with wells, pits, and reservoir construction gives practical information in relation thereto, including the cost of drilling artesian wells.

Irrigation, C. H. PEAD (*Proc. Rhodesia Sci. Assoc.*, 12 (1913), pt. 3, pp. 152-161).—The author attempts to point out the economic possibilities of irrigation in Rhodesia.

Drainage, LESSMANN (*Illus. Landw. Ztg.*, 34 (1914), No. 30, pp. 289, 290, figs. 7).—This is a discussion of land drainage from the German viewpoint, giving information as to depth and distance between drains in different soils.

Moor drainage, A. VON VEGESACK (*Mitt. Balt. Moorver.*, 3 (1913), No. 1-2, pp. 63-84, figs. 2).—The author discusses the economic importance of swamp-land drainage, methods, and related subjects, and reports drainage experiments conducted in 1911 and 1912 on an undecomposed lowland swamp soil of uniform chemical composition and varying in depth from 4 to 6 meters (13.1 to 19.7 ft.). Sixteen drainage combinations were tested, the depths being 90 and 130 to 135 cm., the distance between drains 15, 20, 30, and 40 meters, and the types of drain being clay tile and poles. Only the ground water level movements midway between drains during the different seasons are so far reported.

The following tables show the depths of ground water level as established by the different drainage combinations:

Position of water table with 90 cm. drainage depth.

Distance between drains.	Middle of May.		Middle of June.		Middle of July.		Middle of August.		Middle of September.		Average.	
	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.
<i>Meters.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>
15	68.4	62.9	65.8	61.3	79.0	72.1	79.4	72.1	65.6	62.7	71.6	66.3
20	70.0	64.0	65.6	59.8	79.5	73.6	81.1	72.9	65.3	62.1	72.3	66.5
30	62.8	62.9	58.3	59.6	77.6	75.5	78.9	74.3	59.0	60.0	67.3	66.5
40	61.0	63.2	54.7	60.4	76.2	77.9	78.1	83.6	55.0	59.8	65.0	68.9

Position of water table with 130 to 135 cm. drainage depth.

Distance between drains.	Middle of May.		Middle of June.		Middle of July.		Middle of August.		Middle of September.		Average.	
	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.	Pole drain.	Tile drain.
<i>Meters.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>
15	80.5	89.0	79.4	88.4	89.5	116.1	88.1	119.2	74.8	87.0	82.5	99.9
20	77.9	92.7	72.6	87.1	87.4	105.4	90.8	113.5	70.8	95.1	89.9	98.3
30	60.7	83.9	57.3	79.0	88.4	102.4	85.5	114.7	59.1	88.0	70.2	93.6
40	51.7	52.6	48.0	56.1	79.4	89.6	83.6	96.0	56.8	65.0	63.9	71.9

The ground water level reached a position of equilibrium more quickly and fluctuated less with the shallower than with the deeper drainage, and with deeper drainage it rose higher in wet periods and sank lower in dry periods. With deeper drainage the tile drains had a more intensive effect than the pole drains, and only in case of sudden heavy rainfall did the water level rise higher with the tile than with the pole drains. The tile were on the whole the more effective at both drainage depths, and at all distances between drains except with the shallow drains 15 meters apart.

Blasting experiments with agricultural dynamite, H. VON FEILITZEN (*Svenska Mosskulturfor. Tidskr.*, 27 (1913), No. 3, pp. 262-281, figs. 10; 28 (1914), No. 1, pp. 29-34, figs. 3; *abs. in Mitt. Balt. Moorver.*, 3 (1913), No. 4, pp. 205-207).—Experiments in subsoiling, soil drainage, and stump removal by blasting are reported.

Blasts in a sandy soil overlying a hardpan with the holes spaced 15 ft. apart and bored through the hardpan pulverized the soil within a radius of 1 to 2

meters, but beyond that the hardpan was intact. Drainage experiments in brush-covered sand soil and in upland moors were fairly successful as were also stump blasting experiments. It is concluded that blasting is an effective process for ditch digging, tree planting, and stump removal, and that the value of subsoil blasting will depend upon the original productiveness of the soil, the gain in productiveness, and the cost of the operation.

Laws of Missouri relating to roads, highways, and bridges, 1913, C. ROACH (*Jefferson City, Mo., 1913, pp. 136+XIII*).—A text of these laws is given.

Design and construction of earth roads in Iowa, T. R. AGE (*Engin. News, 71 (1914), No. 16, pp. 821-825, figs. 10*).—The author deals with the work of the Iowa Highway Commission relative to the improvement of earth roads. The cross-sections adopted for these roads are illustrated and explained, and the limiting grades are given together with recommendations for alignment at railway grade crossings and on curves. The use of the elevating grader is explained, and the cost of road work done by this machine and equipment in Iowa is given.

Forms for concrete work, A. GRAHAM (*Abstr. in Concrete and Construct. Engin., 9 (1914), No. 5, pp. 339-344*).—Brief specifications are given for forms for concrete work in general and for silos and bridges in particular.

Knots, hitches, and splices, H. W. RILEY (*Cornell Reading Courses, 1 (1912), No. 8, pp. 45-88, figs. 201*).—It is the purpose of this pamphlet to show "as clearly as possible each step in the quickest and easiest methods of making such knots, hitches, and splices as will be found most generally useful."

Economical selection of belts and pulleys, W. F. SCHAPHORST (*Power, 39 (1914), No. 17, pp. 588-590, figs. 4*).—Data are given pertaining to the selection of pulleys and belts for the purpose of obtaining the best results with the least initial cost. Tables and curves are employed to assist in making a determination of pulley and belt sizes.

Standard American gas and oil engine, automobile, and farm engine guide, STEVENSON and BROOKES (*Chicago, 1913, pp. 719+232+243, pls. 4, figs. 487*).—This is an encyclopedia of the construction and operation of gas and oil engines, containing information on questions relating to the care, construction, and operation of gasoline and electric automobiles, farm and traction engines, and a threshing machine, including a full description of its various parts and their uses. Questions and answers for examination when applying for an engineer's license are also given.

Working up a boiler test, F. R. LOW (*Power, 39 (1914), No. 17, pp. 592-595*).—An efficiency test is worked up item by item in which some of the more important features are the reduction to a dry coal and combustible basis; how to find the evaporation per pound of coal as fired, per pound of dry coal, or of combustible material under actual conditions, or from and at 212° F.; and different boiler efficiencies, boiler horsepower, and cost per 1,000 lbs. of steam.

A graphic representation of traction efficiency resulting from practical tests and experience (*Farm Machinery, No. 1175 (1914), p. 19, fig. 1*).—A curve showing the traction efficiency of the tractor, the percentage of slip of drive wheels, and the number of plows, shows that with a 20,000-lb. tractor under average conditions the slip with 2 plows is 1 per cent; with 8 plows, 8 per cent; with 10 plows, 20 per cent; and with 12 plows, 38 per cent. With 14 plows the tractor does not move, but spins the drivers.

The modern gas tractor, its construction, operation, application, and repair, V. W. PAGE (*New York, 1913, pp. 475, pls. 3, figs. 201*).—This is a nontechnical treatise intended as a guide for the average farmer and mechanic, in which the endeavor has been made to present some principles of design of

the gas tractor. It is the author's purpose to discuss the engineering features of various constructions only with a view of familiarizing the reader with the salient points of design so that the advantages of the various systems of construction may be intelligently analyzed and the mechanism best adapted to individual requirements be selected.

The subject matter is presented under the following chapters: The scope, advantages, and applications of power traction; review of conditions on which tractor design is based; design and construction of gas tractor power plants; gas tractor power-plant components; making and exploding the gas; cooling and lubricating the power plant; functions and construction of clutch, gear set, and differential; the tractor frame, wheels, and axles; driving and housing the traction engine; traction-engine troubles and their elimination; and miscellaneous rules and formulas.

Plowing by electricity in Italy, L. J. KEENA (*Daily Cons. and Trade Rpts. [U. S.]*, 17 (1914), No. 90, pp. 316, 317).—Data are quoted which show that electrical power for plowing, when secured at 3, 4, and 5 cts. per kilowatt hour, is considerably cheaper than steam or animal power.

Electricity for country houses (*Sci. Amer. Sup.*, 17 (1914), No. 2000, pp. 287, 288).—The subject is discussed from the English standpoint, dealing particularly with the generator and accumulator and quoting prices.

Report of the departmental committee on the probable duration of buildings and other works for small holdings (*London: Bd. Agr. and Fisheries*, 1912, pp. 21).—Numerous inspections made in England and Wales on buildings, fences, and roads for small farms are reported. A large proportion of the timber buildings and fences which have been in existence for from 20 to 80 years were found to be in good condition. The report favors the use of corrugated galvanized iron in the construction of farm buildings.

The dwelling and the dampness of the dwelling, H. STEINBERGER (*Die Wohnung und die Wohnungsfeuchtigkeit. Berlin*, 1914, pp. 116, figs. 17; rev. in *Gsndhts. Ingen.*, 37 (1914), No. 12, p. 225).—This book, intended for tenants, house owners, architects, and engineers, treats of the sanitary aspects of house location and construction, with particular reference to dampness in walls and atmosphere, and the insanitary conditions resulting therefrom. Various methods of preventing dampness and the growth of injurious fungi are considered, including a discussion on heating and ventilation.

Homemade silos, H. RABILD, A. K. RISSER, and K. E. PARKS (*U. S. Dept. Agr., Farmers' Bul.* 589 (1914), pp. 47, figs. 37).—This discusses the general considerations regarding silos, points out the essential features in their construction, and gives detailed instructions for building the concrete, stave, and the modified Wisconsin silo. The part relating to the stave silo is a revision of a previous circular (E. S. R., 20, p. 688). It is pointed out that to make the silo a profitable investment one should have at least ten cows or their equivalent in other stock owing to the cost of the silo and the silo-filling machinery.

The concrete silo is said to have the advantage of the other two types in permanency and stability but is, as a rule, more expensive. The stave silo is cheap and easily and quickly constructed, but it is a temporary structure lasting only from 5 to 15 years, depending on the kind and quality of lumber used in its construction, and the climate. It is considered to be more liable to blow down, fall down, or otherwise get out of repair than either of the other types of silos. The modified Wisconsin silo is said to be more substantial than the stave silo and is recommended for sections where it is inconvenient to secure hoops or lugs for stave silos. The two objections to this type of silo

are that it is difficult to build with a diameter less than 14 ft. and that it has an unfinished appearance.

Four cheap silos, C. I. BRAY and D. R. FORRESTER (*Oklahoma Sta. Circ. 33* (1914), pp. 16, figs. 14).—This circular gives information regarding the construction of (1) the homemade 2×6 stave silo, (2) the flooring silo with wooden hoops, (3) pit silos, and (4) the homemade concrete block silo.

Lightning rods, W. H. DAY (*Ontario Dept. Agr. Bul. 220* (1914), pp. 38, pl. 1, figs. 39).—This bulletin describes and analyzes lightning action and the lightning discharge and stroke with reference to buildings, fences, animals, and human beings. It describes the principles of lightning rods and gives directions for their proper installation on farm buildings. It is concluded from the results of extended investigations "that lightning rods properly installed are almost absolute protection against lightning."

Domestic refrigeration (*Lait. Belge, No. 4* (1914), pp. 37-43, figs. 2).—A description and general data are given concerning small refrigeration plants designed especially for use in homes and restaurants and in which the refrigeration is obtained by means of an electrically operated carbon dioxide compressor.

A comparative study of circular and rectangular Imhoff [sewage] tanks, T. S. JOHNSON (*Bul. Sci. Labs. Denison Univ., 17* (1914), Art. 9, pp. 341-367, figs. 5).—This thesis attempts an economic design of two Imhoff sewage tanks as applied to the disposal plant of a small community and makes comparisons of rectangular and circular tanks with special regard to costs and clarification efficiency. The comparison of cost data only slightly favors the circular tank, and the author concludes "that the advantage of the circular radial-flow type of Imhoff tank over the type known as rectangular-linear flow must lie mainly upon its advantages as to clarification efficiency. And here, too, enough questions will arise to make the problem one that can be best solved for each location or installation."

A bibliography is appended.

[Telephony in rural districts] (*Electrician* [London], 72 (1914), No. 25, pp. 1035-1038, figs. 6; *abs. in Elect. World*, 63 (1914), No. 17, p. 947).—This is an illustrated article on the Steidle telephone system in use in Germany. There are used a manual main exchange and automatic subexchanges.

The loose leaf drafting manual, C. B. HOWE (*New York and London, 1913*, pp. 82, figs. 146).—A number of exercises in machine and agricultural drafting are given.

RURAL ECONOMICS.

Depopulation of rural districts, E. LAUB (*Fühling's Landw. Ztg., 63* (1914), Nos. 1, pp. 1-22; 2, pp. 53-62).—The author, by a study of the peoples of various countries whose population aggregates over 350,000,000 persons, shows that the urban population is increasing faster than the rural, so that the rural population forms a decreasing proportion of the total. It is only in the older countries, however, that there has been an actual decrease in the rural population. Some of the causes contributing to the migration of people from rural districts are low wages, long hours of work, and the lack of social standing, outlook for the future, amusements, and opportunity for marriage. In many instances there is no provision for old age nor chances for making a large income such as are found in the cities. In many cases the influence of the school does not tend to build up the rural community.

The progress of the small holdings movement (*Bd. Agr. and Fisheries* [London], *Ann. Rpt. Proc. Small Hold. and Allot. Acts* [etc.], 1913, pt. 1, pp. 58; *abs. in Jour. Bd. Agr.* [London], 21 (1914), No. 2, pp. 157-159).—Since the

passage of the Small Holdings Act for England and Wales, applications for small holdings have been made to the county councils by 43,245 individuals and 89 associations, and the total quantity applied for amounts to 723,497 acres. Of the individual applicants, 25,567 have been provisionally approved as suitable and 17,005 of them have obtained holdings. Only 24 per cent of the applicants in 1913 were agricultural laborers. Only a very small percentage of the applicants have expressed a desire to purchase holdings.

The interest of the individual in the operations of large farms, G. SCHULZE (*Landw. Jahrb.*, 46 (1914), No. 1, pp. 41-88).—The author discusses various means that can be employed to arouse an interest among the workers on large agricultural establishments similar to that of ownership. Among the means mentioned are premiums or supplementary wages, sharing in the profits, and the working up of rivalry by assigning a portion of the farm to an individual or a group of individuals. In the care of animals he found a natural pride that is easily stimulated by the use of any of the above means. A brief bibliography is included.

Increasing the efficiency of workers, АРЕВНОЕ (*Deut. Landw. Presse*, 41 (1914), No. 46, pp. 563, 564).—The author calls attention to the fact that the labor supply is one of the most serious of the agricultural problems. He suggests that by the use of the Taylor system the methods of performing farm operations might be improved and the effectiveness of the worker increased.

[Condition of country women], G. SCANNI (*Bol. Quind. Soc. Agr. Ital.*, 19 (1914), No. 9, pp. 313-327).—This article contains abstracts from answers to a questionnaire sent out by the Italian Agricultural Society to ascertain the types of work performed by women on farms and the extent of their migration.

Yearbook of international cooperation, H. MÜLLER (*Ann. Mouv. Coop. Internat.*, 2 (1912), pp. VI+299, pl. 1).—This is a French edition of this yearbook, previously noted (*E. S. R.*, 30, p. 693).

Proceedings of the third provincial cooperative conference held at Mysore (*Proc. Prov. Coop. Conf. Mysore*, 3 (1913), pp. 100).—Among the various papers presented at this conference were the following: Cooperation and State Aid by N. M. Rau; Cooperation in its Relation to Agriculture by Dr. Coleman; Cooperative Movement and the Development of Agriculture by K. S. Rau; Cooperative Credit—Why it Has Taken Root in India in Preference to Other Forms of Cooperation by A. V. Ramanathan; Cooperative Banking Unions by H. Ramachandriah; and Mutual Cattle Insurance Societies in Burma.

The private control and the intervention of the State in matters relating to cooperation, B. MICHEL (*Egypte Contemporaine*, No. 19 (1914), pp. 377-412).—This article gives a brief history and description of the development of cooperative organizations and the function of the State in regard to their control in Germany, England, France, Italy, Roumania, Algeria, and British India.

Report on rural credits and cooperation, J. CUNNINGHAM and W. M. BROWN (*Columbus, Ohio*, 1914, pp. 85).—The authors describe the development of rural credit and cooperation in European countries and its present status in Ohio.

They found that the agricultural credit conditions in Ohio were not satisfactory. In that a high rate of interest is charged, and the amortization plan of repayment is not employed. A number of cooperative associations were found but their number could be extended to the advantage of the farmer. They recommend that a bureau of markets be established and outline as some of the functions to be performed by it the promotion of efficiency and economy in production and distribution; furnishing information on cooperation, accounting and business methods, and legal rights and duties of cooperative agencies; drafting model by-laws for cooperative societies; establishing city markets for

farm produce; and investigating the practice of commission merchants. As appendixes to their report they give the constitution and by-laws of different types of cooperative organizations.

[Laws of Indiana relating to rural loan and savings and building and loan associations] (*Indianapolis: State, 1914, pp. 12+29*).—There have been brought together in this pamphlet the laws regarding the building and loan associations and those relating to rural loans and savings associations.

Cattle loan banks, J. F. EBERSOLE (*Jour. Polit. Econ., 22 (1914), No. 6, pp. 577-580*).—The cattle loan company is a middleman between the borrowing cattle owners and the lending bank manager. It deals principally with large cattle growers. When a loan is desired the company sends an examiner who passes upon the plant, the cattle, and the business capacity of the cattle grower. If the request is acted upon favorably a promissory note and a chattel mortgage are taken. The notes are indorsed by the company and sold and become equivalent to a "debenture" issued by a pledge of specified assets held by the company for the protection of the note holders. The rate charged the borrower on this type of paper ranges from 7 to 10 per cent, of which the purchaser receives 5 to 6 per cent on his money and the remainder goes to the loan companies.

The cooperative insurance of pigs (*Bd. Agr. and Fisheries [London], Coop. Ins. Pigs, 1914, pp. 9+16+8+13*).—This report states that in 1908-9 less than 2 per cent of the pigs in Great Britain were insured. The experience of societies in insuring pigs shows that the average net income from insurance contributions is less than 2s. per pig per annum. The report also includes model rules for registered and unregistered rural cooperative pig insurance societies and gives an explanation of the rules.

Cooperation among farmers, especially in marketing, A. W. SANBORN (*Wis. Bd. Agr. Bul. 2 (1913), pp. 16*).—The author contends that since the farmer has but a small amount of any one product to market, he can not sell it to the best advantage by operating alone. After noting the influence of cooperation in European countries, he calls attention to some of the essentials for success. Among those mentioned are an agreement whereby the members promise to furnish the cooperative societies their entire products for a stated period; a capable manager; a good system of accounting; proper arrangements for grading the produce; and the adoption of the principle of one member one vote. Some of the benefits to be derived from cooperation are its educational influence, increased efficiency in production, better market for agricultural products, and a greater share in the profits of distribution.

Consumer's view of producers' organizations, RUBY G. SMITH (*Farm Poultry, 25 (1914), No. 6, p. 111, fig. 1*).—The author believes that organized producers cooperating with organized consumers will establish more economical methods for transporting, storing, selling, and delivering farm produce. The consumer will welcome standardized goods at lower prices, honestly weighed and measured.

Theoretic basis of the statistics of international statistics of agriculture, U. RICCI (*Les Bases Théoriques de la Statistique Agricole Internationale. Rome: Inst. Internat. Agr., 1914, pp. XII+314, figs. 8*).—The International Institute of Agriculture is attempting to devise a method whereby the area and production statistics as gathered by the various nations may be so modified or reported as to obtain uniformity and accuracy in making summary statements. The author outlines the classification of land according to its agricultural uses and the methods of reporting conditions and yields of agricultural crops. He decides that the system whereby the facts are expressed as a varia-

tion from 100, using the average for the last 10 years as a basis, is the one best adapted to their purpose.

Statistical annual for 1914, E. G. OSMAN (*Price Current-Grain Rptr. Statis. Ann. 1914*, pp. 56).—This report contains statistical data showing the quantity of meats packed, prices of meat, meat products, and live stock, and their movement at the principal centers of the United States, and for a series of years. The production, movement, and prices of grain are also shown.

A geographic study of the growth and distribution of population in Michigan, O. W. FREEMAN (*Rpt. Mich. Acad. Sci.*, 15 (1913), pp. 39-53, figs. 11).—The author shows that between 1900 and 1910 the number of persons in rural districts decreased in 45 of the 82 counties in the State. The cause for this decrease is that not only are the younger generation leaving for the cities but there is a decrease in the average size and in the number of families. He includes a series of maps showing the density of the population by counties, beginning with 1820.

Michigan agriculture, its present status and wonderful possibilities, R. S. SHAW (*Michigan Sta. Spec. Bul. 70* (1914), pp. 3-23, figs. 8).—This bulletin is a digest of the information obtained by the Thirteenth Census concerning agriculture.

The author points out that 51.5 per cent of the total land area is in farms and 67.8 per cent of the land in farms is improved. Among the principal conditions which have retarded the agricultural development have been the large areas covered with heavy timber, the sand areas, and much land that needed drainage. In spite of these handicaps, the author considers that Michigan has made a very favorable progress. He calls attention to the wide range of crops and live stock produced in the State and the relative importance of Michigan in the production of each. A single tabular statement consolidating practically all the statistics collected by the last census of agriculture by counties is appended.

Report of the Grain Markets Commission of the Province of Saskatchewan (*Rpt. Grain Markets Com. Saskatchewan, 1914*, pp. 150+III, pls. 2).—Among the conclusions reached by this commission were that exclusive grain raising as practiced by even the best farmers is not remunerative, that it costs the farmers more to have the exportable surplus of western Canada grain crops placed on the present ultimate market than the farmers of any other large exporting country have to pay, and that all terminal and transfer elevators as well as internal terminal storage elevators should be owned and operated by the Dominion Government as some already are. It recommends that every possible encouragement be given to bring about greater diversity in the products of the farms, that there be a reorganization of agricultural credit facilities, an extension of cooperative marketing, improved transportation facilities, and the storage of grain on the farms instead of public warehouses.

Future of tropical America (*London, 1913*, pt. 2, pp. III+60, pls. 49).—This is a continuation of the publication previously noted (E. S. R., 29, p. 896), and contains information concerning the West Indian Islands.

Agriculture of Argentina, 1912-13, E. LAHITE (*Estad. Agr. [Argentina]*, 1912-13, pp. 187).—This report contains statistical data showing for 1872, 1888, 1895, and 1912 the population, length of railroads, total area cultivated, and area in principal crops. There are also shown for 1911-12, with comparative data for earlier years, the area, production, amount of seed used, and amount exported and consumed at home for wheat, flax, corn, and oats, the number and value of agricultural implements imported, and other data concerning the manufacture of agricultural products and the number and movement of live stock.

The agriculture of Netherlands, 1813-1913 (*De Nederlandsche Landbouw in het Tijdvak 1813-1913, The Hague: Dept. Landb. [1913], pp. VII+465*).—This book contains a number of articles concerning the development of agriculture in Netherlands during the last 100 years. Among the more important articles are Legislation Concerning Agriculture, by L. E. J. F. Mollerus; Agricultural Associations, by C. G. J. A. van Genderen Stort; Agricultural Cooperation, by G. J. Bieleman; The Cultivation of Field Crops and Grass Land, by H. K. H. A. Mayer Gmelin and T. J. Mansholt; The Breeding of Cattle, by L. Broekema; The Breeding of Horses, by A. W. Heidema; and The Breeding of Small Animals, by F. B. Löhnis.

Commerce in agricultural products, fruits, vegetables, and flowers, E. POHER (*Le Commerce des Produits Agricoles, Fruits, Légumes, Fleurs. [Paris], 1912, pp. 498, figs. 128*).—The author gives a detailed description of the organization of markets, cooperative selling, methods of packing, transportation and rates, preservation, prevention of fraud, and international markets and French commerce. A large number of illustrations are given showing various types of containers and other phases in the distribution of the above products.

Agricultural statistics of Denmark (*Danmarks Statist. Meddel., 4. ser., 42 (1914), No. 1, pp. 63*).—Contained in this report are statistical data showing by minor subdivisions the total yield and value of farm crops. For Denmark as a whole, comparative data are shown for earlier years.

[The agriculture of the Belgian Congos], H. BÜCHEL (*Tropenpflanzer, Beihefte, 15 (1914), No. 4-5, pp. 329-374*).—The author describes the various types of agricultural plants and animals found in this country and discusses various phases of the trade in palm nuts and oil, India rubber, and ivory.

AGRICULTURAL EDUCATION.

Report of the Royal Commission on Industrial Training and Technical Education (*Roy. Com. Indus. Training and Tech. Ed. [Canada], Rpt. 1913, pt. 1-2, pp. XIV+437; pt. 3, vols. 1, pp. XXII+443-1011+XVIII, figs. 56; 2, pp. XXIV+1011-1633+XV, figs. 93; pt. 4, pp. XXV+1639-2354+XXIX*).—This is the report of the commission already discussed editorially (E. S. R., 31, p. 401).

Among the provisions recommended by the commission as necessary in a system or systems of industrial training and technical education for Canada are the following for rural communities: (1) Intermediate rural classes or schools with 2-year courses of from five to seven months each and the rest of the year at a farm or home. (2) Rural high schools offering 4-year courses, the first two of which would be similar to the intermediate rural school with the exception that each school year might be longer. Science subjects should be taught particularly in relation to their application to rural work and problems and the principles underlying the systems, methods, and operations of farming and housekeeping. They should prepare students for engaging in rural occupations and housekeeping and for admission to agricultural, housekeeping, and arts colleges. In both these types of schools for pupils having completed the elementary school, the work should provide for a series of experiences in proper sequence relating to the conditions of farming and housekeeping in the area served. (3) Resident or traveling county or district instructors for farming to act as advisers in coordinating the school work and farm projects carried on at home by pupils attending the intermediate rural schools and rural high schools; to arrange for short courses for young men not attending these schools; to provide systematic short demonstration courses in soils, live stock, farm machinery, etc., for adults, and to become associated with the work of a neighbor-

hood improvement association and an illustration farm for the locality, similar to those arranged for by the committee on lands of the Commission of Conservation. (4) Resident or traveling district instructresses in housekeeping to meet a class of women arranged for by a women's institute or other similar organization in the locality, one-half day a week for a term of 20 weeks, and to carry on work for the other half of the same day with the girls and teachers in an elementary, intermediate, or high school of the locality, to act in an advisory capacity as coordinators for housekeeping projects carried on at home by pupils of the intermediate rural schools and the rural high schools, and to provide demonstration lectures in cooking and housekeeping. (5) County or district agricultural and housekeeping residential schools for students 17 years and over with 1 or 2-year courses and also short courses of from one to three months in special subjects and industries. The courses should provide for a series of experiences in proper sequence to enable students to acquire a wider knowledge of the principles underlying the systems, methods, operations, and processes of their special occupation and a wider range of knowledge and skill in the actual management of soils, crops, live stock, products, and homes, in the use of machines, tools, and utensils, and in the making of things. (6) Young people's social service schools similar to the people's high schools of Denmark. (7) Schools for agricultural apprentices, necessary only in those portions of Canada where settlement is comparatively new, which would pay particular attention to the training of pupils in manual dexterity in the ordinary farm operations, such as plowing, seeding, stacking, threshing, etc. (8) Agricultural and home economics colleges. (9) Correspondence study courses in connection with agricultural and housekeeping colleges or other central institutions.

Vocational education in Indiana (*Dept. Pub. Instr. [Ind.], Ed. Pubs., Bul. 6 (1914), pp. 48*).—The purpose of this bulletin is to give information to superintendents and local school boards relating to the establishment and administration of state-aided vocational schools. It treats of the problem of vocational education in Indiana, constructive provisions of the vocational education law, the function, work, and kinds of vocational schools, their organization and administration, and a copy of the Indiana vocational education law of 1913.

Regulations governing vocational agricultural schools and departments in Indiana (*Dept. Pub. Instr. [Ind.], Ed. Pubs., Bul. 7 (1914), pp. 15*).—This bulletin gives information concerning the establishment of vocational agricultural schools and departments in accordance with the provisions of the Indiana vocational education law of 1913.

Agriculture and domestic science in the Harlem (Ill.) Consolidated School, C. C. BURNS (*Atlantic Ed. Jour., 9 (1914), No. 8, pp. 300-302*).—A detailed description is given of the instruction, following a course in nature study beginning in the first grade, including agriculture in this school in the seventh and eighth grades and four years of the high school, and home economics in the seventh and eighth grades and continuing through three years of the high school.

The Farragut School, A. C. MONAHAN and A. PHILLIPS (*U. S. Bur. Ed. Bul., No. 49 (1913), pp. 23, pls. 6*).—Following a history of the school the authors describe the buildings, equipment, school grounds, curriculum, community service, and results of the Farragut High School, at Concord, Tenn., which represents a most successful attempt at adapting the organization, work, and ideas of the country school to the needs of country life. A list of the agricultural, carpentry, sewing, and cooking equipment of the school is appended.

School gardens at St. Paul, Minn., E. L. FINNEY (*Rural Educator, 3 (1914), No. 4, pp. 73, 74, figs. 5*).—Notes are given by the director of school gardens on the school and home garden work in St. Paul, where school gardens were con-

ducted in 15 centers with an enrollment of over 1,200 children. The per capita cost per month of the gardens was 36 cts. They are operated for the benefit of children in the fourth grade only. Children above this grade must have home gardens.

The third annual report of the School Garden Association of America (*Ann. Rpt. School Garden Assoc. America*, 3 (1914), pp. 16, figs. 6).—Reports of the president, treasurer, and secretary of the association are given.

The University Home and School League (*Bul. Univ. Tex.*, No. 322 (1914), pp. 62).—The University Home and School League, which is fostered by the department of extension of the University of Texas, has for its object closer cooperation of the school, the home, and the church of the community for mutual improvement. Its purposes, organization, and activities are outlined. Suggestions to the program committee and references to literature on social center work and rural life are also given.

Extension work of the Louisiana State University, A. F. KIDDER (*Rice Jour. and South. Farmer*, 17 (1914), No. 4, pp. 1, 2).—The author gives an account of the various phases of the agricultural extension work of the university.

Boys' and girls' clubs, W. R. HART and O. A. MORTON (*Boston: Mass. Bd. Agr.*, 1914, pp. 32, pls. 8).—This publication contains a brief history of the boys' and girls' clubs in Massachusetts from 1908 to 1913, inclusive, lists of premiums, rules governing clubs and contests, and suggestions for the organization and promotion of boys' and girls' club work.

The pig clubs of the South, B. W. CURRIE (*Country Gent.*, 79 (1914), No. 16, pp. 786, 787, 808, figs. 5).—An account is given of the boys' and girls' pig club work in Louisiana and Georgia.

Agricultural education in Latin America, C. D. SMITH (*Proc. Soc. Prom. Agr. Sci.*, 34 (1913), pp. 73-94).—The systems of agricultural education in Brazil, Uruguay, Argentina, Peru, and Chile are described.

The educational system of rural Denmark, H. W. FOGHT (*U. S. Bur. Ed. Bul.*, No. 58 (1913), pp. 46, pls. 6).—The educational system of rural Denmark is outlined in detail as the result of a personal investigation by the author.

Instruction in nature study is given in the first seven or eight grades. In the four years after leaving the elementary school the children learn practical agriculture and household duties at home or are apprenticed at recognized model farms where they get the benefit of the knowledge of specialists in farm science maintained in the field at state and local expense. Statistics for 1906 show that 33 per cent of all young men, and a slightly smaller number of young women, of 18 years and over, attend the folk high school for a longer or shorter period, while 14 per cent of the young men attend special agricultural schools in addition to the agricultural studies offered in many of the folk high schools and a considerable number of young women attend the special domestic-science schools.

Most of the agricultural schools, of which there are 29 scattered throughout the country, require that applicants must have spent some time at a folk high school, and if lacking in practical training, must secure this at one of the government-recognized model farms before they are admitted, these schools teaching primarily the theory of agriculture, land surveying, agricultural chemistry, and the other sciences which underlie the practice of agriculture. There are also so-called "Husmandsskoler," organized particularly for the small farmer, which combine the most valuable features of the folk high schools with those of the agricultural schools and make a strong point of short courses. Such subjects as bee culture, chicken raising, rabbit breeding, etc., receive much attention.

Students wishing to become government experts in agricultural subjects may spend one or more years in study and research at the Royal Veterinary and Agricultural Institute at Copenhagen. Strong schools of household economics are maintained for the women. "The most important task performed by educationists in Denmark has been to impart a remarkably large store of culture without giving the people a contempt for work with the hands."

Schools for fruit growing, H. W. HARRIS (*U. S. Bur. Ed. Bul.*, No. 54 (1913), pp. 66-75).—An account is given, by the consul general at Frankfort-on-the-Main, of the administration, buildings and equipment, curriculum, etc., of the Grand Ducal School for Fruit Growing at Oppenheim-am-Rhein, and of the Provincial School for Fruit Growing at Kreuznach.

Nature study, I. L. KANDEL (In *Elementary Education in England With Special Reference to London, Liverpool, and Manchester. U. S. Bur. Ed. Bul.*, No. 57 (1913), pp. 56-59).—An account is given of the nature study work in elementary schools of England, which includes the study of plants, trees, flowers, and animal life.

Continuation schools; Short courses for colleges, normals, and high schools, A. W. NOLAN (*Agr. Col. Ext. Univ. Ill. [Circ.]*, 1914, Jan., pp. 16, figs. 2).—The courses in agriculture, English, hygiene and good health, history and civics, business arithmetic, and household science outlined in this circular have been successfully given in a few schools. For a beginning a maximum length of six weeks is advised for these courses, which are intended for young men and women and adults of the community who have no prospects for a complete high school course.

A manual of agriculture for the eighth grade, A. M. RICHARDSON (*Wash. (State) Dept. Ed. Bul.* 21 (1914), pp. 27).—This manual is intended to form the basis for the examination in agriculture for the eighth grade in the schools of the State of Washington, in which agriculture is required by the state board of education. Forty-nine exercises are outlined including practically every phase of agriculture. It is stated that if possible they should be studied according to seasons.

Studies of commercial fertilizers, B. M. DAVIS (*Nature-Study Rev.*, 10 (1914), No. 4, pp. 122-129).—Two exercises which should be within the capacity of the seventh and eighth grade pupils are presented, viz., (1) estimating the value of a commercial fertilizer, and (2) calculating the amounts of fertilizer ingredients in the home mixing of fertilizers and in estimating comparative values of fertilizers.

Weed collections for schools, F. J. PIPAL (*Purdue Univ. Dept. Agr. Ext. Bul.* 27 (1913), pp. 12, figs. 8).—Directions for collecting, preserving, and mounting weeds, and suggestions to teachers of studies of weeds that may be made in connection with this work are given, as well as a list of the worst Indiana weeds.

List of workers in subjects pertaining to agriculture and home economics in the U. S. Department of Agriculture and in the state agricultural colleges and experiment stations (*U. S. Dept. Agr., List of Workers in U. S. Agr.*, 1914, pp. 90).—This is an organization list of workers along these lines, and includes in the case of this Department brief statements as to organization and scope of its various branches.

NOTES.

Delaware Station.—Dr. J. J. Taubenhaus has been made associate research plant pathologist.

Purdue University.—Oscar G. Anderson has been appointed instructor in pomology in the school of agriculture.

Maryland College and Station.—The faculty has voted to grant annually a restricted number of certificates of merit (usually three) to men who have achieved distinction in some field of agricultural activity, and in this way tended to advance the economic, social, or moral conditions of rural life. For the present these honors are to be confined to citizens of the State, but ultimately it is planned to remove this limitation.

C. E. Temple, botanist at the Idaho University and Station, has been appointed associate pathologist in the state horticultural work.

Massachusetts College.—The addition to French Hall has been completed and is being occupied by the departments of forestry and market gardening.

Recent appointments include H. E. Baldinger as assistant in dairying, Loyal F. Payne, poultryman of the Oklahoma College and Station, as instructor in poultry husbandry, Benjamin W. Ellis as extension instructor in farm management, and Miss Harriet J. Hopkins as extension instructor in home economics. Promotions include E. L. Quaipe as assistant professor of animal husbandry, A. H. Nehrling as associate professor of floriculture, F. H. Van Suchtelen as associate professor of microbiology, B. N. Gates as associate professor of bee keeping, E. Anderson as associate professor of chemistry, and R. H. Bogue as instructor in chemistry. A. A. Brown, instructor in poultry husbandry and Ivan McKellip, instructor in dairying, have resigned.

Michigan College and Station.—H. T. Darlington of the Washington College has been appointed assistant professor of botany and will have special charge of the botanical garden and herbarium. E. F. Woodcock of the botanical department of West Virginia University has been appointed instructor in botany, vice Dr. Ruth F. Allen, resigned to accept a similar position in Wellesley College. S. P. Doolittle, a 1914 graduate of the college, has been appointed to an industrial fellowship in cucumber diseases recently established by the H. J. Heinz Pickle Company.

New Hampshire College and Station.—Ford S. Prince, instructor in soils in the Michigan College, has been appointed instructor in agronomy in the college and assistant agronomist in the station.

Texas College.—Press reports announce the appointment as president of Dr. W. B. Bizzell, since 1910 president of the college of industrial arts at Denton, Texas.

Wisconsin University.—J. F. Wojta has been appointed superintendent of agricultural extension courses and Fred H. Scribner field agent in animal husbandry.

SUBJECT LIST OF ABSTRACTS.

AGRICULTURAL CHEMISTRY—AGROTECHNY.

The chemical constitution of the proteins, Plimmer.....	607
On the occurrence of dextrorotatory albumins in organic nature, Beard.....	607
Experiments on the precipitation of suspensoid protein by various ions, Heard.....	607
Nitrogenous hydrolysis products of phosphatids, MacArthur and Norbury....	608
Fatty acids from cephalin, Burton and MacArthur.....	608
Nature of enzym action.—III, The synthetic action of enzymes, Bayliss.....	608
The mutual action of pepsin and trypsin, Long.....	609
Starch-liquefying and saccharifying power, Chrzaszcz and Terlikowski.....	609
The enzymes of Linaceæ, Eyre.....	610
The gasometric determination of aliphatic amino nitrogen, Van Slyke.....	610
Gasometric determination of amino-acid nitrogen in the urine, Van Slyke.....	610
A method for the determination of small amounts of fat, Bloor.....	610
Analysis of maple products.—I, Electrical conductivity test for purity, Snell..	610
Analysis of maple products.—II, Study of methods, Snell and Scott.....	611
Spica's method for citric acid in citrates and lemon juice, Scurti and Tommasi..	612
The accuracy of a modified Meigs method for fat in milk, Croll.....	612
A new apparatus for determining the water content of cheese.....	613
A new apparatus for determining the water in cheese, Mai.....	613
A new apparatus for determining the water in cheese, Rusche.....	613
Methods for determining fat in cheese, Kooper.....	613
The determination of the acidity of cheese.....	613
Estimation of nicotin in tobacco, Conta.....	613
The molds of cigars and their prevention, True.....	613

METEOROLOGY—WATER.

EXPERIMENT STATION RECORD.

VOL. XXXI.

NOVEMBER, 1914.

No. 7.

The *Journal of Agricultural Research*, inaugurated by this Department something over a year ago, was opened to contributions from the agricultural experiment stations beginning with its third volume, October, 1914. This action was taken in response to a suggestion from the executive committee of the Association of American Agricultural Colleges and Experiment Stations, in conference with the Secretary of Agriculture. The latter readily agreed to extending the pages of the *Journal* to the experiment stations for the publication of their technical research papers, and a committee of three was appointed by the association to act with the Department representatives as an editorial board. A meeting of the joint committee was held in Washington last June, and procedure agreed upon. As a result, a circular letter announcing the completion of arrangements was addressed to the various institutions and their workers. The way is therefore open for enlarging the scope of the *Journal* as a record of agricultural research in the United States, and for prompt and adequate presentation of the stations' contributions to it.

The Department and the experiment stations constitute, of course, the two great agencies for agricultural research in this country. Until recently, however, the product of their activities in this line has been so widely scattered through many independent series of bulletins, and so enveloped in more popular writings, that it has lost both in immediate effect and in permanence. It has been difficult for librarians and more so for investigators to hunt out these contributions and preserve them in form accessible for reference. Many of the station mailing lists are not classified, their publications are not sent regularly to persons outside the State, and the bulletins can not be subscribed for or purchased through the general publication agencies. Under the old system, the Department's bulletins reporting research must be selected and ordered separately, and were often soon exhausted. These things have had the effect of making these contributions to agricultural science less accessible than they should be. With the classification of the publications of the Department an effective means was provided for segregating accounts of the more technical investigations, and placing them where they might be made permanently available to scientific readers.

The establishment of such a journal is regarded as a distinct step in advance. There has always been confusion in the public mind from indiscriminate mixing of popular and technical work in the bulletins. The practice has had the effect of detracting from a just appreciation of these publications by both the farmer and the man of science, in about equal degree. The former and the public in general have felt that unless the matter in the bulletins could be fully understood, the work was impractical and the reading unprofitable. Men of science, on the other hand, while they have recognized these publications as containing much of interest to science, have complained of the material being enveloped in so much that was of no interest to them, and of the scattered and fugitive form in which it was issued. Hence a classification of the published matter is to the distinct advantage of all classes of readers, makes the popular or practical and the research publications more effective, and prevents misunderstanding and confusion.

The publication of the research work of the experiment stations was a matter of considerable concern when the amount of research began to materially increase under the stimulus of the Adams Act. There were movements for a journal or common organ, growing out of the recognized advantages of such an organ and the large expense of separate publication, but nothing came of these efforts until recently. Meanwhile, the provision of a series of research bulletins by a considerable number of the stations has relieved the situation, but is not felt to have fully solved it. These bulletins result in a segregation which was greatly needed, but they do not overcome the objection to fragmentary publication. The plan has relieved the farmer from the annoyance of getting papers of purely theoretical and technical interest, but it has not fully enabled the scientific world to keep track of what is being done or to find it after a few years.

The same arguments in favor of a central or common agency for the publication of agricultural investigation apply now that prevailed a few years ago, and probably with equal or greater force. For the stations which have made no attempt at its separate publication such an organ is increasingly important, and for those which have established research series, it adds the advantage of wide circulation, preservation, and adequate indexing of their reports of investigation.

Two main objects are sought in publishing the reports of research—reaching a wide audience of persons interested in the work in question, and recording it where it can be permanently found. Promptness is usually a desirable factor, and the author is naturally

anxious to give as wide publicity as practicable to his contribution. Permanency is a matter of large importance, and this of course is difficult to secure in separate unbound pamphlets.

The people to whom such literature especially appeals are naturally interested in having the material made conveniently accessible to them, and in such form that it not only can be preserved but will be indexed. Hence the index is an important feature of all journal literature, and gives it a material advantage over loose pamphlets or bulletins. Agricultural bibliographies are as yet only sparingly provided. Much search is therefore necessary for the investigator to bring together the literature on a given subject, as it is scattered through such an unusually diverse collection of journals, reports, bulletins, etc. Papers in an indexed journal are much less likely to be overlooked in a review of literature, and are more conveniently cited.

The wide distribution which the *Journal of Agricultural Research* has already reached among institutions and libraries, agricultural and otherwise, and its extensive foreign list established through exchanges, insures unusually wide publicity of articles published in its pages. Already the *Journal* is accessible to a very large share of the world's workers in natural science whose studies bear on the broad field of agriculture, and its circulation will steadily increase with time. This will mean much to its contributors in securing recognition among scientific men.

Furthermore, such an organ offers the opportunity for publishing preliminary and minor papers not suited to a bulletin. This obviates the necessity of withholding publication until the work has been fully concluded, or of publishing in an organ devoted to general science. The liberal provision of separates enables special distribution to be made by the institution or the author.

Aside from these considerations, the effect of collective publication in giving an adequate idea of the extent of American investigation in agriculture, and securing for it the recognition it deserves, is perhaps well worth taking into account. The mass of research material turned out by these agencies, which were long thought of as engaged largely in working out practical farm problems by simple trials and experiments, would make an impression on the scientific world if brought together that the scattered method of publication can not secure. The first year of the *Journal* has served to establish its character and give it standing as a research publication, so that henceforth it may be regarded as a dignified and desirable place for high-grade contributions.

Agricultural investigation has waited many years for the provision of an organ where its work could be brought together and published without prejudice or misunderstanding. The new journal has com-

mended itself to the scientific world and has found a place. It is matter for congratulation that the Department and the stations are now to join in its maintenance, and it is believed that the opportunity which it offers will be recognized and welcomed by many experiment station workers.

The establishment of a section for agriculture in the American Association for the Advancement of Science places this subject on a footing with the other great branches of science, pure and applied, in the foremost scientific association of the country. At the same time it serves to round out the purview of the association, making it more fully representative of all science. It thus recognizes the subject of agriculture in a manner which will be gratifying to those associated with its study, and it expresses its broad relations to science as hardly any other action could.

In this step the American Association followed the lead of its sister organization, the British Association, which some ten years ago provided a subsection for agriculture; and it also carries out the plan of the corresponding association for natural science and medicine in Germany, which for some years has provided for agriculture in its program.

It is noteworthy that the movement for a section representing agriculture did not emanate from those directly associated with the subject, but came primarily from without the agricultural colleges and the various agricultural societies. It was felt by the council to be a logical expansion of the association, to round out its scope, and to give recognition in its organization to the place agriculture has assumed in science and as an industry developing through science. The broadening interest in it among men of science is one of the notable changes which have come about in its recent development. For many years the various sections of the American Association have given much attention to special aspects of agricultural investigation and economics, and the Society for the Promotion of Agricultural Science has been listed among its affiliated societies. But heretofore the subject has had no definite place in the organization of the association or on the program of its meetings. It had come to be "conspicuous by its absence."

The number of special agricultural societies is now sufficient to provide for the communication of technical papers dealing with the progress of investigation in almost any branch of agriculture, and the largest of these, the Association of American Agricultural Colleges and Experiment Stations, deals with the questions of policy and administration respecting the institutions represented in it. But the new section will afford an opportunity not otherwise provided for the discussion of agricultural topics of a more general

nature, on an occasion which will naturally bring together a large body of men to consider scientific, social, and economic questions. Hence, without interfering with any other agency, it should tend to promote the broadest interest and understanding in this many phased subject. And what is more, it is hoped that it may serve to bring the men of agricultural science into more close association with the men of general science, who although working in distinct fields yet have much in common. For there is a danger in too narrow specialization, and especially in too narrow association.

Many now go to the association meetings for their more intimate touch with science and fellowship with its followers, and to the gatherings of agricultural specialists for their contact with agricultural investigation and the men engaged in it. The separation of these meetings in time and place involves an added expense and often results in less frequent attendance upon them. The new section may possibly serve in time as a nucleus around which the meetings of specialists may be gathered, furnishing the double opportunity for discussion of specialized subjects in agronomy, animal nutrition, and the like, and for the broader affiliations in science at one and the same occasion. If so, one of the important objects of the federation of agricultural societies attempted without success a few years ago would be accomplished, and the interest and affiliations of men engaged in agricultural work would be less widely removed.

It will not be the policy of the new section to encroach upon the field of any of the special societies in the presentation of papers and reports, but rather to afford a place where some of the large subjects relating to agriculture, its organization, its investigation, its teaching, or its general upbuilding on the basis of modern science, may be discussed in an academic way. The initial meeting of the section will be held at the annual convocation in Philadelphia during the holidays. A feature of the program will be a symposium on the subject of The Field of Rural Economics, to be discussed by several speakers invited to present their views on different phases. The symposium will be opened by the Assistant Secretary of Agriculture, Hon. Carl Vrooman, who will deal with Rural Economics from the Standpoint of the Farmer. Others will consider the marketing of agricultural products, rural organization, rural credit, and related topics in relation to the industry and the people living under it. So many of the live questions in agricultural advancement to-day center in its economic relations that the subject opens up a broad and profitable field. The vice-presidential address will be upon The Place of Research and of Publicity in the Forthcoming Country Life Development.

The vice president for the new section is Dr. L. H. Bailey of New York, who will preside at its first meeting. The section is repre-

sented on the council of the association by Dr. W. A. Taylor of this Department, and on the general committee by Dean E. Davenport of Illinois. The members of the sectional committee are Dr. E. H. Jenkins of Connecticut, Prof. H. A. Morgan of Tennessee, Dr. W. H. Jordan of New York, Dr. C. W. Dabney of Ohio, and Dr. H. P. Armsby of Pennsylvania. These names attest the highly representative character of the section at the outset, and command for it the interest of all those who are allied with the material and intellectual promotion of agriculture, its organization and scholarly advancement.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY—AGROTECHNY.

The chemical constitution of the proteins, R. H. A. PLIMMER (*London, New York, Bombay, and Calcutta, 1913, 2. ed., pt. 2, pp. XII+107*).—In the second edition of this book (E. S. R., 21, p. 210) the subject matter has been somewhat rearranged to give a more complete idea of the problem of the synthesis of the proteins.

On the occurrence of dextrorotatory albumins in organic nature, J. BEARD (*Biol. Centbl., 33 (1913), No. 3, pp. 150-170*).—In this work the author seeks to show that dextrorotatory albumins occur and are widely distributed in organic nature. To prove this hypothesis the Fischer "lock and key" procedure was utilized. The enzymes employed were a mixture of trypsin and amylopsin (Fairchild) diluted with clear fresh rain water. The organisms submitted to the action of the enzymes were a *Verticella Planaria lactea*, *Hydra fusca* alone or in water containing either *Trichodina pediculus* or *Daphnia pulex*; *Amœba* alone or with crustacean "nauplii;" *Nais proboscidea* with either *Melicerta ringens* or *Carchesium polypinum*; *Cordylophora lacustris*, *Carchesium polypinum*, and a hydrachnid; *Actinosphaerium eichhorni*; and *Stentor cœruleus*. Various flagellate monads and micro-organisms(?) were also studied.

"The 17 experiments carried out have established the thesis that living asexual generations of animals are attacked, killed, and their albumins pulled down by solutions of the pancreatic ferments, trypsin, and amylopsin (Fairchild), in which sexual generations of animals go on living. The following asexual generations of animals exhibited the deadly pulling-down action of pancreatic ferments, and thus revealed the dextrorotatory nature of their albumins; *Hydra*, *Cordylophora*, *Trichodina*, *Vorticella*, *Carchesium*, *Amœba*, *Actinosphaerium*, and *Stentor*, eight in all. . . . The following sexual generations of animals continued to live in solutions of these ferments . . . : *Daphnia*, a hydrachnid or water mite, crustacean *nauplii*, *Planaria*, *Nais*, and *Melicerta*, six in all. Zoologically, the experiment with *H. fusca* and *D. pulex* has special interest, as *D. pulex* is a common prey of *Hydra*."

The value of enzymes for the treatment of tuberculosis, the chief tropical diseases, and other infectious diseases caused by unicellular organisms is discussed. Enzymes when introduced into the diseased body serve as an auxiliary in the defensive mechanism and also help to digest the food of the individual.

Some experiments on the precipitation of suspensoid protein by various ions and some suggestions as to its cause, W. N. HEARD (*Jour. Physiol., 45 (1912), No. 1-2, pp. 27-38, figs. 2*).—"The power of an electrolyte to precipitate negatively charged suspensoid protein, while primarily dependent upon the valency of the cation, is greatly modified by the relation of the latter to the OH group, and its capacity to reduce the ionization of that group. The reason the order of precipitation somewhat resembles the order of hydrolysis is due to the fact that in both cases the reaction is between the cation and the OH

group; but the law of the ions and the complicated conditions present in the mixture of protein and electrolyte cause considerable differences between the two orders which are only superficially alike. Hydrolysis may or may not increase the precipitating power of an electrolyte according to the power of the cation and its relation to H. The trivalent and most powerful divalent metals have two curves of precipitation, and it is suggested that the first is the throwing down by the anion of the protein which has been made electropositive by the cation.

"Positively charged suspensoid protein being kept in solution by the charge given it by H, the power of the anion to precipitate is due to its capacity to reduce the ionization of the compound of acid and protein. Though the cation is the principal element in the precipitation of alkaline protein, and the anion in the precipitation of acid protein, the accompanying ion is probably never without some effect. Probably this influence is of a complex nature and due to different causes."

Nitrogenous hydrolysis products of several phosphatids, C. G. MACARTHUR and G. NORBURY (*Abs. in Science, n. ser., 38 (1913), No. 984, p. 678*).—The phosphatids studied were sheep brain cephalin, sheep brain lecithin, ox heart cuorin, and ox heart lecithin. Each of the preparations was purified and hydrolyzed with dilute hydrochloric acid. In every case the fatty acid residue contained nitrogen and usually it represented one-sixth of the total substances.

Fatty acids from cephalin, L. V. BURTON and C. G. MACARTHUR (*Abs. in Science, n. ser., 38 (1913), No. 984, p. 678*).—The fatty acids obtained as a result of hydrolyzing purified cephalin with a dilute hydrochloric acid solution were separated into the saturated and unsaturated fatty acids by the lead acetate method. The acids were identified.

Researches on the nature of enzym action.—III, The synthetic action of enzymes, W. M. BAYLISS (*Jour. Physiol., 46 (1913), No. 3, pp. 236–266, figs. 3*).—This continues previous work (E. S. R., 27, p. 612).

"Reactions in the system, glycerol, glucose, glycerol-glucosid, and water, as accelerated by emulsin, follow in all respects the laws deduced from mass action for an equilibrium in a reversible system, catalyzed by a single enzym. The equilibrium position is the same from whichever end it is approached. The glucosid produced is the β form and the same which is hydrolyzed by emulsin. The rate of the reaction is directly proportional to the concentration of the enzym, although not in linear proportion. The final equilibrium attained is independent of the concentration of the enzym.

"Results in which it appeared that a large amount of enzym was capable of producing a different equilibrium position from that produced by a smaller amount are shown to have been due to removal of the enzym, either by destruction or paralysis by products, before true equilibrium was attained. Van't Hoff's view as to the greater ease of synthesis of the glucosids of the primary alcohols, as compared with those of the tertiary alcohols, is confirmed in the case of the two kinds of amyl alcohol. Evidence is given to show that the action of emulsin, which takes place in liquids in which it is completely insoluble, is exerted on its surface. The reacting substances are probably brought into close contact by condensation on this surface (adsorption), owing to their causing diminution of surface energy.

"Rosenthaler's hydrolyzing form of emulsin is shown to be capable of synthetic action in addition; while his experiments supposed to show the separate existence of an emulsin with synthetic powers only could not be confirmed. Both powers were found to disappear together, so that the equilibrium point under enzym preparations, treated and untreated, was the same, although the rate of the reaction was different. The results of dilatometer experiments are

shown to be very difficult of interpretation, and although they show that the glucosids of tertiary alcohols are much more difficult to synthesize than those of primary alcohols, no conclusion can be drawn as to complete absence of reversibility in the former case. The glucosid formed by the action of acid was found to be a mixture of α and β forms in the ratio of 75.3 parts of the former to 24.7 parts of the latter. The $[a]_D$ of the former is 91.2° and that of the latter -38° . As regards emulsin and maltase in their behavior toward glucosids, the same optical isomer is hydrolyzed and synthesized. Robertson's 'synthesis of paranuclein by pepsin' is not a synthesis, nor is it produced by pepsin, while the substance formed is not paranuclein. It is, in fact, a colloidal precipitation and has no connection with enzym action.

"From the results given in this paper some general conclusions may be drawn. Since we find that, in a simple system, easily investigated, the action of an enzym, emulsin, is found to follow without exception the laws of catalysis by a single agent, the conclusion seems justified that, whenever we meet with apparent deviations from such laws, instead of inventing new enzymes or making assertions as to the nonapplication of the laws of physical chemistry to enzym action, we should endeavor to find the reasons for the divergence. Until the impossibility of finding such reasons has been demonstrated, it is more in accordance with scientific method to hold provisionally the application to all enzymes of the laws which we can show to apply to so many. I think that we ought, in the interest of clear conceptions, to go even farther and to deny the application of the name 'enzym' or 'ferment' to any substance not manifesting the properties of a catalyst."

The mutual action of pepsin and trypsin, J. H. LONG (*Abs. in Science, n. ser.*, 38 (1913), No. 984, p. 674).—Making due allowance for the reaction of the medium, the experiments show that within the practical limits of body behavior trypsin has no important action on pepsin. Pepsin, on the other hand, is markedly destructive to trypsin, and an acid medium weakens trypsin. Pepsin and acid present with trypsin in the same medium destroy the latter rapidly.

Experiments on the separation of the starch-liquefying from the starch-saccharifying power, and the demonstration of starch-dextrinizing and starch-precipitating powers of amylase of cereals, T. CHRZASZCZ and K. TERLIKOWSKI (*Wchnschr. Brau.*, 29 (1912), Nos. 41, pp. 590-593; 42, pp. 607-610; 43, pp. 623-626; 44, pp. 636-639, fig. 1; *abs. in Jour. Soc. Chem. Indus.*, 31 (1912), No. 22, pp. 1089, 1090).—This is a study of the amylases of barley, oats, millet, corn, wheat, and rye. The amylases were precipitated from cold water extracts of the cereals with a 35 to 40 per cent solution of ammonium sulphate. The resulting precipitates were dissolved in water and reprecipitated fractionally by treating the solution with successive quantities of ammonium sulphate, i. e., from 5 to 35 per cent.

"The ratio of liquefying power to saccharifying power varied widely in different fractions. In some cases the later fractions, possessing considerable saccharifying power, appeared to exert no liquefying action whatever. With barley, rye, and wheat the functions of maximum liquefying power possessed also the maximum saccharifying power, but this was not so with maize and millet, and even in the former cases the increase or decrease of the two powers in successive fractions did not proceed *pari passu*. The measurement of the liquefying power was in some cases rendered difficult by coagulation of the starch, effected by an enzym (amylo-coagulase) present in different amounts in the various grains and in greatest quantity in rye. The action of this enzym was observed also in carrying out the saccharification tests, for it gave rise to turbidity when the amylase was added to the starch solution.

"There was found to be no close correspondence between the saccharifying power of the different fractions and the iodine reaction of the saccharified starch solutions obtained in determining this power. The authors conclude that the quantitative value of the liquefying power of the amylases of grains is independent of their saccharifying power, that their starch-dextrinizing power is to some extent independent of both of the former, and that they possess also in varying degrees a starch-precipitating power due to amylo-coagulase."

For previous work see an earlier note (E. S. R., 23, p. 410).

The enzymes of *Linaceæ*, J. V. EYRE (*Chem. News*, 106 (1912), No. 2758, pp. 167, 168; *abs. in Chem. Ztg.*, 37 (1913), No. 28, p. 281).—The results show that quite a number of enzymes may be present in the leaves and seeds of this plant and that the amount varies considerably. Linase acts less strongly upon linamarin than upon prunassin. During growth enzyme activities toward linamarin become less and an increase in hydrolysis of prunassin and amygdalin is noted. The enzymatic activity seems to stand in close relation with the presence of cyanogenetic glucosids. The varieties of plants having blue, white, or red flowers contain cyanogen while those of a yellow color have neither an enzyme nor a glucosid.

The gasometric determination of aliphatic amino nitrogen in minute quantities, D. D. VAN SLYKE (*Jour. Biol. Chem.*, 16 (1913), No. 1, pp. 121-124).—The apparatus previously described (E. S. R., 29, p. 108) has been reduced in size so that it may be used for small quantities of material, which brings the procedure into the class of micromethods. With the microapparatus the error need not be more than 0.005 mg. of nitrogen when 2 cc. or less of gas is measured, or 0.01 mg. when more is obtained.

Improved methods in the gasometric determination of free and conjugated amino-acid nitrogen in the urine, D. D. VAN SLYKE (*Jour. Biol. Chem.*, 16 (1913), No. 1, pp. 125-134).—"The previously published process of determining the total amino-acid nitrogen (free amino acids + conjugated amino acids in the form of hippuric acid, peptids, proteins, etc.)^a has been simplified so that the operation is much shortened and the more laborious parts, boiling off ammonia and washing bulky precipitates, are dispensed with. The free amino acids alone can readily be determined after decomposition of the urea with soy-bean urease, which hydrolyzes urea completely without either freeing conjugated amino acids or deaminizing free ones. The applicability of the gasometric method for the determination of hippuric acid is indicated."

See also other notes (E. S. R., 25, p. 710; 26, p. 22).

A method for the determination of small amounts of fat (preliminary report), W. R. BLOOR (*Abs. in Science, n. ser.*, 38 (1913), No. 984, p. 678).—The method consists of extracting the fat from tissues or liquids with an excess of alcohol-ether (25 per cent of ether), putting an aliquot of the filtered extract into distilled water, and determining the amount of fat by comparing it with a cloudy suspension of known fat content in a nephelometer. The method has given good results with blood and milk.

The analysis of maple products.—I, An electrical conductivity test for purity of maple sirup, J. F. SNELL (*Jour. Indus. and Engin. Chem.*, 5 (1913), No. 9, pp. 740-747, figs. 2).—The method (E. S. R., 27, p. 207) is designed for the detection of additions of sucrose to maple sirup. Inasmuch as sucrose is a nonconductor of electricity and salt constituents conductors, a maple sirup adulterated with sucrose will show a lower conductivity. The method is of special value because the conductivity determination can be made in a few minutes.

^a *Jour. Biol. Chem.*, 12 (1912), No. 2, pp. 301-312.

The mean densities and conductivities of 42 genuine maple sirups were found to be 1.333 at 15° C. and 18.7 ($K \times 10^5$) at 25°, the minimum 1.305 and 9.6, and the maximum 1.355 and 33.6, respectively. A sirup not included in the 42 samples showed a specific gravity of 1.279, a conductivity ($K \times 10^5$) of 45, and a moisture content of 38.59 per cent. As a general rule, sirups of high density show low conductivities and sirups of low density high conductivities, indicating that in undiluted sirups the concentration of the sugar has more influence upon the conductivity than has the concentration of the electrolyte components. The measurements show that the more dilute the sirup the greater the conductivity. When sirup is diluted with water to contain only 33½ per cent of actual sirup by volume, a point of maximum conductivity is reached. If the dilution is continued beyond this point the conductivity begins to decrease.

As on either point of maximum conductivity there is a considerable range of concentration without which the conductivity differs very little, it is possible to measure the maximum conductivity of a maple sirup without observing much precaution in making up the sirup-water mixture. "The mean conductivity at 25° ($K \times 10^5$) of the diluted solutions of the 42 sirups [mentioned above] was 153, or over eight times the mean conductivity of the same sirups in the undiluted state. The minimum was 120, the maximum 203, the latter being the conductivity value of the sirup made in the iron kettle. . . . Genuine sirups have given values of 110 to 200, but further experience may extend these limits a little. Sirups giving conductivity values distinctly outside these limits may be condemned. Those giving normal values are not necessarily pure and should be further examined by well-established tests."

In addition to the 43 sirups mentioned above, 22 taken from the trees of Macdonald College grounds and prepared in the laboratory were examined. These showed a range from 119 to 164, with an average of 143. Three Vermont sirups gave conductivity values of 110, 115, and 122. The minimum value found in the work was 110 and the maximum 203. The highest value for a sirup actually prepared for the market was 197. By weighting the 22 sirups made from the trees on the Macdonald College farm as 2, a mean conductivity value is obtained of 150. This is approximately equal to the electrical conductivity of an 0.01 molar aqueous solution of potassium chlorid (141.2)."

No conclusions were drawn from the results obtained as to the value of determining the conductivity of the ash solution.

The analysis of maple products.—II, A comparative study of the delicacy of methods, J. F. SNELL and J. M. SCOTT (*Jour. Indus. and Engin. Chem.*, 5 (1913), No. 12, pp. 993-997).—In studying the value of the electrical conductivity test for detecting adulterations in maple sirup it appeared desirable to compare the delicacy of this test with that of other methods in vogue. Three sirups were chosen for the experiment—one a light-colored sirup, another a mixture of several pure sirups, and the third a sirup prepared at the Macdonald College.

The determinations made were insoluble ash and alkalinity of insoluble and soluble ash (E. S. R., 17, p. 1038; 24, p. 266; 26, p. 661); soluble ash by difference; conductivity value, by the method outlined in the preceding abstract; Canadian lead number; Winton lead number (E. S. R., 18, p. 420); Ross's modified Winton number (E. S. R., 22, p. 709); and Sy lead value (E. S. R., 20, p. 1106).

In the work the rates at which the conductivity value, ash data, and the various lead values fall off when maple sirup is diluted were noted. The Canadian lead value showed the most rapid falling off, while the conductivity value showed the narrowest range. The duplicates obtained by the Winton

lead method were in closer agreement than those of the Canadian method. In the latter method practically no difference was noted when the precipitates were washed at 80 and 100°. Almost identical results are obtained when 100 to 150 cc. of wash water was used, but higher results were noted when only 50 cc. was employed.

“Results obtained in the Canadian method, using the quantity of sirup containing 5 gm. of dry matter, are higher than those obtained with the use of 5 gm. of sirup and calculated to the dry basis. On the other hand, in the modified Winton method, prescribed in the Canadian standards, lower results are obtained with the use of the quantity of sirup containing 25 gm. of dry matter than when 25 gm. of sirup is used and the results calculated to the dry basis. The use of cane-sugar sirup instead of acetic acid in the Winton blank is suggested.”

Spica's method for determining the citric acid in citrates and lemon juice, F. SCURTI and G. TOMMASI (*Ann. R. Staz. Chim. Agr. Sper. Roma*, 2. ser., 6 (1913), No. 1, pp. 61-65; *abs. in Chem. Ztg.*, 36 (1912), No. 139, p. 1362).—The method, according to its originator, can always be used providing tartrates and oxalates are absent. It has, however, been found in this investigation that other substances such as grape sugar, levulose, arabinose, lactose, starch, inulin, cellulose, wood, gum, lactic acid, egg albumin, etc., when treated in the manner described by Spica will also yield carbon dioxide; consequently the method is unusable for most purposes.

An investigation to determine the accuracy of a modified Meigs method for the quantitative determination of fat in milk, with a description of an improved form of apparatus, W. L. CROLL (*Biochem. Bul.*, 2 (1913), No. 8, pp. 509-513, pl. 1).—Although the Adams paper-coil method with a Soxhlet extracting apparatus is considered the most accurate procedure for determining the fat in milk, it requires much time and care for its execution. The original Meigs method (1882) is neither extremely rapid nor simple, but it possesses certain advantages that make its use preferable for biochemical and pediatric investigations.

As the results obtained by the method compared favorably with those given by the Soxhlet method, an investigation was made to determine whether this was a mere coincidence or due to the efficiency of the method. “For this purpose there were secured 12 samples of human milk from women in various stages of lactation, and six of cow's milk from as many dairies, so widely separated that in no two cases were the milks from the same herd. In all determinations the milk for both the Meigs and the Soxhlet methods was taken from one specimen and at the same time, so that the samples were as nearly uniform as it was possible to get them. In every weighing the figures were recorded to 0.01 mg. The average difference in the results of the 18 determinations recorded in the table is 0.0234 per cent.”

In the manipulations it was found that the use of the pipette was exceedingly tedious and required a great deal of skill and practice, and that the probability of error was great. An inexpensive piece of apparatus was therefore devised which renders the use of a pipette unnecessary and obviates the need of care in regard to the protein layer. “The improved Meigs method possesses the following advantages over the Soxhlet: (1) The time in weighing out is shortened and the danger of accidental loss is diminished, for no absorption of the milk by fat-free material is necessary; (2) two or three hours are saved as no drying is required; (3) the extraction requires ten minutes for its execution against three hours as the minimum for the Soxhlet process.”

A new apparatus for determining the water content of cheese (*Milchw. Zentbl.*, 42 (1913), No. 4, pp. 107, 108, figs. 1).—The apparatus consists of a distilling flask held in a square glycerin bath, and a metal condenser. The Rusche apparatus may also be arranged so that its use is permissible for the determination of moisture with petroleum according to Mai and Rheinberger's method (E. S. R., 28, p. 612).

A new apparatus for determining the water in cheese, MAI (*Milchw. Zentbl.*, 42 (1913), No. 7, p. 220).—An objection to some of the statements made in the article abstracted above. It is maintained that all of the specifications set down by Mai and Rheinberger must be strictly adhered to in order to obtain accurate results.

A new apparatus for determining the water in cheese, RUSCHE (*Milchw. Zentbl.*, 42 (1913), No. 10, pp. 315, 316).—A polemic as to priority.

Various methods for determining fat in cheese, and a comparative study of the volumetric and gravimetric methods, W. D. KOOPER (*Milchw. Zentbl.*, 42 (1913), No. 12, pp. 353–368).—The results obtained with the gravimetric Bondzynski-Ratzlaff method were higher than those given by the volumetric methods of Burstert (E. S. R., 20, p. 112), Hammerschmidt (E. S. R., 30, p. 208), Wendler (E. S. R., 30, p. 208), and Kooper (E. S. R., 30, p. 207). Pure butter fat was apparently not attacked by the solvents used in the Wendler and Kooper methods.

The specific gravity of cheese fat is not the cause of the differences observed between the two methods, as the difference between the specific gravities of the fats is too small. Mixtures of pure cheese fat and the fat residue obtained from one of the gravimetric milk tests and a mixture of cheese fat and cheese gave high results. The high figures obtained by the gravimetric method are said to be due to the fact that the solvents extract decomposition products of cheese fat, i. e., fatty acids, and these are weighed finally as fat. In the volumetric determination the decomposition products do not appear in the fat column to be read off.

The determination of the acidity of cheese (*Milchw. Zentbl.*, 42 (1913), No. 10, pp. 306, 307, fig. 1).—A description and illustration of an automatic pipette for determining the acidity in cheese and milk. The cheese is rubbed up with water in a mortar graduated up to the 100 cc. mark, and then made up to 100 cc. with water. The emulsion is titrated with fourth-normal sodium hydroxid solution, using phenolphthalein as the indicator.

Estimation of nicotin in tobacco, N. CONTA (*Rend. Soc. Chim. Ital.*, 2. ser., 4 (1912), No. 9, pp. 258–260; *abs. in Chem. Ztg.*, 36 (1912), No. 139, p. 1363).—The nicotin is precipitated by means of a 10 to 20 per cent solution of potassium silicotungstate. The base is liberated from the washed precipitate by means of magnesium oxid and distilled with steam into a solution of sulphuric acid of known strength.

The molds of cigars and their prevention, R. H. TRUE (*U. S. Dept. Agr. Bul.* 109 (1914), pp. 8).—This paper discusses the losses due to the development of molds on cigars, outlines the studies directed toward their prevention, and presents practical directions for the use of an effective remedy.

“The molds were found to be introduced principally through the gum-tragacanth paste used to fasten the small flap at the head of the cigar. The sterilization of the paste by using a nearly saturated solution of boric acid instead of water in mixing it has proved so successful that it has become a routine process in the factory in cooperation with which the investigations were conducted.”

METEOROLOGY—WATER.

Meteorological observations in connection with botanical geography, agriculture, and forestry, R. ZON (*Mo. Weather Rev.*, 42 (1914), No. 4, pp. 217-223, fig. 1).—This article shows how present meteorological observations on temperature, pressure, precipitation, humidity, and wind movement may be regrouped and classified so as to be more useful in the study of plant growth, indicating at the same time certain other observations, especially on soil temperature and moisture, which may be utilized for the same purpose.

It is stated that in order "properly to understand plant life it is essential to group temperature data by periods of growth and rest." A map is given showing the vegetal regions of the United States based on such periods and deduced from the mean monthly temperature for 685 Weather Bureau stations. It is suggested that temperature data should also be grouped with reference to periods of snow cover and to the direction of the wind.

"The method of computing average temperatures, or the summing up of temperatures for different species of plants separately," is considered of little practical value to the biologist. It is more important to distinguish groups of days with a given range of temperature. A classification based on this idea is outlined. The importance of observations on soil temperature and humidity of the air is recognized, but no classification of such data is attempted.

As regards precipitation, it is suggested that "it will be well to compute the number of days with considerable precipitation in per cent of the total number of days of observation in general, as well as specifically, for winds of different direction. . . . Detailed information concerning the snow cover is especially instructive at the time of its appearance and disappearance. . . . It would be of great advantage to students of plant life if [soil moisture] determinations could be made at agricultural and forest experiment stations. . . .

"Some simple sunshine record, especially for winds of different directions, is also necessary. The occurrence of days with sunshine should be given in per cent of the total number of observations.

"Air pressure has no direct bearing upon plant life, except that its observation often makes it possible to forecast changes of importance to agriculture."

In conclusion the author points out that, "with the exception of the records of soil humidity and soil temperature, the system of meteorological observations outlined can be carried out with the data which are regularly obtained by our weather stations."

Period of safe plant growth in Maryland and Delaware, O. L. FASSIE (*Mo. Weather Rev.*, 42 (1914), No. 3, pp. 152-158, pl. 1, figs. 8; *abs. in Bul. Amer. Geogr. Soc.*, 46 (1914), No. 8, pp. 587-590, fig. 1).—The frostless period in these States was determined from data obtained from all meteorological stations in the States having a record covering a period of 10 years or more.

Records at fifty stations covering an average period of 20 years "show that the frostless period, based on the observations of a temperature of 32° F., is about 10 days longer than the period based on the occurrence of killing frosts. This relation holds good in general for stations in open, level places, but apparently does not hold for stations in the mountain districts, where the period based on the occurrence of frosts is longer than that determined from a record of freezing temperatures in a shelter 5 ft. above the ground."

Along the shores of the Chesapeake Bay and the Atlantic Ocean the average period of safe plant growth is shown to be about 210 days, but rapidly decreases with increasing distance from the water's edge. On the western side of the Blue Ridge Mountains and in the lower levels of the Cumberland Valley the period is about 160 days, while on the eastern side of the mountains the period

increases to 190 or even 200 days. In the most western and elevated portion of Maryland the period is but little more than 100 days.

See also a previous note (E. S. R., 30, p. 814).

Monthly Weather Review (*Mo. Weather Rev.*, 42 (1914), Nos. 3, pp. 137-194, pls. 9, figs. 11; 4, pp. 195-256, pls. 8, figs. 10).—In addition to notes on weather forecasts for March and April, 1914, river and flood observations, lists of additions to the Weather Bureau library and of recent papers on meteorology, notes from the Weather Bureau library, the weather of each month, a condensed climatological summary, and climatological tables and charts, these numbers contain the following articles:

No. 3.—The Eruption of Sakurashima, January, 1914; Solar Radiation Intensities at Mount Weather, Va. (illus.), by H. H. Kimball; Standard Units in Aerology, by T. W. Richards, A. E. Kennelly et al.; The C. G. S. System and Meteorology, by V. Bjerknes; Progress in Meteorological Optics during 1912, by C. Jensen; Period of Safe Plant Growth in Maryland and Delaware (illus.), by O. L. Fassig (see p. 614); The Progress and Present State of Research on the Evaporation of Moisture in the Atmosphere, by A. Weilemann; Report of the Meteorological Station at Berkeley, Cal., for the Year Ending June 30, 1913, by W. G. Reed; Electric Paragrêles, by A. Angot; A New Turbidimeter, by P. V. Wells; The Lowest Temperature Obtainable with Salt and Ice, by R. A. Gortner; The Motion of the Solar Atmosphere; Lightning at Mount Wilson Observatory, by W. P. Hoge; Continuous Pictures of the Weather; Proposed Daily Weather Map for the Southern Hemisphere; Seismic Disturbances in the Philippines, by M. S. Masó and W. D. Smith; and Possibility of Recurrence of the Floods of March, 1913, by J. W. Smith.

No. 4.—Principia Atmospherica: A Study of the Circulation of the Atmosphere (illus.), by W. N. Shaw; Birkeland's Theory of the Zodiacal Light; A Possible Connection Between Magnetic and Meteorologic Phenomena, by K. Birkeland; Radiotransmission and Weather, by A. H. Taylor; Maurer and Dorno on the Progress and Geographical Distribution of the Atmospheric-Optical Disturbance of 1912-13; Meteorological Observations in Connection with Botanical Geography, Agriculture, and Forestry (illus.) by R. Zon (see p. 614); Tasks and Problems for Meteorological Explorations in the Antarctic (illus.), by W. Meinardus; Conversion of Barometric Readings into Standard Units of Pressure, by R. N. Covert; The Beaufort Wind Scale; Ice Patrol Over the North Atlantic Ocean, by E. H. Bowle; A Lake Huron Current, by J. D. Persons; and Proposed Asiatic Extension of the Russian Weather Service, by J. F. Jewell.

Climatological data for the United States by sections (*U. S. Dept. Agr., Weather Bur. Climat. Data*, 1 (1914), Nos. 5, pp. 226, pls. 3, figs. 7; 6, pp. 228, pls. 2, figs. 7).—These numbers contain, respectively, brief summaries and detailed tabular statements of climatological data for each State for May and June, 1914.

Meteorological records, E. F. LADD (*North Dakota Sta. Rpt. 1913*, pp. 13-20).—Records are given of daily observations at the station on temperature, precipitation, sunshine, and wind during 1913, and monthly summaries for 1910 to 1913, inclusive.

Ohio weather for 1912, J. W. SMITH and C. A. PATTON (*Ohio Sta. Bul. 259* (1913), pp. 299-403, figs. 86).—The temperature and precipitation throughout the State during each month is shown in charts. The usual summary tables are given showing temperature and rainfall at Wooster and throughout the State (1888 to 1912).

The mean temperature for the year at Wooster was 47.8° F., for the State 49.6° F. The highest temperature at the station was 93°, September 10; for the State 101°, July 15. The lowest temperature at the station was -24°, Jan-

uary 13; for the State -37° , January 13. The annual rainfall at the station was 46.6 in., for the State 37.82. The number of rainy days at the station was 124, for the State, 112. The prevailing direction of the wind was southwest at the station and in the State at large.

Water resources of Hawaii, 1912, C. H. PIERCE and G. K. LARRISON (*U. S. Geol. Survey, Water-Supply Paper 336 (1914), pp. 392*).—This report describes the geography of the Hawaiian Islands and presents results of measurements of flow of certain streams and ditches in the Territory made during 1912. Tables giving gage heights and daily and monthly discharges at each station are given, also rainfall measurements.

“The yearly rainfall of the Hawaiian Islands is extremely variable, ranging from a few inches at several low-level leeward localities to more than 400 in., usually at elevations above 2,000 ft. and on the windward sides of the islands. Valleys lying on the same sides of the islands and within a few miles of each other may have a variation in mean annual precipitation of several hundred per cent. The rainfall may also vary greatly at different elevations in the same valley.”

Quality of the surface waters of Washington, W. VAN WINKLE (*U. S. Geol. Survey, Water-Supply Paper 339 (1914), pp. 105, pls. 2, fig. 1*).—This paper, prepared in cooperation with the state board of health, describes the natural and economic features of Washington, reports investigations of the surface water supplies with particular reference to their value for domestic and industrial use and for irrigation, and discusses denudation and the influence of natural features.

The conclusion states that “the river waters of Washington are low in mineral content and are good for general industrial use or for irrigation. What little suspended matter they carry is coarse and readily removable. The color of some renders it advisable to purify them by coagulation and rapid sand filtration rather than by slow sand filtration.

“The Columbia River enters the State as a secondary saline water, but it receives large additions of alkaline water and finally carries a water of mixed type with a slight tendency toward primary alkalinity.

“The Cascade Mountain region is being eroded and dissolved at the rate of 1 in. in 500 to 900 years, and the rate of denudation near the summits is nearly equal on both sides of the divide. The rate in the lower altitude is greater on the western than on the eastern slope and greater in the Cascade intermountain region than in the Columbia plains. The rate in the basin of the Columbia River is about 1 in. in 1,300 years. . . . As denudation is not uniform throughout the basin, but is most pronounced in the watercourses themselves, the rivers are deepening and widening their canyons and valleys.

“No lakes are known whose waters are economically important as sources of commercial salts. Waters from the coulee lakes of Washington contain a greater proportion of common salt than the lake waters of southeastern Oregon, and are therefore less valuable for recovery of soda.”

Colloids in water and sewage purification, M. F. STEIN (*Engin. Rec., 69 (1914), No. 19, pp. 524, 525*).—The author discusses the peculiar properties of colloids and their influence in settling basins, sand filters, and processes of color removal.

SOILS—FERTILIZERS.

The separation of soil particles according to their specific weight and the relations between plants and soil, J. KÖNIG, J. HASENBAUMER, and R. KRÖNIG (*Landw. Jahrb., 46 (1914), No. 2, pp. 165-251*).—Continuing investigations previously noted (*E. S. R., 30, p. 123*), the authors report experiments on the

mechanical separation of the constituents of seven soils according to their specific weights for the determination of humus, colloids, etc., and several years' cropping experiments with six soils to determine the manner in which individual crops are nourished from the same soil.

In the first experiments bromoform having a specific weight of 2.83 was diluted with benzol until at a specific weight of 2.64 the heaviest parts of the soils sank in the mixture. By further decreasing the specific weight of the liquid mixture to 2.55, 2.49, and 2.36 the soils were separated into five fractions, according to specific weight, the lightest of which was suspended on the liquid having a specific weight of 2.36.

The ease or difficulty with which a soil was separated into its constituents was found to indicate the uniformity of its composition. An abundant separation of the specifically lighter constituents indicated a soil rich in colloids, humus, and available plant food, while the separation of an abundance of specifically heavier constituents indicated a less productive soil, poor in humus and available plant food, although not necessarily with a small absolute plant-food content.

Clay soil contained none of the constituents of specific weight higher than 2.64, and the sand, loamy sand, loam, and limy soils contained only 1 per cent, while the shale soils contained up to 7.3. The greatest percentages of organic matter, colloids, and available plant food were usually found in the fifth and lightest fraction, and there was usually a steady increase from fraction 1 to fraction 5 in this respect. The most silica, iron oxid, and clay were found in the fraction containing the most plant food. It is concluded that the analysis of a soil with fluids of different specific weights indicates the relative quantities of its constituents and the distribution of plant food in them.

In pot experiments in the plant house crops yielded more dry matter per unit area of soil than those grown in the open. The assimilation of plant food, especially phosphoric acid, by crops was much greater in warm, dry summers than in cool, wet summers, but the increase in dry matter was not correspondingly great. Definite relations existed between the quantity of plant food and the quantity of dry matter obtained, the most marked of which was with nitrogen. It is concluded that if 100 gm. of plant dry matter contain less than 1.61 gm. of nitrogen, 0.59 gm. of phosphoric acid, or 1.66 gm. of potash, the soil needs fertilization with the deficient foods, while if the 100 gm. of dry matter contain more than 2 gm. of nitrogen, 1 gm. of phosphoric acid, or 2.14 gm. of potash, no fertilization with these plant foods is necessary.

Considerable variation was found in the quantities of plant foods absorbed by individual crops, especially the legumes. Red clover contained much nitrogen and relatively little phosphoric acid, while serradella contained more phosphoric acid than any other crop. Red clover and potato plants absorbed the most potash, and red clover absorbed the most lime, followed in order by red beets and potatoes. Lime and potash were found in practically the same amounts in plant dry matter. A one-sided fertilization with potash and phosphoric acid in dry weather when the soil was not deficient in either did not increase the quantity of dry matter.

In the six soils, with one exception, definite relations were established between the quantity of dry matter obtained from crops and the following physical and chemical properties of the soils: The absorptive power for ammonia, according to Knop, and for potash and phosphoric acid, according to Fesca, hygroscopicity, according to Mitscherlich (E. S. R., 24, p. 419), the absorptive power for methyl violet, osmotic water absorption, and the electrolytic conductivity.

Steaming for five hours at five atmospheres pressure proved to be the best method for the determination of available potash in soils. The phosphorus in a soil appeared to be less available the greater the content of lime, magnesia, iron oxid, and clay in the soil. It was also affected by weathering and the kind of crop.

No fixed relations were established between the amounts of phosphoric acid, nitrogen, and lime assimilated by plants and the amounts found to be easily soluble by different methods. The electrolytic conductivity, and also steaming for five hours at five atmospheres pressure before and after harvest, served to indicate the decrease of plant food in soils resulting from plant growth.

Distribution of certain constituents in the separates of loam soils, L. A. STEINKOENIG (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 7, pp. 576, 577).—Experiments conducted with a view to finding the distribution of the commoner elements in the finer separates of a series of ten loam soils are reported.

In every separate examined the percentage of silica was greater than that of any other oxid and decreased from the coarser to the finer particles. Zirconia usually followed the same variation. In all but two cases alumina was second in order of abundance, and in most cases iron was third. The percentages of iron oxid, alumina, titanium, potash, and phosphoric acid usually increased with the fineness of the particles. Lime, magnesia, and soda seemed to follow no general rule.

The influence of electrolytes on the coagulation of clay suspensions, G. WIEGNER (*Landw. Vers. Stat.*, 84 (1914), No. 3-4, pp. 283-299, figs. 5).—The author in a discussion of the effect of sodium and calcium hydroxids on clay suspensions explains their flocculating effects on electrical grounds. He points out that the hydroxyl ions of the salts are more easily adsorbed on colloidal surfaces than are the calcium or sodium ions, but that each has a certain limited mechanical power for being adsorbed. On being added to a negatively charged clay suspension the negative hydroxyl ion is first adsorbed and the electrical charge, and therefore the stability of the suspension, increased to a certain limit at which the positively charged calcium or sodium is adsorbed, thus neutralizing the negative charge of the suspension and causing precipitation. That the calcium hydroxid causes precipitation at much lower concentrations is attributed to the higher valence of the calcium ion.

The properties of red colored soils, E. BLANCK and J. M. DOBRESCU (*Landw. Vers. Stat.*, 84 (1914), No. 5-6, pp. 427-445; *abs. in Jour. Chem. Soc. [London]*, 106 (1914), No. 621, I, pp. 915, 916).—Chemical studies of a typical red soil and a deep red-colored weathered soil from augite porphyry showed that a difference existed in their composition which was due to the colloidal condition prevailing in the red soil and the absence of colloids in the augite porphyry. Van Bemmelen's method for determining the colloidal content was found to be inadequate, while on account of the structure of the soils the Rodewald-Mitscherlich hygrosopicity method (*E. S. R.*, 15, p. 847) was favored.

See also a previous note (*E. S. R.*, 29, p. 514).

Acid mineral soils, G. DAIKUHARA (*Bul. Imp. Cent. Agr. Expt. Sta. Japan*, 2 (1914), No. 1, pp. 1-40, pl. 1).—Continuing preliminary studies by Kozai (*E. S. R.*, 21, p. 18) the author reports investigations on the nature and origin of acidity in soils, the relation between various salt solutions and soil acidity, the relation of soil acidity to heating and to size of soil particles, methods of detecting and determining soil acidity, and the relation between soil acidity and the lime factor.

The author concludes from the results of these investigations that in mineral soils acidity is due to absorption of aluminum and iron compounds by the soil

colloids, and in humus soils both to this cause and to humus acids. The use of fertilizer salts was found to render the absorbed aluminum and iron compounds soluble and thus injurious to plant growth. Over three-fourths of the soils of Japan and Korea examined were found to be acid and in one-half of these the acidity was due to aluminum and iron compounds absorbed by the soil colloids. The highest percentage of acid soils was found among those derived from Mesozoic formations, followed in descending order by Tertiary, Paleozoic, Diluvial, and Alluvial soils. Soils from so-called acid rocks were more frequently acid than those derived from basic rocks, but the smallest percentage of acid soils was found among those derived from volcanic ashes.

The author tested various methods of detecting and determining soil acidity and discusses their relative merits. He describes and recommends as simple and reliable a potassium nitrite test. For the exact determination of acidity he proposes a method based upon the fact that when acid soils are treated with a neutral salt solution, preferably potassium chlorid, the aluminum and iron compounds absorbed by the soil colloids are set free in such form as to give an acid reaction to the solution, the degree of which can be accurately determined by titration with standard alkali solution.

Acid soils were found to contain as a rule little lime, and their lime factor was generally unfavorable owing to an excess of magnesia.

Soils and subsoils, W. H. SHERZER (*Mich. Geol. and Biol. Survey Pub. 12, Geol. Ser. 9 (1913), pp. 130-149, pl. 1*).—The soils of Wayne County, Mich., are classified as glacial and river clays, sand and gravel, loam, silt, and muck soils.

The glacial clays consist mainly of silt and clay with a considerable quantity of fine sand. The river clays are more limited in extent than the glacial clays, but their average texture is finer and much more uniform. The sand and gravel soils possess relatively little available plant food, but are light and easily tilled and drained. The loam soils are deemed the most valuable in the county from a purely agricultural standpoint and are adapted to the growing of all crops which may be raised on either the clay or sand. The silt soils are closely related to the loam but are more limited in extent. The muck soils are from one-fifth to one-fourth sand and nearly two-thirds organic matter and contain very little clay. They can not be utilized for agricultural purposes until properly drained and their acidity corrected.

The excessive quantities of nitrates in certain Colorado soils, W. P. HEADDEN (*Jour. Indus. and Engin. Chem., 6 (1914), No. 7, pp. 586-590*).—This article summarizes a number of articles previously noted (*E. S. R., 28, p. 31; 29, p. 621; 30, p. 818*).

The soils of the island of Luzon, A. J. COX and A. S. ARGÜELLES (*Philippine Jour. Sci., Sect. A, 9 (1914), No. 1, pp. 1-50, pls. 7, figs. 4*).—The authors discuss the significance of the physics, chemistry, and biology of soils in general and give information based on a number of chemical and mechanical analyses concerning the fertility of some of the agricultural sections of Luzon.

The majority of the soils analyzed appear to be fine-grained and slightly acid. The soils of the Batangas district, consisting mostly of loam or clayey loam resulting from the disintegration of water-laid tuff, agglomerate, etc., are said to be very fertile. The area around Batangas is made up of alluvial and littoral deposits. The Pangasinan soils vary in texture from heavy tenacious clay loam to fine silt and sand or gravel. In certain wooded districts of the Mountain Province the soils are deficient in potash, and in spite of the general fertility of the soil there is a rice shortage in time of drought. The soils of the Cagayan Valley, the composition of which is continually changing owing

to occasional inundations, are generally considered exceedingly fertile and are used for the cultivation of corn, tobacco, etc. The soils of Laguna and Tayabas Provinces are said to be especially suited to the production of coconuts.

Miscellaneous chemical and mechanical analyses of soils from other provinces are given.

Analyses of soil samples from German Southwest Africa, C. GRIMME (*Arb. Deut. Landw. Gesell.*, No. 262 (1914), pp. 84-101).—Chemical and mechanical analyses of samples of soils from five localities are reported and discussed. The prevailing soils appear to be sands and loamy sands. Loess, loams, loamy clays, loam marls, and sandy loams are among the remaining soils.

The soils analyzed were most generally deficient in nitrogen and phosphoric acid, with an occasional deficiency in lime and potash also.

Nyasaland soils (*Bul. Imp. Inst. [So. Kensington]*, 12 (1914), No. 2, pp. 179-208).—Chemical and mechanical analyses of a number of samples of cotton and tobacco soils from this region are reported and discussed in continuation of previous work of the same kind.

Moor culture, E. SIERIG (*Die Moorkultur. Berlin, 1913, pp. VII+126, figs. 11*).—This publication deals with the subject of moor culture largely from an economic and sociological standpoint, although the strictly agricultural phase of the subject is briefly discussed.

The soil solution and the mineral constituents of the soil, A. D. HALL, WINIFRED E. BRENCHLEY, and LILIAN M. UNDERWOOD (*Jour. Agr. Sci. [England]*, 6 (1914), No. 3, pp. 278-301, pls. 5).—This is a reprint of an article already noted from another source (E. S. R., 30, p. 124).

How does the plant obtain its nutriment from the soil? A. D. HALL (*Mem. and Proc. Manchester Lit. and Phil. Soc.*, 58 (1913-14), pt. 2, Art. 6, pp. 22, pls. 6).—This article is based upon the results of the same experiments reported in full in the article noted above.

Harmful effects of aldehydes in soils, O. SCHREINER and J. J. SKINNER (*U. S. Dept. Agr. Bul. 108* (1914), pp. 26, pls. 8).—Salicylic aldehyde, found to occur in considerable amounts in certain field and garden soils from various localities, was used at rates of from 10 to 200 parts per million of medium in water cultures with wheat, corn, rice, cowpeas, and cabbage; in pot experiments with wheat, corn, and clover; and in field experiments with cowpeas, string beans, and garden peas.

The results showed that the aldehyde "in very small amounts is harmful to plants in distilled water and in nutrient solutions. It is harmful to plants grown in pots of soil. It greatly decreases the yield of crops grown in the field. It persists in the field soils for months. There is some evidence which suggests that lime and phosphate ameliorate the effects of salicylic aldehyde."

Of 14 poor garden soils examined 5 contained aldehydes, and of 30 unproductive field soils 9 contained aldehydes. Of 30 productive field soils examined 3 contained aldehydes. There appeared to be little or no relation between the occurrence of aldehydes and locality, soil type or texture, or crop grown.

Occurrence of aldehydes in garden and field soils, O. SCHREINER and J. J. SKINNER (*Jour. Franklin Inst.*, 178 (1914), No. 3, pp. 329-343, figs. 4).—The substance of this article is contained in the bulletin noted above.

Contributions to our knowledge of soil fertility, VII-XI, R. GREIG-SMITH (*Proc. Linn. Soc. N. S. Wales*, 38 (1913), pt. 4, pp. 725-746).—In a continuation of previous investigations on the growth of bacteria in soils (E. S. R., 30, p. 322) the author studied the combined action of disinfectants and heat upon soils; soil toxins and their formation; the action of chloroform upon blood treated with vaselin; and the action of naphthalin in soil.

The effect of heat was found to be small compared with that of chloroform, and in the double treatment tests the differences between heat then chloroform and chloroform then heat were marked. Toxic extracts were obtained from soils, but it was found that the demonstration of toxins in soils depends upon obtaining a soil in which the toxins exceed the nutrients in amount. Equal parts of soil and water generally yielded the most toxic extract. It was further found that an accumulation of toxic substances does not occur in dry soils and that two kinds of bacteriotoxins exist, viz, those thermolabile in the soil and those thermostable in the subsoil. Soils were found to have a variable bacteriotoxic content. A soil originally toxic became nontoxic when washed with water and upon incubation again became toxic.

The ammoniacal fermentation of blood saturated either with paraffin or vaselin was not accelerated by chloroform treatment. While naphthalin induced an increase in the number of bacteria in unmanured soils, it is concluded that there is no corresponding increase in the formation of ammonia from the organic matter originally present or added as dried blood.

The sterilization or disinfection of the soil, F. BERTHAULT (*Jour. Agr. Prat., n. ser., 27 (1914), No. 17, pp. 523, 524*).—Various investigations bearing on this subject are briefly summarized, with the general conclusion that it is well established that sterilization of the soil by heat or antiseptic substances, such as carbon disulphid, tar liquor, toluene, and sulphur, is capable of greatly increasing the yield of crops although the mode of action of these substances has not yet been determined with certainty.

Special reference is made to box and plat experiments by Miège during 1912 and 1913 on the effect of partial sterilization of soil by toluene, carbon disulphid, sulphur, formic aldehyde, chloroform, tar water, creosote, acetic ether, naphthol, phenol, copper and barium sulphates, and potassium permanganate on mustard and barley. Boxes 0.43 meter square each received from 1 to 15 cc. of the liquids and from 0.2 to 2 gm. of the solids. Plats 10 meters square received from 50 to 200 cc. of the liquids and from 5 to 20 gm. of the solids.

Most of the substances used were beneficial especially in small doses. Barium sulphate, naphthol, and creosote were injurious. Copper sulphate was injurious in the box experiments but beneficial in the plat experiments.

Rock and soil in relation to plant nutrition, E. BLANCK (*Landw. Vers. Stat., 84 (1914), No. 5-6, pp. 399-425*).—Pot experiments were conducted with oats and peas using three kinds of granite, shale quartzite, and porphyry pulverized as the growth medium to determine the relative crop yields and extent to which the plant food in these rocks is available to plants. The yields of peas and oats were greater with the granites and porphyry than with the shale quartzite, but the plant food contained in the latter was better utilized than that in the granite and porphyry. A further proof of the author's views (*E. S. R., 27, p. 520*) that mica potash, especially that of biotite, is more easily available for plants than feldspar potash was obtained.

A comparison of the results with those obtained in sandstone experiments (*E. S. R., 27, p. 513*) showed that greater yields were obtained with the sandstone and that the sandstone plant food was better utilized.

Relation of the mineralogical and chemical composition to the fertilizer requirements of North Carolina soils, J. K. PLUMMER (*North Carolina Sta. Tech. Bul. 9 (1914), pp. 3-29*).—Chemical and mineralogical analyses of the mountain, Piedmont, and coastal plain soils of North Carolina are reported, together with a summary of the results of field experiments previously noted (*E. S. R., 23, p. 635; 24, p. 336; 25, p. 721; see also p. 629*).

A close relation is shown between the chemical and mineralogical composition and the fertilizer requirements of the soils. The mountain and Piedmont soils are usually better supplied with potash, lime, and phosphoric acid than the coastal plain soils. The micas are the principal sources of potash for the former types. The potash feldspars are much more abundant in the Piedmont than in the mountain soils, and orthoclase and microcline supply most of the potash in the coastal plain soils, on which the greatest response has been secured from the use of potash fertilizer. The phosphoric acid content of most North Carolina soils is small, being often found in the mountain and Piedmont soils in the practically unavailable form of apatite, included in quartz and other minerals. The coastal plain soils contain less available lime than the soils of the other sections and derive their main supply from epidote. In the Piedmont and mountain soils hornblende and plagioclase feldspars are found in larger quantities than in the coastal plain soils. Little difference is shown in the mineralogical composition of the soil and subsoil in each section.

Fertilizer experiments in the German colonies (*Düngvers. Deut. Kolon.*, Nos. 2 (1913), pp. VI+94, pls. 5, figs. 5; 4 (1914), pp. VI+90, pls. 4, figs. 9).—Experiments with different fertilizers on a variety of crops in Kamerun, Togo, German New Guinea, and Samoa are reported.

Penguin guano from the Falkland Islands (*Bul. Imp. Inst. [So. Kensington]*, 12 (1914), No. 2, pp. 208-210).—Five samples of penguin guano showing from 0.16 to 0.32 per cent of potash, 1.22 to 4.22 per cent of phosphoric acid (largely soluble in 2 per cent citric acid), and 0.96 to 1.71 per cent of nitrogen (mostly organic) are reported.

The samples as analyzed contained a high percentage of water, 64 to 80 per cent, and this in part accounts for the fact that the guanos contained much less fertilizing matter than good Peruvian guano.

Fertilizer factory for the Bahamas (*Daily Cons. and Trade Rpts. [U. S.]*, 17 (1914), No. 158, p. 140).—The establishment of a factory for the preparation of fertilizers from loggerhead sponge and fish is suggested.

The atmospheric nitrogen industry in its economic relations, A. PERLICK (*Die Luftstickstoff-Industrie in ihrer volkswirtschaftlichen Bedeutung. Leipsic*, 1913, pp. 140; *rev. in Chem. Ztg.*, 38 (1914), No. 40, p. 432).—The technical methods of fixing the nitrogen of the air and their industrial and agricultural importance are discussed. The methods of Serpek and Haber are considered as most nearly solving the nitrogen problem for agriculture.

Influence of phosphatic and potash fertilizers on the chemical composition of meadow hay, C. DUSSERRE (*Ann. Agr. Suisse*, 14 (1913), No. 4, pp. 271-273).—Data are reported which show that fertilizers containing phosphoric acid, as well as those containing phosphoric acid and potash, not only increase the yield but also the nitrogen and phosphorus content of the forage. From 55 to 74 per cent of the phosphorus was found to be combined in mineral compounds or in phytin, 5 to 9 per cent in lecithin, and 21 to 40 per cent in nucleoproteids. The use of fertilizers doubled and in some cases quadrupled the phosphorus content, the greatest increase being in the mineral phosphorus.

Geology of the phosphate deposits northeast of Georgetown, Idaho, R. W. RICHARDS and G. R. MANSFIELD (*U. S. Geol. Survey Bul.* 577 (1914), pp. 76, pls. 14, figs. 3).—This report briefly reviews the history of the discovery of the western phosphate field and presents in some detail a discussion of the structural geology, particularly as related to what has been named by the authors the "Bannock overthrust," of an area in addition to those reported in previous bulletins (*E. S. R.*, 26, p. 125), comprising portions of Bear Lake and Bannock counties in western Idaho, in which are located the phosphate deposits of Georgetown Canyon.

The estimated available phosphate rock in this region is given as 1,347,370,000 long tons, which, added to the estimates for areas previously surveyed, gives a total tonnage for the area covered by detailed surveys to date of 2,663,290,000 long tons.

The chemical analyses already made indicate that clean rock from the thick workable beds usually maintains an average of over 32 per cent of phosphoric acid, but this percentage is increased somewhat in the weathered outcrops of the phosphate beds. The phosphate usually contains less than 1 per cent of iron or aluminum and hence is of good quality for the manufacture of super-phosphates.

It is stated that too little is at present known concerning the land and the marine conditions that prevailed during the process of formation of the phosphate deposits to permit the formulation of a satisfactory hypothesis.

Note on certain phosphate deposits in western Madagascar, P. DE LA BATHIE (*Gouv. Gén. Madagascar. Feuille Mens. Inform. Agr. et Com., 1914, Nos. 20, pp. 8-10; 21, pp. 10-12*).—Phosphatic nodules associated with marl and containing from 20 to 50 per cent of tricalcium phosphate are described.

The effect of ensilage fermentation and animal digestion on the solubility of phosphoric acid in phosphate rock, C. A. MOOERS (*Jour. Indus. and Engin. Chem., 6 (1914), No. 6, pp. 487, 488*).—Referring to an article by Forbes and Fritz (*E. S. R., 31, p. 422*), reporting results which indicate that the ensiling process may be used to render floats soluble and hence available both to animals and plants, the author reports experiments made at the Tennessee Experiment Station in which 2 lbs. of finely ground phosphate rock was mixed with over 100 lbs. of corn at the time the silo was filled and the resulting silage fed to cattle, with the result that although the silage was excellent in odor and appearance the animals refused to eat it after a short time. Extraction with 1 per cent nitric acid showed that the solubility of the phosphoric acid of the phosphate rock in the dung of the animals fed phosphated silage was increased only 3.28 per cent of the total phosphoric acid.

“Based on the assumption that all of the phosphoric acid was voided in the dung, the data at hand indicate that a reversion of the soluble phosphoric acid took place during the process of animal digestion. The general conclusion is indicated that the silo does not offer a practical means of making the phosphoric acid of phosphate rock available for plant use.”

The effects of the ensilage process on the solubility and metabolism of floats, E. B. FORBES (*Jour. Indus. and Engin. Chem., 6 (1914), No. 7, p. 605*).—This is a reply to the criticisms by Mooers in the article noted above.

The effects of the ensilage process on the solubility and metabolism of floats, C. A. MOOERS (*Jour. Indus. and Engin. Chem., 6 (1914), No. 8, p. 695*).—A further discussion of this subject.

Potash (*Mich. Geol. and Biol. Survey Pub. 13, Geol. Ser. 10 (1913), pp. 93-96*).—The possibility of the discovery of potash salts associated with Michigan brines is briefly discussed. While the limited evidence so far collected is largely negative, the conclusion that there is no possibility of potash salts being found within the limits of the State is not considered warranted. Some of the difficulties and possibilities of drilling for potash salts are pointed out.

The lime factor theory, O. LOEW (*Die Lehre vom Kalkfaktor. Berlin, 1914, pp. 31. fig. 1*).—Investigations bearing on this subject are critically reviewed.

The question of sulphur in agriculture, E. MIÈGE (*Rev. Sci. [Paris], 52 (1914), I, No. 25, pp. 778-784*).—Investigations on this subject are reviewed in relation to their bearing on the direct and indirect action of sulphur on the growth of plants, but attention is called particularly to a theory explaining the

action of sulphur as due to its absorption of the oxygen of the soil while leaving the nitrogen free to be utilized by the nitrogen-fixing bacteria.

Analyses of fertilizers, spring season, 1914, B. W. KILGOBE ET AL. (*Bul. N. C. Dept. Agr., 35 (1914), No. 6, pp. 85*).—This bulletin contains analyses and valuations of fertilizers collected by the fertilizer inspectors of the state department of agriculture during the spring of 1914, as well as a list of brands of fertilizers registered for sale during the spring season.

Analyses of commercial fertilizers, P. H. WESSELS ET AL. (*Rhode Island Sta. Insp. Bul., 1914, June, pp. 8*).—This contains analyses and valuations of samples of fertilizers, collected in the spring of 1914, which the manufacturers designated as potato fertilizers. It also contains analyses and valuations of bones, fish, and tankage collected during the season.

AGRICULTURAL BOTANY.

Comparative morphology of some Leguminosæ, J. N. MARTIN (*Bot. Gaz., 58 (1914), No. 2, pp. 154-167, pls. 4*).—A study was made of the development of the embryo sac, embryo, and endosperm of *Trifolium pratense*, *T. hybridum*, *T. repens*, *Medicago sativa*, and *Vicia americana*.

Among some of the contrasting features observed, the author found that the number of ovules is always two in *T. pratense*, but more than two in the other species. In *Trifolium* the embryo sac rapidly destroys the antipodal end of the nucellus, and thus forms a long tubular sac. The embryo sac remains vacuolate in *Trifolium*, while in *Vicia* and *Medicago* it is filled with cytoplasm. In *Trifolium* and *Vicia* the starch appears in the micropylar end of the nucellus and in the inner integument, while it fills the sac in *Medicago*. Sterility was found most marked in *T. pratense*.

A study of the germinating power of seeds, M. L. DARSIE, CHARLOTTE ELLIOTT, and G. J. PEIRCE (*Bot. Gaz., 58 (1914), No. 2, pp. 101-136, figs. 18*).—By means of silvered Dewar flasks, the use of which has been previously described (*E. S. R., 20, p. 734*), the authors have made a study of the germination of seed of corn, oats, wheat, clover, barley, and hemp of known age to determine the viability of the seed as influenced by age.

It was found that with the different seeds the germinating power and vigor of growth is indicated by determining the temperatures which they will develop in Dewar flasks under conditions suitable for germination. Each species of plant studied appears to have a normal temperature, departures from which indicate departures from the best condition of the organism. Temperatures in excess of normal indicate an infection of the seed, while subnormal temperatures indicate lessened vigor. Decreased vigor was generally found due to increased age. Departures from normal temperatures were found to be accompanied by differences in amount of growth immediately following germination, and it is thought that possibly this might be true of the other stages in the growth of the plant, although this was not investigated.

A physiological study of the germination of *Avena fatua*, W. M. ATWOOD (*Bot. Gaz., 57 (1914), No. 5, pp. 386-414, figs. 13*).—Results of studies testing the relations of germination to water intake, wounding, oxygen access and absorption, acidity, etc., are given.

It is claimed that after-ripening of seed in wild oats occurs along with drying of the seed, but independently of the water content and also of the seed coats as controlling the entrance of water. Their removal, however, hastens germination, although this is independent of light. The delay in germination is attributed to a restriction of the oxygen supply, due to the seed coat, as shown by the hastening effect of breaking or searing these coats, removal of the

embryo, increasing and decreasing the oxygen concentration, and direct measurement of the oxygen intake with intact and seared seeds, and with seeds in varying concentrations of oxygen. It is thought that after-ripening may consist in an increased permeability of the seed coat to oxygen, together with a rise in the embryo acid content, which is accompanied by an increased water absorbing power of the embryo.

A bibliography is appended.

Transpiration in relation to growth and to the successional and geographic distribution of plants, A. DACHNOWSKI (*Ohio Nat.*, 14 (1914), No. 4, pp. 241-251).—Discussing the results of work previously reported (E. S. R., 28, p. 733), the author considers it probable that the absorbing power of the root system of a plant is not regulated by the amount of water transpired but by the differential permeability of the absorbing epidermal root cells and the metabolic requirements during the life cycle; that absorption of inorganic and organic constituents is not connected with transpiration but with metabolism; and that no direct relation exists between growth, green and dry weight of plants, and transpiration, even under the same conditions of experiment. The rate and amount of growth and final size of a plant depend in part on favorable conditions of temperature, light intensity, food supply, and amount of water present in the plant, the rate or total amount of water transpired giving no indication as to the quantity normally required for metabolic processes and for growth. It is held that the quantity of transpiration water in most plants is not coordinated with or directly related to the absorption and translocation of solutes or to the green and dry weight of plants, that it is not an index of metabolism and growth or vegetable luxuriance, but that it has its own advantages, such as protection from high temperatures in direct sunlight and aid in gaseous exchanges. It is thought that transpiration may be a factor in determining the final form of plants.

The physiological water requirement and the growth of plants in glyco-coll solutions, A. DACHNOWSKI and R. GORMLEY (*Amer. Jour. Bot.*, 1 (1914), No. 4, pp. 174-185; *abs. in Science*, n. ser., 39 (1914), No. 1017, p. 956).—This paper, though regarded as of a preliminary nature, continues physiological studies of Dachnowski (see above).

Tabulated results are given of experiments with bog plants tested in regard to transpiration and growth in glyco-coll solutions of varying strength. It is stated that the transpirational water loss in the experiments cited is a function of the vapor pressure of the water, affected by the quantity of salts in solution and the factors modifying the atmospheric conditions. The absorption of glyco-coll is not connected with the transpirational water loss, but with the differential permeability of the absorbing root cells, with the efficiency of the nutritive metabolism characteristic of the plants, and with the amount of water retained within the plants.

The insufficiency of a salt operates as a limiting factor to growth, but transpiration does not decrease consistently with retardation thereof. The amount of water retained is decreased when the strength of the solution passes a certain optimum concentration, the available water rather than the solute becoming then the limiting factor, unlike plants reacting differently to physiologically limiting water conditions. The variations appear to be inherent peculiarities of the growth capacity and metabolism of plants. Plants may show loss in weight without a corresponding loss in amount of water transpired, or an increase of growth may occur with little or no increase in transpiration. A decrease in the increment of body weight may arise through faulty nutrition and enforce compensating processes. Weaker acid solutions are more effective than stronger solutions in affecting the hydration capacity of tissues.

and thus in increasing the transpiration of plants (but not their growth). The retention of water is the physiological function correlated with and indispensable to growth in general, and to survival and greater areal distribution of the plants entering physically or physiologically arid habitats.

The tensile strength of sap, H. H. DIXON (*Sci. Proc. Roy. Dublin Soc., n. ser., 14 (1914), No. 16, pp. 229-234*).—The author has investigated the tensile strength of the sap of beech and other trees and found that it does not differ materially from that of water. In the few experiments made the ease with which tension was generated and its magnitude before rupture occurred are believed to indicate that sap is somewhat more stable under tension than pure water.

Oxidases and their inhibitors in plant tissues, I-III, W. R. G. ATKINS (*Sci. Proc. Roy. Dublin Soc., n. ser., 14 (1913), No. 7, pp. 144-156; 14 (1914), Nos. 8, pp. 157-168; 11, pp. 199-206*).—The author has given a detailed account of investigations on the distribution of oxidases in certain tissues, a large number of plants having been examined.

Special studies were conducted on the occurrence of oxidase in *Iris germanica*. It was found that in the leaf of this plant there exists a substance which prevents the detection of oxidases by the direct application of guaiacum solution and hydrogen peroxid.

In the second paper the author reports studies to determine qualitatively the effect of light and darkness upon the oxidases and reducing substances of the *Iris* leaf and their relationship to the production of color in the flower of *Iris*. Prolonged darkness is said to have no decided effect upon the distribution of the indirect oxidase (peroxidase) reactions or of the inhibitor in the leaf of *I. germanica*. The distribution of the oxidase and inhibitor in the flowers of a number of varieties of *Iris* was examined and correlated with the natural coloring of the flowers, the author concluding that the behavior of *Iris* flowers closely follows that of other species reported by Keeble, Armstrong, and Jones (*E. S. R., 29, p. 421; 30, p. 129*).

The concluding paper gives an account of a study on the localization of oxidases and catalase in some marine algæ. Catalase was found in all of the 29 species studied. Only one species gave a direct oxidase reaction with guaiacum while six gave an indirect reaction with hydrogen peroxid. The presence of water-soluble phycophæin in small quantity during life and its reduction to a colorless substance at death is suggested as an explanation of the much discussed color change occurring in brown algæ.

Bibliographies are appended to the different papers.

The production of anthocyanins and anthocyanidins, A. E. EVEREST (*Proc. Roy. Soc. [London], Ser. B, 87 (1914), No. B 597, pp. 444-452*).—The author, presenting experimental data, claims to have demonstrated the production of anthocyanins from yellow glucosids and states that in cases where hydrolyzed solutions were taken only anthocyanidins were produced, claiming that these facts with others cited oppose the hypothesis offered by Miss Wheldale (*E. S. R., 21, p. 726*) to the effect that anthocyanin pigments are the oxidation products of colorless or faintly colored chromogens and that these chromogens are products of hydrolysis of glucosids present in the tissues of the plant. Studies previously published by the author in connection with Willstätter (*E. S. R., 30, p. 324*), also reports by Keeble, Armstrong, and Jones (*E. S. R., 30, p. 129*), are considered to have shown that if the anthocyanins are produced from the yellow glucosids, it must be by some interaction in which the glucosids and not the hydrolyzed glucosids take part and that anthocyanin pigments are not oxidation, but reduction, products of the yellow glucosids.

The relation of cultivated plants to certain soil salts, **III**, B. HANSTEEN CRANNER (*Jahrb. Wiss. Bot. [Pringsheim]*, 53 (1914), No. 4, pp. 536-602, pls. 3, figs. 5).—This report gives a fuller and more detailed account of studies by the author, previously noted from another source (E. S. R., 28, p. 426), and following up earlier communications on the same subject (E. S. R., 23, pp. 28, 328).

Effect of strongly calcareous soils on the growth and composition of certain plants, P. L. GILE and C. N. AGETON (*Porto Rico Sta. Rpt. 1913*, pp. 14, 15).—A study has been made of pineapples, beans, radishes, sugar cane, sweet cassava, and rice to determine the effect of varying the quantity of carbonate of lime upon their growth and composition.

Some plants showed a variation in their ash composition, but in general the results indicate that if a soil is not absolutely deficient in calcium it is useless to attempt to increase the lime content of forage plants by liming the soil.

Quantitative criteria of antagonism, W. J. V. OSTERHOUT (*Bot. Gaz.*, 58 (1914), No. 2, pp. 178-186, figs. 4).—In order to bring about more uniform methods of determining antagonism, the author presents data which indicate that the method of mixing equally toxic solutions furnishes the best criterion of antagonism, since it is known at the outset just what effect each mixture must have, provided there is no antagonism. Mixtures of two equally toxic solutions must have precisely the same effect on growth as the pure solutions themselves, provided the effects of the salts are additive. If antagonism exists, there is an increased growth in the mixtures, and the amount of this increase, expressed as percentage of the growth obtained in the pure solutions, is the most satisfactory measure of antagonism. It is said that the most reliable results may be obtained by the use of uniform material and by taking for measurement only such parts as come into immediate contact with the solution.

The effect of one crop upon another, DUKE OF BEDFORD and S. U. PICKERING (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 136-151, pl. 1).—In continuation of their investigations (E. S. R., 26, p. 639), in which the authors claim that grass roots interfere with the growth of orchard trees, experiments were carried on in earthenware pots in which tobacco, tomatoes, barley, and mustard each were grown in one pot, surrounded by a second containing the same kind of soil, but in which was grown not only various grasses, clovers, etc., but the same plants as in the first pot.

The results of this investigation are given in some detail, and it is claimed that every growing crop results in the formation of a substance which is toxic to the growth of other plants and still more so to itself. By oxidation this toxin loses its toxic properties and enhances the fertility of the soil. The toxic effects is found to vary with the nature of the soil, the kind of plant, and the vigor of growth. There is not believed to be any reason for assuming the excretion of any toxic matter from a plant, as the débris from the growing roots is believed sufficient to account for the formation of toxin. Heating of soil produces toxic matter from organic substances present in it and in much greater quantities than that produced by the growth of a crop. In both cases the toxin, after oxidation, increases the fertility of the soil.

The spread of morbid changes through plants from branches killed by heat, H. H. DIXON (*Sci. Proc. Roy. Dublin Soc., n. ser.*, 14 (1914), No. 12, pp. 207-210, figs. 2).—In a previous publication (E. S. R., 17, p. 452) the author has shown that if a branch of a plant is killed by heat and the rest of the plant supplied with water through this branch, some of the leaves on the uninjured branches may become injuriously affected. Further studies have shown that branches killed by heating them with steam and afterwards supplying them

with water often have some of their leaves visibly affected, indicating that changes are produced in the sap which are largely responsible for the alterations in the leaves above, and these changes should not be attributed to the cutting off of the water supply, but rather assigned to its contamination.

The effect of city smoke on vegetation, A. L. BAKKE (*Iowa Sta. Bul.* 145 (1913), pp. 383-409, pl. 1, figs. 22).—A report is given of a study of the smoke problem in Des Moines, Iowa, in which a discussion is given of the sources of smoke, various smoke belts, their characteristics, and the susceptibility of plants to smoke. Some investigations were conducted on the nature of smoke, physiological factors in plant injuries, the effect of different smoke constituents, and the relation of smoke to the storage of material in plants.

It was found that about manufacturing plants the region may be mapped off in concentric belts, each represented by certain forms of plant life, as some species are more susceptible to smoke injury than others. On account of their resistance to smoke, certain plants are recommended for planting about industrial centers.

Toadstools and mushrooms of the countryside, E. STEP (*London* [1913], pp. XVI+143, pls. 136).—Popular descriptions are given of a considerable number of mushrooms, with notes on their distribution, habitat, edible or poisonous qualities, etc.

FIELD CROPS.

The effect of soil moisture, plant food, and age on the ratio of tops to roots in plants, F. S. HARRIS (*Jour. Amer. Soc. Agron.*, 6 (1914), No. 2, pp. 65-75).—In this paper previous literature on this subject is reviewed and results given of pot experiments conducted at the Utah Station in which wheat, corn, and peas were grown in soil extracts, sand, and clay loams that were of varying concentrations and of different moisture content and differently fertilized.

The results "show with wheat seedlings growing in soil extracts the green weight, dry weight, and length of roots was proportionately greater in the dilute than in the concentrated soil extract. Corn, wheat, and peas growing a number of weeks in sand containing different amounts of moisture showed a proportionately greater root growth in the drier sand. Corn grown in glass tubes 75 days showed a relatively greater root growth where the level of free water was a considerable distance below the surface. Different roots of the same corn plant grown in very wet and in moist sand showed a greater root growth with the lower amount of water.

"Tests with corn and wheat showed that the ratio of tops to roots was affected by soil moisture even during the germination stage. Wheat harvested at different stages showed relatively more roots during early stages of plant growth than later. Wheat grown to maturity showed a greater relative root growth with low than with high soil moisture, and the moisture during the early stages of growth had the greatest influence on that ratio. Fertilizers added to the soil reduced the relative root growth of wheat."

Fertilization and cultivation of corn, cotton, and tobacco, C. B. WILLIAMS (*North Carolina Sta. Circ.* 18 (1914), pp. 16).—This gives fertilizer formulas for corn and cotton on land in fair condition in the coastal plain section and in the Piedmont section, and also for tobacco.

Annual report, 1913-14, R. E. BLOUIN and A. H. ROSENFELD (*Rev. Indus. y Agr. Tucumán*, 4 (1914), No. 9-10, pp. 369-492, pl. 1, figs. 21).—This report summarizes the work at the experiment station at Tucumán, Argentina, in varietal, manurial, and cultural tests with sugar cane, maize, cotton, and legumes for the calendar year 1913.

Physiological correlations and climatic reactions in alfalfa breeding, G. F. FREEMAN (*Amer. Nat.*, 48 (1914), No. 570, pp. 356-368, fig. 1).—This paper discusses the factors of temperature, relative humidity, and water supply in their relation to development, yield, and chemical composition of 44 regional varieties of alfalfa grown at the experiment station farm at Phoenix, Ariz., and gives tables showing the correlation between stand and yield, between nitrogen content of hay and percentage of leaves, between nitrogen content of hay and nitrogen content of leaves, between percentage of leaves and stand, between percentage of leaves and height, between percentage of leaves and yield, and between nitrogen content of hay and period required for maturity.

It is noted that in respect to yield "the different regional varieties take the following relative order: Peruvian, European, Turkestan, American, and Mediterranean. It is here noticeable that though the European and Mediterranean varieties have similar seasonal yield curves they are not contiguous in the arrangement based on total yields. This is a result of a market difference in the stand maintained by the two varieties, which averaged 92 per cent for the former and 74 per cent for the latter. In their ability to maintain stand, the Peruvian, European, Turkestan, and American varieties were about equal, averaging 92, 92, 93, and 94 per cent, respectively. The lack of stand on the part of the Mediterranean alfalfas was not due to the poor quality of the original seed, for all of these plats once had perfect stands."

The author concludes that "in economic plant breeding one frequently encounters physiologically negative correlations, such as those in alfalfa, between height, stooling capacity, height and percentage of leaves, and between yield and quality. In seeking improvement, therefore, the breeder must recognize and make use of these facts in the interpretation of results obtained, and also search for races which violate such naturally antagonistic correlations to the greatest possible extent."

The cultural value of Turkestan alfalfa, G. BOHUTINSKÝ (*Monatsh. Landw.*, 7 (1914), No. 3-4, pp. 73-81, fig. 1).—The results of trials here given indicate a superiority of Hungarian over Turkestan alfalfa.

A new method of growing corn, C. C. CUNNINGHAM (*Jour. Amer. Soc. Agron.*, 6 (1914), No. 2, pp. 84-88, figs. 2).—The author describes a method of planting corn that has been successfully tried out in western dry-land conditions of western Kansas. By this method the corn is planted in rows twice the usual distance apart while the plants are twice as thick in the row. The stand is therefore the same, but as this method seems to preserve the moisture midway between the rows the supply is often sufficient to maintain the corn in a flourishing condition during temporary periods of drought, while occasionally it may complete the development of the crop. It is noted that by this method the yields were around 30 bu. per acre while adjoining fields in which the rows were 3½ ft. apart the yields were only 10 to 12 bu. per acre.

Variety tests of corn for 1913, G. M. GARREN (*Bul. N. C. Dept. Agr.*, 35 (1914), No. 2, pp. 16).—This bulletin gives data in tabular form covering about 40 varieties of corn grown in 1913 at the test farms at Buncombe, Iredell, Central Station, and Edgecombe, and summaries of yields of certain varieties grown at Iredell and Edgecombe in 1909-1913, inclusive.

Brief notes discuss these results and point to the varieties, Weekly Improved and Biggs Seven Ear, as most suitable for North Carolina.

Fertilizer experiments with cotton on the sandy loam soils (Norfolk sandy loams) of the coastal plain, B. W. KILGORE, C. B. WILLIAMS, G. M. MACNIDER, and R. W. SCOTT, JR. (*Bul. N. C. Dept. Agr.*, 35 (1914), No. 4, pp. 48).—This bulletin continues previous work (*E. S. R.*, 24, p. 336), and reports the results of experiments with cotton to determine the fertilizer needs of the coastal plain soils.

The main increased yields and profits came from the use of nitrogen and potash. With phosphoric acid and potash the yield was slightly greater than with nitrogen and phosphoric acid, but not nearly so great as with nitrogen and potash. Nitrogen added to phosphoric acid and potash, making a complete fertilizer, apparently increased the yield and gave an additional profit. The application of lime alone was in general accompanied with some profit.

Tests of the effect on the yield of cotton of varying quantities of nitrogen, leaving the phosphoric acid and potash constant, indicated that nitrogen is one of the controlling constituents, if not the most important one, for crop production on this soil. Corresponding tests of the effect of varying the quantities of phosphoric acid and potash showed no very marked effect on the yield of cotton, and indicated that their application is not accompanied with much profit. Tests of the comparative value of dried blood and nitrate of soda as sources of nitrogen for cotton showed them to be about equally satisfactory.

Experiments on the effect of different methods and time of application of fertilizer showed that it made very little difference whether all the fertilizer was applied in the drill before planting or whether one half was put in the drill before planting and the remainder applied as a side dressing about July 1, according to season.

Information regarding varieties, culture, and fertilization of cotton on these soils is appended.

Fertilizer experiments with cotton on Piedmont Cecil sandy loam soil, and varieties, culture, and fertilization of cotton on Piedmont Cecil sandy loam and red clay soils, C. B. WILLIAMS, B. W. KILGORE, and A. R. RUSSELL (*North Carolina Sta. Bul. 227 (1914), pp. 5-52*).—Part 1 of this bulletin gives results of a study to determine the proper fertilization for cotton on Piedmont Cecil sandy loam and similar soils. "The use of a mixture carrying normal amounts of phosphoric acid and nitrogen gave an average increased yield of seed cotton per acre of 43 per cent over the yield secured on the same character of land without fertilization. The net profit over cost of fertilizer of this combination was \$15.14 per acre. Where a normal amount of potash was used with the phosphoric acid in place of the nitrogen there was an average increase in yield of 46 per cent of seed cotton and an average profit over cost of fertilizer used of \$19.17 per acre."

The use of a fertilizer mixture carrying normal amounts of nitrogen and potash was far less effective and profitable, the average net profit per acre being only \$4.84 per acre. Nitrogen, phosphoric acid, and potash combined in a complete fertilizer yielded on an average only slightly more than when nitrogen was left out of the mixture.

Lime alone was used at a very small profit, while in a complete fertilizer it has shown up on an average to a slightly better advantage. "Slightly the largest profit per acre was secured by applying all the nitrogen along with the phosphoric acid and potash before planting, having four-fifths of it derived from dried blood and one-fifth from nitrate of soda. . . . The most profitable method, everything considered, of applying the fertilizer mixture, the results would seem to indicate, would be in the drill at planting time at the ordinary depth. . . . For the conditions prevailing and the length of time covered by the experiments comparing the relative value of acid phosphate, basic slag, and finely ground phosphate rock, the former material was found to be decidedly the most efficient and profitable carrier of phosphoric acid for cotton."

Part 2 gives suggestions to growers of cotton on Piedmont sandy loam and red clay soils as to varieties, culture, and fertilization.

Results of variety tests of cotton in Mecklenburg County, C. B. WILLIAMS (*North Carolina Sta. Circ. 16 (1914), pp. 4*).—This circular describes tests on two types of soil.

The results are reported as emphasizing the importance of using the best of the early maturing varieties on a rather stiff clay soil of the Piedmont portion of the State, especially if the section is near the limit of the growth of cotton. For the Cecil sandy loam with a red clay subsoil, the best of the later varieties will, in many cases, produce the greatest net return per acre.

Testing cotton seed for germination, W. C. LASSETTER (*Arkansas Sta. Circ. 22 (1914), pp. 2*).—A practical method for testing cotton seed and corn is described.

Spinning tests of upland long-staple cottons, F. TAYLOR and W. A. SHERMAN (*U. S. Dept. Agr. Bul. 121 (1914), pp. 20*).—This bulletin discusses soil types represented, variations in grades and staple, lengths, invisible loss, card waste, relation of grade to waste, comparisons at the comber, comber tests, value of waste differences, accuracy of machine work, factors influencing waste, tests of breaking strength, and cultural characteristics, compares early and late picked cotton, and gives data on tests made at the New Bedford Textile School.

"These tests show that careful breeders in the Carolinas are producing cotton fully equal in almost every respect to average Deltas of the same length. They also show that several strains now grown in commercial quantities in the Southeast are less wasty than average Deltas, although not so strong. These varieties are earlier, have larger bolls, and are usually more prolific than Delta types. These uniform varieties are the result of intelligent breeding work. The importance to the spinner of such work can hardly be overestimated. It suggests the wisdom of more direct dealing between spinners and careful producers, that the latter may be guaranteed suitable premiums for their superior products."

A new cover crop, W. G. CRAIB (*Roy. Bot. Gard. Kew. Bul. Misc. Inform., No. 2 (1914), pp. 76, 77*).—A description of a leguminous plant (*Dolichos hosei*) indigenous to Sarawak and grown experimentally at Kuala Lumpur. It is noted as proving a successful cover crop and as growing from cuttings.

Notes on a creeping bean, E. HOSE (*Agr. Bul. Fed. Malay States, 1 (1913), No. 7, p. 276*).—The plant noted above is described and its successful cultivation as a cover crop reported.

Mireken nuts [candle nut] (*Aleurites moluccana*) (*Agron. Colon., 1 (1914), No. 10, p. 120*).—The analyses here given show the fat to range from 62.48 to 67.12 per cent and the protein from 19.4 to 25.3 per cent.

Oats, M. NELSON and C. V. RUZEK (*Arkansas Sta. Bul. 118 (1914), pp. 625-637, fig. 1*).—In this bulletin are given the methods and results of several years' cultural variety tests.

For winter oats variety-test-yields reached up to 54.5 bu. per acre during 1909-1913 and spring oats up to 65 bu. It was found that the winter varieties produce taller straw, larger yields per acre, and heavier grain per bushel than do the spring varieties, but the spring varieties mature earlier and stand up better. Virginia Turf, Winter Gray, Winter Turf, and Snoma are the best winter varieties included in these tests, and Burt, Hybrid No. 45, Red Rust Proof, and Daubenny the best spring varieties. The northern varieties of oats have not given good results in comparison with the other varieties.

For the northern part of the State the results indicate that the first half of March is the best time for seeding spring oats, while for the central and southern part of the State the last half of February is preferable. For the northern part of the State the latter half of September gives best results of seeding winter oats, but for the central and southern parts of the State the first two

weeks in October are preferable. As an average of five years' tests, seeding spring oats at the rate of 10 and 12 pk. per acre gave the best and most economical returns.

On the assimilation of soil constituents by oats, J. W. PATERSON and P. R. SCOTT (*Jour. Dept. Agr. Victoria, 12 (1914), No. 4, pp. 193-201, fig. 1*).—In making these determinations the crop was divided into roots; straw, including stems, leaves, floral axes, and chaff; and grain, including flowers or fruit with the poles. Nitrogen, potash, lime magnesia, phosphoric acid, and silica were determined at three harvestings: (1) Just before flowering, (2) the plants well headed with the lower leaves turning yellow, and (3) the crop ripening.

The results showed that "the oat crop forms about 95 per cent of its substance from the air. The necessary soil constituents form only a small part of the crop by weight. Seven soil constituents are essential. Each of them is absorbed in solution. 'Deficiency' in any constituent means deficiency in a soluble form. In such a case the crop will also be deficient. With most of the soil constituents the acid reaction of living roots helps in their solution. This solvent action requires time.

"Nitrogen and potash cease to be absorbed by the oat plant about the time of full bloom. This fact renders a larger available supply of these constituents necessary at seed time than would otherwise be the case. The absorption of phosphoric acid continues to a later stage of vegetation. This fact is in favor of the action of phosphatic manures. Silica is absorbed still later than phosphoric acid, and as long as the plant is green. Silica is not a plant food. Little or none of the phosphoric acid absorbed is afterwards lost to the plant.

"These experiments show that a good deal of the absorbed nitrogen and still more of the potash may be lost. It is not clear that the lost substances were useful, although such losses are probably inevitable in oats grown under field conditions. Materials absorbed and excreted by the plant impose no extra drain upon the soil for subsequent crops."

Paddy cultivation in Ceylon during the nineteenth century, E. ELLIOTT (*Trop. Agr. and Mag. Ceylon Agr. Soc., 37 (1911), Nos. 3, pp. 225-232; 4, pp. 305-312; 5, pp. 393-397; 6, pp. 501-507, 559; 38 (1912), Nos. 1, pp. 21-31; 4, pp. 313-318; 5, pp. 403-408; 6, pp. 506-511; 39 (1912), Nos. 1, pp. 21-24; 2, pp. 118-125; 3, pp. 235-238; 40 (1913), Nos. 2, pp. 115, 116; 3, pp. 100-102; 6, pp. 322-326; 41 (1913), Nos. 2, pp. 116-119; 3, pp. 203-205; 4, pp. 286-290; 5, pp. 393, 394; 6, pp. 465-467; 42 (1914), Nos. 2, pp. 98-100; 4, pp. 286-290; 5, pp. 381-383*).—This article consists of a study of the rice industrial and cultural conditions, including a statistical review and descriptions of cultural and market conditions of the century in successive periods.

New varieties of rice imported from Japan in 1913, P. POLI (*Gior. Riscolt., 4 (1914), No. 8, pp. 115-117, figs. 4*).—Two varieties of rice are here described that were introduced into Italy from Japan.

Preparation of seeds of the sugar beet, S. VON WILKONSKI (*Bl. Zucker-rübenbau, 21 (1914), No. 8, pp. 121-126*).—Results of experiments are given in which beet seeds were soaked in a water solution of superphosphate (25° Brix) for from 7 to 9 days and then planted in comparison with unfertilized and fertilized seeds. In general the treated seeds gave more satisfactory results than the untreated, although not uniformly so.

Cultural experiments with artificially dried beet seeds in Hungary in 1912, B. VON JANCSÓ (*Österr. Ungar. Ztschr. Zuckerindus. u. Landw., 43 (1914), No. 2, pp. 174-188*).—This paper reports a continuation of work previously noted (E. S. R., 29, p. 739), showing practically identical results, i. e., that while laboratory experiments showed a better percentage of germination of seeds and somewhat more thrifty plants, yet no practical difference could be detected from point of yield in field experiments.

It is also noted that root blight was not reduced by the drying methods, except in the laboratory experiments. This advantage was attributed to a more vigorous early growth which the dried seed seemed to induce.

On the character of beets derived from the same seed ball, O. MUNERATI, G. MEZZADROLI, and T. V. ZAPPAROLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 9, pp. 576-588, figs. 9; *Sucr. Indig. et Colon.*, 83 (1914), Nos. 5, pp. 105-110, figs. 8; 6, pp. 130-134, fig. 1).—The results show that beets, whether sugar beets, semisugar beets, or stock beets, grown from the same ball present the same variety in form and sugar content that may be noted in field culture. There seemed to be no relation between the weight of individual beets and the sugar content.

A method of planting seeds in sectional cylinders, from which the young plants may be transplanted when they have developed from 4 to 6 leaves, and which has proved successful in obtaining beets of uniform and regular form, is described. It is noted that by the time the plants have attained a development of from 4 to 6 leaves the root form is determined.

The weight and sugar content of sugar beets in relation to the area at the disposition of each plant in the field, O. MUNERATI, G. MEZZADROLI, and T. V. ZAPPAROLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 11-12, pp. 755-779, figs. 6).—In a study of this question with sugar beets, semisugar beets, and stock beets the authors conclude that the condition of the soil has more to do with the points in question than the spacing.

On the fluctuation of nitrogen content in sugar beets of the same parentage, F. STROHMER, O. FALLADA, and L. RADLBERGER (*Österr. Ungar. Ztschr. Zuckerindus. u. Landw.*, 43 (1914), No. 2, pp. 193-207, figs. 6).—The results here reported showed no relation between the absolute weight or dry matter and the nitrogen content of beets, but well-bred beets of the same parentage showed a variation of nitrogen content of less than 0.1 per cent.

The wild cotton plant (*Thurberia thespesioides*) in Arizona, V. BAILEY (*Bul. Torrey Bot. Club*, 41 (1914), No. 5, pp. 301-306, figs. 2).—This article describes the wild cotton plant, *Thurberia thespesioides*, found in Arizona, giving its zonal range and a list of other plants generally associated with it.

The state grain laboratory and the Montana seed laws, A. ATKINSON and B. W. WHITLOCK (*Montana Sta. Circ.* 30 (1913), pp. 73-88).—This circular describes the purpose of the state grain laboratory, gives the text of the state laws establishing it and providing for seed inspection, and rules and regulations promulgated.

On germination tests in natural mediums, W. OETKEN (*Fühling's Landw. Ztg.*, 63 (1914), No. 5, pp. 167-177).—To test the value of field soil as a medium for making germination tests of seeds, the author placed wheat kernels in loam, humus, and clay soils at 2, 3, and 4 cm. depths, ranging from 5 to 15° C. in temperature, and the soils moistened to from 40 to 70 per cent of saturation. The results were inconclusive.

Minnesota weeds, II, W. L. OSWALD and A. BOSS (*Minnesota Sta. Bul.* 139 (1914), pp. 47, figs. 25).—This bulletin contains illustrations and descriptions and gives methods of eradication of 24 kinds of weeds, in continuation of work previously noted (E. S. R., 28, p. 836).

Eradication of wild mustard, RECH (*Landw. Ztschr. Rheinprovinz*, 15 (1914), No. 22, pp. 402-404, figs. 2).—The results here given show that calcium cyanamid applied to oat fields at the rate of about 25 lbs. per one-half morgen (79.3 lbs. per acre) while the dew was on completely destroyed wild mustard, and while the growth of the oats was temporarily checked the final effect of the nitrogen was a vigorous growth.

A mixture of 15 lbs. calcium cyanamid to 100 lbs. of kainit also destroyed the weed and improved the growth of the oats.

On the conservation of the vitality of weed seeds in lower strata of cultivated soils, O. MUNERATI and T. V. ZAPPAROLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 5, pp. 347-371, fig. 1).—The factors heat, moisture, oxygen, light, and compression are discussed as influencing the vitality of the seeds and their germination when exposed to the surface by plowing and cultivation. The condition of the seed at the moment it becomes buried is considered the most important factor.

The effect on the germinative ability of seeds of *Orobanche crenata* by passing them through cattle and by fermentation of the feces, A. MORETTINI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 9, pp. 589-606).—The results of feeding animals with forage containing these seeds are given as follows: Digestion by cattle and horses did not reduce the germinative ability, even when the seeds remained in the digestive tract from 12 to 48 hours; the seeds lost their germinative ability in the fermentation of the manure; the destructive action of the manure was in causing the decomposition of the seeds; and well-rotted manure was not a means of infection.

HORTICULTURE.

Large seed a factor in plant production, M. B. CUMMINGS (*Vermont Sta. Bul.* 177 (1914), pp. 89-123, pls. 4).—The author here reports a series of experiments conducted with seeds of a number of plants, including sweet peas, sweet pumpkins, Hubbard squash, lettuce, beans, parsley, radishes, spinach, and garden peas with the view of determining the relative value of large and small seed on plant production. The results are here presented in tabular form and fully discussed.

The experiments as a whole show a distinct advantage in using large and heavy seed. In the case of sweet peas large and heavy seed resulted in earlier blooming, a larger total number of blossoms, and a larger number of blossoms of good quality. The plants also were heavier and more prolific and thrifty. Small squash and pumpkin seed gave a larger number and a greater total weight of fruit, but were markedly inferior with reference to number and weight of ripe fruit. The use of large lettuce seed resulted in the production of larger seedlings, an increased weight of edibly matured plants which displayed better heading-up capabilities, earliness, and uniformity. Of the crops tested, garden peas alone made little or no response to size selection of seed when the seed was harvested as green peas. There was a slight gain for plants from large seed allowed to mature. Large bean seed gave an earlier product, but at the same time the large seed was slower in germinating. Some observations were made of the place origin of small seeds in pods of beans and peas. In beans 49 per cent of the small seed were found to occur in the basal end, while 18 per cent occurred in the middle of the pod. In the garden peas the small seeds were almost always found at the ends of the pods, with one end as prolific as the other.

Report of the horticulturist, C. F. KINMAN (*Porto Rico Sta. Rpt.* 1913, pp. 16-21, pls. 2).—Investigations with fruits, vegetables, and miscellaneous plants were continued along the lines previously noted (*E. S. R.*, 29, p. 637).

Although the cooperative fertilizer experiments with citrus fruits were practically closed during the previous year, the plats on which the effects of muriate and sulphate of potash were being compared were continued. The results again show that there is no great difference between these two fertilizers and that the general belief among Porto Rican growers that muriate of potash is injuri-

ous to citrus trees is not well founded. The beneficial effect of fertilization on the citrus groves throughout the island was more noticeable during the year than ever before. Experiments are being conducted to determine whether the time of blooming of the citrus trees can be influenced by the application of fertilizers at certain seasons of the year.

Experiments with leguminous green-manure and orchard cover crops were continued and a number of new varieties tested. Among the most promising of those recently tested are a few varieties of *Stizolobium* received for trial from the Office of Seed and Plant Introduction of this Department. The velvet and Lyon beans have proved to be excellent cover crops, especially as a green manure, in rotation with pineapples or on an otherwise unoccupied field. They are sometimes troublesome in groves, as they climb over the trees. During the past two years the sword bean and pigeon pea have been tested as nitrogenous manure crops and cover crops with pineapples by planting them in the pineapple beds. Both crops have a more or less injurious effect on the growth of the pines. More damage was done to the Cabezona variety than to the Red Spanish, and the pigeon peas were more injurious than the sword beans in every case. Where the sword beans had been allowed to grow during the wet season only, the injury was the least.

The cooperative fertilizer experiment with coconuts was continued. During the past year four pickings of fruit were made, the last one being 16 months after the first application of fertilizer. No beneficial effect from the fertilizer has been observed thus far.

Dynamiting for loosening the soil and facilitating drainage has been used in a number of places in Porto Rico, both in land devoted to citrus trees and to pineapples. Thus far no striking beneficial results have been observed from the use of dynamiting. Where it has been tried in old groves and in pineapple fields no improvement has been noted that can be attributed to it. It is believed that where there is a substratum that can be broken through or the charges are placed so as to afford subsoil drainage from one loosened area to another, dynamite should prove beneficial to the heavy soils, as poor subsoil drainage is one of the greatest hindrances to citrus culture in Porto Rico.

Cultural directions for vegetables and flowers, P. J. WESTER (*Philippine Bur. Agr. Circ. 25 (1913), pp. 5*).—This popular circular contains general directions for the preparation and management of vegetable and flower gardens.

The fresh vegetable trade in Germany, H. MICHAELIS (*Arb. Deut. Landw. Gesell., No. 261 (1914), pp. 30*).—This embraces the results of a survey of the marketing problems connected with the fresh vegetable industry in Germany. The subject matter is discussed under the general headings of the development of the German fresh vegetable industry, existing organizations for the sale of vegetables, organizations for marketing vegetables in Holland, and recommendations for the improvement of trade conditions in Germany.

Suggestions for the control of injurious insects and plant diseases, G. M. BENTLEY (*Tennessee Sta. Bul. 106 (1914), pp. 121-148, figs. 4*).—This bulletin contains directions for the preparation and use of various insecticides and fungicides in the control of the important injurious insects and plant diseases, and also of herbicides. Attention is also called to preventive measures, such as cultivation, drainage, time of planting, rotations, and the encouragement of beneficial insects and birds.

Fungicides and insecticides for Montana, H. E. MORRIS and J. R. PARKER (*Montana Sta. Circ. 36 (1914), pp. 207-261, figs. 4*).—This circular discusses the composition, preparation, application, and cost of the more important fungicides and insecticides adapted to Montana conditions. A spraying calendar revised from a previous circular is also included (E. S. R., 28, p. 47).

The Arkansas dilution table for lime-sulphur compound, J. L. HEWITT (*Arkansas Sta. Circ. 23 (1914), folio*).—This table contains concise data for the preparation of diluted spray mixtures of various strengths from concentrated lime-sulphur compounds.

The manuring of orchards, W. J. ALLEN (*Dept. Agr. N. S. Wales, Farmers' Bul. 79 (1914), pp. 24, figs. 15*).—A popular treatise on the manuring of orchard and small fruits.

Observations on the hybridizing of fruits, C. G. PATTEN (*Minn. Hort., 42 (1914), No. 8, pp. 297-301, pl. 1*).—A brief popular review of progress made in the hybridizing of various orchard fruits.

The orchard census (*Ann. Rpt. Missouri Bd. Hort., 7 (1913), pp. 57-440, pls. 5, figs. 118*).—This comprises an orchard census of the State of Missouri taken in 1913 under the direction of the Missouri State Board of Horticulture and includes data on orchards of 16,789 growers.

Fruit growing in New South Wales.—What to grow and where to start, W. J. ALLEN (*Dept. Agr. N. S. Wales, Farmers' Bul. 83 (1914), pp. 58*).—A popular bulletin of information relative to the fruit districts of New South Wales, varieties adapted for specific localities, cost of establishing an orchard, etc.

A study of variation in apples, J. K. SHAW (*Massachusetts Sta. Bul. 149 (1914), pp. 21-36, fig. 1*).—In continuation of previous reports (*E. S. R., 26, p. 45*) the results are given of a statistical study of the variation in number, size, and form of the apples borne during a period of six years on several Ben Davis and Baldwin apple trees growing in the station orchard. The influences causing such variations are also considered.

Summarizing the data as a whole, it appears that the Ben Davis trees have borne much more heavily than the Baldwins and have shown hardly any tendency to biennial bearing. Relative to tree individuality the most prolific of five Ben Davis trees yielded over 60 per cent more apples in the total for six crops than the least prolific. The Baldwins have shown even greater differences.

The upper south quarters of the Ben Davis trees have borne a few more apples than any of the other three quarters, and these apples were constantly larger than those from the other parts, while those from the opposite quarters were generally smaller. Some Ben Davis trees showed a fairly constant tendency to produce apples larger or smaller than the average, whereas others fluctuated from season to season. Only one crop of apples was sufficiently heavy in numbers to affect the size of the fruit. Some slight indications of a relationship between size and the average summer temperature were observed, but the fluctuations in temperature were not considered large enough to overcome other influences affecting size. Certain trees showed slight individuality in the amount of variability—the larger the apples the more variable the fruit. This was not true as between the different parts of the trees.

Some trees were quite constant as to form of fruit, while others were variable. There is no strong evidence that individuality in size and form is to be found in the same tree. Apples from the upper south parts of the trees which were largest were also constantly the most flattened. A fairly constant relationship was observed between the form of the apple and the temperature for a period following bloom. The cooler this period the more elongated the apple. In general the period from the sixth to the sixteenth day following full bloom coincides with the observed fluctuation in form more closely than any other.

How sod affected an apple orchard, II, F. H. HALL (*New York State Sta. Bul. 383, popular ed. (1914), pp. 3-7, fig. 1*).—A popular edition of the bulletin previously noted (*E. S. R., 31, p. 337*).

Breeding *Rotundifolia* grapes, F. C. REIMER and L. R. DETJEN (*North Carolina Sta. Tech. Bul. 10 (1914), pp. 5-47, figs. 19*).—In continuation of pre-

vious investigations dealing with the self-sterility of *Rotundifolia* grapes (E. S. R., 23, p. 734) the results to date are here given of breeding investigations which have been conducted with the view of determining the laws of inheritance in this species and for the purpose of securing improved varieties.

An examination of the seedlings procured in the breeding work thus far has shown that the sexes are about equally divided. Colors in *Rotundifolia* grapes behave as Mendelian characters. By using proper combinations seedlings of either white, red, or black can be produced. Relative to the transmission of color it was found that the Scuppernong and all other white-fruited varieties, together with all light-colored male vines, are pure for the white color and do not carry the dark color as a recessive factor. Such varieties as Flowers, Mish, and Thomas are pure for dark colors and do not carry the white color as a recessive. Other varieties such as James, Memory, and Smith were found to be natural hybrid vines heterozygous for the black and white colors. Latham is a natural hybrid heterozygous for red and white. Many of the dark-colored vines, both male and female, growing wild were heterozygous for the colors black and white, black and red, or red and white. White is recessive to all dark colors. Black is dominant over red. The light and dark colors of the vines are correlated with similar colors in the fruits of those respective vines.

Within certain limits the average size of the fruit cluster can be enlarged by the judicious selection of very large-sized flower-clustered male vines. The actual size of the flower cluster, however, under good conditions for cross pollination does not determine the actual size of the resulting fruit cluster. Self-sterility alone is not altogether responsible for the small-sized fruit cluster. Considerable variation was observed in the seedlings procured with reference to size of berry, flavors and qualities, thickness of skin, character of pulp, and size of seed. It is believed that by proper combination of parent vines desirable seedlings can be produced. The Scuppernong grape does not readily hybridize with *Vitis aestivalis*, *V. cinerea*, nor the Herbemont, Winchell, and Niagara varieties.

A brief review of earlier attempts to improve *Rotundifolia* varieties is included in the bulletin.

The hybrid direct bearers in the valley of the Rhone in 1913, A. DESMOULINS and V. VILLARD (*Prog. Agr. et Vit. (Ed. l'Est-Centre)*, 35 (1914), Nos. 28, pp. 52-59; 29, pp. 81-89).—This comprises observations for the fourteenth year (E. S. R., 27, p. 540; see also E. S. R., 30, p. 238) relative to the behavior of a large number of hybrid direct bearing grapes with special reference to their resistance to disease and drought and adaptation to various soil conditions.

Report of strawberry shipments, season, 1913 ([*Springfield, Mo.*]: *Ozark Fruit Shippers' Assoc.* [1913], pp. 19).—This comprises condensed data on the receipts and expenses of marketing 501 cars of strawberries for the season ended June 30, 1913.

Report of the assistant horticulturist, T. B. McCLELLAND (*Porto Rico Sta. Rpt. 1913*, pp. 22-25).—A brief progress report of the station's work with coffee, cacao, vanilla, and rubber (E. S. R., 29, p. 641), including a brief statement relative to a study of coffee and cacao plantation practices in Venezuela.

Plantings of promising foreign varieties of coffee are being made of sufficient extent to serve as valuable tests. The cultural, shading, pruning, liming, and fertilizer tests are being continued. Some striking results are being observed in the fertilizer work, although no definite conclusions can be drawn at this time. In one planting trees which had received an ample allowance of stable manure gave double the yield obtained from the check plats. A good method of controlling the guamá ant which attacks the guamá tree used as shade in coffee plantations was worked out. This consists of removing and burning the

younger growth and smaller branches of the trees on which the colonies occur and then banding the trunks with tanglefoot. In this way a large part of the ants was destroyed and practically all of the large fleshy pink scale on which they feed. Though the remaining ants continued to live for a while on some of the trees, they eventually disappeared from all of those treated.

Monthly tappings are being made of 38 of the 10 to 11-year old Castilla rubber trees which run from 24½ to 40 in. in girth at 3 ft. above the base. For eight tappings the average yield per tree per tapping was a little less than 0.5 oz. of rubber. The quality of this rubber was pronounced as along with the best and toughest Castilla rubber on the market.

A study of the results of the manurial experiments with cacao conducted at the botanic station, Dominica, H. A. TEMPANY (*West Indian Bul.*, 14 (1914), No. 2, pp. 81-119, pls. 6).—This comprises a review as a whole of fertilizer experiments which have been conducted during the past 11 years and have been noted from time to time (E. S. R., 30, p. 741).

Analyses are given showing the composition of the soil of the cacao plats in the original series, together with the effects of the various manurial applications on the composition of the soil. In respect to the nitrogen content the soils of certain plats, notably those which have been mulched with grass and leaves, show considerable accretions to the nitrogen content which are unaccounted for by the quantities of this constituent added in the manurial applications. It is suggested that these accretions are due to the action of free nitrogen-fixing bacteria of the *Azotobacter* type, since this type of organism was found in the soils of each of the plats of the original series.

Laboratory studies of changes occurring in these soils when kept in a moistened condition showed that whereas the humus content of the soils tended to diminish very rapidly the nitrogen content did not tend to fall off in the same way as a rule, while an appreciable amount of nitrification always took place. It is suggested that the ammonia formed in the early stages of ammonification may function as a base to neutralize the nitric acid produced in the latter stages of the process.

The results of a study of the soil moisture conditions obtaining on each of the plats show that none of the manurial treatments practiced has exerted any appreciable direct effect on the moisture-retaining properties of the soil.

An investigation was also made of the temperature of the soils of the plats at different hours of the day and different seasons of the year. The results show that when the plats are adequately shaded the soil temperature remains very nearly constant at the value of the air temperature during the coolest portions of the day. When adequate shading is absent, however, the soil temperature varies to a much greater extent. These results emphasize the utility of shade in young cacao orchards.

A record of the annual yields for each of the plats shows the beneficial influence of various manurial applications. The largest increases were secured by mulching and the next largest by complete manuring. A survey of the fertilizer data for the whole period indicates that under the conditions of the experiment it takes from three to five years for the trees to indicate differences derived from various forms of treatment.

In the concluding portion of the paper the relations between the annual rainfall and the yields of cacao are considered and analytical information regarding the manurial constitution of various materials used for mulching is appended.

Robusta coffee (*O Café Robusta. Sao Paulo, Brazil: Sec. Agr., Com., e Obras Pub.*, 1913, pp. 59, pls. 5).—This comprises various reports presented to the

secretary of agriculture of Sao Paulo relative to the culture and exploitation of Robusta coffee in the East Indies.

Coffee in Java, C. CHALOT and R. THILLARD (*Le Café a Java. Paris, 1914, pp. 39, figs. 3*).—This comprises observations on the culture and varieties of coffee in Java based upon a survey of a number of plantations growing different species of coffee.

A kaki classification, H. H. HUME (*Jour. Heredity, 5 (1914), No. 9, pp. 400-406, figs. 6*).—In this paper the author proposes a scheme for classifying the varieties of *Diospyros kaki* based on the behavior of these varieties when pollinated. Some data are presented to show the influence of seed development on the fruit.

Lime culture in Santo Domingo, C. CHALOT and R. DESLANDES (*Culture du Citronnier a la Dominique. Paris, 1914, pp. 68, figs. 3*).—An account of the culture and exploitation of limes in Santo Domingo.

A report on a study of the tea industry on the east coast of Sumatra and in the uplands of Padang, Sumatra, C. BERNARD (*Dept. Landb., Nijv. en Handel [Dutch East Indies], Meded. Proefstat. Thee, No. 29 (1914), pp. 95, pls. 8, figs. 3*).—This report embraces observations and data secured on an inspection trip made in 1913.

The production of vanilla in the French colonies (*Bul. Off. Colon. [France], 7 (1914), No. 77, pp. 209-249, figs. 3*).—A statistical review of vanilla production in the various colonies of France.

The coconut in the Seychelles, R. DUPONT (*Le Cocotier aux Seychelles. Paris, 1914, pp. 13*).—A discussion of the coconut industry in the Seychelles Islands with special reference to cultural operations, management of coconut plantations, and the use of fertilizers.

FORESTRY.

Forest types: Symposium (*Proc. Soc. Amer. Foresters, 8 (1913), No. 1, pp. 53-104, fig. 1*).—In this symposium the following subjects are considered: A Standard Basis for Classification, by S. T. Dana (pp. 53-60); An Analysis and Synthesis of the Term from a Geographic Standpoint, by F. G. Plummer (p. 61); Shall the Physical Conditions or the Dendrological Mixture be the Basis for Forest Typing? by T. T. Munger (pp. 62-68); Use of Forest Types in the Work of Acquiring Lands under the Weeks Law, by K. W. Woodward (pp. 69-72); Definition and Use of Forest Types, by B. Moore (pp. 73-75); Classification of Forest Types, by W. B. Greeley (pp. 76-78); What is the Proper Basis for the Classification of Forest Land into Types? by G. A. Pearson (pp. 79-84); Basis of Classification into Forest Types and Its Application to District 1, by F. H. Rockwell (pp. 85-90); Physical versus Cover Types, by D. T. Mason (pp. 91-93); Physical Factors as a Basis for Determining Forest Types, by C. R. Tillotson (pp. 94-99); and Quality Classes and Forest Types, by R. Zon (pp. 100-104).

The technique of seed testing, C. G. BATES (*Proc. Soc. Amer. Foresters, 8 (1913), No. 2, pp. 127-138*).—A discussion of methods of seed testing with special reference to their standardization among American foresters and seed dealers.

Coordination of growth studies, reconnaissance, and regulation of yield on National Forests, H. H. CHAPMAN (*Proc. Soc. Amer. Foresters, 8 (1913), No. 3, pp. 317-326*).—In this paper the author discusses methods of coordinating growth studies and reconnaissance with reference to securing data for the regulation of yield on National Forests.

The use of frustum form factors in constructing volume tables, D. BRUCE (*Proc. Soc. Amer. Foresters*, 8 (1913), No. 3, pp. 278-288).—As a result of some tests made in Idaho the author concludes that satisfactory volume tables can be made by the use of frustum form factors from a far smaller number of trees than was previously considered possible.

Some financial forest problems, W. B. BARROWS (*Proc. Soc. Amer. Foresters*, 8 (1913), No. 3, pp. 362-365, fig. 1).—The author here briefly discusses the determination of forest percentage and capital invested in forestry.

The farm wood lot, E. G. CHEYNEY and J. P. WENTLING (*New York*, 1914, pp. XII+343, figs. 62).—This work is presented as a handbook of forestry for the farmer and the student in agriculture.

The phases discussed include the significance of the forest, its place in farm management, the growth of the tree, dendrology, practical silviculture, forest protection, mensuration and utilization, by-products of the northern woodlot, the durability and preservation of woods, arboriculture and ornamental planting, history of the forest, and forest influences. The concluding chapter contains a number of tables and rules dealing with wood, lumber, and tree growth.

The management of second-growth hardwoods in Vermont, A. F. HAWES and B. A. CHANDLER (*Vermont Sta. Bul.* 176 (1914), pp. 31-86, pls. 12).—A practical treatise on the management of second-growth hardwoods based largely on a study of various woodland areas in Vermont. The successive parts of the bulletin discuss estimating the contents of a woodlot, improvement of the stand, yield tables, crop maturity and the selection of the crop, market conditions, and enemies of northern hardwoods. Volume tables to be used in estimating timber of various species are appended.

Studies in tolerance of New England forest trees.—I, Development of white pine seedlings in nursery beds, G. P. BURNS (*Vermont Sta. Bul.* 178 (1914), pp. 127-144, pls. 4, figs. 2).—This bulletin reports a study of seed bed practices in the forest nursery with special reference to the development of pine seedlings.

The experiments conducted at the station indicate that damping-off of white pine seedlings can be controlled by the use of formaldehyde or sulphuric acid. A series of trials was made to determine the proper depth for planting seed, and the results indicate that in sandy soil seed should be planted not less than $\frac{1}{2}$ in. deep. When the seed is sown early in wet weather no top shade is needed to get an even stand. When sown late in dry weather, however, the surface soil must be kept moist by watering or by full shade top. A study of the effect of lath shade on germination showed that shade reduces the temperature and delays the time of germination. After the period of germination all shade should be removed because it hinders the development of the seedling. The seed beds should be provided with solid sides during the first season, as the sides greatly decrease the loss of water by transpiration.

A brief bibliography of consulted literature is appended.

Experimental forest planting in the Hawaiian Islands, R. S. HOSMER (*Proc. Soc. Amer. Foresters*, 8 (1913), No. 2, pp. 211-221).—A general account of forest conditions in Hawaii including progress made in experimental forest planting.

The tree species of Java: Contribution No. 13, S. H. KOORDERS and T. VALETON (*Meded. Dept. Landb. [Dutch East Indies]*, No. 18 (1914), pp. VII+286).—This is the thirteenth of a series of reports on the tree species of Java (*E. S. R.*, 25, p. 142). In the present report the genera and species of Aquifoliaceæ, Convolvulaceæ, and Thymelæaceæ are taken up by T. Valetton; and of Violaceæ, Moraceæ, Hamamelidaceæ, Clethraceæ, and Ericaceæ by J. J. Smith.

A table of contents and an index to the series as a whole are included.

Lumbering industry of the Philippines, J. R. ARNOLD (*U. S. Dept. Com., Bur. Foreign and Dom. Com., Spec. Agents Ser., No. 88 (1914), pp. 22*).—This report reviews briefly the forest resources of the Philippines, the degree to which they are being exploited, the prospects for increased activity in lumbering, the kind of machinery now used, and the selling methods usually followed.

Progress report on forest administration in the Northwest Frontier Province for 1912-13, M. R. K. JERRAM (*Rpt. Forest Admin. Northwest Frontier Prov., 1912-13, pp. 3+II+15+XXVI*).—This is the customary progress report relative to the administration of the state forests, including a financial statement for the year 1912-13. All important data relative to forest areas, surveys, working plans, protection, and miscellaneous work, silvicultural operations, yields, revenues, etc., are appended in tabular form.

DISEASES OF PLANTS.

Notes on plant diseases of Connecticut, G. P. CLINTON (*Connecticut State Sta. Rpt. 1914, pt. 1, pp. 1-29, pls. 7*).—After giving a discussion of the relation of weather conditions to the diseases prevalent during the year, the author describes a number of diseases which are either new to the State or not previously reported upon the host plants given.

Among these are fasciation, frost bands, syncarpy, and water core of apple, heart rot of celery (*Bacillus carotovorus*), corn mold (*Cephalothecium roseum*), Shasta daisy leaf spot (*Septoria leucanthemi*), rust of Chinese juniper (*Gymnosporangium haræanum*), arsenical burn of Lima beans, oil injury to hard maple, parsnip soft rot (*B. carotovorus*), scrub pine rust (*Peridermium comptoniæ*), poplar crown gall (*Bacterium tumefaciens*), potato blackleg (*Bacillus phytophthorus*), privet anthracnose (*Glomerella cingulata*), Sclerotium disease of redbud (*S. rhizodes*), mechanical spotting of rose (*Pilobolus crystallinus*), salsify soft rot (*B. carotovorus*), phyllostictia or string leaves of tobacco, and orange leaf rust of wheat (*Puccinia triticina*).

Report of the imperial mycologist, E. J. BUTLER (*Rpt. Agr. Research Inst. and Col. Pusa [India], 1912-13, pp. 55-69*).—Besides other information this report deals with a wide range of studies on diseases of plants, among which may be noted ufra, eelworms, bunt, false smut, and gwa-bo (probably due in part to *Sclerotium oryzae*) of rice; red rot and three minor diseases, not yet determined as to cause, of sugar cane; Colocasia blight and potato blight; poppy blight (caused by *Peronospora arborescens*); orange and yellow rust of wheat; a fungus disease of peanuts; cotton and sesame wilts; anthracnose of sisal hemp (due to *Colletotrichum agaves*); indigo diseases (thought to be of other than fungal origin); some phanerogamic parasites; and other miscellaneous plant troubles and investigations.

A species of *Rhizophidium* parasitic on the oospores of various *Peronosporaceæ*, I. E. MELHUS (*Phytopathology, 4 (1914), No. 2, pp. 55-62, pl. 1*).—In conducting some studies on oospore germination the author encountered considerable difficulty on account of the presence of the parasite *R. pollinis*. Attempts were made to germinate the oospores of *Cystopus bliti* from leaves, stems, and flowers of *Amaranthus retroflexus*, but many of them were destroyed by the parasitic organism. Subsequently the oospores of *C. candidus* and *C. cubicus* were exposed to infection by transferring infected oospores of *C. bliti*, and infection resulted in ten days. In a similar way the oospores of *Peronospora effusa* and *Sclerospora graminicola* showed the infection after six days.

Later experiments were carried on with pollen from the hyacinth and the calla lily, which showed that the pollen also was parasitized by *R. pollinis*.

Heterodera radiculicola attacking the Canada thistle, L. E. MELCHEERS (*Science, n. ser., 40 (1914), No. 1024, p. 24*).—The author notes the occurrence, on the roots of the Canada thistle, of the nematode *H. radiculicola*, thus adding another host plant to the long list already known.

Spore germinations of cereal smuts, E. C. STAKMAN (*Minnesota Sta. Bul. 133 (1913), pp. 52, pls. 25*).—This is a technical bulletin in which the author gives results of observations on the germination of spores of *Ustilago tritici*, *U. nuda*, *U. hordei*, *U. avenæ*, *U. zeæ*, and *Tilletia fætens*.

These smuts are found to fall into two classes as far as germination is concerned, *U. nuda* and *U. tritici* producing no sporidia, while the others produce sporidia. The period of germination was found to vary considerably in different forms, *U. hordei* germinating most readily, only 6½ hours being required in some cases, while *T. fætens* required the longest time, the minimum for germination of these spores being 48 hours. The germination characteristics are said to be quite closely connected with the life history of the parasite, those forms which live over in the seed producing no sporidia, while those which live over in the soil or on the kernels produce sporidia which help to insure their chances of persistence. Differences are also noted in the behavior of the promycellium of the different species. The spores of all forms were exposed to winter conditions in Minnesota and all germinated readily in the spring, demonstrating that smuts may survive the winter in the spore form under field conditions.

A bibliography of the subject is given.

Studies on club root.—I, The relation of *Plasmodiophora brassicæ* to its host and the structure and growth of its plasmodium, B. F. LUTMAN (*Vermont Sta. Bul. 175 (1913), pp. 27, pls. 4, figs. 6*).—The results of a study of the relation of the fungus causing the club root of various cruciferous plants to the host plant is given, together with a summary of earlier work.

It is stated that the parasite enters the host either through the epidermis or root hairs, and once within the plant it spreads from cell to cell, either through penetrating the cell walls or through host cell divisions. It is found present in the cortex, but sometimes the organism makes its way into the cells of the central cylinder. The infected host cells become hypertrophied, but nuclear and cell division is not seriously interfered with in the earlier stages. In advanced cases both processes are entirely suspended and the nucleus undergoes degeneration. The plasmodium of the fungus is said to be clear and almost transparent at first and is distinguished with difficulty from the protoplasm of the host. The nuclear divisions in the plasmodium are both vegetative and reduction. In the study reported most of the material was taken from cabbage plants.

A brief bibliography is appended.

Occurrence of bacterial blight of alfalfa in the Salt Lake Valley, Utah, P. J. O'GARA (*Science, n. ser., 39 (1914), No. 1016, pp. 905, 906*).—The author reports the occurrence of the bacterial blight of alfalfa, due to *Pseudomonas medicaginis*, in Utah, and he states that the alfalfa weevil is a factor in the distribution of the disease. It is said that the disease sometimes destroys 80 per cent of the first cutting of alfalfa, and while the chief damage is usually done at the first cutting, the plants may be so seriously injured in the crown and roots as ultimately to cause their death.

The cob rot of corn, E. G. ARZBERGER (*Ohio Sta. Bul. 265 (1913), pp. 69-82*).—Attention was called in 1911 to a disease of corn in which the cob of the ear was infected by a fungus. This appeared abundantly in 1911 and again in 1912, and an investigation was undertaken to determine whether the fungus, *Coniosporium gecevi*, was parasitic or only present as a saprophyte.

A large number of inoculation experiments were made and field observations taken, which indicate that *C. gecevi* develops and acts as an obligate saprophyte, and can not, therefore, be considered as the cause of the disease. Inoculations with an unknown fungus, or possibly with several fungi, produced good infections resulting in diseased ears, but these are to be the subject of further study. It is considered that *C. gecevi* is of economic significance only in that it destroys the cob tissue as a saprophyte, and that its effect on the kernels is rather limited when compared with the injury caused by *Diplodia*, *Fusarium*, and other fungi.

Hot water treatment for cotton anthracnose, H. W. BARRE and W. B. AULL (*Science, n. ser., 40 (1914), No. 1020, pp. 109, 110*).—A preliminary report is given of experiments to test the effect of hot water at different temperatures on the anthracnose fungus and on cotton seed, the object being to determine whether the fungus could be killed without injury to the seed.

As a result of the test it was found that cotton seed can remain at 70° C. for 15 minutes without injury to germination. This temperature seems to be destructive to the fungus, as seed so treated has been germinated free from disease, while an average of 22 per cent of the seedlings in the checks from the same lot of seed were diseased.

Two fields of cotton on the Clemson College farm have been planted with seed so treated and are under observation to determine the ultimate effect of the treatment.

Disease resistance of potatoes, W. STUART (*Vermont Sta. Bul. 179 (1914), pp. 147-183, pls. 4, figs. 7*).—In continuation of previous reports on investigations carried on at the Vermont Station on disease resistance of potatoes (E. S. R., 17, p. 1078), the author gives a final account of his investigations on varietal resistance of potatoes to the attacks of the early blight (*Alternaria solani*), late blight (*Phytophthora infestans*), and the scab (*Oospora scabies*).

Tests of a large number of varieties of potatoes of American and European origin have been conducted. The varieties which showed the greatest resistance or freedom from early blight were, with few exceptions, of foreign origin. The resistant foreign varieties were almost without exception of little commercial value, as they were usually light yielders and rather poor in quality. The author considers the value of disease resistance in potatoes as rather problematical, but suggests that by crossing some of the resistant European varieties with the more desirable commercial American types some resistant varieties of commercial value might possibly be obtained.

In testing different varieties for resistance to scab none were found to show markedly resistant qualities when grown on soil well infested with the scab organism. The commonly prevalent idea that russet-skinned varieties do not become scabby was found not to be based on fact, as one of the pronounced russet varieties was very low in the scale of resistance. Some varieties are said to have been found somewhat less subject to scab than others, but it has been impossible to determine whether or not this immunity is inherent. The author believes there is little hope of securing scab-resistant varieties through selection.

Notes are given on the growing of seedling potatoes, desirable types of potatoes, and varietal response to Bordeaux mixture. Under the last head the author states that some varieties respond better to spraying than others, and that heat, moisture, and sunshine modify the outcome when Bordeaux mixture is used. The beneficial effect of Bordeaux mixture is attributed to diminished transpiration, the maintenance of optimum light intensity, and the lengthening of the season of growth.

Discussing the value of foreign varieties of potatoes introduced into this country, it is stated that very few have proved satisfactory. For the most part those which have come under the author's observation have produced tubers of inferior table quality, although some were highly resistant to disease. It appears that high disease resistance of the vine was correlated with a low and undesirable tuber yield.

Chlorosis of sugar cane, P. L. GILE and C. N. AGETON (*Porto Rico Sta. Rpt. 1913, pp. 13, 14*).—A brief report is given of investigations on the occurrence and cause of chlorosis of sugar cane.

Two crops of chlorotic cane have been under observation, and the authors state that there did not appear to be any definite period when it became diseased. As a rule ratoon cane seems to be affected more severely and generally earlier than plant cane. In some cases the appearance of the diseased cane was much improved after a rainy period, while in others new leaves appearing directly after the rain were strongly chlorotic.

The areas of chlorotic cane so far have been confined to strongly calcareous soils, although all cane grown on calcareous soils is not affected. Some small areas are known that have been planted year after year that always produce chlorotic cane and many of these are on the slopes of limestone hills.

Tomato diseases, J. L. HEWITT (*Arkansas Sta. Circ. 21 (1914), pp. 4*).—Popular descriptions are given of the late blight, black rust, fungus wilt, bacterial wilt, blossom end rot, and root knot of tomatoes, with suggestions for their control.

Some important diseases of tomato in North Carolina, H. R. FULTON (*North Carolina Sta. Circ. 19 (1914), pp. 8*).—This publication is designed to give information regarding tomato diseases for the benefit of members of tomato clubs which have been formed throughout the State. Brief descriptions are given of the more common diseases, with suggestions for their control, which include the proper selection of seed and cultivation of plants, together with spraying where this method of treatment is known to offer protection.

Two tomato diseases (*Agr. News [Barbados], 13 (1914), No. 315, p. 174*).—Descriptions are given of the leaf mold due to *Cladosporium fulvum* and the blossom end rot of tomatoes, which is considered due to bacteria.

For the first disease, where conditions are favorable for the development of the fungus the author recommends spraying at frequent intervals with a 4:4:50 Bordeaux mixture. For the second disease it is said that attention to the water supply and preventing excessive transpiration will reduce the amount of disease present.

Fruit diseases in Montana, D. B. SWINGLE (*Montana Sta. Circ. 37 (1914), pp. 263-330, pl. 1, figs. 21*).—The purpose of this publication is to give fruit growers of the State information to aid them in combating the diseases in their orchards. After a general discussion of fruit diseases and methods of combating them, the author describes the apple blight, crown gall, scab, Baldwin spot, and Jonathan spot; pear blight, crown gall, and scab; peach leaf curl and crown gall; gooseberry mildew; raspberry and blackberry crown gall; and strawberry leaf spot, with specific directions for combating the different diseases.

The blight of apples, pears, and quinces, B. S. PICKETT (*Illinois Sta. Circ. 172 (1914), pp. 10, figs. 4*).—A description is given of the blight of apples, pears, and quinces due to *Bacillus amylovorus*, the author stating that this disease severely attacks not only these, but a number of other plants belonging to the same family.

The symptoms of the disease are popularly described and suggestions given for preventive and remedial measures to be adopted against it. These consist

largely of the removal of the infective sources which carry the disease over winter.

A contribution to our knowledge of apple scab, H. E. MORRIS (*Montana Sta. Bul. 96 (1914), pp. 65-102, pl. 1, figs. 3*).—The author gives an account of the apple scab, due to *Venturia inaequalis*, in Montana, tracing the history of its appearance and giving data regarding the amount of injury done, periods of infection, etc. The question of the identity of *V. inaequalis* on the apple and *V. pirina* on the pear is discussed, and the author is inclined to believe that the species are not identical.

Notes are given on methods of control, in which the author recommends the planting of resistant varieties and thorough spraying. Lists are given of different varieties of apples commonly planted in Montana, arranged according to their resistance.

A bibliography of 505 references is given.

A destructive strawberry disease, F. L. STEVENS (*Science, n. ser., 39 (1914), No. 1017, pp. 949, 950*).—Attention is called to the fact that long-distance strawberry shipments during the past season have suffered serious injury due to molds or "leaks," the loss in some cases being very large.

The berries subject to this trouble came largely from Louisiana and Mississippi. The author, early in May, examined in Louisiana berries which had been in the refrigerators over night, and found in many instances that boxes showed fruit with small rotten spots. Visits to the field showed many berries rotting on the vines. Examination of the material showed the presence of a Botrytis, probably *B. cinerea*. In the later stages other fungi were present, notably *Rhizopus nigricans*. Examination made of a large number of berries showed almost uniformly the presence of Botrytis, and its predominance led the author to believe that it is the primary cause of the trouble. The Botrytis is thought to initiate the decay, which is completed by other saprophytes, among them *Rhizopus*. Both fungi have been separated in pure cultures and are to be subjected to further study.

The presence of endocellular fibers in tissues of grapevines and in those of other dicotyledons, EVA MAMELI (*Atti R. Ist. Bot. Univ. Pavia, 2. ser., 16 (1914), pp. 47-65, pl. 1*).—This is a fuller account of studies previously noted from another source (*E. S. R., 29, p. 551*).

Report of the plant pathologist, G. L. FAWCETT (*Porto Rico Sta. Rpt. 1913, pp. 26-29*).—A progress report is given of the work carried on by the author in his study of the diseases of cacao, citrus trees, and coffee.

The cacao disease reported upon at length is that known as black pod in Porto Rico, but which is said to be distinct from the disease generally known by that name. It is confined to young fruits, and the loss apparently is very great, as on many trees not more than 5 per cent of the fruits reach maturity. In order to find what relation there might be between fungi and bacteria and the failure of pods to mature, the author made cultures from the interior tissues of a large number of fruits, and occasionally found some fungi, among them a fungus which agrees fairly well with the description of *Colletotrichum cradwickii*. Inoculation experiments were conducted with the different fungi, but with the exception of the *Colletotrichum*, which proved weakly parasitic, the author concludes that the work would indicate that the trouble is not due to parasitic fungi. Spraying experiments with Bordeaux mixture were carried on for two seasons, but without any very definite beneficial results. The effect of fertilizers on the tree is also being considered in connection with this disease. Thus far the fungus *Phytophthora faberi* has not been found in Porto Rico.

The study of citrus diseases has been largely confined to the lemon scab. The fungus producing this disease has been found to attack grapefruit while

small, producing wart-like outgrowths and seriously reducing their market value. The disease is said to be very common, and a study has been made of various host plants harboring species of *Cladosporium*. On the gandul or pigeon pea a species of *Cladosporium* was found present which inoculated upon young grapefruit produced warty outgrowths, and young lemon plants similarly inoculated developed scab identical in appearance with that caused on lemon leaves by *C. citri*. The pigeon pea is used to a considerable extent as a cover crop, and should it prove a host for the citrus fungus its further employment in this way should be abandoned.

The coffee disease reported upon is that caused by *Cercospora coffeicola*, which hitherto has been considered simply a leaf parasite, but the author has found that it also is responsible for a considerable proportion of bad grains of coffee.

Rot of orange trees in Francofonte, and its treatment, L. SAVASTANO (*R. Staz. Sper. Agrum. e Frutticol. Acireale, Bol. 9 (1912), pp. 8*).—Continuing the work previously noted (*E. S. R.*, 23, p. 149), the author here deals more particularly with diseases of citrus fruits as affected by local conditions, and states that modifications of cultural methods employed and timely tree surgery or substitution of sound young trees have been followed by good results.

The hereditary transmission of rust in mallows, L. BLARINGHEM (*Compt. Rend. Acad. Sci. [Paris], 157 (1913), No. 26, pp. 1536-1538*).—Referring to the claim previously made (*E. S. R.*, 30, p. 453) that in the association of *Aithya rosea* and *Puccinia malvacearum* the host is favored by abundance and the parasite by lack of water in the tissues, the author states that later experimentation described shows that the addition of 5 per cent of saccharose or glucose to the nutritive solution is followed by a development of rust pustules as the medium dries out, whereas under other conditions no such development is noted.

A disease of Narcissus bulbs, G. MASSEE (*Jour. Bd. Agr. [London], 20 (1914), No. 12, pp. 1091-1093, pl. 1*).—The author describes an injury to Narcissus bulbs ascribed to *Fusarium bulbigenum*, known since 1887 but not until recently recognized as parasitic.

Very young leaves of Narcissus, about 1 in. long, were inoculated, developing characteristic disease spots in about six days, and others as growth proceeded. It is thought that the process is advanced by secondary as well as primary infection. It is held that soaking slightly diseased bulbs in a fungicide will not kill the mycelium in the bulbs or the resting spores, but that during germination the secondary spores may be destroyed by a dressing of kainit or of potassium sulphate worked into the soil. Rotation with nonsusceptible plants is also recommended.

The technique of operation for rot and gummosis of trees, L. SAVASTANO (*R. Staz. Sper. Agrum. e Frutticol. Acireale, Bol. 8 (1912), pp. 15, figs. 11*).—The author deals briefly with typical operations employed in tree surgery as regards roots and trunks and instruments adapted to the same.

Notes on diseases of trees in the southern Appalachians, III, A. H. GRAVES (*Phytopathology, 4 (1914), No. 2, pp. 63-72, pl. 1, figs. 10*).—In this paper the author gives an account of diseases of the spruce and hemlock, thus concluding a series of papers noted elsewhere (*E. S. R.*, 31, p. 348).

The diseases of spruce described are blight of seedlings, due to *Ascochyta piniperda*, *Sclerotinia fuckeliana*, and *Phoma* sp.; twig blight, due to *Pestalozzia* sp. and *Phoma piceana*; heart rot, caused by *Trametes pini*; and frost injury. Among the diseases of hemlock, descriptions are given of the timber rot, due to *Fomes pinicola*; leaf rust, caused by *Pucciniastrum myrtilli*; and twig blight, which is attributed to *Rosellinia* sp.

New facts concerning the white pine blister rust, P. SPAULDING (*U. S. Dept. Agr. Bul. 116 (1914), pp. 8*).—In a previous publication (*E. S. R., 29, p. 554*), the author presented information regarding the white pine blister rust up to 1913. In the present publication additional information is given based on extensive investigations conducted during the summer and fall of 1913. This includes an account of the work with infested white pine trees near Geneva, N. Y., new outbreaks in northern Vermont, near Ipswich, Mass., and near Meriden, Conn., observations on the wintering-over of the disease on *Ribes*, *Pinus excelsa* as a host, spore distribution of *Cronartium ribicola*, and a tabular account of the general results of inspections.

The damping-off of coniferous seedlings, P. SPAULDING (*Phytopathology, 4 (1914), No. 2, pp. 73-88, pl. 1, figs. 2*).—On account of the seriousness of damping-off of coniferous seedlings, the author has made a study of methods of control, particularly that of soil sterilization.

The damping-off of coniferous seedlings is due to a number of organisms, among them *Fusarium*, *Pythium*, and *Rhizoctonia*. In the experiments reported, tests were made of a number of fungicides for soil treatment as well as modifications of nursery methods. The experimental work indicates that soil sterilization sufficient to prevent damping-off is effectively accomplished with formalin (1 oz. to 1 gal. water, or stronger), sulphuric acid (1 oz. to 1 gal. water, or stronger), and rather dilute ammonium copper carbonate. These chemicals should be applied before seedling, as no chemical was found that was effective in stopping outbreaks of the disease after germination. Weak formalin applied after germination of seeds was found worse than useless, as it destroyed many of the young plants. The quality of the seed was found to have something to do with damping-off, as light weight, poorly filled seed produced weak seedlings, which were longer in germinating and were very subject to this disease.

A bibliography of the subject is appended.

Preliminary tests of disinfectants in controlling damping-off in various nursery soils, C. HARTLEY and T. C. MERRILL (*Phytopathology, 4 (1914), No. 2, pp. 89-92*).—The results are given of cooperative experiments for the control of damping-off of pine seedlings, caused mainly by *Pythium debaryanum* and *Fusarium* sp. In the experiments copper sulphate, zinc chlorid, formalin, and sulphuric, nitric, and hydrochloric acids have been tested.

So far the best results on most soils have been secured with sulphuric acid. This has proved more successful than heat, where both have been tested, and it also protects the soil against reinfection. In an experiment in which air-slaked lime was applied following the acid disinfection, the treatment seemed to be successful without injury to the plant, but it allowed reinfection. For soils on which sulphuric acid is not an efficient disinfectant, zinc chlorid and copper sulphate seemed to possess greater efficiency than formalin.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Revision of the American harvest mice (genus *Reithrodontomys*), A. H. HOWELL (*U. S. Dept. Agr., Bur. Biol. Survey, North American Fauna No. 36 (1914), pp. 94, pls. 7, figs. 6*).—In this revision the author recognizes 58 species and subspecies as belonging to the genus *Reithrodontomys*, of which seven are described as new.

The American harvest mice are said to occur abundantly in or near meadows and cultivated lands over a large part of the United States. While their exact economic relation is still little known they belong to a group of mammals

many species of which are injurious to agriculture, and there is no doubt that they consume large quantities of forage and some grain.

Maps showing the range of the more important species accompany the account.

Birds and their value to the agriculturist with some notes concerning insects, P. L. GUPPY (*Bul. Dept. Agr. Trinidad and Tobago*, 13 (1914), Nos. 79, pp. 116-128; 80, pp. 148-156, pls. 4).—This article includes lists of birds frequenting cacao fields and of those useful to sugar planters.

First report on the economic features of the amphibians of Pennsylvania, H. A. SURFACE (*Bi-Mo. Zool. Bul. Penn. Dept. Agr.*, 3 (1913), No. 3-4, pp. 67-152, pls. 10, figs. 25).—This paper deals with the mud puppy, salamanders, toads, and frogs known to occur in Pennsylvania, their habits, hibernation, reproduction, enemies, food, and economy. The author takes up the collecting and preserving of specimens, the classification, gives a key to the orders of Pennsylvania Amphibia, and a color key to the salamanders of the State, reports upon the stomach contents of Pennsylvania amphibians and popular errors concerning them, and defines the terms used. A bibliography of 19 titles and an index are included.

The investigations show that none of the amphibians of Pennsylvania are injurious or harmful in any way but that on the other hand they are often very useful destroyers of insect pests, snails, and slugs, and some are valuable because of their edible flesh. Others are of value as bait for fish and as food for fish and birds.

Bibliography of Canadian zoology for 1912, L. M. LAMBE (*Proc. and Trans. Roy. Soc. Canada*, 3. ser., 7 (1913), Sect. IV, pp. 187-199).—This annotated list covers the literature exclusive of entomology.

Bibliography of Canadian entomology for 1912, C. G. HEWITT (*Proc. and Trans. Roy. Soc. Canada*, 3. ser., 7 (1913), Sect. IV, pp. 161-173).—One hundred and twenty-one titles are listed in this annotated bibliography.

Eleventh annual report of the state entomologist of Montana, R. A. COOLEY (*Montana Sta. Bul.* 98 (1914), pp. 121-136, fig. 1).—This report consists of concise accounts of the occurrence of the more important pests in Montana during 1913, with the texts of the state laws relating to plant quarantine and the establishment of a state board of entomology.

Insect pests in 1912, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scot.*, 5. ser., 25 (1913), pp. 192-208, figs. 9).—This is the author's annual report on the occurrence of the more important insect pests during the year and continues previous work (*E. S. R.*, 27, p. 552).

Insect pests in 1913, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scot.*, 5. ser., 26 (1914), pp. 170-187, figs. 15).—The author's annual report on the occurrence of the more important insect pests, in continuation of that above noted.

The principal insect pests of field crops in European Russia for the last twenty years, N. M. KULAGIN (*Exheg. Dept. Zeml. [Russia]*, 1913, pp. 585-638, pl. 1; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 201, 202).—The author reviews in this article the appearance and distribution of and damage done by the principal insect enemies of field crops for the past 20 years in Russia, together with the more important measures for combating them.

List of pests of alfalfa, E. M. VASSILIEV (*Khovzâistvo*, No. 16-17 (1913), pp. 8; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 12, pp. 526, 527).—A list of pests arranged by orders.

First supplement to the list of animal pests of alfalfa, E. M. VASSILIEV (*Khovzâistvo*, No. 6 (1914), pp. 189-193; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 262, 263).—This lists additional enemies of alfalfa and supplements that noted above.

The imported cabbage worm and the cabbage aphid, J. R. PARKER (*Montana Sta. Circ. 28 (1913), pp. 9-24, figs. 12*).—This circular consists of a general account of these pests and means for their control.

African cotton pests, F. ZACHER (*Arb. K. Biol. Anst. Land. u. Forstw., 9 (1913), No. 1, pp. 121-230, figs. 83; abs. in Rev. Appl. Ent., 2 (1914), Ser. A, No. 1, pp. 1, 2*).—The insect enemies of cotton in Africa and remedial measures are described at considerable length.

Insect enemies of lettuce, P. NOEL (*Bul. Lab. Régional Ent. Agr. [Rouen], No. 4 (1913), pp. 4-6*).—The author lists 50 enemies of lettuce.

Animal enemies of the sugar beet in 1913, A. STIFT (*Bl. Zuckerrübenbau, 21 (1914), Nos. 4, pp. 60-64; 5, pp. 72-73*).—This is a summarized account with references to the literature of the year.

Tree crickets injurious to orchard and garden fruits, P. J. PARROTT and B. B. FULTON (*New York State Sta. Bul. 388 (1914), pp. 417-641, pls. 10, figs. 9*).—This is a detailed report of studies, data relating to which have been previously noted (*E. S. R., 29, p. 354*).

It is stated that the more common and injurious species of tree crickets in plantings of garden and tree fruits in New York are the snowy tree cricket (*Ecanthus niveus*), the narrow-winged tree cricket (*O. angustipennis*), and the striped tree cricket (*O. nigricornis*). While these species display great similarity in external appearance, they show marked differences in habits and economic status. During their early nymphal existence they possess pronounced predaceous habits, but as they approach maturity they exhibit phytophagous and mycophagous tendencies, subsisting on floral organs, foliage, fruit, and minute fungi. The eggs are deposited during the latter part of August and throughout September and hatch during early June; 5 nymphal instars are passed and the adults make their appearance in August.

The snowy tree cricket oviposits in a great variety of plants, most abundantly in the apple, plum, and cherry, and somewhat commonly in raspberry and walnut. The eggs are deposited singly in soft, fleshy bark. On the raspberry oviposition takes place in the fleshy area at the side of the bud in the axils of the leaves, and usually there is not more than one egg on each side of a bud. Microscopical examinations of the crop contents have shown that the San José scale may, under certain conditions, form a large part of the diet of this cricket. It has also been observed to eat holes in raspberry and apple leaves and is reputed to attack ripening fruits. It derives its reputation as an orchard pest chiefly from the occurrence of diseased areas about wounds in the bark of apple trees. The areas of infection in their external appearance and effects resemble superficially certain stages of the common apple cankers. Cultural and microscopical studies indicate that in 1913 a fungus (*Leptosphaeria coniothyrium*) was in a majority of cases the infecting organism.

The narrow-winged tree cricket has feeding habits similar to the snowy tree cricket. It is said to be common in apple orchards and has been observed in considerable numbers on alders and scrub and bur oaks. As with *O. niveus* various disorders of bark may attend oviposition in apple trees.

The striped tree cricket, unlike the other two, prefers plants which have a central pith surrounded by a woody outer layer in which to oviposit. Oviposition occurs in many plants, but the eggs are deposited most abundantly in the raspberry and blackberry, *Erigeron canadensis*, and the larger species of Solidago. The eggs are placed in a series, forming a single row in the current year's growth, and with raspberries have ranged in number from 2 to 80 or more eggs in a row. It feeds on anthers and petals of flowers, raspberry leaves, and fruit. Leaf tissues, fungus mycelium, and spores constituted a large part of the crop contents of a number of specimens that were examined.

It has attained its standing as a destructive pest because of its injurious work on the raspberry and blackberry. The injuries arise from the long series of punctures which it produces in canes during the process of egg laying. As a result of the rupturing of woody tissues the cane splits at the point of injury and becomes so weakened that it eventually breaks down from the weight of the upper growth or from twisting by the wind.

These tree crickets have a number of natural enemies, the more common and efficient being egg parasites of which there are 8 species. These include 3 chalcidoids and 5 species of proctotrupoids, namely, *Macrorileya æcanthi*, *Anastatus (Antigaster) mirabilis*, *Polynema bifasciatipenne*, Teleas (?), *Caloteleia* sp., *Baryconus æcanthi*, *Cacus æcanthi*, and *Idris* sp. Of the three species discussed *O. nigricornis* appears to be the most subject to parasitism.

In regard to preventive and remedial measures it is stated that cultivation to destroy foreign vegetation, as weeds and brush, about and in plantings of fruit, and to keep the ground about trees and vines clean is an efficient measure for the prevention of damage. While the susceptibility of these insects to arsenicals has not been conclusively demonstrated it is believed that the numbers of the tree crickets are reduced by summer applications of these poisons. Raspberry canes showing extensive oviposition should be removed in the course of winter and spring pruning and burned to destroy the eggs contained in them.

Tree crickets of garden and orchard, F. H. HALL (*New York State Sta. Bul.* 388, popular ed. (1914), pp. 8, pls. 4, figs. 3).—A popular edition of the above.

The Acridiidae of Minnesota, M. P. SOMES (*Minnesota Sta. Bul.* 141 (1914), pp. 7-100, pls. 4, figs. 11).—A synopsis of this order, with tables for the separation of the forms described as occurring in Minnesota. A brief bibliography is appended.

The tarnished plant bug (*Lygus pratensis*), C. R. CROSBY and M. D. LEONARD (*New York Cornell Sta. Bul.* 346 (1914), pp. 463-526, pls. 6, figs. 9).—This summarized account of the present knowledge of *L. pratensis* includes the results of observations and experiments commenced by the authors in 1911. Some 50 plants are mentioned as being injured by this plant bug.

In New York as a rule the pest hibernates in the adult stage. Oviposition was observed on August 10, 1898, by Slingerland, who found about 10 days to be required for the incubation of the egg. Five nymphal stages are described and illustrated. It is stated that Haseman (*E. S. R.*, 29, p. 354) has found 25 to 30 days to be required in September and October for the completion of the life cycle, thus indicating that there are four or five annual generations. The insect has but few natural enemies. The eggs, however, are destroyed to a slight extent by the minute mymarid parasite *Anagrus ovijentatus*.

The greatest injury by this insect appears to be caused to peach nursery stock. Nursery stock thus attacked presents a dwarfed and bushy appearance, due to the killing of the terminal buds of both the laterals and the main shoot by the feeding punctures of the adults in late June and early July. Observations which extended over the last two years show that only a very few tarnished plant bugs are to be found in the peach blocks before the latter part of June. In 1912 and again in 1913 about June 23 they suddenly increased in numbers and within a week became extremely abundant. The injury to the buds followed closely after the increase in the number of the insects. When the tip has been punctured the leaves wilt, turn brown, and die; the bud also is killed and further growth of the plant is prevented.

While this injury to peach nursery stock, known as peach stop-back, has been ascribed to other causes experiments have shown that it is produced by the tarnished plant bug. The fact that the injury may be produced by nymphs, as

experiments show, would indicate that it is caused by feeding punctures. The fact that injury was not produced by needle punctures would suggest that in feeding the insect injects some substance poisonous to plant tissue.

The losses occasioned to peach nursery stock are very great. The trees are stunted and bushy and do not have a strong leader and must therefore be sold as second or third class stock. It is stated that while these trees do not have proper form nevertheless they are perfectly thrifty and in many cases are as good for planting as those having a large, fully developed leader, if not better.

Control measures are discussed at length. It is stated, however, that the control of this plant bug is still an unsolved problem. Most of the remedies suggested are either inadequate to meet the demands of practical growers, unsuited to the conditions under which the crop is grown, or impracticable in other ways.

An extensive bibliography is appended.

Susceptibility to spraying mixtures of hibernating pear psylla adults and their eggs, H. E. HODGKISS (*New York State Sta. Bul.* 387 (1914), pp. 389-418, pls. 3, figs. 2).—Investigations of failures to control the psylla in pear orchards led the station to inquire into the susceptibilities of hibernating adults and their eggs to spray mixtures.

Studies of its seasonal history and habits have shown that the pear psylla passes the winter as an adult and that it deposits its eggs in the spring within a short period after its emergence from hibernating quarters. It was observed to winter over on various fruit trees, such as apple, cherry, plum, and peach, but the largest number was found to hibernate in the rough bark of the pear tree. When mild weather prevailed the eggs were found to be largely deposited within a few days after the emergence of the hibernating adults in the spring. Oviposition continued for several weeks, especially if the weather was variable, but usually most of the eggs were deposited before the last of April. Some of the eggs were deposited on foliage, but it appeared that these normally are comparatively few in numbers and result in little or no serious infestation of the foliage.

The practice of clean culture and removal and destruction of the rough bark left the psylla with few opportunities of escape from application of contact mixtures. "Miscible oils, nicotin preparations, and soapy solutions were effective sprays against the psylla adults. Homemade oil emulsions were less satisfactory, which may have been owing to varying percentages of oil in the mixtures, caused by imperfectly prepared emulsions.

"The best means of killing the flies is spraying during a period of warm weather, preferably in November or December, or during March or early in April. The most satisfactory mixture, from the standpoints of safety to fruit and leaf buds and effectiveness against the insect, is 0.75 pt. of tobacco extract (40 per cent nicotin) in 100 gal. of water to which are added from 3 to 5 lbs. of soap.

"Eggs about to hatch and newly emerged nymphs succumb to an application of the lime-sulphur solution. By postponing the dormant treatment for the San José scale until the blossom cluster-buds are beginning to separate at the tips, very effective work can be done against the eggs. The lime-sulphur should be used in the proportion of 1 gal. of the concentrate, 32° B., to 8 gal. of water. In some tests of other contact sprays the miscible oils, oil emulsions, weak dilutions of nicotin, and soapy solutions were of small value for the destruction of the eggs. Ova deposited on the twigs after the wood was thoroughly sprayed with the lime-sulphur solution hatched, and the young nymphs were not harmed through contact with the material on the bark of the trees. On the other hand, the wash having considerable amounts of sediment (15:20:50

formula) was less destructive to the eggs, but the young psyllas which hatched for the most part failed to reach the opening buds and these succumbed to the action of the sediment which became attached to their bodies after leaving the egg shells."

The pear psylla and its control, F. H. HALL (*New York State Sta. Bul.* 387, popular ed. (1914), pp. 3-10, pl. 1, figs. 4).—A popular edition of the above.

Observations and experimental studies of the life cycle of the beet plant louse (*Aphis euonymi*), A. MALAQUIN and A. MOITIÉ (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 19, pp. 1371-1374).—The authors find that the eggs of *A. euonymi* deposited in the fall on the bean, an alternate host plant, have not hatched notwithstanding that they hatched normally on *Euonymus europæus*, the primary host plant, and that if the young which issue from eggs are experimentally placed upon the leaves of the beet they do not attempt to feed thereon. It is thought probable that in this migratory species the generation issuing from the fecundated eggs is by heredity closely restricted to its primary host plant, and that the adaptation to an alternate host plant becomes established only in later generations.

Catalogue of the Lepidoptera Phalænæ in the British Museum.—XII and XIII, Catalogue of the Noctuidæ in the collection of the British Museum, G. F. HAMPSON (*London, 1913, vols. 12, pp. XIII+626, pls. 30, figs. 134; 13, pp. XIV+609, pls. 18, figs. 130*).—Volume 12 of this work (E. S. R., 28, p. 856) catalogues the noctuid subfamily Catocalinæ and volume 13 the remainder of the Catocalinæ and the subfamilies Mominæ and Phytometrinæ.

The gipsy moth, J. BARSACQ (*Rev. Phytopath. Appl.*, 1 (1913), No. 5, pp. 70-73, figs. 2; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 12, p. 481).—This article describes the ravages of the gipsy moth in the Crimea. The young caterpillars are frequently parasitized by *Apanteles fulvipes*, *A. solitarius*, *A. glomeratus*, *Pristomerus vulnerator*, *Echinomyia fera*, *Tachina larvarum*, and *T. rustica*; the more mature caterpillars and pupæ by *Sarcophaga affinis*, *S. albiceps*, *Parexorista lucorum*, *Pimpla instigator*, *Ræselia antiqua*, *Scotia saturnia*, *Theronia flavicans*, and others of less importance.

The destruction of the leopard moth, P. NOËL (*Bul. Lab. Régional Ent. Agr. [Rouen]*, No. 4 (1913), p. 14; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, pp. 396, 397).—Injury to the cork oaks of the Massif de l'Edough in the Department of Constantine is said to be chiefly due to *Zeuzera pyrina*, which burrows in the trunk and branches. This pest is thought to be the same as *Z. æsculi* since the habits of the two are identical.

Carbon bisulphid is said to have been used with success in Algeria against the caterpillars of *Z. pyrina*, the liquid being injected into the gallery and the opening stopped up with plaster or clay.

The sequoia pitch moth, a menace to pine in western Montana, J. BRUNNER (*U. S. Dept. Agr. Bul.* 111 (1914), pp. 11, figs. 5).—The sequoia pitch moth (*Vespa pamina sequoia*) menaces the lodgepole pine timber in the area near and at the divide between the Swan River and the Clearwater River in western Montana, and is at present the most destructive insect pest in that region. Roughly the area in which the insect is a very serious factor in forest destruction is about 12 miles square, or more than 90,000 acres.

Observations of the emergence of the adult show that the general flight of the mature insects and oviposition occur between June 25 and July 15, the greater number of them probably flying about July 10 and the flight and oviposition being over by August 1. While the period required for the incubation of the egg has not been determined, the injury to the newly infested trees by the young larvæ is quite perceptible by August 15. The larvæ are said to have attained considerable size by the time frost arrests their activity

about October 1. About 30 days are passed in the pupal stage. In summarizing the life cycle, it is stated that larvæ hatching from the eggs deposited in June or July of one year develop into adults during the same months two years later, thus making the generation biennial.

This moth is apparently little subject to the attack of either parasitic or predaceous enemies. The attack of pine by *Dendroctonus monticolæ* in the Clearwater country is said to be nearly always fatal to the pitch moth since the former kills the trees almost immediately, and without the flow of sap the larvæ of the moth can not survive.

While lodgepole pine is numerically the principal species of tree in the region and, with the rare exception of the yellow pine, is the species subject to attack by the pitch moth, this moth attacks almost all kinds of conifers in other localities within its range. The infested trees are readily located by the never-absent pitch exudation over the tunnel of the larva. They are attacked at the extreme base, and the exuding pitch flows out from the tree not infrequently a distance of 10 or 12 in. upon the humus which covers the ground.

The larva begins its mine in a crevice in the bark where the egg was deposited, then proceeds through the outer layers until it reaches the cambium. Close to the wood it begins to construct a transverse mine running in both directions from where it entered. It widens this tunnel at the center, thereby causing the appearance of a central chamber. In small trees the mine is always practically straight across the grain of the wood. A count made of the annual rings and measurements on a tree which was considered to be a fair example of the general injury in the area brought out the fact that during the first 41 years of its life and normal health it added annually about $\frac{1}{4}$ in. to its diameter, while it added only about $\frac{1}{2}$ in. annually during the 23 years it had been infested by the pitch moth.

The author finds that the peculiar results of the work of this pest are the chief and primary contributing cause of the frequency and possibly continuity of fire damage to forest growth in this area. There is said to be only one way to reduce the insect and that is to destroy it while in its larval stage. By September 1 all of the eggs which have not been lost have hatched, and the young larvæ have attained a size sufficient so that they can be seen and destroyed. Killing the larvæ outright or hand picking is said to be the only method of reducing the number of this pest.

The peach tip moth, W. W. FROGGATT (*Agr. Gaz. N. S. Wales, 25 (1914), No. 5, pp. 413, 414, pls. 3*).—This article relates to an undetermined tortricid, the larvæ of which were first observed four or five years ago in the vicinity of Sydney. It burrows into the side of the tips and by eating its way downward causes the terminal leaves of peach and nectarine trees to die back and the top of the injured twigs to gum. "Later on in the season it was found that a large percentage of the fruit was marked with several blotches, covered with exuding gum, under which some insect had gnawed through the skin. . . . The damage done to the surface of the fruit is more serious than that to the twigs, for it causes large scars to form before the fruit is ripe." The insects also bore distinct circular holes and gnaw irregular tunnels through the tissue of quinces and apples, but do not work into the center for the core like the codling moth.

Experiments in the destruction of fly larvæ in horse manure, F. C. COOK, R. H. HUTCHISON, and F. M. SCALES (*U. S. Dept. Agr. Bul. 118 (1914), pp. 26, pls. 4*).—This bulletin presents the results of experiments carried on at Arlington, Va., and Audubon Park, New Orleans, La., by the Bureaus of Entomology, Chemistry, and Plant Industry of this Department working in cooperation.

Of 17 substances experimented with but two, namely, borax and calcined colemanite, gave satisfactory results. Borax in the commercial form in which it is available throughout the country was found to be by far the most effective, economical, and practical. It increases the water-soluble nitrogen, ammonia, and alkalinity of manure and apparently does not permanently injure the bacterial flora. The application of manure treated with borax at the rate of 0.62 lb. per 8 bu. or 10 cu. ft. to soil does not injure the plants thus far tested, although its cumulative effect, if any, has not been determined. It is recommended, however, that not more than 15 tons per acre of the borax-treated manure should be applied to the field.

In treating manure with borax to kill fly eggs and maggots it is recommended that 0.62 lb. of borax or 0.75 lb. of calcined colemanite be applied to every 10 cu. ft. of manure immediately on its removal from the barn. The borax should be applied particularly around the outer edges of the pile with a flour sifter or any fine sieve, and the borax-treated manure sprinkled with 2 or 3 gal. of water. "As the maggots congregate at the outer edges of the pile, most of the borax should be applied there. The treatment should be repeated with each addition of fresh manure, but when the manure is kept in closed boxes less frequent applications will be sufficient. Where calcined colemanite is available, it may be used at the rate of 0.75 lb. per 10 cu. ft. of manure, and is a cheaper means of killing the maggots. In addition to the application of borax to horse manure to kill fly larvæ, it may be applied in the same proportion to other manures, as well as to refuse and garbage. Borax may also be applied to floors and crevices in barns, stables, markets, etc., as well as to street sweepings, and water should be added as in the treatment of horse manure. After estimating the amount of material to be treated and weighing the necessary amount of borax a measure may be used which will hold the proper amount, thus avoiding subsequent weighings."

The estimated cost of treatment with borax at 5 to 6 cts. per pound in 100-lb. lots is estimated at practically 1 ct. per horse per day. If calcined colemanite is purchased in large shipments the cost should be considerably less.

A bibliography of 12 titles is appended.

[Eliminating a city's flies], J. DAWSON (*Sci. Amer.*, 111 (1914), No. 2, pp. 28, 29, 34, figs. 9).—This is an account of the campaign against the house fly in Cleveland, Ohio.

Flies and diarrheal disease, D. B. ARMSTRONG (*N. Y. Assoc. Improving Condition Poor Pub.* 79 [1914], pp. 29, pls. 3, figs. 3).—This reports investigations of the Bureau of Public Health and Hygiene of the Department of Social Welfare. Although the work, which was carried on in New York City, is not considered sufficiently extended for general deductions, it is interesting and suggestive. There was apparently a marked reduction in the amount of diarrheal diseases in the area protected from flies as compared with similar unprotected areas.

Control of cabbage maggot on early cabbage, F. H. HALL (*New York State Sta. Bul.* 382, popular ed. (1914), pp. 3-12, figs. 9).—A popular edition of the bulletin previously noted (*E. S. R.*, 31, p. 352).

The chief remedies against the larvæ and adults of *Lema melanopus*, a pest of summer-sown grain, E. M. VASSILIEV (*Trudy Opytn. Ent. Stantsii Vseross. Obshch. Sakh. Zavod.* [Kiev], 1912, pp. 1, 2; abs. in *Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 12, p. 479).—During 1910-11 the adult and immature stages of *L. melanopus* are said to have injured oats and barley and summer-sown wheat in the Government of Kharkof.

Bothynoderes punctiventris and methods of fighting it, V. POSPIELOV (*Sveklovichnyi Dolgonosik i Mëry Bor'by s Nim. St. Petersburg: Glav. Uprav. Zemleustroistva i Zeml.*, Dept. Zeml., 1913, 2. ed., pp. 116, pls. 3, figs. 8; rev.

in *Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 3, pp. 177-180).—A beetle, *B. punctiventris*, is said to be one of the most permanent and serious pests of sugar beets, occurring from Austria-Hungary to Caucasia and the southern part of Siberia. The author gives a list of 25 species of Curculionidæ which he observed from 1903 to 1905 in beet plantations in Kief, of which 14 species are recorded for the first time from the beet.

Dendrolimus pini and *D. segregatus*, their life history, injurious activities, and methods of fighting them, I. V. VASSILIEV (*Trudy Bûaro Ent. [St. Petersburg.]*, vol. 5, No. 7, 2. enl. ed. (1913), pp. 99, pls. 2, figs. 34; abs. in *Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 220-223).—A detailed discussion of the biology and means of controlling these forest pests.

The alfalfa weevil, R. A. COOLEY (*Montana Sta. Circ. 35* (1914), pp. 191-206, figs. 24).—A general account of this pest which occurs in Utah, Idaho, and Wyoming but has not as yet appeared in Montana.

Birds in relation to the alfalfa weevil, E. R. KALMBACH (*U. S. Dept. Agr. Bul. 107* (1914), pp. 64, pls. 5, figs. 3).—This bulletin dealing with the food habits and economic status of birds, and of the toad, frog, and a few other vertebrate enemies of the alfalfa weevil is based upon investigations carried on from May 8 to July 25, 1911, and from April 1 to August 15, 1912. In the course of the two seasons' work 45 species of birds were found to have eaten the pest, all of which are briefly discussed by the author.

The English sparrow was found to be a most effective enemy of the pest, this being particularly true of nestling birds in May and June. In view, however, of the ability of the bird to do serious damage to standing grain and to take heavy toll from the farmers' chicken feed, the author states that he can not recommend legal protection for this species.

The investigation is said to verify the statement frequently made that the abundance of an insect, and consequently the ease with which it may be secured, are important factors governing the food habits of birds. The ground-feeding birds come into most intimate contact with the alfalfa weevil but birds which feed on the wing may secure the insect at the time of its spring and summer flights; and such species as search for their food over trunks of trees may come into contact with a few hibernating adults. Over much of the territory covered by the author the bird enemies of the weevil have learned to search for the insect as a food in the comparatively short period of four or five years, a fact which makes the large proportion of this food eaten by some species the more remarkable.

It is stated that with the exception of a fungus disease, which in some localities destroyed large numbers of the pupæ, there probably was at the close of 1912 no other natural agency which had done more in controlling the alfalfa weevil than the native birds. The valley quail (*Lophortyx californica valli-cola*) is said to be deserving of additional legal protection for a short period at least.

Egg laying of the rice weevil, *Calandra oryzae*, F. H. LATHROP (*Ohio Nat.*, 14 (1914), No. 7, pp. 321-327, figs. 5).—A descriptive account.

Psallidium maxillosum in the Government of Podolia on transplanted seedlings, E. M. VASSILIEV (*Trudy Opytn. Ent. Stantsii Vseross. Obshch. Sakh. Zavod. [Kiev]*, 1912, pp. 3-6; abs. in *Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 12, p. 478).—The curculionid weevils *P. maxillosum* and *Tanymecus palliatus* are a source of injury to beets and the former to vine seedlings in the Government of Podolia.

Brood diseases of bees, F. C. PELLETT ([Iowa] *State Bee Insp. Bul. 3* (1914), pp. 12, figs. 4).—A summarized account of the more important brood diseases.

The manioc ant (*Cecodoma cephalotes*), G. DEVEZ (*Agron. Colon.*, 1 (1913), Nos. 5, pp. 129-135; 6, pp. 164-174, fig. 1; 1 (1914), Nos. 7, pp. 13-18; 8, pp. 42-51, pl. 1; abs. in *Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 223-225).—A report of studies in Guiana of this leaf-cutting ant and its destruction by means of sulphur dioxide.

A revision of the Ichneumonidæ based on the collection in the British Museum (Natural History), C. MORLEY (*London*, 1914, pt. 3, pp. XIII+148, pl. 1).—This third part of the work previously noted (*E. S. R.*, 30, p. 59) deals with the tribes Pimplides and Bassides.

A first contribution to a catalogue of the zooecidia of Switzerland, M. MOREILLON (*Bul. Soc. Vaud. Sci. Nat.*, 5. ser., 49 (1913), No. 181, pp. 251-286).—This catalogue is arranged according to host plants.

A case of tick bite followed by widespread transitory muscular paralysis, E. M. EATON (*Austral. Med. Gaz.*, 33 (1913), No. 17, pp. 391-394; abs. in *Jour. Trop. Med. and Hyg.* [London], 16 (1913), No. 12, pp. 188, 189).—This article relates to a transitory muscular paralysis in a child of 4½ years, apparently caused by *Ixodes ricinus* or *I. holocyclus*.

The predaceous mite, *Pediculoides ventricosus*, F. C. WILLCOCKS (*Agr. Jour. Egypt*, 4 (1914), No. 1, pp. 31-52, pl. 1).—This paper deals with *P. ventricosus*, which has been found to be a parasite of the pink cotton bollworm in Egypt, and also discusses its relation to the outbreak of a supposed skin disease among laborers engaged in handling cargoes of Egyptian cotton seed at the London docks and at a Colchester oil mill. It is stated that so far as known *P. ventricosus* was first discovered in Egypt at Zagazig in 1908 on the pupa of a buprestid beetle (*Sphenoptera trispinosa*). The mite was first observed as a parasite of the pink bollworm in cotton seed obtained from Alexandria in 1913.

FOODS—HUMAN NUTRITION.

Concerning bouillon cubes, seasonings, and meat extract, II, K. MICKO (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 27 (1914), No. 7, pp. 489-502).—The results of the examination of a large number of samples are presented and discussed.

See also a previous note (*E. S. R.*, 30, p. 257).

A note on soup cubes, E. REMY (*Pharm. Zentralhalle*, 54 (1913), No. 48, pp. 1238-1240; abs. in *Chem. Zentbl.*, 1914, I, No. 2, p. 174).—Data regarding the composition of commercial soup cubes are reported.

Concerning fish milt and fish roe (caviar), J. KÖNIG and J. GROSSFELD (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 27 (1914), No. 7, pp. 502-520).—The results of special studies of the protein, fat, ash, and acid content are reported, the analytical methods followed being described.

Canned snails (*Pure Products*, 10 (1914), No. 5, p. 244).—Data are given regarding the production and marketing of edible snails, fresh and canned.

Food value of milk and its products, R. HARCOURT (*Ontario Dept. Agr. Bul.* 221 (1914), pp. 20).—In this discussion of milk and milk products recipes are given for cheese dishes, and also data regarding their relative cost as sources of protein and energy in comparison with meat dishes.

Ice cream, A. MCGILL (*Lab. Inland Rev. Dept. Canada Bul.* 276 (1914), pp. 15).—Of the collection of samples examined, 77 were found genuine, 49 adulterated, 8 slightly below standard, and 1 sold as imitation.

The importance of Indian corn for the Colonies and for Germany as a cheap and good foodstuff, O. RAMMSTEDT (*Tropenpflanzer*, 18 (1914), No. 4, pp. 201-214).—The importance of Indian corn as a foodstuff is pointed out in this summary of data, which includes the results of the author's own work.

The chemistry of bread making, J. GRANT (*London, 1912, pp. VIII+224, figs. 47*).—This volume deals with the application of science to the bread making industry and is designed as a guide for students in bread making. The atmosphere, water, acids, alkalis, and salts are considered in relation to baking, as well as bakery physics, cereals and their character and composition, milling, ferments, yeasts, etc., bread making processes, antiseptics and bakehouse hygiene, fuels and ovens, cereal foods, and some related topics. A bibliography is appended and an index is provided.

So-called chestnut blight poisoning, G. P. CLINTON (*Connecticut State Sta. Rpt. 1914, pt. 1, pp. 30-42*).—Since a number of cases of illness and a few deaths attributed to eating chestnuts from blighted trees have been reported in the public press, an investigation was undertaken to determine whether or not the blight fungus was poisonous and thus responsible for such trouble as had been implied.

According to the author's conclusions, the investigations showed that there may have been some relation between the illness of at least some of the persons and the eating of chestnuts. The illness might have been due "to overeating or to the eating of immature or partially germinated chestnuts, or to the age and physical condition of the persons who were made sick, or to a combination of these factors.

"On the other hand, there was no evidence discovered that the blight fungus or other fungi were directly connected with the sickness, since experimental feeding of white rats with these fungi failed to produce any injurious effects. Small amounts of pure cultures of the blight were also eaten by the writer without ill effect.

"The only connection the blight could have with such sickness would be indirect, the trees being so injured thereby as to produce a greater proportion than usual of nuts not perfectly matured which possibly contained some self-produced poisonous principle; but even this supposition does not seem very probable."

Supposed poisonous properties of chestnuts grown on trees affected with chestnut blight, C. D. MARSH (*Jour. Amer. Med. Assoc., 63 (1914), No. 1, pp. 30, 31*).—Investigation of reported cases of poisoning from eating chestnuts collected from trees affected by the chestnut blight gave no evidence that the nuts collected from such trees have any more deleterious properties than chestnuts collected from healthy trees. The symptoms attributed to eating blighted chestnuts were in almost all cases such as might be produced in some persons by chestnuts from healthy trees. Chemical examinations, as the author states, and laboratory experiments in feeding the whole fruit and in the use of extracts failed to show any toxic properties in the nuts.

Bromin compounds in table salts, L. CHELLE (*Bul. Soc. Pharm. Bordeaux, 54 (1914), No. 1, pp. 19-24; abs. in Zentbl. Biochem. u. Biophys., 16 (1914), No. 15-16, p. 592*).—A number of salts of different origin were examined and all contained bromin. From his investigations, the author concludes that the quantity of bromin absorbed with the food is probably sufficient to account for the amount normally contained in the urine.

[Food analyses and other pure food and drug topics], E. F. LADD and ALMA K. JOHNSON (*North Dakota Sta. Spec. Bul., 3 (1914), Nos. 3, pp. 17-40; 4, pp. 41-56; 6, pp. 73-88; 7, pp. 89-104*).—The first of these bulletins discusses general questions connected with the state pure food supply; gives some data regarding a test with a commercial "hog cholera specific," which indicate that "it is not a cure or preventive for hog cholera"; records the data obtained in inspections of grocery stores and meat markets; and gives a list of beverage registrations for 1914.

The second bulletin discusses macaroni and other food topics; reports results of examination of a number of drug products, proprietary remedies, and food products; gives data regarding inspection of slaughterhouses; and lists the beverages registered.

The third of these bulletins discusses macaroni and noodles, sausage frauds, bouillon cubes, and other pure food and drug topics; gives data regarding beverages registered and registrations canceled; gives the results of examinations of miscellaneous samples of food, beverages, rubber products, and damaged flax seed. Papers by C. P. Guthrie on camphor liniment (see p. 676) and by W. L. Stockham, entitled *The Color of Flour from North Dakota Wheat Varieties*, are also included.

According to the latter author, few factors are of more importance from the standpoint of possible improvement through blending, or breeding the improved types of wheat, than the natural characteristics of color possessed by the different varieties. The ideal color for bread would probably be slightly creamy. In considering the influence of environment on this natural color, the probable changes which occur in storage are taken into account. Wheat kept in storage and milled at intervals for the last few years "produced at first a creamy loaf. It is now approaching the gray to such an extent as to score lower in color. Changes take place much more rapidly in the flour than in the wheat, especially in a warm, moist atmosphere."

The author notes further that "the process of bleaching which was quite generally practiced until the last few years, has been claimed to produce changes similar to aging. The flour so treated became a lighter cream in color and gradually went over into a gray on standing, this grayness being more pronounced with the lower grades, as they contained more of the outside portion of the wheat, dirt, etc." He gives the results obtained in judging the color of a number of different varieties of the Fife, Bluestem, and Velvet Chaff wheats, and concludes that a slightly creamy color is preferable for a standard blend and that the breeder should select wheat of that type. "The Bluestem and Velvet Chaff flour mixed with the Fife, Marquis, and Ghirka, which are liable to go to the gray, should raise the standard of all."

The last of these bulletins discusses the use of snuff and the evil effects attending it; the coating of coffee; gives data regarding the examination of a proprietary remedy, and regarding the inspection of bakeries and confectionery stores; and reports beverage registrations and gives results obtained in the examination of samples of miscellaneous foods and beverages. A brief paper, *Varnish Talk*, by R. W. Darner, is also included.

[*Food analyses and other pure food and drug topics*], E. F. LADD and ALMA K. JOHNSON (*North Dakota Sta. Spec. Bul.*, 3 (1914), No. 5, pp. 57-72).—This bulletin discusses hog cholera nostrums, patent or proprietary medicines, reports beverage registrations, and gives results of examination of a number of samples of foods, beverages, and water.

The bulletin also includes a paper, *Investigation of Commercial Condensed Soups*, by L. A. Congdon, which reports analyses of many samples. According to the author's conclusions, the principal constituents found in condensed bouillons were "salt and water with some extractive of beef and added spices."

The principal constituents of celery soup were found to be "celery paste, salt, small amount of butter, spices and water [with the exception of one sample] which was composed principally of starch (probably wheat), with small amount of celery seed as flavor, salt, and water."

The condensed tomato soups "were made principally of tomato pulp, spices such as paprika, etc., salt, sugar and water."

The condensed vegetable soups were variable in their constituents; "the majority of those analyzed contained Lima beans, kidney beans, tomato pulp, barley, parsnips, carrots, peas, celery, parsley, spices, salt, water, with an extraction of a beef soup bone."

"In regard to the condensed beef soups, the principal ingredient found was vegetable matter, mostly in the form of boiled barley. This soup might better be named vegetable and beef soup. In regard to the condensed chicken soups, the principal ingredients found were rice and salt water. A compound of this kind whose chief ingredients are rice and salt water can hardly be classed as 'condensed chicken soup,' but might more properly be called 'rice chicken soup' or 'rice soup—chicken flavor.' The principal ingredients of chicken gumbo soup were boiled rice, small amount of other vegetables, and in one case a small amount of corn beef and chicken." Similar soups were also found to contain small quantities of meat substance in proportion to other constituents.

"Consomme was found to be a water-salt solution of meat extractive. Clam broth in all cases was a water-salt solution of clam extractive. In clam chowder, beside a small amount of clams, the chief ingredient was found to be boiled potatoes and some onions with some incorporated water. Pea soup in all cases was found to be principally composed of mashed peas with salt and spices."

Fourteenth annual report on food adulteration under the pure food law, W. M. ALLEN, E. W. THORNTON, and C. E. BELL (*Bul. N. C. Dept. Agr.*, 34 (1913), No. 12, pp. 112).—Under the provisions of the state law a number of samples of miscellaneous food products were examined, and are here reported upon.

The department of food sanitation and distribution, DORA E. WHEELER (*Women's Munic. League Boston Bul.*, 5 (1914), No. 5, pp. 54-56).—A progress report, with an outline of plans for future work.

The influence of low temperatures upon the decomposition of foods, H. KÜHL (*Hyg. Rundschau*, 23 (1913), No. 17, pp. 1025-1028; *abs. in Chem. Zentbl.*, 1914, I, No. 2, p. 173).—The relation of ferments to the changes brought about in milk, meat, and fish during storage is considered.

According to the author, meat and fish exhibit marked differences with reference to the character of the changes brought about by autolytic processes. In the case of meat, these result in "ripening" and are desirable, whereas in the case of fish they are undesirable, the fish becoming unfit for food. Fish are therefore frozen for storage instead of kept at a low temperature above the freezing point.

One reason why canned goods should be dated, J. T. SEIDEL (*Pure Products*, 10 (1914), No. 5, pp. 227-231).—In this summary of data the author points out that the tin content of canned goods increases with age and therefore goods should be dated.

[Food and its cost at] the Garland School of Home Making (*Half Yearly Rpt. Garland School Home House 1913-14, Oct.-Feb.*, pp. 11).—Resident pupils act in turn as housekeepers at this home house, located in Boston, Mass. The system of management followed is described and its statement of income and disbursements given. The total number of meals served was 2,595, at an average cost of 16 cts. per person per meal.

Cost of living in New Jersey (*Ann. Rpt. Bur. Statis. Labor and Indus. N. J.*, 36 (1913), pp. 153-164).—Information is summarized regarding the retail prices of a selected list of food supplies.

"Since 1898, a period of 15 years, the average annual wages or earnings of factory and workshop employees in New Jersey show an advance of 26.9 per cent while food prices as represented by 43 articles are shown to have advanced 27.7 per cent."

Infant mortality.—[Care of children] (*Rpt. Bd. Health Wis.*, 24 (1911–12), pp. 124–130).—Feeding, care of milk, clothing, and related topics are considered in this summary of statistical and other data.

A bulletin on the baby (*Bd. Health Ala. [Bul.]*, 1913, pp. 8).—Infant feeding is one of the subjects discussed in this publication.

School lunches in Philadelphia (*School Lunch Com. Home and School League Ann. Rpt.*, 2 (1912–13), pp. 21, pl. 1, figs. 5).—Standards in school lunch administration, the organization and administration of work, and the business and psychology of the school lunch are the subjects included in this report, together with a contribution to the bibliography of the subject.

As shown by the data collected with reference to serving cost and food cost, it appears that “the cost of food is largely determined by the number of children served. The cost of service is mainly affected by the way in which the food is served. It costs less to serve 600 in one place once than it does to serve 100 in six places or at six times. It costs less to serve food as purchased than when it requires cooking or special handling. Foods that may be stored cost less than perishable goods. Allowing for such variations, the cost of serving may be put down as between one-fourth and one-third of the total cost of food and service.

“The charge to the children can be made to cover the cost of food and service where the business is large enough and the control central and continuous. Where responsibility for the management is divided between the school and a private organization there is a loss of at least 15 per cent for service. In the case of elementary school lunches the cost of supervision can not be made chargeable to the receipts from the children, for the value of supervision is primarily educational and is properly charged against the public fund for education.

“It is not so easy to measure the degree to which attendance on the lunches is affected by the approval of the teaching staff. A few words from the teacher will do much to make a new dish popular or unpopular.

“As business increases and steadies, it is possible to get for the same money food of better quality and a greater quantity. This is because large quantities can be bought at once and advantage taken of advance-order prices. . . .

“The initial cost of movable equipment is about 10 cts. per child, . . . deteriorating at the rate of 20 per cent per year. It consists of cooking and serving utensils. This cost is kept down by having children served in relays and the dishes washed between servings. It is also kept down by the fact that not all the food sold requires serving dishes; for example, crackers.

“The fixed equipment, such as gas stoves, sink, closets and tables, is permanent, and no special fund need be set aside for its renewal. . . .

“The cost of supervision varies inversely with the numbers served. In the high schools, where large numbers are served under public control and where portions are based on 3-ct. units, \$1 out of every \$9 spent goes to supervision. In the elementary schools, where there are fewer lunches served, and where control is divided between the school and private committees, \$1 in every \$6 goes to supervision.”

Is cooking an error? (*Lancet [London]*, 1914, I, No. 12, pp. 841, 842).—A discussion of the general question of the destruction of vitamins by heat.

Cooking and vitamins, L. HILL (*Lancet [London]*, 1914, I, No. 14, p. 1002, fig. 1).—In a communication in reply to the question raised in the above article, the author summarizes some data (including his own experimental work with pigeons), regarding vitamins, substances which occur in small amounts in a number of foodstuffs and which are necessary, “some for nutrition and others for growth.”

"These," he states, "by processes of milling and canning food . . . are often removed or destroyed. Thus they are removed in the polishing of rice and in the preparation of white flour. Vitamins are soluble in water and may be removed if food is stewed and the liquor thrown away. Those separated from rice polishings are destroyed by heating to 120° C. and diminished by boiling. . . . Those present in whole meal wheat flour are not destroyed by baking. . . . The vitamins which prevent scurvy are not destroyed by boiling. . . . The addition of a very little milk to white bread, either boiled or raw, makes the latter a sufficient food. . . . So far as the evidence goes, then, the vitamins present in milk are not destroyed by boiling, and there is no objection on this ground to the sterilization of milk for infant feeding. . . ."

"The question of white bread does not concern the well-to-do, who get their supply of vitamins from milk, eggs, fresh vegetables, etc., but it is of vital matter to the children of the very poor brought up on white bread, margarin, and tea. For them whole meal bread is essential."

Variations of the food and body weight under the action of solar rays in different seasons—nutrition by heat, M. DE LAROQUETTE (*Compt. Rend. Acad. Sci. [Paris], 158 (1914), No. 8, pp. 586-588*).—In these experiments, which extended over a period of one year, the body weight and food consumption were observed daily in the case of three rabbits exposed in glass cages to the heat of the sun. Each rabbit received a constant daily ration of 100 gm. of green vegetables, which was always eaten, and a ration of oats, of which the amount eaten depended upon the appetite of the animal.

The average amount of oats eaten varied inversely with the intensity of the sun's rays. The amount consumed per 100 gm. of body weight was approximately 4 gm. in winter, with a minimum temperature of 15° C. (59° F.); 3 gm. in the spring and fall, with a minimum temperature of 22°; and only about 2 gm. in the summer, with a minimum temperature of 30°.

From the fact that the body weight of the animals increased during the spring when there was a decrease in the amount of food consumed, and that the loss in body weight during the summer was not proportional to the decrease in the amount of food consumed, the author concludes that there is a certain absorption and utilization of the energy from the sun's rays in the case of animals as well as plants. In support of this view, he states that in the case of natives of hot countries whose more or less naked bodies are exposed to the sun's rays for a greater part of the day the fuel value of the diet is low. He cites also the beneficial results obtained by sun baths in treatment of certain cases of malnutrition, especially gout and obesity. [The author has apparently disregarded the effect of external temperature upon metabolism.]

The economy of foods possible by increase of surrounding temperature, L. LAPIQUE (*Compt. Rend. Acad. Sci. [Paris], 158 (1914), No. 10, pp. 732-734*).—A critical discussion of the above article.

The effects of protein starvation and feeding on the amino acid content of the tissues, D. D. VAN SLYKE and M. M. GUSTAVE (*Proc. Soc. Expt. Biol. and Med., 11 (1913), No. 1, p. 25*).—Neither protein hunger nor high protein feeding influenced the amino acid content of the tissues.

"Nitrogen retained as the result of high protein feeding is not in the form of stored digestion products, but rather as body protein.

"The free amino acids of the tissues can originate not only from the food, but also from autolyzing tissues, as the latter are the only apparent source from which the amino acid supply can be maintained during starvation."

Protein metabolism from the standpoint of blood and tissue analysis.—VII, An interpretation of creatin and creatinin in relation to animal metabolism, O. FOLIN and W. DENIS (*Jour. Biol. Chem., 17 (1914), No. 4, pp.*

493-502).—According to the authors, the creatinin figures recorded in connection with their experiments “clearly indicate that the creatinin does originate in the muscles, since the preformed creatinin found in the muscles, small as it is, is nevertheless invariably greater than the preformed creatinin found in the blood. We have several other experiments in addition to those recorded in this paper, all of which have yielded the same result.

“Another interesting fact . . . discovered in the course of these investigations is that though the heart yields very much less creatin than do the striated muscles, yet in nearly every case the heart contains more preformed creatinin than is found in the striated muscles. . . . According to our point of view, the figures simply indicate that the tissue metabolism in the heart is very much more rapid than the tissue metabolism in the voluntary muscles.

“Our experiments have failed to show any creatinin formation out of the administered creatin. There is a slight accumulation of creatinin in the blood and a slight diminution of the creatinin in the muscles. It looks as if the unusually large influx of creatin into the muscles tended to force out the creatinin, but the variations are so small that we hesitate to attach much significance to them, although we have observed the phenomenon many times. If correct, this observation will help to explain the findings of those investigators who believe that the administration of creatin is accompanied by a demonstrable increase in the creatinin elimination.”

See also previous work (E. S. R., 28, p. 665).

The secretory activity of stomach glands under the influence of Liebig's extract, I, Z. TOMASEWSKI (*Zentbl. Physiol.*, 27 (1913), No. 12-13, pp. 627-630).—Experimental data are briefly reported in this preliminary account of the author's investigations.

The conclusion was reached that the secretion of gastric juice was due to a substance which could be extracted with ethyl or methyl alcohol from the phosphotungstic acid precipitate of the meat extract and not to any mineral matter which the extract contained. Atropin prevented the secretion. He concludes, therefore, that the active body in meat extract is probably an alkaloid similar to muscarin. When meat is boiled the lecithin present is broken down, yielding cholin, and this in turn is broken down, yielding the muscarin-like substance. Experiments have also shown, it is stated, that extractive substances differ materially from the digestion products of protein, only the former possessing the property of stimulating the intestinal secretions in this way.

The effect of change in diet on the carbon dioxid excretion of nursing infants, K. FRANK and A. NIEMANN (*Charité Ann.*, 37 (1913), pp. 94-100; *abs. in Zentbl. Biochem. u. Biophys.*, 16 (1914), No. 15-16, p. 531).—According to the author, an increased carbon dioxid excretion was noticed in changing from breast feeding to artificial feeding. This is stated to be due to the increased metabolism brought about by the larger amount of protein consumed.

Man a machine, J. O. DE LA METTRIE, trans. by GERTRUDE C. BUSSEY (*Chicago*, 1912, pp. 6+216, pl. 1).—The author has made available for English readers this work, published in the latter part of the eighteenth century. It has to do chiefly with philosophical speculations, but is interesting historically in the consideration of theories of body work. The text is supplemented by philosophical and historical notes.

ANIMAL PRODUCTION.

The composition of crops and feeding stuffs, H. J. VIPOND (*Union So. Africa Dept. Agr. [Pub.]*, No. 1 (1914), pp. 29).—This treats of the nutritive requirements of animals as determined by Kellner and others, and outlines possible

rations for the different classes of farm animals. There is included a table giving the composition of farm feeding stuffs as determined by American, English, and South African analyses.

Tomato seeds for fodder (*Sci. Amer.*, 110 (1914), No. 15, p. 805).—"The Chamber of French Commerce at Milan announces successful attempts to produce a valuable cattle fodder from the tomato seeds which are a by-product of the canneries. The seeds are desiccated in drying furnaces and then sifted to separate them from the woody fiber of the débris. They are then crushed by heated millstones and the oil which they contain in considerable quantities is separated by a hydraulic press. The residue is pressed into loaves, each about 2 kg. in weight. According to tests at the agricultural station at Portici, they contain an abundance of proteids and carbohydrates."

Commercial feeding stuffs.—Concerning feeding practice (*Vermont Sta. Bul.* 180 (1914), pp. 187-232).—Analyses are reported by J. L. Hills, C. H. Jones, C. G. Williamson, and G. Anderson of cotton-seed meal, linseed meal, gluten feed, distillers' dried grains, brewers' dried grains, hominy feeds, buckwheat bran and middlings, rye middlings, ground oats, rye meal, fish scrap, meat scrap, corn meal, wheat bran, middlings, red dog flour, alfalfa meal, dried beet pulp, and various mixed and proprietary feeds.

General instructions on balancing rations and feeding practice by A. A. Borland and E. H. Loveland are appended.

Inspection of feeding stuffs (*New York State Sta. Bul.* 386 (1914), pp. 315-385).—Analyses are reported of the following feeding stuffs: Cotton-seed meal and feed, linseed meal, malt sprouts, distillers' dried grains, dried brewers' grains, tankage, bone meal, gluten feed, gluten meal, hominy feed, alfalfa meal, wheat bran, middlings, dried beet pulp, screenings, buckwheat meal, corn bran, corn meal, buckwheat bran, barley middlings, beef scrap, meat meal, fish scrap, pulp, screenings, buckwheat meal, and various mixed and proprietary feeds.

The testing of calculations according to Kellner's starch values in practical feeding in Germany, A. STUTZER (*Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 2, pp. 155-158).—The author reviews the development of the principle of starch values and comments on its importance in practical feeding operations.

In reviewing fattening experiments with oxen and pigs it is stated that without exception the rations "determined according to Kellner's starch values were correct, and that this method of reckoning the amount of feed required was preferable to all other systems." "With regard to the feeding of milch cows, there is still a difference of opinion as to what proportion of the starch values must be given in the form of digestible protein."

The mineral balance of animals, M. HESPEL (*Ann. Gembloux*, 24 (1914), No. 4, pp. 190-213).—The author discusses the importance of calcium, phosphorus, magnesium, sulphur, sodium, potassium, and silicon to the animal body and the part each plays in the various body processes.

Metabolism during pregnancy and the lactation period, L. DIENES (*Biochem. Ztschr.*, 55 (1913), No. 1-2, pp. 124-133; *abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 2, p. 231).—The results of experiments are reported on the metabolism taking place in a bitch during pregnancy and before and after the lactation period.

"The metabolism appears to decrease slightly in the middle of the term of pregnancy, while it increases considerably during the second half of the time. During lactation it is much more active than during pregnancy. During the lactation period the mother and young expend the same amount of energy

per surface unit. With the cessation of lactation the expenditure of energy rapidly decreases again."

Growth restraint of young animals by the X-ray, RICHARDSON (*Deut. Landw. Tierzucht*, 18 (1914), No. 8, pp. 89, 90, figs. 2).—The results of the application of the X-ray to chicks, lambs, young guinea pigs, and dogs indicated that the X-ray has a physiological influence in restraining growth of the animal cells, especially in the very young animals. The growth of wool on the head of lambs was restrained where the X-ray was applied soon after birth, while in older lambs less influence was noted.

Report of the animal husbandman, E. G. RITZMAN (*Porto Rico Sta. Rpt.* 1913, pp. 30-34, pl. 1).—In the cattle breeding experiments the crossing of pure-bred zebu sires of one of the largest and most improved breeds of India on Shorthorn and Hereford cows has resulted in broad framed, deep bodied, early maturing progeny. The zebu characters of constitutional vigor, active movement, strong bone, straight legs, hard hoofs, a straight, easy, and rapid gait, almost complete immunity to tick infestation, together with natural adaptation to tropical heat and short pasturage, have been retained by the progeny. The progeny of these bulls from Porto Rico cows are larger and stronger than the native stock, yearlings and 2-year-olds are larger and keep better flesh on short pasture, carry practically no ticks, keep in excellent health, are vigorous and thrifty, and show strong indications of some advance toward earlier maturity.

Sheep-breeding operations have been abandoned at the station owing to the difficulty experienced in keeping the animals in good health. Flukes are a constant menace during the rainy season. Trials with African wool-less sheep indicate that they are not affected with scab. These sheep breed at any season after one year of age and almost without exception drop twins. They keep in good flesh, their meat is of good flavor and quality, and they are naturally adapted to this latitude. Their advantages for a hot tropical climate are a black skin, which permits of rapid radiation of excess body heat, and a yellowish-brown coat of hair, which is a good reflector of heat and light rays. Efforts are being made to improve their mutton form by selection rather than by crossing with any of the mutton breeds.

Data are also given as to work with horses and poultry.

Fattening cattle in Alabama, D. T. GRAY and W. F. WARD (*U. S. Dept. Agr. Bul.* 110 (1914), pp. 41, figs. 4).—This is a continuation of work previously noted (*E. S. R.*, 27, p. 673; 28, p. 69; 31, p. 169) and is in three parts.

Part 1 deals with the wintering of steers preparatory to summer fattening on pasture. Two- and 3-year-old native tick-infested grades, classed as common or fair stockers, and weighing approximately 640 lbs., were used. The steers ran in inclosed fields at all times, but had no shelter aside from the natural protection of trees and hillsides, although the winter was severe. The test began in December and continued until the following March, a period of 91 days. Lot 1 of 23 animals on range alone lost an average of 106 lbs. per head during the period; lot 2 of 15 animals, receiving range plus a half ration of cotton-seed meal and hulls, gained an average of 43 lbs. per head; and lot 3 of 23 animals on range plus a half ration of coarse hay lost an average of 72 lbs. per head during the period. The steers of lot 2 received approximately 2.4 lbs. of cotton-seed meal and 8.9 lbs. of hulls per steer per day.

Comparing these results with those of the previous two winters, it is seen that in each case range-fed steers lost in live weight most heavily, the grand average for the three years showing a loss of 101 lbs. for each of the steers on range alone, a gain of 8 lbs. for those fed on meal, hulls, and range, a loss of 9 lbs. on those which received cowpea hay, a loss of 64 lbs. on those which were fed the coarse, damaged hay, and a loss of 40 lbs. for those which had

range supplemented with cotton seed. The average amount of meal and hulls consumed per day per steer during the three winters was 2.38 lbs. cotton-seed meal and 8.7 lbs. of hulls, which amount proved to be enough to make 700-lb. steers hold their fall weight throughout the winter.

It is estimated that the cost price of wintering steers when no charge is made for winter range was for the range steers 45 cts. per hundredweight, 69 cts. for cattle fed hulls and meal, 53 cts. for those receiving either cowpea hay or damaged hay, and 64 cts. for steers given cotton seed to supplement the range.

Part 2 deals with fattening steers on pasture. Native 2- to 4-year-old steers, weighing approximately 560 lbs., of mixed breeds, but the majority carrying some beef blood, were used. During 1910 the feeding period was from April 7 to August 3, and included the three lots: Pasture alone, pasture and cotton-seed cake, pasture, cotton-seed cake, and alfalfa hay; and during 1910 from April 21 to September 8, comprising two lots: Pasture alone, and pasture and cotton-seed cake. The pasture consisted of a mixture of sweet clover, Japan clover, Johnson, crab, and Bermuda grasses. During 1910 the steers received on an average 3.48 lbs. cotton-seed cake per head per day, and during 1911, 3.58 lbs. The average daily gain during 1910 was for lot 1, 1.64 lbs., lot 2, 1.98 lbs., and lot 3, 1.86 lbs. During 1911 lot 1 gained 1.75 lbs. and lot 2, 1.7 lbs. The estimated cost per pound of gain, including cost of pasture, during 1910 was 1.1, 3.19, and 4.37 cts., respectively, and during 1911, 1.02 and 4.03 cts., respectively; the average profit per steer in 1910, \$6.84, \$8.91, and \$4.18, and during 1911, \$5.28 and \$6.29, respectively. The average dressing percentage of steers of lot 1 for 1910 was 51.3, lot 2, 54.2, and lot 3, 67.3; in 1911, lot 1, 51.1 and lot 2, 51.4. Hay-fed steers suffered a heavy shrinkage in weight in transit. During both years cotton-seed cake-fed steers sold for approximately one cent more per pound than pasture-fed steers. The final results agree with those of former experiments, and indicate that it does not pay to use alfalfa hay alone with pasture and cotton-seed cake, but that it does pay to feed cotton-seed cake along with the pasture.

Part 3 deals with the influence of winter feeding upon gains made the following summer and comprises three years' work, 1908-1910. Native tick-infested 2- to 4-year-old steers, averaging in weight 700 lbs., and purchased in the fall, were wintered as follows: Lot 1, range alone; lot 2, range, cotton-seed meal, and hulls; lot 3, range and cowpea hay; lot 4, range and damaged hay; lot 5, range and cotton seed. Lot 1 comprised 72 steers summer fed by groups on pasture and the following supplements: None, cotton-seed cake (medium ration), cold-pressed cake, cotton seed (heavy ration), and cotton-seed cake and alfalfa hay. The average daily losses per steer for the winter ranged between 1.19 and 0.94 lbs., and the gains for the summer between 1.79 and 2.31 lbs., making the winter and summer gains combined between 0.49 and 0.93 lb. for the several groups, with an average of 0.74. lb. Lot 2, of 68 head, comprised summer-fed groups similar to lot 1. The average daily gain per steer for the winter ranged between -6.16 and 0.63 lb.; for the summer between 1.53 and 1.92 lbs.; and for the combined winter and summer gains between 0.83 and 1.26 lbs. for the several groups, with an average gain of 1.06 lbs. Lot 3, of 24 head, comprised three summer-fed groups, as follows: Pasture alone, pasture and cotton-seed cake, and pasture and cold-pressed cake. The average daily gain per steer for the winter ranged between -0.25 and 0.07 lb.; for the summer between 1.52 and 2.22 lbs.; and the combined winter and summer gains between 0.76 and 1.22 lbs for the several groups, with an average of 1.01 lbs. Lot 4, of 43 head, comprised four groups summer fed on pasture and the following supplements: None, cotton-seed cake, cotton seed,

and cotton-seed cake (heavy ration). The average daily losses per steer for the winter ranged between 0.7 and 0.53 lb.; for the summer the gains were between 1.59 and 2.22 lbs.; and for the combined winter and summer the gains between 0.79 and 1.15 lbs. for the several groups, with an average of 0.77 lb. Lot 5, of 25 head, comprised summer-fed groups as in lot 4 and ranged in losses during the winter between 0.48 and 0.26 lb.; for the summer there were gains between 1.76 and 2 lbs.; and for the combined winter and summer gains between 0.89 and 1.07 lbs., with an average of 1 lb. The average daily gains of steers summered on pasture alone was 1.64 lbs. per head; of steers summered on pasture and cotton-seed cake (medium rations), 2.02; of steers on pasture and cold-pressed cake, 1.85; of steers on pasture and cotton seed, 2.05; of steers on pasture and cotton-seed cake (heavy rations), 1.87; and of steers on pasture, cotton-seed cake, and alfalfa hay, 2.11 lbs. per head.

A graphic presentation of the results of the three years' feeding shows that "the longer the summer-feeding period the nearer the total gains in weight approach the mean of all lots; in other words, the longer the summer period the nearer the steers, which made heavy winter losses, overcome these losses and approached the weight of the winter-fed steers. If the feeding periods [112 and 154 days] had been 60 days longer, and all steers had continued to increase in weight at the rate they had established during the actual summer-feeding period, the total gains at this time would have been practically the same for all lots, irrespective of the method of wintering."

The results of these feeding trials are summarized, in part, as follows:

"Cattle which became very thin during the winter made larger daily gains the following summer on pasture than steers which were in better flesh at the beginning of the pasture season. Usually the greater the winter loss experienced, the greater was the gain the following summer, and vice versa.

"Steers which are to be finished for the early summer markets should enter the pastures in good flesh in the spring. Such cattle sell for a premium which justifies the expense of giving them feed in addition to the range during the winter months and a heavy ration of cotton-seed cake while on pasture during the summer. . . .

"When cotton seed is worth but \$14 per ton it can be used with greater economy than cotton-seed meal and hulls for wintering steers which are to be finished on pasture the following summer."

Cattle raising in South America (*Daily Cons. and Trade Rpts.* [U. S.], 17 (1914), No. 106, pp. 693-699).—In these reports attention is directed to the opportunities for future development of the cattle industry in Chile, Colombia, and Argentina.

Care and management of sheep on the farm, R. F. MILLER (*Montana Sta. Circ. 31* (1913), pp. 89-112).—This circular gives general information on the feeding, care, and management of sheep and lambs and includes a discussion of shearing, packing, and storing wool and the treatment of sheep for parasites and disease.

A review of American investigations on fattening lambs with special reference to the protein and energy requirements, S. BULL and A. D. EMMETT (*Illinois Sta. Bul. 166* (1914), p. 48, figs. 4; abstract, pp. 3, 4).—"From the results obtained in this review, which embrace 265 lots containing in all 5,127 lambs, the following average values for protein and energy are suggested as being, in general, the most economical for fattening lambs: (a) Lambs weighing 50 to 75 lbs., 3.1 to 3.3 lbs. of digestible protein and 17 to 19 therms of net energy. (b) Lambs weighing 70 to 90 lbs., 2.5 to 2.8 lbs. of digestible protein and 18 to 20 therms of net energy. In certain instances 1.8 to 2 lbs. of digestible protein and 18 to 20 therms of net energy are sufficient. (c) Lambs weighing

90 to 110 lbs., 2.2 to 2.4 lbs. of digestible protein and 17 to 20 therms of net energy. (d) Lambs weighing 110 to 150 lbs., 2.6 to 3 lbs. of digestible protein and 16 to 19 therms of net energy. It seems probable, however, that 1.4 to 1.9 lbs. of [digestible] protein would be sufficient for lambs of this weight."

A bibliography is appended.

The digestion of crude fiber by sheep and pigs, G. FINGERLING, E. BRETSCHE, A. LÖSCHE, and G. ARNDT (*Landw. Vers. Stat.*, 83 (1913), No. 3-4, pp. 180-210; *abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 2, pp. 231-233).—Four digestion trials were conducted with two wethers and two pigs, each period lasting 11 days. The wethers received during the first period a basal ration of meadow hay, gluten, starch, and salt; the pigs, a basal ration of ground barley, fish meal, and salt. During the second period both the wethers and the pigs received the basal ration plus "digested" straw, in the third period the basal ration and grass, and in the fourth period the basal ration and wheat chaff, in which the crude fiber was much lignified. The "digested" straw was prepared by boiling it under pressure with alkali.

The average digestion coefficients for the three fodders experimented upon are given in the following table:

Digestibility of "digested" straw, grass, and wheat chaff by sheep and pigs.

Kind of animal.	Dry matter.	Organic matter.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.
"Digested" straw:	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>
Wethers.....	72.65	73.19	72.23	77.27	55.20
Pigs.....	101.22	88.85	63.75	94.81
Grass:							
Wethers.....	65.29	69.77	76.85	66.93	67.29	69.49	37.68
Pigs.....	49.58	51.86	52.05	84.35	52.07	39.39	35.92
Wheat chaff:							
Wethers.....	40.33	46.93	55.56	51.54	30.34	19.86
Pigs.....	20.53	22.95	27.86	12.85

"It will be seen from the above that the pigs digested the crude fiber which was not or only slightly lignified better than the sheep, while the latter were able to utilize better the crude fiber more or less [covered] with encrusting matter. The better utilization of the crude fiber of 'digested' straw by pigs depends partly upon the fact that with the sheep some of the crude fiber of the basal ration escapes digestion. It can therefore hardly be stated that pigs are superior to ruminants in their power of dissolving pure cellulose. The pigs digested 39.39 per cent of the cellulose of grass, but they were not able to attack that of wheat chaff, the reason of this difference being that the incrustations are less readily dissolved in the alimentary canal of pigs than in that of ruminants. The superiority of ruminants as regards the power of dissolving cellulose in young grass and in wheat chaff is very probably due to the finer division obtained by better mastication and to a more intense fermentation of the feed in the digestive organs.

"Summarizing the results, it may be said that pigs are as capable as ruminants of dissolving pure crude fiber or that containing but little encrusting matter, but lose this power in proportion as the encrustation or lignification of the crude fiber increases."

Swine fattening with large quantities of potatoes, F. LEHMANN (*Mitt. Ver. Deut. Schweinezüchter*, 21 (1914), Nos. 6, pp. 107-112; 7, pp. 128-133; 8, pp. 149-153).—Successful trials in feeding large quantities of potatoes to fattening swine are reported. It was found necessary to supply protein in the form of meat meal or fish meal, together with a small grain allowance of barley meal.

Potato-fed swine compared favorably with corn-fed and barley-fed swine. It is suggested that the potato ration be supplemented with an allowance of lime.

Horse-feeding experiments, R. W. CLARK (*Montana Sta. Bul. 95 (1913), pp. 57-66*).—In experiments to determine the amount and kind of hay to feed horses it was found that “the horses that received the smaller amount of hay (two-thirds as much as they would have eaten) had more life and sweat less than those that were unlimited in their hay. Clover hay proved as satisfactory as timothy hay when not more than 1 lb. per day for every 100 lbs. of live weight was fed. Horses doing light work can be carried through the winter on 0.75 lb. of hay and 0.5 lb. of grain per 100 lbs. live weight per day. Early cut timothy hay was relished more and eaten in larger quantities than late cut timothy hay.”

A continuing study of constitutional vigor in poultry, C. A. ROGERS (*New York Cornell Sta. Bul. 345 (1914), pp. 439-457, figs. 4*).—In continuing work previously noted (*E. S. R.*, 28, p. 367), two pens of yearling hens and four pens of pullets, White Leghorns, were studied. The yearling hens had participated in the previous experiment, while the pullets were the progeny of earlier lots.

The conclusions confirm those of the earlier studies. Among the pullets the strong flocks consumed more feed than the weak flocks, but produced more eggs. The reverse was true of the yearling hens, probably due to the presence of several exceptional layers in the weak flock. The consumption of ground grain and meat scrap was in favor of the flocks that produced the largest number of eggs. The heaviest-producing flocks consumed a larger amount of feed, a lower proportion of carbohydrates and fat to total dry matter consumed, and a higher proportion of protein to carbohydrates and fat consumed than did the others. In general the cost of eggs for each dozen eggs laid was less for the strong than for the weak flocks. As to the number of pounds of feed consumed for each dozen eggs laid, the heavier the laying the less was the consumption, with one exception.

The fertility of the eggs in all pens was high, but the percentage of eggs hatched was variable. In the weight of eggs set there was not much difference between the strong and the weak flocks or between the yearling hens and pullets. In general the mortality among the chicks varied in proportion to the size of the hatch. In each comparison the eggs that hatched better produced a larger proportion of chickens that lived beyond the critical period of the first six weeks. In general the advantage in low mortality was with the strong flocks. From a financial standpoint the balance profit in the case of the pullets was decidedly in favor of the strong flocks, but in favor of the weak flocks in the case of the yearling hens, which was an exceptional flock throughout the study.

In summarizing all flocks, including those of early studies and comparing the averages of the strong with the weak, it is noted that the number of pounds of dry matter consumed per pound of live weight averaged the same for both the strong and the weak flocks. The strong fowls required, however, only 7.68 lbs. of feed for every dozen eggs laid, while the weak flocks required 8.46 lbs. of feed, and difference in cost of production was nearly 1 ct. a dozen in favor of the strong flocks. The strong flocks produced an average of 17.75 more eggs per hen than the weak, and the actual difference in profit amounted to 40 cts. a hen in favor of the strong hens. There was little difference in the hatching record, but a difference of 1.4 per cent mortality in favor of the strong pens.

From these results the advantages of selection of fowls are deemed evident. It is suggested that one selection only “is not sufficient to keep a flock consistently superior. The selection of mature pullets is of more value than that of partly grown chickens. Selection at the beginning of the second year is of equal importance with that in the first year. The heavier-laying hen is not

necessarily the stronger hen at all times of the year; and [results indicate] that in selecting for breeding stock to produce a large number of chickens and capable pullets, the first essential is to select according to strength, with the expectation that hens so selected will usually be the most productive."

A biometrical study of egg production in the domestic fowl.—III, Variation and correlation in the physical characters of the egg, R. PEARL and F. M. SURFACE (U. S. Dept. Agr., Bur. Anim. Indus. Bul. 110, pt. 3 (1913), pp. 171-241, figs. 14).—This bulletin is a continuation of work previously noted (E. S. R., 24, p. 675), and reports the results of a detailed study made of the normal variation and correlation of the egg of the domestic fowl in respect primarily to size and shape. While the studies were made with the egg of the Barred Plymouth Rock, it is thought probable that many of the results found for the egg of this breed will also obtain for the eggs of other breeds. The authors summarize their results as follows:

"The egg is, to a significant degree, relatively more variable in length than in breadth. The egg is considerably more variable in shape, as measured by the length-breadth index, than it is in either of the linear dimensions length or breadth. The weight of the egg and its volume (determined from length and breadth on the assumption that the egg is a perfect prolate spheroid) are much more variable than any of the other characters. There is a close agreement between the egg of the domestic fowl and the human skull in respect to the degree of variation exhibited in the corresponding size and shape characters of the two structures. A consideration of the processes concerned in the production of the definitive size and shape of the egg and the skull suggests, though it does not prove that this similarity with reference to variation constants is not fortuitous, but rests upon a basis of general similarity in regard to mechanical factors operative in both cases during the development and fixation of the final form.

"With the exception of breadth, all other dimensional characters studied show significantly skew (asymmetrical) variation. The different egg dimensions give frequency distributions following different ones of Pearson's curve types. Variation of the egg in length and in shape (length-breadth index) follows a curve of type IV; variation in breadth type II, and variation in volume type I.

"All of the egg dimensions studied are positively correlated with each other in varying degree. Intraracially egg length and egg breadth are correlated only slightly. Furthermore, neither the weight nor the volume of the egg is more than very slightly, if significantly at all, correlated with its shape. As would be expected, both length and breadth are significantly correlated with the weight and the volume of the egg. The bulk measures (volume and weight) are more highly correlated with breadth than with length. There is a very high correlation between volume and weight. This implies what was found in fact to be the case, that the specific gravity of the egg exhibits only a very small degree of variation. There is no significant net correlation between the shape of an egg and its absolute size. The skull and the egg show a correspondence in respect to the degree to which their chief dimensions are correlated. The correlation results parallel those set forth above for simple variation.

"A detailed study of the regression of the weight of the egg on length and breadth results in certain equations from which the former quantity can be estimated from a knowledge of the linear dimensions of the egg with a considerable degree of accuracy. A comparison of the egg of the domestic fowl with those of a number of species of wild birds in respect to relative variability leads to the result that in general the eggs of wild birds are neither less nor more variable than those of the domestic bird. It is concluded that probably

the essential factors concerned in the determination of the degree of variation in size and shape exhibited by birds' eggs are purely physiological and in no direct or immediate way (if at all) related to the action of natural selection. It does not appear from the evidence that it is essential to the survival of a wild bird that its egg shall be less variable than those of the domestic fowl, in which egg variation obviously has no survival value whatsoever.

"A study of intraindividual variation indicates that the relative variability of eggs is a definite characteristic of the individual, some birds characteristically laying eggs which are extremely variable and other birds characteristically producing eggs which are very uniform. There is on the average a considerable reduction in variability in passing from the race to the individual. This amounts in the case of length to 32 per cent and in the case of breadth to 41 per cent. Some individuals may show a greater variability both absolute and relative than a random sample of the eggs of the race from which the individual comes. The rule that length is more variable than breadth is reversed in the eggs of some individuals. Seven per cent of the birds studied produce eggs which are more variable in breadth than in length. In general a hen which characteristically lays an egg longer than the average also lays an egg which tends to be wider than the average. The same sort of correlation holds in regard to the variability of the product. A hen which characteristically lays an egg which is unusually variable in length also exhibits an unusual degree of variation in the breadth of her product."

These "data are of value in connection with all physiological and genetic studies in regard to the production of eggs. They also have a significant relation to the economic problem of the improvement of eggs in respect to quality and uniformity by breeding."

Artificial hatching of chicks, W. F. SCHOPPE (*Montana Sta. Circ. 34 (1914), pp. 169-189, figs. 5*).—This circular gives general information on the care and management of incubators, the type of eggs to use for hatching, etc.

DAIRY FARMING—DAIRYING.

Investigations in milk production, T. L. HAECKER (*Minnesota Sta. Bul. 140 (1914), pp. 7-79*).—This is a continuation of work previously noted (*E. S. R., 14, p. 1003*), a portion of the results of which are used in the general summary of results in the present work. The studies herein reported covered seven winters, 1902-1909.

A summary of the average dry matter and digestible nutrients consumed and dairy products yielded daily during nine winters of stall-feeding is given in the following table:

Summary of average nutrients consumed and dairy products yielded per cow in stall feeding.

Winter.	Nutritive ratio of rations.	Dry matter	Digestible protein.	Digestible carbohydrates.	Digestible ether extract.	Milk fat produced.	Solids-not-fat produced.
		Lbs.	Lbs.	Lbs.	Lb.	Lbs.	Lbs.
1894-1895.....	1 : 6.8	24.40	2.00	12.46	0.56	1.069	2.09
1895-1896.....	1 : 5.3	23.91	2.59	12.24	.67	1.011	2.02
1902-1903.....	1 : 9.4	19.86	1.28	11.16	.46	.931	2.06
1902-1903.....	1 : 6.7	21.77	1.92	11.86	.48	1.048	2.21
1903-1904.....	1 : 9.0	19.68	1.32	11.04	.39	.996	2.10
1903-1904.....	1 : 6.1	20.65	1.97	10.99	.36	1.032	2.02
1904-1905.....	1 : 9.8	20.52	1.30	11.71	.50	.852	1.81

1906-1907.....	1 : 8.3	22.87	1.74	13.05	.63	1.068	2.26
1907-1908.....	1 : 8.1	23.89	1.75	12.78	.64	1.094	2.28
1908-1909.....	1 : 7.7	24.13	1.86	12.62	.80	1.094	2.29

"From this table it is seen that during the winter of 1894-1895, with a daily protein supply of 2 lbs. and a nutritive ratio of 1:6.8, there was obtained a greater yield of milk fat than during any winter following until the winters of 1907-1908 and 1908-1909. The period covered by the data was 154 days, and the members of the herd maintained their body weight. During the winter of 1895-1896 the daily average protein supply was 2.59 lbs. and a nutritive ratio of 1:5.3, with a depression in the yield of milk fat and solids-not-fat, and an increase in the weight of the cows."

From 1902-1905, the herd was divided into two groups, one receiving a low protein and the other a high protein allowance. The milk-fat yield of the low-protein group for all three years was uniformly the lower.

The following table "was arranged by eliminating the data for the three groups with low-protein rations, and converting the average nutrients consumed per day each winter to nutriment. This was done by multiplying the ether extract in the rations by 2.2, adding the product to the carbohydrates and protein in the rations, multiplying the butter-fat yielded daily by 2.25, adding the solids-not-fat to obtain the total product, and calculating the nutriment used for body maintenance, the net nutriment per unit of product, and the weights of the herd."

Summary of average live weight, nutriment daily, total for maintenance, for product, and in product yielded, and net nutriment per pound of product.

Winter.	Live weight.		Nutriment.				
	First half of period.	Second half of period.	Total.	For maintenance.	For product.	Total in product daily.	Net nutriment used per pound in product.
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
1894-1895.....	954	958	15.69	7.57	8.13	4.490	1.81
1895-1896.....			16.30	7.75	8.55	4.295	1.99
1902-1903.....	882	878	14.84	6.96	7.88	4.576	1.72
1903-1904.....	900	913	13.74	7.18	6.56	4.341	1.51

Average without 1902-1903.	903	907	15.55	7.24	8.31	4.517	1.84

"The exceptional amount of nutriment charged to a pound of product, 1.99, during the winter of 1895-1896 was due to the fact that part was diverted to gain in weight at the rate of 0.2 lb. per day during period II. The exceptionally small amount used during the winter of 1903-1904 is due, at least in part, to the fact that more roots were fed than during any other winter, and possibly to light feeding and a narrower nutritive ratio. The large yield, 4.576 lbs. for the winter of 1902-1903, was due to the fact that it covered a period of only 97 days."

It is stated that heavy feeding, as a rule, causes more waste than light feeding. It appears that during the last four winters more net nutriment was consumed to a pound of product yielded. A study of the relation of the feed to the size of the cows "shows that the average amount per day of nutriment consumed per 1,000 lbs. live weight ranged from 15.15 to 18.44 lbs., and averaged for the eight winters 17.03 lbs. After deducting the amount calculated for

maintenance, that which remained available for product ranged from 7.23 to 10.52 lbs. and averaged 9.11 lbs. Of this there appeared in the milk solids yields ranging from 4.401 to 5.481 lbs. and averaging 4.952 lbs."

During the four winters in the period previous to 1905 the cows received per 1,000 lbs. live weight 16.22 lbs. of nutriment per day, with a nutritive ratio of 1:6.2, and returned an average daily product of 4.699 lbs., being 1 lb. of product to 1.77 lbs. of net nutriment.

During the four succeeding winters the cows received 17.83 lbs. of nutriment daily with a nutritive ratio of 1:8.1 and returned an average daily product of 5.205 lbs., being 1 lb. of product to 1.9 lbs. of net nutriment.

A study of the variation in nutriment consumed per 1,000 lbs. live weight shows that the average consumption ranged from 15.15 to 18.44 lbs. per day, and the average for seven winters was 17.08 lbs. The average product yielded ranged from 4.693 to 5.481 and averaged 5.031 lbs. of water-free solids. Aside from two winters when conditions were abnormal the percentages returned in product during the other years were remarkably uniform, the greatest variation being only 0.9 per cent. The average percentage returned in product for all seven years was 29.49.

Analyses were made of 544 samples taken from 7,616 milkings, and the milk divided into 10 grades testing from 2.5 to 7 per cent fat. It is seen that "as milk increases in fat content it also increases in protein content, but not at the same rate. In a general way, an increase of 0.5 per cent in fat is followed by an increase of 0.02 per cent in protein. . . . The sugar content of milk increases from 4.6 per cent in milk testing 3 per cent fat to 4.98 per cent in 5 per cent milk, and then gradually decreases to 4.84 per cent in 7 per cent milk. The carbohydrate equivalents of the total solids of the different grades of milk range from 14.03 for 3 per cent milk to 24.81 for 7 per cent milk. The nutritive ratio of the various grades of milk ranges from 1:4.23 for milk testing 3 per cent fat to 1:4.88 for milk testing 7 per cent fat. In 3 per cent milk there are 2.43 lbs. of solids-not-fat to 1 lb. of milk fat; and in 6 per cent milk, 1 lb. of fat to 1.45 lbs. not fat, indicating that milk fat only is not a logical basis for feeding for milk production."

Comparing the relation of the solids of milk taken from cows while on low-protein ration and on medium-protein ration, it is shown "that without exception the cows gave milk containing a lower percentage of solids when fed a ration containing a nutritive ratio of 1:9.4 than they did when receiving rations ranging in nutritive ratio from 1:6 to 1:8.3 and when on pasture. There was also a depression in both fat and protein in every case. Taking the total solids as a basis the fat is lowered 1.2 per cent and the protein 1.3 per cent, and the milk sugar or carbohydrate raised 2.2 and the ash raised 0.3 per cent, thus offsetting the depression in fat and protein."

During the first four years, when the nutritive ratio of the rations averaged 1:6.2, "the daily protein supply was 1.95 lbs. with a daily yield of 24.5 lbs. of milk containing 1,045 lbs. of fat and 2.11 lbs. of solids-not-fat, while during the last four years [when the nutritive ratio averaged 1:8.1], the daily protein supply was 1.745 lbs. with a daily average yield of 25.6 lbs. of milk containing 1,067 lbs. of fat and 2.244 lbs. of solids-not-fat.

"Of the 1.95 lbs. daily protein supply during the first four years, 0.64 lb. is the protein calculated for maintenance. . . . The daily average protein content in the milk was 0.781 lb., being a return of 1 lb. of milk protein to 1.68 lbs. of net crude protein in the ration, with a yield of 4.462 lbs. of total product in milk solids reduced to a common factor. During the last four years there was a daily supply of 1.74 lbs. of crude protein with calculated protein require-

ments for maintenance of 0.63 lb. . . ., the daily average protein content in the milk, 0.806 lb., being a return of 1 lb. of milk protein to 1.38 lbs. of net crude protein in the ration, with a daily yield of 4.645 lbs. of total product in milk solids."

Based upon these results a table has been calculated which gives the estimated organic composition of milk for each 0.1 per cent increase in percentage of fat from 2.5 to 7, and the net nutriment prescribed for production. The following table is a contracted form of the complete table:

Estimated composition of milk for each 0.5 per cent increase in fat content, and net nutriment recommended for production.

Organic solids.			Solids in carbohydrate equivalent.	Components in 1 lb. of milk in carbohydrate equivalent.		Net nutrients for the production of 1 lb. of milk.		
Fat.	Protein.	Carbohydrates.		Nitrogenous.	Nonnitrogenous.	Protein.	Ether extract.	Carbohydrates.
<i>P. ct.</i>	<i>P. ct.</i>	<i>P. ct.</i>	<i>P. ct.</i>	<i>Lb.</i>	<i>Lb.</i>	<i>Lb.</i>	<i>Lb.</i>	<i>Lb.</i>
2.5	2.55	4.45	12.62	0.0255	0.1007	0.0446	0.0151	0.176
3.0	2.68	4.60	14.03	.0268	.1135	.0469	.0170	.199
3.5	2.81	4.75	15.43	.0281	.1262	.0492	.0189	.221
4.0	3.08	4.85	16.93	.0308	.1385	.0539	.0208	.242
4.5	3.27	4.97	18.36	.0327	.1509	.0572	.0226	.264
5.0	3.45	4.98	19.68	.0345	.1623	.0604	.0243	.284
5.5	3.65	4.92	20.94	.0365	.1729	.0639	.0259	.302
6.0	3.82	4.91	22.23	.0382	.1841	.0668	.0276	.322
6.5	4.12	4.90	23.64	.0412	.1952	.0721	.0293	.342
7.0	4.22	4.84	24.81	.0422	.2057	.0738	.0308	.359

The standard for body maintenance proposed is 0.07 lb. of crude protein, 0.7 lb. of carbohydrates, and 0.01 lb. of ether extract per 100 lbs. in live weight. The application of this standard to ration calculation is explained in full.

The appendixes include tables on the composition of feeds used and milk produced, and other data.

Clover and corn silage as feeds for dairy cows, R. W. CLARK (*Montana Sta. Bul. 94 (1913), pp. 33-54, figs. 3*).—As an average of three experiments of two periods each, and comparing clover hay and clover silage as feeds for dairy cows, the average daily production of milk per head on clover hay was 22.8 lbs. and of fat 0.93 lb., while on clover silage the daily production of milk was 24.08 lbs. and of fat 0.97 lb. On clover hay the cost of producing 100 lbs. of milk was 73.9 cts. and of 1 lb. of fat 17.9 cts., while on clover silage the cost of producing 100 lbs. of milk was 73.4 cts. and 1 lb. of fat 17.8 cts. It is estimated that in milk production 2.33 lbs. of clover silage was required to equal 1 lb. of good clover hay.

The average value of clover silage for milk production is estimated at \$2.55 per ton, of corn silage \$2.38. Clover silage was relished by the cattle during the winter months, but became dark in color, strong in odor, and was not relished after the weather became warm.

Experience elsewhere with clover silage is summarized, and brief descriptions given of the silos at the station.

On the possibility of increasing the fat content of milk, GRUMME (*Ztschr. Expt. Path. u. Ther., 14 (1914), No. 3, pp. 549-554; abs. in Zentbl. Physiol., 28 (1914), No. 5, p. 286*).—Three goats fed an ordinary ration produced during four days an average of 2.97 kg. milk per day, testing 4.2 per cent fat, while during three days fed a preparation, malt tropon, at the rate of 200 gm. per animal per day, they averaged 3.5 kg. milk per day, testing 5.62 per cent fat.

The comparative composition of human milk and of cow's milk, E. B. MEIGS and H. L. MARSH (*Jour. Biol. Chem.*, 16 (1913), No. 1, pp. 147-168, figs. 2).—"Human milk differs from cow's milk in three important ways. It contains considerably more lactose than cow's milk and more substances of unknown nature which contain little or no nitrogen; it contains very much less protein than cow's milk. The composition of milk varies more or less regularly with the progress of lactation so that average figures for its composition are not very satisfactory. The following, however, may be taken as the limits of normal variation of the constituents of the two kinds of milk from the beginning of the second month of lactation onward, the figures representing percentages of whole milk. Human milk, protein 0.7 to 1.5 per cent, fat 2 to 4 per cent, and lactose 6 to 7.5 per cent; cow's milk, protein 2.5 to 4 per cent, fat 2 to 4 per cent, and lactose 3.5 to 5 per cent.

"Both kinds of milk contain substances [some of which can be crystallized], which are important constituents of diet, which are soluble in alcohol and ether, which contain little or no nitrogen, but of which the chemical nature is still unknown. These substances are most plentiful in early human milk and diminish in amount with the progress of lactation. Early human milk contains about 1 per cent of these unknown substances; milk from the middle period of lactation about 0.5 per cent. Cow's milk from the middle period of lactation contains about 0.3 per cent of the unknown substances."

Many of Camerer and Söldner's results were verified.

On the hygienic bacteriological character of Bern market milk with reference to the presence of tubercle bacilli, J. THÖNI (*Centbl. Bakt. [etc.]*, 1. *Abt., Orig.*, 74 (1914), Nos. 1-2, pp. 11-69, fig. 1).—Tests were made and the results compared of the leucocyte, fermentation, catalase, and alizarol methods and the germ estimate or count. Aside from the catalase test all demonstrated the need of a strict hygienic control of market milk. The leucocyte and fermentation tests were considered the most practical for general use.

A new method of determining milk quality, F. H. HALL (*New York State Sta. Buls.* 373 and 380, popular ed. (1914), pp. 3-15, pls. 2).—This is a popular edition of Bulletins 372 and 380, previously noted (E. S. R., 31, pp. 78, 372).

Cream testing, H. H. DEAN (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm.*, 39 (1913), pp. 95-99).—Continuing previous work (E. S. R., 30, p. 74), a comparison of weekly, semimonthly, and monthly composite tests showed all of these methods to be practically correct. Composite samples kept in open bottles tested too high. There was not much difference in the average results, whether glass, cork, wood, or paper cap stoppers were used. Creosote proved to be a good preservative and has the advantage of requiring less sulphuric acid for a test than the preservatives commonly used. Formalin as a preservative tends to require a larger volume of sulphuric acid when making the test.

A new casein-fat milk test is described, in which 20 cc. of acid mercuric nitrate (made by dissolving mercury in twice its weight of nitric acid, of a specific gravity of 1.42, to which an equal bulk of water is added after solution and diluted with 30 times its bulk of water) is placed in a test bottle, then 5 cc. of milk, and the whole allowed to stand from six to seven minutes without shaking. The temperature of the milk and acid should be between 65 and 70° F. The bottles are then placed in a centrifuge, 15 in. in diameter, and whirled at a speed of 2,000 revolutions per minute for from seven to eight minutes. The bottles are then read in percentage as combined casein and fat.

Results of this test agree quite closely with separate determinations of fat and casein made by other methods.

Butter making, H. H. DEAN (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm*, 39 (1913), pp. 71-73).—This report continues previous work (E. S. R., 30, p. 75).

In comparing the yield obtained in salted and saltless butter, 103.37 lbs. of the former was secured per churning as against 99.66 lbs. of the latter, while the average moisture contents were 14.83 and 14.78 per cent, respectively. A comparison of Canadian and English brands of salt for butter making again showed very little difference in the results obtained.

In working butter in a combined churn it was observed that the average percentage of moisture in the finished butter was increased about 0.25 per cent and the salt nearly 0.2 per cent by keeping the churn drainage tap closed during the working of the butter, and the butter scored over one point higher. This practice, however, is not advised until further tests have been made.

Butter held in cold storage for three months was found to have decreased nearly 2 per cent in moisture from the time of printing.

Farm butter making.—Creamery industry in Montana, R. C. JONES (*Montana Sta. Circ. 32* (1913), pp. 113-152, figs. 22).—This circular includes general information on approved methods of farm butter making, together with a discussion of the organization and management of creameries, and plans for creameries and cheese factories.

Siberian butter of Hamburg markets, P. BERG (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 27 (1914), No. 12, pp. 881-893, fig. 1).—An account of the Siberian butter which has been found in great quantity on the Hamburg market, together with a study of its acidity, refraction, Reichert-Meissl and Polenske numbers, melting point, water, and salt content. A large percentage of the samples range from 10 to 15 per cent in water content. The butter has a good flavor, but is not deemed desirable for cooking purposes.

Cheddar cheese experiments, H. H. DEAN (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm*, 39 (1913), pp. 74-91).—The results of tests comparing milks of high and low fat and casein contents for cheese making agree with previous work (E. S. R., 30, p. 76), and showed a gain per 1,000 lbs. of milk of 5.57 lbs. of cheese by using the milk with the higher percentages of casein and fat. The cheese made from this milk also contained a higher percentage of fat, but there was not much difference in the percentages of moisture contained in the green or ripe cheese from the two lots, or much difference in the quality of the cheese.

There was little difference in the yield or quality of cheese whether ripened above normal, with 0.21 per cent acid, or below normal with 0.177 per cent acid. Overripe milk for cheese making produced 4.69 lbs. less cheese per 1,000 lbs. milk than normal milk, and required on the average 0.65 lb. more milk to make a pound of cheese. The shrinkage during one month was greater, the moisture in both green and ripe cheese was higher, and the quality of the cheese was inferior from the lots of overripe milk.

Cheese from curds salted high, 2½ lbs. per 1,000 lbs. milk, contained slightly less moisture and scored slightly lower than curd salted at 2¼ or 2½ lbs. per 1,000 lbs. milk. Cheese ripened in ice cold storage retained more of the original cheese moisture during the month of testing than cheese ripened in an ordinary room at from 60 to 70° F. Most of the moisture loss took place in both lots during the first week and in the first inch of the cheese from the surface inward. It was evident that the moisture near the center of the cheese remains fairly constant during a ripening period of one month whether the cheese was ripened in cold storage at 40° or in a room where the temperature ranged from 60 to 70°. The shrinkage was slightly lower in the cheese ripened in 40°, but both lots contained about the same percentage of moisture in the green and ripe cheese.

Whey obtained in making Camembert cheese from raw milk contained 0.015 per cent fat; from pasteurized milk, 0.01 per cent. Whey obtained in making double cream cheese from raw milk contained 0.272 per cent fat, from pasteurized milk 0.228 per cent. In making buttermilk cheese the results depended to a great extent on the kind of buttermilk used. Cream that was pasteurized sweet gave good results, while cream that was ripe or partially ripened before pasteurizing gave as a rule poor returns. It was often very fine in grain and pasty, and in some cases there was no coagulation.

Methods of making Stilton and Wensleydale cheese are described, and notes given on other cheeses.

VETERINARY MEDICINE.

Text-book of milk hygiene, W. ERNST, trans. by J. R. MOHLER and A. EICHORN (*Chicago, 1914, pp. X+281, pls. 5, figs. 29*).—This is the first American edition of this work, and is an authorized translation of the German edition noted (E. S. R., 29, p. 877). The book treats of the subject from the standpoint of veterinarians, who according to the preface are "the proper experts who must stand by the side of the producers and give them the necessary advice and instruction."

In the preparation of the English edition the conditions prevailing in this country have been especially considered, and accordingly much material has been included from the reports of the various milk commissions and other sources. The chapter dealing with the German laws and regulations relating to the handling, production, and standards of milk has been replaced by a chapter which deals solely with the conditions and standards existing in the United States. Various tests, microscopical and otherwise, for judging milk, which may be easily conducted by the veterinarian, are presented. The methods for eradicating tuberculosis from dairy herds are plainly although briefly stated, and the relation of bovine tuberculosis to tuberculosis in man, especially alimentary tuberculosis, is discussed. The subject of mastitis is given special treatment.

Linimentum camphoræ (camphor liniment), C. P. GUTHRIE (*North Dakota Sta. Spec. Bul., 3 (1914), No. 6, pp. 83-85*).—No difference in the camphor content was noted whether the camphor was dissolved in cold cotton-seed oil or with the aid of gentle heat under the water bath. It is possible, however, to dissipate some of the camphor if a gentle heat is not employed.

A Halphen test was made on all samples obtained in the open market (37 in all) and five did not give the reaction, one of which was soap liniment, and the remainder gave refractive indexes lower than that of a sample of pure cotton-seed oil. Control samples of camphorated oil, made strictly according to the U. S. Pharmacopœia, gave readings of 1.4708 at 25° C., which compares well with that of pure cotton-seed oil, i. e., 1.4710. Pure olive oil gave a refractometric reading of 1.4672 at 25°. From this it would seem that the four samples mentioned above contained olive oil.

The percentage of camphor present in the samples collected on the market varied from 2.56 to 25.9, with an average of 16.99 per cent. The U. S. Pharmacopœia camphor liniment is essentially a 20 per cent solution of camphor in cotton-seed oil.

The method used for determining camphor in camphor liniment is as follows: "Weigh out accurately about 5 gm. of the sample in an aluminum evaporating dish and heat in the water oven until all camphor is driven off. This may be determined by the odor and by frequent weighings. Between 10 and 11 hours

are required to drive off all the camphor from a 5 gm. sample using an evaporating dish of 2½ in. diameter."

In the samples prepared in the laboratory, only 96 per cent on the average of camphor could be recovered. Oil heated for 11½ hours under certain conditions increased 0.91 per cent in weight. This fact should be considered when interpreting camphor liniment analysis.

The disinfection of anthrax hides, G. ABT (*Bul. Soc. Encour. Indus. Nat. [Paris]*, 120 (1913), No. 2, pp. 248-289).—This is a report of studies of the relative value of the Seymour-Jones method, consisting of the use of bichlorid of mercury and formic acid, and the Schattenfroh and Kohnstein method, in which hydrochloric acid is employed, in destroying anthrax spores in hides and the effect of these disinfectants on the value of the hides.

Both methods are found to possess merit. The Seymour-Jones method appears to be somewhat more economical, while the Schattenfroh and Kohnstein method seems to be more effective in disinfecting suspected hides.

A bibliography of 49 titles is appended.

Experimental sterilization of anthrax spores, G. ABT (*Ann. Inst. Pasteur*, 28 (1914), No. 2, pp. 149-180).—In continuing his studies the author has investigated the resistance of spores at 100° C., the neutralization of corrosive sublimate, the antiseptic power of corrosive sublimate in the presence of acid and of protein, the action of chlorin in the presence of protein, etc. A bibliography is included.

A preliminary report of experiments on the cultivation of the virus of rinderpest in vitro, W. H. BOYNTON (*Philippine Jour. Sci., Sect. B*, 9 (1914), No. 1, pp. 39-44).—"From the results obtained from various experiments it is evident that the virus of rinderpest requires either partial or complete anaerobic conditions for its existence. The virus of rinderpest has been carried in virulent form in two separate series up to the sixth transfer in glucose-blood culture media, covering periods of 19 and 21 days, respectively. In one series the medium first inoculated was nonvirulent at the end of 12 days, while the fourth transfer from this tube of culture medium after the same period of time was virulent.

"Results obtained from numerous experiments indicate that fresh blood from nonimmune cattle as a main constituent and glucose as an addition are essential components of the culture media."

An atypical case of rinderpest in a carabao, W. H. BOYNTON (*Philippine Jour. Sci., Sect. B*, 9 (1914), No. 1, pp. 45-47, fig. 1).—"From the facts of this case the evidence is conclusive that an animal may experience a fatal attack of rinderpest without the occurrence of a rise in temperature. The blood of a carabao was shown to be infected within 48 hours after it was originally injected with virulent blood. It was shown that the blood was virulent on the eleventh day when injected into a susceptible animal, yet exposure to the same animal from which blood was drawn did not cause rinderpest in the exposed susceptible animal.

"With regard to the three animals which failed to contract rinderpest by exposure, the question is raised as to whether rinderpest spreads by contact readily in the later stages of the disease or whether the disease must necessarily be accompanied by a rise of temperature before it can be spread by contact."

Experiments upon the transmission of rinderpest, A. R. WARD, F. W. WOOD, and W. H. BOYNTON (*Philippine Jour. Sci., Sect. B*, 9 (1914), No. 1, pp. 49-79, pls. 2, figs. 6).—"Rinderpest virus was not shown to have survived beyond 24 hours in corrals bare of vegetation but containing water. The conditions under which tests were made included all seasons of the year with ac-

companying variations in sunlight, rain, and condition of the soil. The amount of shade varied widely. Animals became infected in such corrals within one-half hour, 12, and 17.5 hours, respectively, after removal of the sick.

"Animals infected with rinderpest were shown to be capable of transmitting the disease to susceptible animals by close contact only during the febrile period of the disease, and most certainly during the period in which the temperature was declining. The disease was not contracted by susceptible animals when exposed to sick animals during the convalescent stage when the temperature was nearly normal.

"Blood of animals infected with rinderpest was shown in two cases to be infected during the height of the febrile period. The virus in urine, diluted with water and sprinkled on grass, was demonstrated to survive for 36 hours in some instances, but not always, and not for a longer period of time. Feces mixed with water and sprinkled on grass infected an animal 24 hours later. Feces and urine diluted with water and kept in a vessel in the shade remained infective for susceptible animals for 36 hours, but no longer.

"No evidence was secured to show that recovered cases transmit the disease. The foregoing facts indicate that the virus of rinderpest perishes soon after being discharged by the infected animal. Nothing in the foregoing experiments indicates that rinderpest virus is harbored for long periods upon the soil of contaminated areas."

Lesions of the nervous system in verminous intoxication, A. RACHMANOW (*Ann. Inst. Pasteur*, 28 (1914), No. 2, pp. 181-193, pl. 1, figs. 6; *abs. in Amer. Vet. Rev.*, 45 (1914), No. 3, pp. 269-271).—The investigations here reported, which were carried on in the laboratory of Weinberg (E. S. R., 30, pp. 278, 784) at the Pasteur Institute, have led to the following conclusions:

"The central nervous system of guinea pigs does not always react to verminous toxins. Lesions of the nervous system are not found in this animal except when it presented more or less serious clinical symptoms during life. Some individuals may absorb considerable quantities of verminous products without presenting the slightest nervous reaction.

"The lesions that are observed in the acute and subacute intoxication are of the nerve-cell, the neuroglia cell, and the fiber of the white substance. Besides the different degrees of chromatolysis, the nerve-cell often presents a large number of sinuous canals hollowed in the whole thickness or in a part of its protoplasm. In severe cases, the nucleus is displaced toward the periphery of the cell and shows a deformed nucleolus. The neurofibrils are preserved in light forms of intoxication, but in severe cases they disappear. The neuroglia cell offers the various stages of the 'amiboid' transformation; it keeps its form, but its nucleus becomes pycnotic, or again it takes the aspect of the amiboid cell of Alzheimer. There is also found, especially in cases of chronic intoxication, an abnormal collection of neuroglial elements about some nerve cells (phenomena of neurophagy). In the same conditions the fibers of the white substance are also altered; they are tumefied, but in an irregular manner.

"The lesions of the brain and spinal cord in verminous anaphylaxy are very small or do not exist, if the guinea pig dies of peracute anaphylactic shock in three to ten minutes. They are, on the contrary, very pronounced if the serious anaphylactic phenomena have lasted for half an hour or longer. They present the same characters in both the subacute or the chronic intoxication. There is nearly always a parallelism between the duration of the grave symptoms and the intensity of the lesion of the nerve-cell.

"The lesions of the central nervous system observed in animals anaphylactized with horse serum are exactly similar to those in animals suffering from

verminous anaphylaxy. As the lesions of the nervous system are much more marked and frequent in the anaphylaxy by worms than in the direct intoxication by the parasitic toxins, it seems probable that the nervous phenomena, sometimes very severe, as for instance the symptoms of meningism, sometimes observed in certain helminth carriers, must be considered as being of anaphylactic nature."

Physiological investigations of the fixation and mode of nutrition of some nematode parasites of the alimentary canal, C. GABIN (*Ann. Univ. Lyon, n. ser., I, No. 34 (1913), pp. 160, figs. 55*).—The parts of this comparative study of the manner in which intestinal nematodes gain their nutrition deal with the technique and methods of work, and a study of the fixation and the mode of nutrition of nematodes of the genera *Ascaris* and *Heterakis*, *Oxyurus vermicularis*, *Strongylus strigosus* and *S. retortiformis*, the genera *Trichuris* and *Spiroptera*, *Gnathostomum hispidum*, etc.

The studies indicate that the intestinal nematodes find nourishment in the intestinal mucosa of the host and not from the contents of the alimentary canal. The majority of the nematodes are attached to the wall of the alimentary canal either temporarily or in a definitive manner. The nutrition imbibed by the intestinal nematodes from the walls of the alimentary canal of the host differs with the species but may consist of lymph, epithelial cells, erythrocytes, and pus cells.

A bibliography of five pages is appended.

Aerobic micro-organisms in the omasum and colon of bovines, A. W. BUEMANN (*Centbl. Bakt. [etc.], I. Abt., Orig., 71 (1913), No. 4, pp. 291-319*).—Following a somewhat extensive review of the literature relating to the subject the author reports original investigations and includes descriptions of a number of new species of bacilli. A bibliography of 77 titles is appended.

The treatment of tick bite in stock (*Agr. Gaz. N. S. Wales, 25 (1914), No. 7, p. 569*).—It is stated that a tick, identified as *Ixodes holocyclus*, is very troublesome in New South Wales in late autumn and early spring, proving fatal to calves, dogs, and pigs, and very painful to cows and horses. It is recommended that a laxative be administered as soon as symptoms of paralysis appear, and followed by a tonic.

Spraying for control of ticks in Antigua, P. T. SAUNDERS (*West Indian Bul., 14 (1914), No. 2, pp. 122-125, pl. 1*).—A brief account of work carried on in Antigua.

Some results of blood counting on cattle, A. B. CLAWSON (*Amer. Vet. Rev., 45 (1914), No. 5, pp. 527-536*).—This is a report of studies carried on in connection with work conducted by the Office of Poisonous Plant Investigations of this Department at Limon (altitude 5,360 ft.) and at Mount Carbon (altitude 9,000 ft.), in Colorado. The results are summarized as follows:

In the older animals there was an average of 7,504,400 red corpuscles as compared with 9,159,222 in the younger. The animals when taken from an altitude of 5,360 ft. to an altitude of 9,000 ft. showed an increase in the number of red corpuscles from 8,749,388 to 9,255,878. The counts at the lower elevation, however, were made in early summer, while those at the higher altitude were made largely in midsummer, and had the counts at the two altitudes been made at more nearly the same time the difference might have been greater. The counts at Mount Carbon showed a larger number of red corpuscles in early than in middle or late summer.

Is there a bacillary hog cholera? W. PFEILER (*Mitt. Ver. Deut. Schweinezüchter, 20 (1913), Nos. 6, pp. 111-121; 7, pp. 135-143; abs. in Berlin. Tierärztl. Wchnschr., 29 (1913), No. 47, p. 837*).—After reviewing the history and the

opinions of others relative to the disease caused in young pigs by *Bacillus voldagsen*, the results of some tests are briefly mentioned (E. S. R., 31, p. 87). A positive method for immunizing against the Voldagsen pest has been devised, which consists of administering a vaccine. The disease is prevalent in Germany and probably in Italy and Hungary.

The significance of bacterial infection in hog cholera, R. R. DINWIDDIE (*Arkansas Sta. Bul. 117 (1914), pp. 593-619*).—The author discusses the effect of bacteria (secondary invaders) on the cycle of hog cholera, the effect of the presence or absence in the serum of antibodies to bacterial infection, the significance of *Bacillus suisepiticus*, and related questions, and reports experiments along these lines.

By inoculation tests it has been previously found that virulent strains of *B. suisepiticus* may be present at the base of typical hog cholera ulcers, "and at the same time (by the use of rabbits immunized against this species) the apparent absence of virulent hog cholera bacilli [E. S. R., 22, p. 788]. In order to learn something of the effects attributable to mixed infection and the influence of contagion (bacillar) in producing this condition, post-mortem examination and bacteriologic culture tests have been made as far as possible on all material available during the past two years. This includes experimentally infected animals, pigs artificially infected for serum production, hogs condemned for cholera at the packing plant or city abattoir at Little Rock, and material obtained from outbreaks of hog disease on farms in this State." The material from the serum plant differed from that obtained from farm outbreaks or experimental pens, since these animals (listed as "virus pigs") were often killed several days before death would naturally have occurred; they were also usually infected by strains of cholera virus of which no bacteriologic study had been made.

Out of 40 cases obtained from farm outbreaks, all with one possible exception were hog cholera. *B. suisepiticus* was found generally distributed in four animals, although two of these showed no intestinal lesions. In the liver of one animal *B. coli* was present and in another streptococci were found. In three others unidentified nonfermenting bacilli representing three different species were noted, and in three other animals cocci were present. Negative results were obtained in 30 cases. A coccus morphologically resembling the *Micrococcus catarrhalis* was obtained from the engorged spleen of a hog having a marked bilateral pulmonary involvement. "Preparations from the lung showed microscopically numerous organisms of varied species including small bi-polar staining ovals." The animal culture tests for bacilli of the hog cholera group were negative.

Tests made in connection with these experiments showed the infrequency with which bacilli of the hog-cholera type occur in the animals in natural outbreaks of the disease as compared with those artificially infected. The disease which now mostly prevails in Arkansas (termed "Winslow type") is not accompanied by this mixed infection either in animals naturally infected or in those inoculated from them. One experiment indicated that "a generalization of *B. suisepiticus* in the body of the animal greatly increases the severity of the disease and aggravates the ante-mortem symptoms although producing no characteristic post-mortem lesions. However, this mixed infection and increased virulence was not transmitted by cohabitation."

From the material obtained from the serum plant "it is shown that of 70 cases examined, *B. suisepiticus* was found generalized in 21. Of these 16 had been infected by inoculation (cholera infection), four by exposure, and one without record. Of the animals furnishing the blood for inoculation bacteriologic data are on record for 21. It is seen that in the four cases in which *B.*

suipestifer was present in the animal furnishing the virus for inoculation, this organism appeared also in the inoculated animal as a mixed infection. It occurred four times in animals infected by exposure only, and in all cases (3) which were recorded as having received an intravenous inoculation, also in five of the six hogs which died after serum-simultaneous vaccination. As for the post-mortem lesions present in animals showing this mixed infection it will be seen that there is no uniformity; that is, none which occur only in such cases. Two are recorded as showing only slight lesions. *B. suisepiticus* was obtained in one case in which there were no pulmonary lesions reported. In the two cases in which this species was present in the original virus it was not found in the inoculated animal, nor were pulmonary lesions present.

"To obtain more direct evidence of the effect of mixed infection with *B. suisepiticus* and hog cholera virus (filterable virus), experiments were carried through in which pigs were infected simultaneously with cholera virus (blood) and with cultures of the bacilli, in comparison with others receiving the blood infection alone. The virus employed was the 'Winslow virus,' which had never been found to give rise to this mixed infection in previous tests. The culture of *B. suisepiticus* employed was one which had been grown in the laboratory for 18 months. At the time it was isolated this strain was of less than the usual degree of virulence for guinea pigs. It had not previously been tested on pigs." Some control animals were placed in the pens and seven days after infection showed signs of sickness. In all of these cases when *B. suisepiticus* was not fed or inoculated the bacilli were not detected.

This experiment indicated as to mixed infection, (1) a shortening of the incubatory period, (2) a greater severity of the symptoms and more rapid course of the disease, and (3) an absence of any essential and uniform differences in the patho-anatomical changes as seen on dissection. The peculiar form of exudative inflammation with necrosis of the surface epithelium of the large intestine, which occurred in both of the pigs in the pen infected with bacilli by feeding and in one of the pigs infected by inoculation, was present also in an exposure pig which survived for three weeks. "Since this condition quite regularly results from successful infection experiments by ingestion of cultures of *B. suisepiticus* alone, we must look upon it as an inflammatory reaction due to the presence of this bacillus."

Although the controls (exposed animals) became sick, *B. suisepiticus* could not be detected, and this shows that *B. suisepiticus* infection in hog cholera is probably not dependent to any great extent on transference from animal to animal. Any positive assertion on this question, however, must be based on more extensive tests made under varying conditions.

When *B. suisepiticus* is introduced artificially, by inoculation or ingestion, in conjunction with the true hog cholera virus a generalized infection with the bacillus usually results. "Since infection with *B. suisepiticus* is not known to occur unassociated with true hog cholera infection, except when artificially induced, a complete immunity to the latter virus should indirectly afford protection against the bacillar invasion as well." To what extent the bacillar antibody content in serum may add to the potency of an antihog cholera serum needs still to be investigated. "In the practice of 'serum simultaneous vaccination' accidents arising from this cause are no doubt of occasional occurrence. That they are not frequent may be explained by the facts: (1) That most samples of antiserum contain bacterial antibodies; (2) most samples of virus do not contain bacilli; (3) inoculations of bacillar cultures subcutaneously are often ineffective."

The agglutinins in antihog cholera serum for *B. suisepiticus* are assumed to be due mainly to a reaction against the bacilli injected with the blood in hyper-

immunizing or to the invasion of the bacilli from the intestine when these are not present in the injected blood. The serum of hogs treated with a strain of virus which had never been associated with *B. suispestifer* yielded hardly any or no agglutinins for *B. suispestifer*.

From some immunizing tests with *B. suispestifer* it is inferred that it is not essential that an antihog cholera serum intended for simultaneous vaccination should agglutinate *B. suispestifer*, providing the same virus is used for the vaccination as was employed for preparing the serum. "However, the immunity thus acquired, while apparently sufficient to protect against subcutaneous inoculation of small doses of bacilli, seemed to break down under intravenous inoculation of large amounts of bacilli containing blood. . . . It may be mentioned also that most serum hogs which die during treatment (when not due to mechanical overloading of the circulation) show a generalized *B. suispestifer* infection which is suggestive of insufficient preliminary immunization against this bacillus."

Of the associated bacteria found in the filterable virus of hog cholera, next to *B. suispestifer* is the colon bacillus. A coccus which is described as morphologically resembling *M. catarrhalis* was found in the spleen, liver, and blood in several cases of hog cholera. This organism grows feebly upon ordinary media and its cultures were nonpathogenic for guinea pigs. *B. pyocyaneus* was noted occasionally in the pulmonary lesions of hog cholera, but more frequently in the large local lesions which followed inoculation. *B. suissepticus* was found very infrequently, and in all except one case it was associated with marked pulmonary involvement in pneumonia and pleurisy. A variety of organisms were noted occasionally in the culture tubes.

Of the many cultures obtained from organisms in cholera hogs giving a fermentation reaction, which was regarded as presumptive evidence of *B. suispestifer*, a number were given a study relative to their fermentative behavior toward various carbohydrates (dextrose, galactose, maltose, and mannit). All of the organisms studied gave the general cultural reactions ascribed to the hog cholera or *B. enteritidis* subdivision of the colon group of bacilli.

"The one feature in which these strains showed a considerable variation was in the production of indol in Dunham's peptone solution after one week's incubation. According to the text-books indol production in peptone solution is not a feature belonging to this species, although it may occasionally occur."

From the agglutination tests with antiserum it is concluded that "the view which some have entertained, that the bacilli which have been so generally cultivated from the organs of cholera diseased hogs and described as *B. suispestifer* or *B. choleraesuis* really include a variety of organisms presenting on closer study differences in cultural characteristics, is not supported by this investigation where all the strains studied are practically identical in cultural and biologic characters. . . . It seems therefore that cultures from the organs of cholera diseased hogs giving the fermentation tube reaction which we have called presumptive evidence of *B. suispestifer* are probably always this species. It is of interest that this same fermentation tube reaction has occasionally been found in city water tests here but never further investigated. . . . Swine plague as an independent disease has not been met with during this investigation."

Hog cholera in Montana, W. J. TAYLOR (*Montana Sta. Circ. 33 (1913), pp. 153-165, figs. 7*).—This deals in a popular way with the extent of the hog raising industry and hog cholera in Montana. It discusses how hog cholera is spread, the symptoms and the post-mortem changes in the disease, methods for controlling hog cholera, disposition of dead carcasses, disinfectants and disinfection, hog cholera vaccine, and methods of vaccinating against hog cholera.

The occurrence of avian tuberculosis in hogs, M. JUNACK (*Ztschr. Fleisch u. Milchhyg.*, 23 (1913), No. 20, pp. 457-461).—Of 15,000 hogs slaughtered at the abattoir at Kottbus, Germany, 2 per cent were found to have caseated areas in the mesenteric lymph glands, and in 25 per cent of the animals actually found tubercular on inspection the same condition was noted. Many of the latter animals also showed caseated areas in the lymphatic nodules of the large intestine which were of a granular, crumbling consistency.

The lymph glands of 32 cases were examined microscopically and acid-fast bacilli could be noted in 31 cases in a very short time by the Ziehl-Neelsen method. There was nothing typical about these organisms. In four instances the caseated areas of other organs were examined, and although the organisms were easily detected, they were not acid fast.

Further investigations were made at the Berlin abattoir and out of 200 hogs 7 showed the caseated areas, but the seventh animal was also affected with local mesenteric anthrax. In all 7 instances acid-fast bacilli could be noted in smears within 40 seconds. The caseous material from 5 of the cases which included the anthrax hog was injected into guinea pigs, which after 7 to 16 weeks showed no visible changes in those lymphatic glands which could be palpated in the living animal. The animals are to be kept under further observation.

From the caseous area of the hog affected with local anthrax the avian type of tubercle bacillus was isolated. Cultures were also made in glycerin and agar media and on glycerin-potato. In all three instances the agar-glycerin medium remained sterile but with the potato a growth was obtained. The organisms from the potato were found to be acid fast, and their biology will be the subject of further study.

The confusing of swine plague with tuberculosis in hogs is also discussed.

Mammary gland tuberculosis in a mare, LEIBENGER (*München. Tierärztl. Wchschr.*, 56 (1912), No. 44, p. 786; *abs. in Centbl. Bakt. [etc.]*, 1. Abt., Ref., 56 (1913), No. 7, p. 201).—A description of a case in a 4-year-old mare affected with generalized tuberculosis.

The etiology of infectious abortion of mares, B. B. LAUTENBACH (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 71 (1913), No. 5-7, pp. 349-377).—The author's bacteriological and complement fixation investigations and animal experiments led to the conclusion that the infectious abortion of mares is caused by *Bacillus D*, which has been found by agglutination to belong to the group of hog cholera bacilli and is placed near *B. paratyphosus A*. The paper includes a review of the literature.

On the diagnosis of infection with *Bacterium pullorum* in the domestic fowl, G. E. GAGE ET AL. (*Massachusetts Sta. Bul.* 148 (1914), pp. 20, pls. 5).—Experiments conducted with the view of determining whether the diagnosis of *B. pullorum* infection by testing the eggs of suspected hens is a practical method led to the conclusion that while positive results may be obtained the elimination from the ovary is so irregular the method would be impractical for rapid diagnosis. Preliminary incubation of the eggs in a bacteriological incubator at 38 to 39° C. prior to testing was found to aid in detecting the organism.

The macroscopic agglutination test proved to be a good laboratory method for the detection of adult hens that are harboring, or have harbored, *B. pullorum*. The work is said to substantiate that of Jones (*E. S. R.*, 28, p. 887) in that it is possible to cause a local infection of the ovarian tissue by intravenous injections of pure cultures of *B. pullorum*.

"The agglutinin is very stable, withstanding temperatures of 60° and over for one-half hour. If properly preserved, it will yield results after two weeks. Agglutinins have been found from infected hens which reacted positively in

dilutions from 1:100 to 1:5,000. Polyvalent test fluids yield more uniform results than monovalent fluids, although in birds of marked infection monovalent test fluids gave very good results. Test fluids, if properly preserved on ice, will keep in a very active state for more than two months.

"Rabbits reacted to injections with pure cultures of *B. pullorum*, but by careful immunization yield very active agglutinins and also bacteriolytic sera. Agglutinins produced by immunizing rabbits are much more stable than those from hens harboring the organism.

"A striking pathological condition found in the ovaries of all birds was the exhibition of lobulated and retention cysts which varied greatly in size. From these it was usually easy to isolate *B. pullorum*."

RURAL ENGINEERING.

Irrigation practice in Montana, H. B. BONEBRIGHT (*Montana Sta. Circ.*, 29 (1913), pp. 25-72, figs. 32).—This circular gives in popular language a compilation of detailed information regarding irrigation practice in Montana and related subjects which are of interest to the irrigation farmer.

Annual irrigation revenue report of the Government of Bengal (*Ann. Irrig. Rev. Rpt. Bengal, 1912-13*, pp. 76).—The physical and financial conditions of the irrigated districts of the Province are reported.

Report of the board of state engineers (*Rpt. Bd. State Engin. La., 1912-1914*, pp. 172, pl. 1).—This report deals with drainage reclamation in the State and also with highways, highway bridges, and other State engineering work. A large part of the data as to drainage by levee districts has been previously reported in publications of this Department (*E. S. R.*, 31, p. 185).

Some fundamental engineering features in the drainage of arid soils, R. A. HART (*Iowa Engineer, 14* (1914), No. 8, pp. 308-317).—The author deals chiefly with the drainage of irrigated soils, discussing the main features of such work and pointing out the difference between the drainage of arid and of humid soils. It is stated in conclusion that arid soils containing less than 0.2 per cent of alkali salts need little consideration, but that soils containing over 0.4 per cent of salts, by weight of the soil, need drainage.

Report upon the Black and Boggy Swamps drainage district, Hampton and Jasper Counties, S. C., F. G. EASON (*U. S. Dept. Agr. Bul. 114* (1914), pp. 21, figs. 3).—This report describes the district and the proposed drainage plan and briefly discusses the problems involved.

The district is approximately a rectangle, 12 miles long northwest and southeast, and 9 miles wide. The north, east, and west boundaries are formed by natural watershed lines, with no natural boundary on the south. The general slope of the ground is southward toward the coast and westward toward the Savannah River, which is the outlet for all the drainage of the district. The two main drainage channels for the district are Boggy Swamp, serving the northern and western parts, and Black Swamp, serving the eastern part. The poor drainage conditions are attributed to (1) lack of suitable drainage connection between the wet, flat areas and the drainage channels, and (2) the inability of the drainage channels to remove the water after it has reached them. The predominating and most generally cultivated type of soil of the district is a light sandy loam underlain by a reddish to yellow clay at depths of 4 to 18 in. Other soils are a tenacious gray clay, a red clay, and a heavy black muck.

The complete plan recommended for reclaiming the lands of the district involves the construction of 68 miles of dredged ditches and 98 miles of hand-made ditches. The minimum dredged ditch is one with a 14-ft. bottom width,

7-ft. depth, and $\frac{1}{2} : 1$ side slopes, while the handmade ditches usually have 3-ft. bottom widths, 5-ft. depths, and $\frac{1}{2} : 1$ side slopes. A berm of 8 ft. is recommended for the dredged channels, and of 3 ft. for the handmade ditches. The width of right of way varies as follows: For 3-ft. ditch, 30 ft.; for 14-ft. ditch, 80 ft.; for 16 to 20-ft. ditch, 90 ft.; for 22-ft. ditch, 100 ft.; and for 28 to 30-ft. ditch, 120 ft.

The proposed improvement in Boggy Swamp consists of a ditch throughout the length of the swamp, 13,000 ft. of which is handmade, with 3-ft. bottom width, 6-ft. depth, and side slopes $\frac{1}{2} : 1$; and 62,800 ft. of dredged ditch increasing from minimum size to a bottom width of 30 ft. at the lower end. The proposed improvements on Black Swamp consist of a corresponding dredged ditch about 10 miles long with bottom width varying from 13 ft. to 30 ft. Numerous tributaries to both these ditches comprise several miles of both handmade and minimum dredged ditches, as do also several small improvements in independent watersheds.

An estimate of the cost shows the total for the drainage district to be \$371,598, or an average cost per acre of \$5.50.

Mole-draining and the renovation of old pipe drains, D. T. THRING (*Jour. Roy. Agr. Soc. England*, 74 (1913), pp. 76-89, figs. 10).—The process of mole-draining water-logged soils is described and illustrated. Mole-draining is the making of a long hole, from 3 to 4 in. in diameter, under the surface of the land at varying intervals, and at depths from 3 ft. to 18 in., without digging and without pipes. The draining tool consists of a $3\frac{1}{2}$ in. round steel plug sharp at one end and firmly secured to a steel blade 8 in. wide. A hole is dug to the required depth and the tool dropped into the ground and drawn up the field, thus cutting the earth with the blade to the depth of the plug and leaving a round hole in the clay.

The best results are said to be obtained on a heavy clay soil and the method is useless unless the subsoil is clay. If old tile drains are already installed the mole-drains may be connected with these where the two intersect. The distance apart of mole-drains is governed by the furrows, but where there are no furrows they should be from 5 to 9 yds. apart. The depth of drains is governed by the soil. On very retentive soils 18 to 21 in. is deep enough, while on lighter clay 24 to 27 in. is better. Cost data applicable to English conditions are given, covering the entire process.

Experiences with wood-stave pipe, E. M. CHANDLER (*Engin. Rec.*, 69 (1914), No. 11, p. 299).—Information on the use of wood-stave pipe is given as follows:

For pressure heads between 20 and 150 ft. there seems to be no better type than wood-stave pipe built of redwood or fir. Steel pipe is preferable for pressures above 150 ft. on account of the necessarily close spacing of the steel bands on the wooden pipe for high heads. Wood-stave pipe without a preservative coating buried in a dry volcanic ash soil and not under hydraulic pressure continuously is subject to rapid decay.

Treatment of wood-stave pipe with hot carbolineum is concluded to be beneficial. One of the great advantages of having the pipe above ground is the ease of detecting leaks. Draining of the pipes during freezing weather, if they are promptly refilled afterward, can not increase the rate of decay.

Experience with a machine-banded wood-stave pipe showed that if it were necessary to bury it in arid regions, every precaution should be taken to coat all parts with a proper preservative.

Country road construction, A. LIEBMANN (*Der Landstrassenbau. Berlin and Leipsic*, 1912, pp. 147, figs. 44).—This book deals with the technical side of road design, construction, and maintenance from the viewpoint of the German

engineer. An introductory section dealing with the generalities of the subject, including a historical review, is followed by a discussion of vehicles and a mathematical analysis of the reciprocal effects of vehicles and roads. A section on location, design, and construction discusses alignment, cross section shape and structure, surface and underdrainage, foundations, surfacing, and costs. A final section deals with maintenance, including cleaning, rolling, dust prevention, and costs.

Progress reports of experiments in dust prevention and road preservation, 1913 (*U. S. Dept. Agr. Bul. 105 (1914), pp. 46*).—This report covers the completion of experimental work begun in 1912 (*E. S. R., 29, p. 590*) and gives the details of construction of several new sample roads.

An inspection of the experimental roads at Chevy Chase, Md., most of which have been previously described, showed the bituminous concretes to be in excellent condition. The section laid under the Topeka specification had a slightly wavy surface as compared with the District of Columbia pavement and had compressed in a few places below the top of the adjoining curb. The seal coat on the District of Columbia pavement began to bleed badly with the advent of warm weather. The results of expansion in concrete during hot weather were noted at the joint between experiments 2 and 3, where the roadway buckled across its entire width and to a small extent sheared off some of the concrete base of the District of Columbia pavement.

An inspection of the several bituminous surface treatments applied to concrete did not seem to indicate any noticeable difference between the adaptability of cement concrete and oil-cement concrete to this form of treatment. Practically all of the sections with bituminous surfaces suffered to a greater or less extent from the passage of a traction engine. The exposed concrete surface, as a whole, presenting a smooth, uniform texture and there was apparently no difference in wear between the plain cement and oil-cement concrete. The addition of a hydrated lime had no noticeable effect on the concrete. Cracks developed at a greater average distance where a limestone aggregate was used.

No difference was noted in the character of the various sections of brick pavement. The grouted surface had practically all worn off, and at a few places throughout the length of the section small transverse cracks had developed where the grout had broken loose from a course of brick.

On Rockville Pike, Md., experiments were conducted with tars and oils applied on surfaces hot and cold to demonstrate the relative value of several bituminous products and to ascertain the relative economy, from a maintenance standpoint, of cold treatment with the lighter products as compared with hot treatments with some of the heavier products. In these experiments refined coal tar, refined water-gas tar, asphaltic petroleum, residual asphaltic petroleum, and water-gas tar preparations were used. These were applied to surfaces finished as water bound macadam and covered with trap rock screenings or gravel. An inspection of these experiments showed that trap rock and gravel coverings have given equally good results. The surfaces were, in general, smooth and firm throughout.

At Miami, Fla., experiments were conducted with oils and coralline rock. The oils were applied to the rock subsurface by the semipenetration surface treatment and the penetration methods, using cold, light oil and hot, heavy oil. An inspection of these experiments showed two of the sections to be in very bad condition and demonstrated the impracticability of treating the original coralline rock roadway either by attempted penetration or strictly surface application of bitumen. The other experiments were in fair condition.

Supplementary reports are also given of experiments made at Washington, D. C., on surface treatment by tar preparation and oils; at Chevy Chase, Md., on bituminous construction, surface treatment, and the use of refined semiasphaltic oil; at Jamaica, N. Y., on the use of oil-cement concrete, oil asphalt, tar, and fluxed native asphalt; at New York, N. Y., and Ridgewood, N. J., on oil-cement concrete; at Boise, Idaho, on oil-gravel macadam; at Ames, Iowa, on oil-asphalt gravel; at Knoxville, Tenn., on tar and oil preparations; at Youngstown, Ohio, on slag, slag and lime, slag and waste sulphite liquor preparation, and slag and tar; at Newton, Mass., on asphaltic preparations, tar preparations, residual oil, and molasses-oil-lime; at Garden City, Dodge City, Bucklin, and Ford, Kans., on sand clay; at Independence, Kans., on oil-asphalt earth road; and at Bowling Green, Ky., on Kentucky rock asphalt.

Standard abrasion test for gravel employed by the Ohio State Highway Department, A. S. REA (*Good Roads, n. ser., 7 (1914), No. 23, pp. 315, 316, fig. 1*).—In an attempt to obtain a satisfactory test for gravel which would give a measure of its resistance to wear when subjected to traffic conditions, the standard abrasion test for stone was modified, using the Deval type of abrasion machine and 6 cast-iron spheres such as are used in the standard paving-brick rattler test per cylinder for an abrasive charge. The gravel was screened through screens having 2-in., 1-in., and $\frac{1}{2}$ -in. circular openings, and the sizes used for the tests were equally divided between those passing the 2-in. and retained on the 1-in. screen, and those passing the 1-in. and retained on the $\frac{1}{2}$ -in. screen. The duration of the test and the rate of rotation were 10,000 revolutions at the rate of from 30 to 33 revolutions per minute.

A series of tests made to compare the results obtained with those from the standard stone test show the advantage of this test, aside from the consideration of the size of material, to be in the increased severity of the abrasion on the soft, friable sandstone pebbles and material of a similar nature. "In this test the impact of the cast-iron spheres breaks up the soft pebbles, while in the stone test the impact of the stone on stone tends merely to round off the corners and edges."

Test of wire-cut and re-pressed paving brick (*Engin. Rec., 69 (1914), No. 22, p. 607, figs. 4*).—Experiments to compare the penetration of grout for re-pressed paving brick with horizontal grooves in the end faces and for wire-cut brick with double beveled or bulging ends showed that the penetrations were equally satisfactory, but that the wire-cut samples formed a stronger bond with the grout.

Effect of hydrated lime on change in volume and strength of mortars and concretes, H. S. SPACKMAN (*Nat. Lime Manfrs. Assoc. Bul. 10 (1914), pp. 24, figs. 9; Concrete-Cement Age, 4 (1914), No. 3, pp. 112-116, figs. 9*).—The results of tests on the effect of different conditions of exposure with and without the addition of hydrated lime on the change in volume of Portland cement mortar and concrete and on their tensile and compressive strengths are reported.

Variation in moisture content affected the volume of the test piece more than change in temperature. When kept from contact with water other than atmospheric moisture there was a marked tendency to shrinkage of the test piece, which continued up to and beyond the 6-month period. Where the test piece was in constant or frequent contact with water it tended to expand in volume. With the draining off of excess gaging water there was a marked shrinkage at the 24-hour period, followed in some cases by expansion at 48 hours and further shrinkage if test specimens were out of contact with water and expansion if in contact with water. The addition of hydrated lime, while increasing somewhat the maximum expansion and contraction when the test

specimens were constantly exposed either to water or dry air, markedly reduced the shrinkage due to the draining off of the surplus gaging water and also the extent of the movement when the test piece was ultimately wet and dried.

Portland cement mortars and concrete either with or without the addition of hydrated lime developed the greatest strength when in continuous contact with water, and when allowed to harden in air without water there was a marked diminution of strength. Considered broadly, the addition or substitution of 10 per cent of hydrated lime had no marked effect on the strength of the mortars.

It is concluded that the addition of hydrated lime will be found advantageous under ordinary climatic conditions, not only in concrete road construction but in concrete work generally.

Power from the sun, F. SHUMAN (*Engin. Mag.*, 47 (1914), No. 3, pp. 419-423, fig. 1).—A description is given of the main features of construction and operation of the sun-power plant for irrigation pumping at Cairo, Egypt.

The engine used is a special low-pressure engine previously described (E. S. R., 29, p. 787). The steam is generated in the sun heat absorbers which are approximate parabolic troughs for catching the sun's rays and concentrating them upon the boiler swung at the focal point. Tests of the steam-producing capacity of the heater showed the average production to be 1,100 lbs. per hour of 15 lbs. steam (absolute pressure) for a 10-hour day, giving on an average 50 brake horsepower. A comparison of the cost of erection in that locality of this plant with that of a coal-burning plant of equal horsepower showed a total saving in cost of erection and operation in favor of the sun-power plant of £410 6s. (about \$2,000). The plant is said to have a thermal efficiency of 57 per cent.

Gas-engine indicator diagrams, G. W. MUENCH (*Power*, 39 (1914), No. 22, p. 775, figs. 8).—Seven actual indicator diagrams taken on gas engines are given and compared with a normal diagram from a four-stroke cycle engine, thus showing how some of the common gas-engine troubles, such as improper timing of valves and ignition, preignition, faulty compression, excessive back pressure, etc., may be detected by the indicator diagram.

Strength of shafting required to transmit a given horsepower at different speeds, C. H. CLARK (*Sci. Amer. Sup.*, 77 (1914), No. 2003, p. 331, fig. 1).—Formulas and a diagram are given for computing the size and strength of shafting required to transmit a given horsepower at different speeds.

Transmission of power by Manila rope, R. TRAUTSCHOLD (*Power*, 39 (1914), No. 19, pp. 666-670, figs. 9).—Charts and formulas for figuring the power transmitted by rope drive, the sizes of sheaves, etc., are given, and the characteristics and advantages of rope drive are discussed.

The implements of the industry, H. P. AGEE (*Hawaiian Sugar Planters' Sta., Agr. and Chem. Bul.* 44 (1914), pp. 84, figs. 74).—This is a compilation of information regarding a number of the methods and implements used in the cultivation of sugar cane in Hawaii.

Permanent farm buildings, J. B. DAVIDSON (*Brick and Clay Rec.*, 44 (1914), No. 10, pp. 1140-1143, figs. 9).—The author draws attention to the economic importance of permanent construction of farm buildings, points out in a general way the requirements for such construction, and advocates particularly the use of clay products as building material.

Transmission of heat through building materials, F. L. BUSEY (*Power*, 39 (1914), No. 16, pp. 572-574, fig. 1).—In the interests of both building heating and refrigeration the author analyzes mathematical methods and gives tables of data for computing the heat transmission and the transmission resistance of different building materials.

RURAL ECONOMICS.

Farm management in the Gallatin Valley, E. L. CURRIER (*Montana Sta. Bul. 97 (1914), pp. 103-120, figs. 4*).—In a survey of 50 farms, the author found that the average labor income on the 25 better farms was \$1,365.92 while on the 25 poorer farms there was a loss of \$361.92, the farmers on these farms not receiving 6 per cent interest on their farm investment. Among the conclusions reached by the author in making a comparison of these two types of farms are that the better farms were stock and grain farms while the majority of the poorer farms produced only grain. The most successful farms averaged over four important sources of income while the poorer farms averaged slightly over two. The crop yields of the better farms averaged 22.8 per cent larger than the poorer, due to a more efficient system of soil management through greater diversification. The better farms had 8.6 acres per animal unit to 11.9 acres on the poorer farms, and had more dairy cows and sheep. The better farms produced a net return of \$2.41 per dollar of labor while the poorer farms produced only 49 cts.

Profits in farming on irrigated areas in Utah Lake Valley, E. H. THOMSON and H. M. DIXON (*U. S. Dept. Agr. Bul. 117 (1914), pp. 21, figs. 7*).—In this study 95 farms near Provo and Spanish Fork were used as a basis.

Among the results shown were that the greater part of the farm receipts were from sugar beets. The growing of other crops such as small fruits and vegetables which are suited to intensive agriculture was seriously limited by market conditions.

The total labor expense constituted nearly 50 per cent of the total farm expenses. The average labor income on 35 small farms with 16.5 acres in crops was \$247; on 30 general fruit and sugar-beet farms with 42 crop acres the labor income was \$589; and on 4 grain and live-stock farms with 74 crop acres the labor income was \$620. The profits received were largely influenced by the size of the farm business, the type of farming followed, and the diversity of the income. Many of the farms were so small in magnitude of business that the owners could not possibly make a comfortable living without outside employment. Of the 54 farmers who had less than 40 acres, only 2 men made over \$1,000 labor income, and more than 60 per cent of them made less than \$300. The high initial cost of land plus the cost of water rights and cost of improvements all combine to make such a heavy investment that intensive agriculture becomes almost imperative, even though such a form is wholly unsuited in its market relations. In most successful forms of intensive agriculture diversification of enterprises is important, and the limited markets in this region were in this way a severe handicap to the most efficient farm organization.

The management of farms growing sugar beets in Austria-Hungary, E. C. SEDLMAYR (*Mitt. Landw. Lehrkanz. K. K. Hochsch. Bodenkul. Wien, 2 (1914), No. 3, pp. 487-556*).—The author gives detailed information showing the areas devoted to the different farm purposes, rotations followed, kinds and amount of fertilizers used, number and kinds of agricultural implements owned, average yield of the principal farm crops, number of live stock kept, and the wages paid for male and female laborers at different seasons of the year.

The determination of the cost of production, C. S. ORWIN (*Jour. Bd. Agr. [London], 21 (1914), No. 3, pp. 193-201*).—The author asserts that since farm accounting is in its initial stages it would be easier to develop uniformity in methods than later when different systems have become accepted. He concludes from his study of the present systems that it is not possible to determine the cost of any one farm commodity without a complete calculation of the cost of all the produce of the farm.

The county farm bureau, B. H. CROCHERON (*California Sta. Circ. 118 (1914)*, pp. 18, figs. 9).—The author discusses the functions of the farm bureau, a county organization of those interested in agriculture "to assist the farm adviser in his work in the county," outlines the method of organization, and gives a constitution and by-laws previously noted (E. S. R., 30, p. 695).

Community improvement clubs for the rural and village communities of Kentucky, C. D. BOHANNAN (*Kentucky Sta. Ext. Circ. 19 (1914)*, pp. 31).—This contains a model constitution for a rural community improvement club and suggestions for making a study of a rural community along the lines of health and sanitation, and economic, social, religious, and school conditions. These suggestions are in the form of questions the answers to which the community is to determine for itself. A brief bibliography is included.

Economic associations of rural Poland, A. SZEMBEK (*Les Associations Économiques des Paysans Polonais Sous la Domination Prussienne. Paris and Brussels [1914]*, pp. XVI+461).—This book contains a detailed statement of the history and organization of mutual credit societies, cooperative associations, and agricultural clubs in Poland, and their relation to their respective central organizations. A brief bibliography is included.

Buyers and sellers in the cotton trade, H. B. HEYLIN (*London, 1913*, pp. VIII+234, pl. 1).—This book describes the cotton trade, the sources of supply, the progress of cotton manufacture in England, and various phases of the distribution of cotton and cotton goods. Statistical data are given showing the production, consumption, trade, and prices for a series of years.

Second annual report of the markets commissioner of the Province of British Columbia, J. F. SMITH (*Ann. Rpt. Markets Comr. Brit. Columbia, 2 (1913)*, pp. 31).—This report contains a summary of the work of the markets commissioner during 1913, and gives information regarding the consumption of fruit at prairie centers, freight rates, prices, cost of production, and rules regarding grades.

Stability of farm operators, or term of occupancy of farms (*Bur. of the Census [U. S.] Bul., Agr. U. S., 1910, Stability of Farm Operators*, pp. 22).—In taking the last census of agriculture, the question was asked, "How long have you lived on this farm?" These data have been tabulated by number of years of occupancy and by color and tenure of farmers, and may be summarized as follows:

Farm operators in the United States classified by number of years on farm and by tenure, 1910.

Number of years on farm.	Total number of operators.	Owners, free.	Owners, mortgaged.	Part owners.	Cash tenants.	Share tenants.	Managers.
Total number of farmers.....	6,361,502	2,295,277	1,059,620	593,825	826,287	1,528,389	58,104
Farms reporting.....	5,794,768	2,005,514	947,487	557,867	779,265	1,451,294	53,341
Total years.....	48,539,605	28,056,981	8,723,591	4,823,483	2,950,917	3,746,385	238,248
Less than 1 year.....	1,000,293	98,307	93,765	50,568	203,275	541,018	13,360
1 year.....	627,860	99,895	86,711	50,281	124,570	257,859	8,544
2 to 4 years.....	1,371,607	334,277	222,510	138,894	248,632	412,119	15,175
5 to 9 years.....	992,468	379,561	209,971	126,855	117,161	150,554	8,366
10 years and over.....	1,802,540	1,093,474	334,530	191,269	85,627	89,744	7,896
Not reported.....	566,734	289,763	112,133	35,958	47,022	77,095	4,763

Persons engaged in agriculture, W. E. BEAR (*Trans. Highland and Agr. Soc. Scot., 5. ser., 26 (1914)*, pp. 233-245).—The author by the use of the census data as a basis estimates that the decreases in persons engaged in agriculture in the United Kingdom were 4.6 per cent for males and 19 per cent for females in the decade ended 1891, while the corresponding decreases for the 10 years ended

1901 were 10.24 and 27.96 per cent. For the 10 years ended 1911 there were increases of 1.11 and 0.23 per cent, respectively. During the last 10 years this increase has taken place principally in England, while there has been a decrease in Scotland and Ireland. The English increase is due to the multiplication of small holders, while the Scottish decrease is due in part to a more precise distinction between farmers and crofters in 1911. In Ireland the decrease is due to the consolidation of farms.

Rural population in England and Wales: a study of the changes of density, occupations, and ages, A. L. BOWLEY (*Jour. Roy. Statis. Soc.*, 77 (1914), No. 6, pp. 597-652, figs. 2).—Among the conclusions reached by the author are that the population in purely rural areas is not completely dominated by the number in agricultural occupations. The number of farmers has changed very little in 50 years, but the number in the horticultural and market gardening occupations has increased slightly. A large number have throughout the last 50 years started their working life in agriculture and subsequently moved to other occupations in the country, in the towns, or abroad. At present 17 years seems to be the critical age. There is no evident connection between the numbers of agricultural laborers or the changes in their numbers, on the one hand, and the changes of wages, heights of wages, density of population, or the movement of other parts of the rural population on the other hand.

Agricultural population of Sweden, L. WIDELL (*Statis. Årsbok Sverige*, 1914, p. 13).—A classification of the population of Sweden according to the professions in which they are engaged, and including those who are dependent upon them for support, indicates that in 1870 71.87 per cent were engaged in agriculture, in 1880 67.42 per cent, in 1890 60.92 per cent, and in 1900 53.67 per cent. The total population has increased during this period from 4,168,525 to 5,136,441.

Agricultural statistics of Sweden, L. WIDELL (*Statis. Årsbok Sverige*, 1914, pp. 50-62).—This annual report gives statistics showing for 1911, by departments, the area devoted to different agricultural purposes, area and yields of the principal farm crops, and the number of farm animals, with data for earlier years. Additional data are given concerning the dairy industry and forests.

The agriculture in the Netherlands (*Pubs. Roy. Netherland Agr. Soc.*, No. 10 (1914), pp. 140, pl. 1, figs. 20).—This pamphlet, written in English, contains the following papers: Some Particulars about Dutch Agriculture, by F. B. Lohnis; Cattle Breeding in the Netherlands, by C. Broekema; Dairy Produce in the Netherlands, by V. R. Y. Croesen; Reclamation of the Heaths in the Netherlands, by J. P. van Lonkhuyzen; State Efforts on Behalf of Agriculture in the Netherlands; and The Activity of Farmers' and Market Gardeners' Associations in the Netherlands, by V. R. Y. Croesen and R. P. Bonthuis.

AGRICULTURAL EDUCATION.

Agricultural instruction and its methods, P. DE VUYST (*L'Enseignement Agricole et ses Methodes. Brussels*, 1913, 2. ed., pp. XII+354).—This is the second edition of this book, which has been previously noted (E. S. R., 21, p. 190).

Status of agricultural instruction (*Rap. Trien. Min. Agr. et Trav. Pub. [Belgium]*, 1909-1911, pp. XXVI+330).—This report for the years 1909-1911, inclusive, submitted by the minister of agriculture and public works to the legislative chambers of Belgium, on the collegiate, secondary, elementary, and extension instruction in agriculture, horticulture, and home economics, gives detailed information concerning the faculty, curriculum, attendance, examinations, etc., of the individual institutions.

The organization of agriculture by the department of agriculture in Ireland and its application to the conditions of the Bombay Presidency, W. W. SMART (*Agr. Jour. India*, 9 (1914), No. 1, pp. 23-37).—In this paper, read at the Provincial Agricultural Conference held at Poona in September, 1913, the acting director of agriculture of the Bombay Presidency describes the work of the agricultural branch of the Department of Agriculture and Technical Instruction for Ireland in its cooperation with the 33 county councils and the scheme under which the funds for agriculture are administered, and outlines his ideas as to how this system could be adopted in the Bombay Presidency.

Report of the department of agricultural education, W. H. FRENCH (*Ann. Rpt. Sec. Bd. Agr. Mich.*, 52 (1913), pp. 59-62).—In this report of the professor of agricultural education of the Michigan College attention is called to the teaching of pedagogical subjects leading to teachers' certificates for 15 hours each week during the year to a class of 105 students and to the teaching of agriculture by graduates of the institution in 20 high schools. The high-school agricultural course is a 4-unit course elected by from 10 to 50 per cent of the boys. Eighteen 1-week courses for farmers were held in connection with the high schools, the attendance ranging from 20 to 150. During the spring the organization of 30 boys' and girls' clubs in connection with rural schools was effected, and a pamphlet of instructions and projects has been distributed. About 150 readers have taken advantage of the college extension reading course.

Schools of agriculture, mechanic arts, and homemaking, L. S. HAWKINS (*Univ. State N. Y. Bul.* 543 (1913), pp. 20).—This bulletin contains a discussion of schools of agriculture as a part of the public school system, qualifications of teachers, rooms and equipment, types of schools of agriculture, mechanic arts, and home making; and an outline of the procedure in organizing them, project work in agriculture and summer work of agricultural teachers, suggested courses in agriculture and home making for intermediate and high schools of agriculture, and a list of general reference books relating to agriculture and rural life.

Agriculture in the high school, L. S. HAWKINS (*Univ. State N. Y. Bul.* 563 (1914), pp. 52, pls. 5, figs. 9).—The author discusses methods of instruction, how to keep a record of pupils' and teachers' work, equipment needed, field trips, pupils' notebooks, recitations, the shop, and the purpose and equipment of the farm mechanics work in the high school. A classified list of agricultural books is given.

The New Hampshire type of reconstructed rural high school, H. A. BROWN (*Vocational Ed.*, 3 (1914), No. 5, pp. 327-337, figs. 5).—In this article the author describes the courses in agriculture and home economics which are used in 15 New Hampshire high schools in rural sections in which agriculture is the predominating industry.

State-aided vocational agricultural education (*Ann. Rpt. Bd. Ed. [Mass.]*, 77 (1912-13), pp. 246-261).—This report of progress made in vocational training in agriculture shows, that 77 pupils carried on home project work as compared with 69 in 1912, that 30 pupils—5 from each of the 6 centers where agricultural project work and study were in operation in 1913—earned from farm work, in connection with good standing in the class room, \$9,728.03, and that the number admitted to such training for the 1914 school year is 266. A working agreement has been made by which each instructor is becoming the local representative of the extension service of the Massachusetts College and of this Department for investigations and advisory work among the farmers in his vicinity. The instructor of the extension service has been appointed state leader. Statistical tables are included.

The Massachusetts home-project plan of vocational agricultural education, R. W. STIMSON (*U. S. Bur. Ed. Bul., No. 8 (1914), pp. 104+III, pls. 6*).—The author discusses the elements necessary to successful vocational agricultural education, describes the Massachusetts home-project plan, and gives (1) information and suggestions for school officers and instructors as to courses and methods of agricultural project study approvable for State aid in Massachusetts, (2) project study outlines for vegetable growing, and (3) an agricultural project study bibliography. An appendix by W. T. Bawden has been previously noted from another source (*E. S. R., 30, p. 597*).

Report of the extension work with the schools as carried out through the schools' division, S. B. MCCREADY (*Ann. Rpt. Ontario Agr. and Expt. Union, 34 (1912), pp. 46-48*).—About 250 schools shared in the distribution of planting material and instructions for practical work in school or home gardens. A series of charts containing lessons in agriculture was commenced, and numbers on alfalfa and the best time to sow spring grains respectively, have been distributed. An illustration is given of the alfalfa chart.

A school garden in the making, its objects and uses, J. J. CRONIN (*Agr. Jour. India, 9 (1914), No. 1, pp. 71-76*).—The author points out the objects and uses of a school garden and describes the home and school garden work begun in Burma, India, in 1912. There are now ten school gardens in process of formation.

Rhode Island boys' and girls' home gardening clubs (R. I. State Col. Ext. Bul., 3 (1914), No. 13, pp. 3).—This bulletin outlines the conditions to which some responsible person or organization agrees when taking up home garden work in cooperation with the agricultural college and the state board of agriculture, and includes a blank to be filled out and signed by the applicant. The college, through its extension department, will help to organize a home garden movement in any part of the State, pay the expenses of a lecturer who will speak before organizations, at schools, or wherever it is desired to interest children in home gardening, and give information on gardening problems. The state board of agriculture will furnish leaflets giving instruction as to the details of the gardening work, printed ribbons or badges which may be used as prizes for exhibits of home-grown products, and enrollment and report blanks.

Boys' and girls' clubs in Utah, J. C. HOGENSON (*Utah Agr. Col. Ext. Div. Circ. 14 (1914), pp. 24*).—This circular outlines the purpose, method of organization, and general regulations of boys' and girls' clubs, and regulations for various club contests.

Boys' corn club work in North Carolina, T. E. BROWNE (*North Carolina Sta. Circ. 17 (1914), pp. 3-12, fig. 1*).—This describes the work of the clubs and gives general directions and instructions for growing, harvesting, and handling corn for contests.

Instructions to members of the boys' corn club, W. J. JERNIGAN (*Arkansas Sta. Circ. 24 (1914), pp. 4*).—Instructions are given as to cultural methods employed in corn growing.

Boys' and girls' club work, J. C. HOGENSON (*Utah Agr. Col. Ext. Div. Circ. 21 (1914), pp. 28, figs. 28*).—Eleven lessons in sewing are outlined.

Boys' and girls' home gardens, E. K. THOMAS (*R. I. Bd. Agr. Bul., 1914, Apr., pp. 8, fig. 1*).—This bulletin contains directions for planting and caring for gardens, including planting tables and for selecting, packing, shipping, and staging vegetables for exhibiton.

Hunnicut's agriculture for the common schools, J. B. HUNNICUTT, revised by R. J. H. DELOACH (*Atlanta, 1913, pp. XII+291, pls. 5, figs. 104*).—In this third edition the text has been almost entirely rewritten "with a view to giving

definite instruction on class room work in agriculture, to indicate how and where to find material with which to teach the subject and, lastly, how to use this material to the best advantage." It treats of the soil, plants, farm animals, dairy and poultry husbandry, school gardening, nature study, bird life, boys' and girls' clubs, and the farmer's opportunity. A list of agricultural references and useful tables are appended.

Simple furniture for school agriculture, J. MAIN (*Bul. Okla. Agr. and Mech. Col.*, 10 (1914), No. 79, pp. 8, figs. 7).—Specifications are given for an agricultural display case, book section and library table, bulletin boxes, and bulletin and note covers, and attention is called to four methods for exhibiting small grain, seeds, and similar products, viz, in a seed-mounting case, 2-dram vials, sample tubes, and standard exhibit boxes, and to a cupboard for the storage of equipment.

Illustrated lecture on swine in the United States, W. B. JESSEE (*U. S. Dept. Agr., Office Expt. Stas. Syllabus 16* (1914), pp. 16).—This syllabus is designed for farmers' institute and other extension lecturers and is to be used in connection with 44 lantern slides. Some of the topics considered are the construction of hog houses, sanitation and disease control, selection of breeding stock, swine management, breeds, and cost of production. A bibliography is appended.

Dairy laboratory manual and note book, E. L. ANTHONY (*Philadelphia and London, 1914*, pp. 72, figs. 10).—This group of 41 exercises, all of which have been used by the author in class work, is designed to cover the use of the Babcock tester, lactometer, and special work with farm separators and churns and to be used with courses having two or more hours laboratory practice each week. It is intended so to familiarize the student sufficiently with the general practice that he may be able to handle the more advanced courses in testing and creamery work.

The field of home economics, FLORA ROSE (*Cornell Countryman, 11* (1914), No. 8, pp. 271, 272, *Advt. Sect. p. 10*).—The author points out how various sciences apply to woman's home work and discusses some vocations open to students in home economics.

MISCELLANEOUS.

Twenty-sixth Annual Report of Colorado Station, 1913 (*Colorado Sta. Rpt. 1913*, pp. 31).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1913, a report of the director on the work and publications of the station, and departmental reports.

Twentieth Annual Report of Montana Station, 1913 (*Montana Sta. Rpt. 1913*, pp. 137-184, fig. 1).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1913, a report of the director on the work and publications of the station, including a list of all publications since the organization of the station, and a summary of meteorological observations for 1913.

Twenty-fourth Annual Report of North Dakota Station, 1913 (*North Dakota Sta. Rpt. 1913*, pp. 31).—This contains the organization list, reports of the director and heads of departments, including meteorological observations abstracted on page 615 of this issue, and a financial statement for the fiscal year ended June 30, 1913.

Annual Report of Porto Rico Station, 1913 (*Porto Rico Sta. Rpt. 1913*, pp. 34, pls. 4).—This contains the organization list, a summary by the special agent in charge as to the investigations conducted at the station during the year, a report by the chemist and assistant chemist, and reports of the horticulturist, assistant horticulturist, plant pathologist, and animal husbandman, abstracted elsewhere in this issue.

NOTES.

California University and Station.—Dr. W. L. Howard, horticulturist at the Missouri University and Station, has been appointed associate professor of pomology beginning in February, 1915. Dr. Jacob Traum, formerly of the Bureau of Animal Industry of this Department, has been appointed assistant professor of veterinary science for the investigation of tuberculosis among domestic animals. Roland S. Vaile has been appointed assistant professor of orchard management, and assigned to the Graduate School of Tropical Agriculture at Riverside.

Georgia College and Station.—The following have been added to the staff of the college since September 1: J. B. Berry, formerly of the Pennsylvania College, as professor of forestry; E. G. Welch as instructor in farm mechanics; and in the extension service, G. L. Bigford, C. J. Goodell, and W. H. Howell as scientific assistants in animal husbandry, R. M. Gridley as instructor in animal husbandry, Dr. A. L. Hirleman and L. G. Proctor as field agents in hog cholera work, R. F. Irvin as instructor in poultry husbandry, D. J. Taylor as field agent in poultry husbandry, and S. H. Starr and E. C. Westbrook as instructors in agronomy.

Arrangements have been perfected by which the station will have at least five cooperative plats in different parts of the State where variety tests of field crops, including cotton, corn, small grains, and forage plants will be conducted. Arrangements have also been made for conducting investigations in fertilizers for apples in the northeast and northwest sections of the State.

Fred H. Smith has been appointed assistant chemist beginning September 15.

Kentucky University and Station.—B. D. Wilson, assistant chemist in the fertilizer department in the station, and C. B. Wilson, assistant in the hog cholera serum laboratory, have resigned. Recent appointments include in the station M. J. Smith and E. Huston as assistants in animal husbandry, and Robert Pfanstiel and E. H. Nollau as assistant chemists, and in the extension department Charles E. Stokes as agent in animal husbandry in cooperation with this Department.

Maryland College and Station.—H. J. Patterson has resigned as president, to take effect July 1, 1915, recommending in his letter of resignation the abolishing of the office of president and the substitution of an administrative commission consisting of a director of college work, the director of the station, and the director of extension work. This plan is under consideration by the board of trustees, as well as a plan for the reorganization of the subcollegiate courses at the institution with an agricultural high school along lines similar to that at the University of Minnesota.

Recent appointments include C. E. Temple, of the Idaho University and Station, as associate plant pathologist in the state horticultural department, R. C. Rose as associate botanist in connection with college and station work, and Stewart B. Shaw, of the North Carolina Station, as horticulturist in connection with the state horticultural work.

Massachusetts College.—Prof. George F. Mills, associated with the institution from 1889 until his retirement last April, died October 27, at the age of 75

years. During this long period of service he had been at various periods professor of English and Latin, head of the division of the humanities, treasurer of the college and station, acting president, and since 1907, dean. These activities brought him into close relations with trustees, faculty, and the student body; and for years his scholarly attainments, breadth of vision, and high character had been a powerful influence in the upbuilding of the institution.

New Mexico College and Station.—E. H. Divelbiss has been appointed assistant professor of horticulture and assistant horticulturist, vice J. W. Rigney, who has been made county agent in Pecos County under the extension division. P. D. Southworth and V. L. Martineau have been appointed county agents in Luna and Colfax counties respectively, and M. R. Gonzales for San Miguel and Mora counties.

North Carolina College.—Exercises in celebration of the twenty-fifth anniversary of the establishment of the college were held October 3. Governor Locke Craig presided, and the program included addresses by ex-Governor Thomas J. Jarvis, Hon. Josephus Daniels, Secretary of the Navy, and Hon. Carl S. Vrooman, Assistant Secretary of Agriculture, and greetings from the State Department of Education by J. Y. Joyner, state superintendent of public instruction; other colleges of the State by Presidents Edward K. Graham of the University of North Carolina and William L. Poteat of Wake Forest College; the State Department of Agriculture by Commissioner W. A. Graham; and this Department by Director A. C. True of this Office.

President D. H. Hill closed the exercises with a historical account of the establishment and progress of the institution. At its opening the equipment consisted of a single building, 62 acres of land valued at \$2,500, and equipment estimated at \$500. At present the college has 486 acres of land valued at over \$125,000, over 20 buildings, and equipment inventoried at \$240,000. The faculty has increased from five members to sixty-three, the experiment station workers from ten to sixty-five, and the student enrollment from seventy-two to seven hundred and thirty-eight. Even more striking has been the change in attitude of the people of the State, and President Hill declared that "the college counts its greatest gain in its quarter century of life to be the winning of the confidence and hearty good will of every class of people."

Oklahoma College and Station.—W. L. Fowler, of the Arkansas University and Station, has been appointed animal husbandman to take up his duties at once. A. H. Wright has resigned as assistant professor of agronomy and assistant agronomist to take up post-graduate work at the University of Wisconsin, and has been succeeded by R. E. Karper, assistant in cereal investigations at the Kansas Station. E. E. Hall has resigned to engage in county demonstration work in South Carolina and has been succeeded as assistant agronomist by Adrian Daane.

Oregon College and Station.—C. V. Ruzek, assistant agronomist at the Arkansas University and Station, has been appointed assistant professor of soils in the college and assistant agronomist in the station. Charles S. Brewster has been appointed research assistant in poultry, vice C. C. Lamb, who has been assigned to extension work in poultry husbandry. D. C. Howard, a 1914 graduate, has been appointed instructor in dairy husbandry.

Pennsylvania College.—Farmers' Week will be held from December 28, 1914, to January 2, 1915, and 180 lectures are scheduled for this occasion. The attendance last year was 980. A special section will be conducted this year for the benefit of boys, who are expected to be present in large numbers on account of the corn club service which has been inaugurated in a number of counties.

The school of agriculture has made exhibits showing the work of the station at sixteen county fairs. The exhibit is prepared in duplicate sets and has been the means of connecting the college with a large number of farmers who have become deeply interested in its work.

Miss Pearl MacDonald, of Wisconsin, has been added to the staff of the agricultural extension department in charge of home economics.

Rhode Island College and Station.—The entering class numbered 103, an increase of 30 per cent over the previous year and making the total enrollment 262. Much difficulty has been experienced in providing accommodations for this number of students.

President Edwards received the honorary degree of doctor of laws from Brown University at its recent celebration of its one-hundred fiftieth anniversary.

The department of extension work is being reorganized with the following personnel: Director of the extension service, A. E. Stene; junior extension work in boys' and girls' clubs and school gardens, Ernest K. Thomas; instructor in farm management and agricultural organization, David Elder; instructor in home economics, Miss Jennie E. Koehler; and demonstrator in agronomy, Myron A. Hawkins.

In the station, Robert A. Lichtenthaler, assistant chemist, has resigned to pursue graduate study at Yale University, and Miss Marguerite W. Elkins, M. S., has been appointed assistant in animal breeding and pathology.

First Farmer's Club House in Indiana.—A farmer's club house of impressive design has been erected at Seymour as a memorial to Capt. Meedy W. Shields, a founder of the town and a donor of a fund utilized for the erection of the building. The club house was dedicated October 9, the principal addresses being made by Secretary Houston of this Department and Prof. G. I. Christie, of Purdue University. Secretary Houston discussed the workings of the Smith-Lever Extension Act, and drew special attention to the studies of this Department of marketing problems and in highway improvement.

Necrology.—Dr. D. E. Salmon, organizer of the Bureau of Animal Industry of this Department and its chief for over twenty years, died at Butte, Mont., August 30. Dr. Salmon was born at Mount Olive, Morris County, N. J., July 23, 1850, and entered Cornell University at its opening in 1868, gradually taking up veterinary studies. After six months spent at the Alfort Veterinary School in Paris, he was graduated from Cornell in 1872 with the degree of Bachelor of Veterinary Science, and four years later received that of Doctor of Veterinary Medicine.

After several years' veterinary practice, Dr. Salmon began his service with this Department in 1878 under a temporary appointment for the study of diseases of swine. Later he was appointed an inspector in New York in connection with contagious pleuro-pneumonia in cattle, and worked in the Southern States on Texas fever and other animal diseases. Early in 1883 he was called to Washington by Commissioner Loring to organize a veterinary division in the Department, which within a year was replaced by the Bureau of Animal Industry, established under an act of Congress, and served as its head until 1905. Among the specific achievements of the Bureau during this period were the eradication of contagious pleuro-pneumonia of cattle in 1892, the establishment of animal quarantine stations at the principal American ports and the promulgation of regulations for the safe shipment and humane treatment of cattle exported from the United States, the development of the export and domestic meat inspection service, and the suppression of foot-and-mouth disease. Im-

portant investigations were also conducted by him personally or under his direction, among them the pioneer work done in collaboration with Dr. Theobald Smith, begun in December, 1885, which established the highly important principle of vaccine therapy, and the determination of a protozoan as the cause of Texas fever in cattle and the method of its transmission through the agency of the cattle tick.

From 1907 to 1912, Dr. Salmon was in charge of the veterinary department in the University at Montevideo, Uruguay. During that time he was instrumental, among other things, in starting a veterinary journal published under the title of *Revista de Medicina Veterinaria de la Escuela de Montevideo*, to which he was a regular contributor. Returning to this country, he gave considerable attention to the preparation of hog cholera serum, and his last contribution was a paper on that subject published in the *American Veterinary Review*.

Francis Humphreys Storer, one of the few remaining pioneers in agricultural science in this country, died July 30, at the age of 82 years. His work was carried on at the Bussey Institution of Harvard University, following his appointment in 1870 as professor of agricultural chemistry, and the following year as dean, of the newly opened enterprise. Here he not only carried on instruction and administrative work until his retirement in 1907, but beginning in 1871 conducted, with his assistants, many researches in agricultural chemistry, notably with fertilizers. His most valuable contribution, however, was his treatise on Agriculture in Some of Its Relations with Chemistry, the first edition of which appeared in 1887, and which has run through seven editions and been twice revised. This book rendered special service because of its timeliness, appearing when the vast store of information it contained was very inaccessible, and was very helpful to the experiment station movement then just starting on a national scale under the Hatch Act.

Dr. William Saunders, director of the Canadian Experimental Farms from 1886 to 1911, died in London, Ontario, September 13, at the age of 79 years, Canadian Government in 1885 to report on experimental work in agriculture comprehensive development. His experimental work was largely as a plant breeder and hybridizer of fruits and cereals adapted to the Canadian climate, the Marquis wheat developed by his son, Dr. Charles E. Saunders, from types selected by him being one of the best-known productions. He was also much interested in entomology, botany, pharmacy, and medicine, a founder of the *Canadian Entomologist* and its editor from 1873 to 1886, and the author of an unusually large number of articles, bulletins, reports, etc., among them his well-known work on Insects Injurious to Foods (1883). He had received many scientific honors, including the presidency of the Royal Society of Canada in 1906, and was made a companion of the Order of St. Michael and St. George by King Edward VII in 1905.

Reorganization of Agricultural Work in Algeria.—Under a law of December 3, 1913, providing for a readjustment of the annual appropriation of \$400,000 for agricultural and other developmental work in Algeria, plans are being put into effect for carrying on this work. Under these plans, \$20,000 will be used for cooperative agricultural credit societies and \$40,000 for long-term agricultural credit institutions. The remainder will be available for grants to building and marketing associations, mutual agricultural insurance societies, instruction, experimental, and extension work in agriculture, and a number of nonagricultural purposes.

The administration of the law is entrusted to a commission of which the Governor General of Algeria is president and the Director of Agriculture,

Commerce, and Colonization vice-president. This commission is to organize an instruction, experimental, and extension service and a superior board of advisers to assist this service in the direction and coordination of its work. The various existing agencies will be reorganized under this plan. Branches are contemplated in meteorology, agrogeology, agronomy, botany, and animal pests, special attention being given for the present to cereals, grapes, forage crops, and tree fruits. There will be a number of experiment stations, as well as a system of extension work through meetings, publications, model farms, and the like, and a corps of itinerant agents or instructors. The experiment station system is expected to include for the present a reorganization of the experimental garden at Hamma, a new station at Habra for the special study of irrigation and dry farming problems, and experimental fields at Sidi-bel-Abbès, Sétif, Serson, and Batna for forage crops, at Orleansville for tree fruits, at Guelma for forage crops, olives, etc., at Tlemcen for fruit growing, and at Kabylie for figs and olives. Dr. Charles Brunel has been appointed director of agriculture under the new system.

Agricultural Research and Education in Italian Africa.—A royal decree of March 3, 1914, provides for the establishment of the Agrarian Office of Tripolitania, the direction of which has been entrusted to Prof. Emanuel Cillis of the Royal High School of Agriculture of Portici. Grounds have been secured in the city of Tripoli and the director is engaged in formulating working plans, the activities of the office being divided into experimental, administrative, and miscellaneous services. The experimental division will be located on government land surrounding the old Turkish agricultural school in the oasis a short distance from Tripoli. The work of the office will include study and research in cultivation by irrigation and dry farming methods, the conduct of small farming units for better ascertaining the entire economic value of a given equipment, animal industry with particular reference to the improvement of native species, such as the camel, donkey, sheep, goat, cow, and horse, and to the increase of grazing land and provender, problems relating to brackish water, farm chemistry, vegetable biology and pathology, meteorology, rural engineering (particularly hydraulic problems), etc. A depository for farm implements and tools will be established not only for the needs of the station but also for loan or hire for private trials.

Agricultural Instruction in Western Australia.—The newly established university at Perth announces a 2-year diploma course in agriculture and a 3-year course leading to the degree of B. S. in Agr., and candidates may be required to pass an additional year at practical work on an approved farm. Two short courses for farmers were offered at the university from June 8 to July 3, 1914, including instruction in cultivation and cropping, elementary inorganic chemistry, elementary botany, and veterinary science, by means of illustrated lectures, laboratory work, demonstrations, etc. Single lectures or short courses of three lectures are also given at country centers by the university agricultural staff, when time permits, in the following subjects: Principles of agriculture, how crops grow, soil and its management, factors in wheat growing, soil moisture and dry farming, crop rotations and forage crops, fertilizers, milk and its management, breeds and management of sheep, principles of breeding, breeds and care of the horse, and parasites of interest to the farmer.

Conclusions Adopted by the International Phytopathological Congress.—The International Institute of Agriculture has recently published the complete text of the convention adopted and signed by the delegates at this congress (E. S. R., 30, p. 700), which has been submitted through the usual diplomatic channels for adoption by the various signatory nations. The principal conclusions agreed upon are in substance as follows:

The contracting countries shall adopt, if not already in existence, the necessary laws and administrative organization for carrying out the inspection of all nurseries, greenhouses, and other establishments offering plants for sale, verify reports of the occurrence of insect and fungus pests, investigate means for their control, and adopt regulations for the packing and shipment of plants. The governments shall, within two years, establish institutes for the scientific investigation of plant pests, provide for the inspection of shipments, and give certificates of freedom from disease or insect pests. For the present, grain, seed, onions, potatoes, grapevines, and all plants which enter into "grand culture" will not be included in the inspection, but no country shall admit nursery stock, bulbs, cuttings, grafts, or cut flowers from any other country except as accompanied by certificates signed by competent officials in the exporting countries. Each country reserves to itself the right to examine plants and their packing, and where pests are found contrary to the certificate of the exporting country, notice will be furnished the exporting country, which shall at once take proper recognition of the condition. The infected plants will be returned to the exporter or burned and evidence of their destruction forwarded.

Certificates of inspection shall be uniform and be printed in French and also in the language of the country of their origin. The importation of living plants without certificates is permitted by scientific institutions duly authorized by their governments, but all reasonable precaution should be taken against the possible dissemination of any pests. For contiguous countries such exchange of plants should be as near the frontier as possible.

Upon their adherence to the convention the different countries shall furnish lists of plant pests against which protection is desired, and these shall be noted in exporting certificates. This list shall be limited to those pests that are liable to become epidemic or destructive to crops of various kinds, or which are readily propagated on living plants or parts of plants.

The International Institute of Agriculture at Rome is recognized as the official center to which all matters regarding plant pests are to be referred. All questions of controversy of two or more countries are to be referred to a mixed commission of phytopathologists for examination with a view to suggesting means for harmonizing the differences. No country is to extend to a noncontracting country any consideration not given the countries signing the convention.

American Association for the Advancement of Science.—In commemoration of the completion of the Panama Canal, an extensive series of scientific meetings in San Francisco and vicinity is being planned for the first week of August, 1915. The meetings concerned with agricultural science will deal in general with questions of food supply and of agricultural conservation, and of these sessions at least one will be devoted to subjects of nutrition, and one to more general questions of agricultural chemistry. It is expected that a number of national chemical and agricultural societies will convene in conjunction with the meetings of the American Association.

EXPERIMENT STATION RECORD.

VOL. XXXI.

DECEMBER, 1914.

No. 8.

From the beginning of agricultural instruction and experimentation, the study of field crops, their growth, nutrition, and reproduction, has naturally occupied a prominence second to no other subject. Crops are aggregations of plants, governed by definite laws and responsive to various factors and conditions. These laws and the influence of factors and conditions on the life activities of crop plants, such as we know of them, are embraced in plant physiology.

Hence an intelligent understanding of plants and their growth implies a study of plant physiology, not in a superficial way but as one of the fundamental subjects in acquiring intimate familiarity with agricultural plants and the factors of their growth. Some general empirical information can be acquired through lectures on botany, agronomy, or agricultural chemistry, as is done in short course instruction, but the needs of a reasoning knowledge and understanding are not satisfied in this way. They require a more thorough insight. The place where the subject is taught is less essential than that it should be taught thoroughly and effectively. And a consideration of it needs to enter more largely into certain features of agricultural experimentation.

In a recent publication^a a criticism is given of the courses of botany in the agricultural colleges of this country, and a plea is made for more attention to plant physiology. If, as the author claims, "the object of agricultural education is to produce farmers who will do their work more intelligently," the criticism is well taken. If the object of education is to train the student how to observe and correlate facts without reference to their practical application, then the pedagogical value of physiology will be found equal to any other branch of the science of botany. For the individual who contemplates following agricultural pursuits a proper understanding of plant life is essential, and such a view can be obtained only by observing how different organs of the plant cooperate to produce the phenomena of growth, nutrition, reproduction, etc.

^a Science, n. ser., 40 (1914), No. 1029, pp. 401-405.

A study of the catalogues issued by the colleges of agriculture shows that there is a wide range in the amount of instruction in plant physiology and in the number of credits given it by the different institutions. In some, work in plant physiology is required of students of agriculture, while in others it is optional. The place it comes in the curriculum may be anywhere from the freshman to the senior year. In some institutions with which the colleges of agriculture are affiliated the students in the so-called arts courses are given opportunity to take more work in plant physiology than is given to the student in agriculture. Some institutions apparently offer no instruction that can in any way be called a course in plant physiology. Some give it a limited amount of attention in a general course in botany that covers one year's time. In these cases there are no statements indicating the relative amount of time given to this part of the general topic.

Most of the colleges offer definite courses in plant physiology, which range from a weekly lecture or recitation and a laboratory exercise for one semester, to three or more lectures and a corresponding amount of laboratory work running through an entire year, with optionals for additional study along the same line. Unfortunately the latter class is in a considerable minority. This is hardly as it should be. The student of agriculture is vitally interested in plant life and should be given ample opportunity to learn the normal behavior of plants, for it is upon the proper development of his crops that his success as a farmer will depend.

In nearly every catalogue examined the course in botany included classification as a rather important part of the work. While the amount of time and relative importance assigned to it are less than formerly, yet it is retained to the at least partial exclusion of other studies. This is due probably to the historical position it has held in college courses, and the conservatism of some who have the making up of the curriculums. The classification of plants and calling them by their scientific names are not to be condemned in themselves, but they are not all of botany any more than the memorizing of symbols and atomic weights are all of chemistry. Fortunately, more attention is now being given to the plant as a living organism; and in order to provide sufficient opportunity to more completely study the plant as such, some of our greatest institutions no longer attempt to equally cover all the branches into which botany has been divided, but content themselves with specializing along a few lines. This principle could safely be adopted by others, leaving to special institutions those branches of the subject that do not immediately articulate with the general course of training. In making such an adjustment the agricultural colleges should frequently give a larger part to plant physiology than is now given it.

In courses of instruction dealing so largely with crops it would seem that more consideration should be given the principles underlying their growth, nutrition, water requirements, reproduction, etc. Doubtless in some way the general facts are set forth, but it is probably true that comparatively few students have first hand information regarding these subjects, and at most as related to more than a single leading agricultural crop.

There can hardly be anything more important to the farmer than definite information and understanding regarding the growth of his crops. As the writer referred to has stated, "plant industry as a science must rest on an understanding of plants." And yet, the normal rate of growth at various stages of development is practically unknown to the average student and indeed to many experimenters for the conditions under which they are working. The influence of various factors on growth is little understood, except in a very general way, although some of these factors can be controlled and growth accelerated or retarded as is necessary or desirable. It is probably true, as the writer referred to intimates, that very few students follow through the various stages of a single crop to determine its normal growth and the influence the more important environmental factors may exert upon it.

Perhaps next in importance are the questions of transpiration and water supply. In the regions where irrigation is generally practiced it is quite evident that there is little or no attempt at a system of applying water that is based upon the physiological activities of the plant. This leads to irrational practice in applying water that may be wasteful and injurious. The assumption that alfalfa, sugar beets, orchard, and horticultural crops all require the same amounts of water and at the same intervals during the growing season is manifestly wrong, yet in many localities the only measure is so many inches of water at certain arbitrarily determined intervals. This is often based upon the engineer's estimate of the amount of water available and not upon what or when it is needed; and it is not only wasteful of water, but may be positively injurious to the crop and detrimental to the soil. It is well known that the water factor can be controlled to a considerable degree, and if students were required to study the matter in detail, paying attention at the same time to transpiration under controlled conditions, a new practice in irrigation farming might ultimately result.

It is probable that plant nutrition receives more attention in our agricultural colleges than any other physiological function. But even here the laboratory work is reduced to the minimum, and much is done in field plats where definite control is lacking. There is need of much more study of plant nutrition than is included in fertilizer tests as they are usually made. Water cultures, supplemented with

pot and plat work, might be carried on in such way that the student could determine for himself the important facts in the mineral nutrition of plants. This is one of the plant activities that can be rather definitely controlled, and the fundamental principles underlying the application of fertilizer elements should be thoroughly mastered.

Photosynthesis, which is very little subject to control or regulation, is generally studied where laboratory work is done, while other functions that may be definitely directed to the advantage of the crop and the profit of the grower are neglected. Respiration, the response to stimulus, and the physiology of reproduction, are usually passed over with slight attention, although all of these functions have a direct bearing on the welfare of the plant.

In the field of investigation, one aspect of plant physiology is almost wholly overlooked, that is, the relation it bears to plant diseases. So long as the normal functions of the plant are not fully understood it will be impossible to know very much of the abnormal or pathological conditions. Studies are generally made of the organisms which cause disease, and experiments are conducted that look to controlling their spread, but very few investigations are undertaken to determine the nature of the effect of the parasite on its host, or as to how the injury is brought about. The study of plant diseases due to fungi and other organisms receives much attention, but the large and important class of plant injuries due to what are usually designated physiological disturbances receives rather scant study. True, little is known of how these disturbed conditions are brought about, but this lack of knowledge should stimulate investigation along this line. In the treatment of plant diseases the outward manifestations are usually given more consideration than the constitutional changes produced. As long as this is true, prevention rather than cure will be the result. But even in the prevention of plant diseases very little is known as to the principles underlying immunity or resistance to the attack of certain organisms.

Some of the above statements are not intended to apply to the teacher alone. Investigators are needed to clear up many little known facts concerning the activities of plants. But if more emphasis were given to the importance of a study of plant physiology in its agricultural relations, more investigators would be trained who might address themselves to the problems in that field.

The extent to which the physiological aspects of plant growth are studied or taken account of in connection with field experiments seems quite inadequate. These experiments are extensive in number and constitute a large feature of experiment station work. But much as we discuss their importance and their limitations, and attempt to provide greater accuracy, features of great significance are

often neglected which would add to their information value and assist in their interpretation. Too often the end sought seems to be comparisons measured by ultimate production, rather than the tracing of relations between causes and effects.

Field experiments with agricultural plants, considered in their fundamental aspects, are to large extent studies of the response of these plants to definitely known environmental conditions; and yet how rarely are these responses measured expressly or continuously at successive stages. To determine the response effectually, the conditions must be definitely known, and the plans must be so made and the observations so taken that correlations can be attempted. The life processes in the growing plant need to be followed if the effects of the special conditions imposed are to be determined.

Consider the usual field experiment with fertilizers, or upon the preparation of the land, or culture methods, or date or rate of seeding, rotations, and the like. The land is selected and prepared with care, divided into plats with mathematical accuracy, and the different treatments carried out systematically. Notes are taken from time to time on the general appearance of the plats, often supported by photographs, the date of blooming or fruiting or other stages noted, and when the crops are harvested provision is made to insure against loss, and the weights or volume are accurately recorded. Analyses may be made of the materials applied or sown, and of the resulting crops. But the growing crop is usually not studied in a way to determine the manner in which it is responding to the special conditions. Rarely, indeed, are any systematic measurements taken of the plants, or attempts made to get at critical stages of growth or the effects of the treatment at such times. The physiological activities of the plants throughout their growth are not followed, and often can not be followed because the field experiments have not been supported by experiments which provide a larger measure of control. The growth under the different treatment can not be compared with the normal growth at various stages, because provision for this is lacking.

If conditions of normal growth were maintained as a check, it would be possible to judge of the accelerating or retarding effect of each treatment at successive stages, and the adaptability of the plant and its capacity to overcome adverse conditions or to minimize their effects later could be arrived at with considerable accuracy. Furthermore, something could be learned of the effects of changes in temperature of the air or soil, or the periodicity of the rainfall and other external phenomena which experiments in the field are subject to. Instead of measuring these, the attempt is usually made to eliminate them by averaging the results of several years.

In short, the usual field experiments, which form such a prominent feature of station work, teach but little in a definite way as to the life of the plants concerned in them or of the exact conditions of their growth, and they contribute far less than they should to a thorough knowledge and understanding of these plants.

In too large a proportion of these experiments the main interest and reliance seems to be placed on the weight or bulk of the harvested crop. This of course is the final measure from an economic point of view, to determine whether a practice or treatment is profitable or advisable. But in investigation, and in all experiments except those of the most rudimentary kind, the aim should be to learn not merely the economic result but something of the way in which the result has been brought about, and the effect upon the plant to the imposed conditions. The living plant must be studied quite as much as the final yield.

These things are highly essential if field experimentation is to develop along scientific lines and make progress in laying the foundation for an intelligent agriculture. They require far more attention to a certain kind of details than is now given. They require continuous study, with attempts at correlations of growth and specific conditions throughout the season. Otherwise the final result is a composite result of all the conditions, and there is no means for determining how much is to be attributed to particular artificial conditions imposed, or how far the effect of these has been masked by other unfavorable conditions.

To make these continuous studies of the plants and their surroundings implies a smaller number and less diversity of field experiments, and greater attention to those which are undertaken. It will mean more study in planning the work, to provide such checks under more refined conditions of experiment as are necessary to furnish reliable comparisons. It will call for some system of accurate measurements at regular intervals, and the recording of uncontrolled phenomena which may influence growth or physiological function. It will require living with the experimental material—a closer association with the plants and concentration on their study.

Under such close observation there will be no lack of problems. The investigator with vision and imagination will be confronted with them on all sides, and instead of allowing them to bewilder him with their confusion he will devise means to regulate them and take account of them in his plan of experiment. This will make the methods of experimental agronomy more exact and more searching in character, and will make interpretation more sure. It might relieve the necessity for some of the repetition that has been going on so many years.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY—AGROTECHNY.

A contribution to the chemistry of phytin, R. J. ANDERSON (*New York State Sta. Tech. Bul.* 32 (1914), pp. 3-44).—The subject is treated under four different headings, as follows:

I. *Concerning the organic phosphoric acid of cotton-seed meal, II* (pp. 4-11).—Since the results of Rather (*E. S. R.*, 29, p. 804) did not harmonize with the earlier work of the author (*E. S. R.*, 28, p. 505) the work on cotton-seed meal was repeated in the hope of establishing more definitely the composition of the organic phosphoric acid of cotton-seed meal. From 25 lbs. of cotton-seed meal 69 gm. of barium salt, after recrystallizing eleven times, was obtained. It was free from heavy metals other than barium and no weighable quantity of alkalis could be obtained from 0.5 gm. of the salt. "It was completely free from inorganic phosphate and it was free from nitrogen and sulphur." Silver salts prepared from the isolated acid did not seem to be suitable for identifying the acid in question. They were obtained as amorphous precipitates and did not represent homogeneous salts. They are believed to be mixtures of more or less acid silver salts of inosit hexaphosphate because after deducting the amount of silver found, allowing for a corresponding amount of hydrogen and water and calculating to free acid, the results agreed very closely with the percentage composition calculated for inosit hexaphosphate. The acid preparation used did not give, as Rather found in his investigations, a precipitate on the addition of alcohol.

II. *Concerning phytin in oats* (pp. 12-21).—The purpose of this investigation was to determine whether the phytin in oats (*E. S. R.*, 21, p. 608) was identical with the phytin from other sources. Several preparations were made from different lots of oats with a 0.2 per cent hydrochloric acid solution and precipitation as a barium salt with barium chlorid. "The substance was then repeatedly precipitated from dilute hydrochloric acid alternately with alcohol and with pure recrystallized barium hydroxid (Kahlbaum) until all bases other than barium were removed and until all the inorganic phosphate was eliminated."

No crystalline substance was obtained, but on analysis the various preparations gave analytical results which agreed well amongst themselves although the composition was considerably different from that of phytic acid. The preparations were found finally to consist of two different organic phosphoric acids, but only one was isolated in a pure form. The portion insoluble in water after removal of the soluble part was obtained as a barium salt in crystalline form in the same manner as in the case of that prepared from cotton-seed meal. "So far as one can judge by crystal-form, composition, properties, and reactions, the crystalline salts obtained from oats and cotton-seed meal are identical." The water-soluble substance noted above could only be obtained as a snow-white amorphous powder the composition of which differed entirely from the

crystalline product, but only very slightly from that isolated from wheat bran (E. S. R., 28, p. 17). Like the crystalline barium salt obtained from cotton-seed meal, that from oat seed does not agree with the usually accepted formula for phytic acid, viz, $C_6H_{24}O_{27}P_6$ (see also E. S. R., 19, p. 966). Apparently oats contain two different phosphoric acids.

III. *Concerning phytin in corn* (pp. 22-26).—This subject has been previously studied by Vorbrodt (E. S. R., 26, p. 501) and Hart and Tottingham (E. S. R., 21, p. 608). The substance isolated in these investigations was re-examined by the author and a crystalline barium salt was prepared with some difficulty. Judging from the crystalline structure, composition, and properties, the substance is identical with the salts previously isolated from cotton-seed meal and oats, namely, salts of inosit hexaphosphate.

“The analytical results obtained from these purified crystalline barium salts do not agree with the formula proposed by Vorbrodt. The phosphorus is over 1 per cent higher and the relation between carbon and phosphorus is as 1:1. The phosphorus content is also considerably higher than that required for a corresponding salt calculated on the usual phytic acid formula. The barium salt analyzed by Vorbrodt had been prepared from the previously isolated acid by partially neutralizing with barium hydroxid and concentrating in vacuum. The crystalline salt which then separated was washed, dried, and analyzed. Apparently no attempt had been made to recrystallize it and it is probable that the substance had contained small quantities of impurities which might be sufficient to account for the difference in analytical results between his product and the repeatedly recrystallized salts which have now been analyzed.”

IV. *Concerning the composition of barium phytate and phytic acid from commercial phytin and a study of the properties of phytic acid and its decomposition products* (pp. 27-44).—The salts of phytin, previously reported upon (E. S. R., 27, p. 712) were prepared from commercial phytin, and most of these were amorphous, particularly the barium salts, and in only one case was a crystalline salt obtained. The amorphous salts on analysis gave results which corresponded closely to the usual formula ascribed to phytic acid. As some doubt was felt as to whether these amorphous compounds were homogeneous an investigation was made of commercial phytin, using the same methods as before, to see if any real difference existed between the barium salts of phytic acid prepared from commercial phytin and the crystalline salts obtained from cotton-seed meal, oats, and corn.

“After carefully purifying the barium salt of the substance we found that it crystallized very readily and no difference could be observed either in crystal form, composition, or reactions of the salts prepared in this way from the crystalline salts previously referred to. All of these compounds are therefore identical and the analytical data indicate that they are salts of the acid $C_2H_6O_5P_2$ or $C_6H_{18}O_{24}P_6$. The composition, as determined by analysis, of the free acid prepared from the crystalline barium phytate also agrees more closely with the above formulas than with the usual formula of phytic acid, $C_6H_{24}O_{27}P_6$. The phosphorus was found too low in this case as well as in the acids previously described. This, however, is undoubtedly due to the fact that the acid is largely hydrolyzed on drying. It appears very probable then that the organic phosphoric acid described above and known as phytic acid is either inosit hexaphosphate, $C_6H_{18}O_{24}P_6$, or else an isomer of the same. We have, however, no direct information concerning the molecular magnitude of the acid.”

Attempts to prepare a neutral ester of the acid with a view of determining the molecular weight and also the preparation of a neutral silver salt failed. “Only acid silver salts have been obtained even from solutions of phytic acid neutralized with ammonia. From such salts, naturally, only acid esters could

be obtained." "Tribarium inosit hexaphosphate, $C_6H_{12}O_{24}P_6Ba_3$, [was] obtained as minute bundles or globules of microscopic needles from dilute hydrochloric acid solutions by the addition of alcohol, and heptabarium inosit hexaphosphate ($C_6H_{12}O_{24}P_6$) $_2Ba_7$, or $C_{12}H_{22}O_{48}P_{12}Ba_7$, which separated from dilute hydrochloric acid solutions in the presence of barium chlorid in globular masses of needle-shaped crystals. The free acid prepared from the crystalline barium salts agrees more closely in composition with inosit hexaphosphate, $C_6H_{12}O_{24}P_6$, than with the usual formula for phytic acid, $C_6H_{24}O_{27}P_6$. . .

"The spontaneous decomposition products of phytic acid under ordinary conditions which are formed within a reasonable length of time appear to be phosphoric acid and substances which contain more carbon and less phosphorus than phytic acid, which substances are probably penta-, tetra-, etc., phosphoric acid esters of inosit. When phytic acid is dried at a temperature of $105^\circ C.$, under reduced pressure, it rapidly decomposes with liberation of inorganic phosphoric acid and the formation of various decomposition products, consisting of inosit and substances varying in composition from inosit tetraphosphate to inosit monophosphate. When the crystalline barium salts are dried at 105° under reduced pressure they suffer but slight hydrolysis. Under ordinary conditions the dry salts are comparatively stable but on longer keeping small quantities of inorganic phosphoric acid are liberated."

The glycerotriphosphoric acid of Contardi, P. CARRÉ (*Bul. Soc. Chim. France*, 4. ser., 13 (1913), No. 2, pp. 66-69).—The theory of Contardi that one molecule of glycerol reacts with three molecules of phosphoric acid to form quantitatively one molecule of $C_3H_5(H_2PO_4)_3$ is deemed incorrect. The products are said to be $C_3H_5OH(H_2PO_4)_3$, $C_3H_5(OH)_2(H_2PO_4)_2$, and a di-ester of the type $C_3H_5(OH)HPO_4$.

Preparation, composition, and properties of caseinates of magnesium, L. L. VAN SLYKE and O. B. WINTER (*New York State Sta. Tech. Bul.* 33 (1914), pp. 3-7).—Continuing previous work by the senior author and Bosworth (*E. S. R.*, 29, p. 9) a study was made of the compounds formed by casein with magnesium.

"In preparing magnesium caseinates, the solution of casein in magnesium hydroxid was effected by suspending pure casein in water with an excess of finely-divided magnesium oxid, allowing the mixture to stand several days with occasional agitation.

"The magnesium hydroxid solution of casein [was] made neutral to phenolphthalein with HCl and the solution dialyzed and evaporated to dryness. The preparation contained 1.06 per cent Mg (1.76 MgO), the theoretical composition being 1.09 per cent Mg (1.81 MgO); or 1 gm. of casein combined with 8.7×10^{-4} gm. equivalents of Mg (theoretical, 9×10^{-4}). The compound [was] easily soluble in water and in a 5 per cent solution of NaCl.

"The magnesium hydroxid solution [was] made neutral to litmus with HCl and the solution dialyzed and the caseinate precipitated with alcohol. The preparation contained 0.71 per cent Mg (1.18 MgO), the theoretical composition being 0.67 per cent Mg (1.12 MgO); or 1 gm. of casein combined with 5.8×10^{-4} gm. equivalents of Mg (theoretical, 5.6×10^{-4}). The compound is easily soluble in water and in a 5 per cent solution of NaCl.

"A solution of base-free casein in magnesium hydroxid was treated with HCl just to the first point of precipitation and then dialyzed. Alternate addition of acid and dialysis [were] repeated, until finally the dialyzed solution formed a permanent precipitate on the addition of any acid. To this solution [was] added one-third of the amount of acid required for complete precipitation of the casein, the solution filtered and dialyzed and divided into two portions. One

portion [was] used for the preparation of monomagnesium caseinate by incomplete precipitation with HCl. The preparation contained 0.13 per cent Mg (0.22 MgO), which is the theoretical composition; or 1 gm. of casein combined with 1.1×10^{-4} gm. equivalents of Mg. This compound [was] insoluble in water but soluble in 5 per cent solution of NaCl; at 65° C. it tended to form strings when drawn out.

“To the second portion of the solution mentioned in the preceding paragraph acid-free alcohol [was] added and a precipitate obtained which contained 0.24 per cent Mg (0.4 MgO), the theoretical composition of di-magnesium caseinate being 0.26 per cent Mg (0.44 MgO); or 1 gm. of casein combined with 2.1×10^{-4} gm. equivalent of Mg (theoretical 2.25×10^{-4}). The compound is quite easily soluble in water and in a 5 per cent solution of NaCl; at 65° it is slightly sticky.

“These four magnesium caseinates correspond to the four calcium caseinates which have been previously prepared, representing octo-, penta-, di-, and mono-caseinates of magnesium.”

Why sodium citrate prevents curdling of milk by rennin, A. W. BOSWORTH and L. L. VAN SLYKE (*New York State Sta. Tech. Bul. 34* (1914), pp. 3-9; *Amer. Jour. Diseases Children*, 7 (1914), No. 4, pp. 298-304).—The practice of adding sodium citrate to cow's milk in the process of modifying it for infant feeding purposes has been common for many years. Its use is especially valuable for those children where cow's milk forms exceedingly large lumps of tough curd after entering the stomach. These lumps of curd can pass practically unchanged through the entire course of the intestinal canal and do, by either mechanical or other means, cause serious interference with the process of digestion. The favorable results attending the use of sodium citrate in preventing the formation of these curds, however, have never been explained on the basis of actual investigation.

It is pointed out as a result of these studies that the addition of sodium citrate to normal milk renders some of the insoluble calcium present soluble. This increase in soluble calcium is due to a reaction between calcium caseinate and sodium citrate by which is formed sodium caseinate (or calcium-sodium caseinate) and calcium citrate. This reaction is also reversible.

“The curdling of milk by rennin is delayed by the presence of sodium citrate; when there is added 0.4 gm. of sodium citrate per 100 cc. of milk (equal to 1.7 gm. per ounce), no curdling takes place. The curd produced by rennin in the presence of small amounts of sodium citrate (0.05 to 0.35 gm. per 100 cc. or 0.2 to 1.5 grains per ounce) increases in softness of consistency as the amount of sodium citrate in the milk increases.

“The results of our work indicate that at the point at which rennin fails to curdle milk we have in place of the calcium caseinate of normal milk a double salt, calcium-sodium caseinate; this double salt, when rennin is added, is changed to a calcium-sodium paracaseinate which, owing to the presence of the sodium, is not curdled. The practice of adding sodium citrate to milk at the rate of 1 to 2 grains of citrate per ounce of milk appears to have a satisfactory chemical basis in the reaction between the sodium citrate and the calcium caseinate of the milk. The amount added is governed by the object in view, viz, whether it is desired to prevent curdling or only modify the character of the curd in respect to softness.”

See also a previous note (E. S. R., 29, p. 805).

Studies on enzym action.—VIII, A continuation of the study of the action of amino acids and castor bean lipase on esters, M. L. HAMLIN (*Jour. Amer. Chem. Soc.*, 35 (1913), No. 12, pp. 1897-1904).—Continuing work previously

noted (E. S. R., 30, p. 806), the selective lipolytic actions of glycine, alanine, phenylalanine, and castor bean lipase on methyl, ethyl, glyceryl tri- and phenyl acetates, ethyl butyrate, and ethyl and phenyl benzoates have been compared, and that of castor bean lipase on castor oil and olive oil has been measured.

It is shown that the selective lipolytic action of glycine on methyl acetate and ethyl butyrate is more marked in the presence of certain concentrations of hydrochloric acid. This selective action was measured. With the glycine-hydrochloric acid solution used, the hydrolysis of methyl acetate and ethyl butyrate was not proportional to the hydrogen ion concentrations of the solution, and the disproportionality, which was measured, was comparatively large.

Studies on enzym action.—IX, Extraction experiments with the castor bean lipase, K. G. FALK (*Jour. Amer. Chem. Soc.*, 35 (1913), No. 12, pp. 1904–1915).—"The result of extraction experiments in which the lipolytic activities of the filtrates and residues of a castor bean preparation after treatment with water, 0.1 molar sodium fluorid, molar sodium chlorid, and molar methyl alcohol solutions, were tested toward ethyl butyrate and triacetin, confirmed the conclusion given in the fifth and sixth papers [E. S. R., 20, pp. 409, 806] that the inhibiting actions of these solutions on the lipase were due to precipitating or coagulating actions.

"Two lipases were shown to be present in the preparation. One of these was soluble in water, the other insoluble. The former exerted a comparatively greater action toward ethyl butyrate than toward triacetin, the latter a greater toward triacetin than toward ethyl butyrate.

"Extraction experiments with solutions of magnesium and manganous sulphates which showed acceleration with unfiltered preparations indicated that the accelerations were due mainly to the action of the salts on the residues. Filtration also appeared to decrease the accelerating actions of these salts."

Quantitative investigation with reference to the action of monochromatic ultraviolet rays upon amylase, A. and MME. CHAUCHARD (*Compt. Rend. Acad. Sci. [Paris]*, 156 (1913), No. 24, pp. 1858–1860; *abs. in Chem. Ztg.*, 37 (1913), No. 103, p. 1036).—The photochemical action of ultraviolet rays upon amylase is proportional to the absorption of these rays by the solution in which the ferment is held. A portion of the radiant energy in the experiments was capable of raising the temperature of the solution 0.25° C. and decomposed four-tenths of the enzym present.

The influence of salicylic acid upon the amylolytic action of aqueous extracts of malt, E. HEUSCH (*Arch. Farmacol. Sper. e Sci. Aff.*, 13 (1912), No. 7, pp. 307–323, fig. 1; *abs. in Zentbl. Biochem. u. Biophys.*, 14 (1912), No. 7–8, p. 297).—Acids play an important part in the hydrolysis of starch to maltose because when present in small amounts they increase the activity of maltase, while large quantities inhibit the activity. Salicylic acid is the most prominent in this regard, because of the presence of a phenol radical in the molecule.

About the biolytic cleavage of gluten, V. S. SADIKOVA (*Zhur. Russ. Fiz. Khim. Obshch., Chast Khim.*, 44 (1912), No. 5, pt. 1, pp. 1026–1053; *abs. in Chem. Ztg.*, 37 (1913), No. 47, *Repert.*, p. 220).—*Proteus vulgaris* and *Penicillium glaucum*, when acting upon gluten, produce more volatile acids and bases than do either acids or enzymes. The experiments also show that *P. vulgaris* and *P. glaucum* assimilate atmospheric nitrogen when grown on a gelatin plate.

Measurement of tryptic protein hydrolysis by determination of the tyrosin liberated, S. J. M. AULD and T. D. MOSSCROP (*Jour. Chem. Soc. [London]*, 103 (1913), No. 604, pp. 281–284; *abs. in Analyst*, 38 (1913), No. 445, p. 153).—The method is a modification of that described by Brown, Millar, and others, which consists of the estimation of the absorption of bromine by the tyrosin liberated.

Instead of determining the end point of the reaction by noting the yellow color or using starch and iodid of potash, it is advisable to employ methyl violet or gentian violet in a 1 per cent solution in 70 per cent alcohol.

"About 10 drops of this solution is added to 10 cc. of 5 per cent hydrochloric acid and dotted over a white tile. The addition of sodium bromate or traces of free bromin causes a change from olive green (the color of the dyestuffs in acid solution) to a deep bluish-violet. The change is sharp, but the color fades after a few minutes. Dibromotyrosin only is apparently formed and the absorption at first is very rapid, but falls off considerably toward the end of the reaction, as experiments cited show. The solution to be titrated is made of not more than 5 per cent acidity with hydrochloric acid; a lower concentration than 2 per cent turns the indicator blue, while more than 5 per cent turns it yellow. To the acid solution is added 15 to 20 cc. of 20 per cent sodium bromid, and the liquid is then titrated with twentieth-normal sodium bromate. Toward the end of the reaction at least 30 seconds should elapse between successive additions of the bromate, and the solution should be well shaken in a stoppered bottle.

"Results quoted show a plus error varying from 0.4 to 2.3 per cent. In two of the test liquids there were present, in addition to tyrosin, leucin, asparagin, and ammonium chlorid. Experiments carried out with edestin digested in dilute sodium carbonate solution with trypsin, and corrected for the bromin absorbed by the protein, confirmed Brown and Millar's contention that the method can be used for determining tyrosin in presence of proteins and other early cleavage products, and also that practically all the tyrosin is liberated in the first stages of tryptic digestion."

Accuracy of the estimation of l-tyrosin in proteins, E. ABDERHALDEN and D. FUCHS (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 83 (1913), No. 6, pp. 468-473; *abs. in Analyst*, 38 (1913), No. 446, pp. 219, 220).—The Folin and Denis colorimetric method for determining tyrosin (*E. S. R.*, 28, p. 805) in proteins is said to yield high results because similar colors are produced by oxytryptophan and tryptophan.

The authors observed, as did Folin and Denis, that the separation of tyrosin by simple crystallization is very difficult. "The cause of this has been traced in certain cases to absorption of acid or ammonia fumes from the atmosphere during evaporation in open basins. Much better results are obtained if the evaporation be conducted under reduced pressure. A more interesting reason for quite considerable quantities of tyrosin failing to crystallize is the formation of salt-like compounds with the basic constituents of proteins, such as the compound of tyrosin with lysin observed by Fischer and Abderhalden. In view of this experience, tests were made to determine whether it is possible to recover quantitatively tyrosin added to gelatin. Tyrosin-free gelatin was dissolved in five times its weight of 25 per cent sulphuric acid, a known quantity of tyrosin added, and boiled for 20 hours. Baryta was then added to remove the sulphuric acid, and the barium sulphate extracted with boiling water until the extract no longer gave a violet color with a 1 per cent aqueous solution of triketohydrindene hydrate (ninhydrin). This reagent proved much more delicate than Millon's reagent. By concentrating the combined filtrates at 45° C., it was possible to recover as much as 90 per cent of the added tyrosin. In certain cases, however, the yield amounted to only 60 to 70 per cent.

"It was found possible to recover the tyrosin almost quantitatively by the following method: The liquid after hydrolysis was diluted until it contained 2.5 per cent sulphuric acid. A 10 per cent solution of phosphotungstic acid was then added with constant stirring, great care being taken to avoid the addition of any excess. The precipitate was filtered off and washed, and the filtrate treated with baryta to remove phosphotungstic acid and filtered. To this filtrate

the exact amount of sulphuric acid needed to remove the excess of baryta was added and the barium sulphate extracted with boiling water until no coloration was given by ninhydrin [E. S. R., 26, p. 804]. The filtrate was then concentrated at 40° C. under reduced pressure until the mother liquor gave no reaction with Millon's reagent. The crude tyrosin which separated was purified by boiling with animal charcoal and fractional crystallization from water until a sample on analysis yielded figures agreeing with pure tyrosin."

Formol-titrametric investigations with proteins, II, F. OBERMAYER and R. WILLHEIM (*Biochem. Ztschr.*, 50 (1913), No. 5-6, pp. 369-385).—Continuing work previously noted (E. S. R., 27, p. 501), the authors emphasize the fact that with the formaldehyde titration method the terminal amino groups of proteins can be determined. The quotient obtained by dividing the total nitrogen by the number of such amino groups, and which shows how much nitrogen belongs to each amino group, is termed the amino index.

The index of euglobulin (average 21.5) is much greater than albumin (average 12). In the Mammalia this also applies to pseudoglobulin, whereas in the hen the index of pseudoglobulins (average about 15) is not so sharply differentiated from albumin.

With the procedure it can be shown that the large protein fractions do not consist of unit substances; thus with pseudoglobulin, by salting out with 44 per cent of ammonium sulphate and albumin with a 66 per cent ammonium sulphate solution, it is possible to obtain two fractions which differ very much in their amino indexes.

This work, according to the authors, for the first time shows that a constitutional difference exists between two different serum proteins. In the case of the hen the amino indexes of the fractions obtained with a 25 per cent ammonium sulphate solution and those given by a 30 per cent ammonium sulphate solution (average 32.5 and 28.5, respectively) were much higher than those given by the serum proteins of the bovine (average 19 and 21.5, respectively). Those of the horse were found to behave in exactly the same manner as in the bovine, and those in the goose like those in the hen.

Detection of saponin, L. ROSENTHALER and H. SCHELLHAAS (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 25 (1913), No. 3, pp. 154-158).—Instead of determining the presence of saponin by noting the hemolytic power, the authors recommend hydrolyzing this glucosid and testing for the cleavage products. This allows of the detection of nonhemolytic regenerated saponin. The method is as follows:

To the solution under examination add 2.5 cc. of hydrochloric acid, filter if a precipitate ensues, and evaporate the filtrate on a water bath until the solution ceases to foam. This indicates that the hydrolysis is complete. Then cool somewhat and shake the still warm solution with acetic ether, taking 50 cc. of acetic ether for each 100 cc. of aqueous extract. Wash the clear acetic acid solution with water until no reaction is obtained with silver nitrate, and evaporate to dryness. If the extract is highly colored, it can be decolorized before evaporation with animal charcoal.

The extract is used for two tests: (1) For prosapogenin with sulphuric acid. This gives an orange red coloration which slowly goes over to a cherry red and finally becomes violet. When small amounts are present this change in colors may take several hours. (2) To see if foaming takes place a little of the extract is dissolved in a small amount of sodium carbonate solution.

Beer can be tested by a modified form of the above procedure.

The determination of the acetyl number [of oils, fats, etc.], E. B. HOLLAND (*Massachusetts Sta. Bul.* 151 (1914), pp. 69-78; *Jour. Indus. and Engin. Chem.*, 6 (1914), No. 6, pp. 482-486).—After reviewing existing methods for determining

the acetyl number of fats, it is pointed out that the acetyl number of a fat and of the insoluble acids affords valuable information relative to the nature and the quality of the product under examination, and a short and simple volumetric method is proposed which is free of many of the objectionable features of the Benedikt and Ulzer and Lewkowitsch methods.

"The development of the method extended over a period of several years and finally resolved into an adaptation of several well-known processes. Ceresin is used to solidify the acetylated fat so that it may be washed by decantation as in the determination of insoluble acids. The saponification number of the acetylated fat is determined by the same process as that of the original fat and the difference measures the amount of acetyl that has been assimilated."

A gravimetric method similar to the one described by Lewkowitsch is also given, but it is stated that it has not received sufficient study to warrant the drawing of definite conclusions.

The acetyl number in this work is defined as the number of milligrams of potassium hydroxid required for the saponification of the acetyl assimilated by one gm. of an oil, fat, or wax on acetylation. The prevalent custom of reporting the acetyl number on the basis of the acetylated product seems to be without foundation.

The estimation of citric acid in the presence of certain other acids, L. GOWING-SCOPES (*Analyst*, 38 (1913), No. 442, pp. 12-19, fig. 1; *abs. in Chem. Ztg.*, 37 (1913), No. 47, p. 480).—The Beau modification of Denigès' method was studied and found unsatisfactory. Instead, a reagent composed of a mixture of mercuric nitrate, manganese nitrate, and nitric acid is recommended. The results obtained by the new method showed a maximum error of only +0.0003 and -0.0004 per cent. The presence of malic and lactic acids influences the results, but tartaric and succinic acids do not.

The use of sodium citrate for the determination of reverted phosphoric acid, A. W. BOSWORTH (*New York State Sta. Tech. Bul.* 34 (1914), pp. 10-12; *Jour. Indus. and Engin. Chem.*, 6 (1914), No. 3, pp. 227, 228).—Previously noted from another source (E. S. R., 29, p. 795).

A new method for determining nicotin in the presence of ammonia, R. SPALLINO (*Gaz. Chim. Ital.*, 43 (1913), II, No. 4, pp. 493-500).—This method is based on the fact that nicotin behaves toward picric acid as a diacid base in aqueous solutions and as a monoacid base in alcoholic solutions.

The method is as follows: From 1.5 to 3.5 gm. of tobacco is mixed with milk of magnesia and distilled with steam. The vapors are then collected in from 50 to 100 cc. of an aqueous solution of picric acid. After from 600 to 700 cc. of distillate is obtained it is diluted with 1 liter of alcohol and divided into two portions, which are separately evaporated to dryness. The residue from one of the portions is dissolved in alcohol and titrated with half-normal barium hydroxid solution against lacmoid. The other residue is then treated with water, made up to 100 cc. with water, filtered, and 75 cc. of the filtrate titrated with half-normal barium hydroxid. The difference between the titration of the alcoholic and aqueous residue solutions, when multiplied by 0.0081, gives the amount of nicotin present in grams.

Estimation of nicotin in the form of silicotungstate, R. SPALLINO (*Gaz. Chim. Ital.*, 43 (1913), II, No. 4, pp. 482-486).—The author states that the gravimetric determination of nicotin as silicotungstate gives good results if the factor 0.1139 is used for calculating the nicotin content. If the procedure of drying, as suggested by Chapin (E. S. R., 25, p. 16), is followed, the results are discordant.

About the occurrence of nicotinic acid (m-pyridin carbonic acid) in rice bran, U. SUZUKI and S. MATSUNAGA (*Jour. Col. Agr. Imp. Univ. Tokyo*, 5

(1912), No. 1, pp. 59-61; *abs. in Zentbl. Biochem. u. Biophys.*, 14 (1913), No. 22, p. 827).—This deals with the preparation of nicotinic acid from fat-free bran. About 1 gm. of acid per kilogram of bran was obtained.

Presence of barium and arsenic in tobacco, R. SPALLINO (*Gaz. Chim. Ital.*, 43 (1913), II, No. 4, pp. 475-481).—The amount of barium in 3 samples of snuff and 3 samples of smoking tobacco dried at 100° C. varied between 0.019 and 0.036 per cent, calculated as barium sulphate. In 4 samples of smoking tobacco and 3 of snuff the arsenic ranged from 0.08 to 1.02 mg. per 100 gm. of dry substance. It is suggested that in purchasing tobacco its arsenic content may well be considered, since arsenicals are used extensively, especially in the United States, for spraying tobacco.

Effects of varying certain cooking conditions in producing soda pulp from aspen, H. E. SURFACE (*U. S. Dept. Agr. Bul. 80* (1914), pp. 63, pls. 9, figs. 20).—“Although the soda process of wood-pulp manufacture is not employed commercially to so great an extent in America as the sulphite and mechanical processes, it is remarkably well adapted for producing pulp fibers from any kind of wood or other fibrous vegetable material, no matter how resistant to chemical attack it may be. For this reason it is much used in the experimental work of the Forest Service. . . .

“It was to secure and make available detailed information which would both facilitate other experimental work in the laboratory and promote the efficiency of commercial plants employing the soda process that the series of tests discussed in this bulletin was undertaken. They were carried out at the Forest Products Laboratory maintained by the Forest Service at Madison, Wis., in cooperation with the University of Wisconsin.

“The report of the experimental work is prefaced by a short description of the soda process and a review of previous investigations. Some general comments on aspen as a raw material for soda pulp and on the pulp itself are found in the appendix. This species of poplar was selected as the test material because it is the most important soda pulpwood. The information secured, however, is of much value also in connection with the cooking of other woods.”

The practical results obtained, which are described and discussed, “show in detail the effect of certain cooking conditions on the yields and properties of the resultant pulp, on the efficiency of the cooking chemicals, and on various items affecting costs of production. From a study of these results it should be possible for a mill operator so to regulate the cooking process as to secure the largest possible yield of pulp of the desired quality at a minimum cost for chemicals, fuel, labor, and overhead charges in so far as the operation is affected by the cooking conditions considered.

“The clear, sound wood used in the experiments afforded yields of good pulp from 10 to 25 per cent higher than the better run of the yields reported by pulp mills. Moreover, some of these experimental yields were obtained with shorter cooking periods and less chemicals than are employed commercially. Although the laboratory results may not be equaled in mill practice, the possibility of greatly increased efficiency in the process of converting wood into soda pulp is indicated.”

A bibliography is appended.

METEOROLOGY—WATER.

International catalogue of scientific literature. F—Meteorology (*Internat. Cat. Sci. Lit.*, 11 (1914), pp. VIII+245).—“The literature indexed is mainly that of 1911, but includes those portions of the literature of 1901-1910 in regard

to which the index slips were received by the Central Bureau too late for inclusion in the previous volumes. There are also entries dated 1912."

Weather and water, M. HOFFMANN (*Jahresber. Landw.*, 28 (1913), pp. 1-20).—Recent investigations on these subjects are classified and reviewed as usual.

Influence of forest cover upon local climate (*Quart. Jour. Roy. Met. Soc. [London]*, 40 (1914), No. 170, pp. 166-168).—This is a brief review of a paper by G. A. Pearson previously referred to (*E. S. R.*, 30, p. 417).

Influence of forest cover upon local climate, T. H. MORGAN (*Quart. Jour. Roy. Met. Soc. [London]*, 40 (1914), No. 171, p. 228).—This is a brief note on the paper referred to above, calling attention especially to electrical differences that may be set up in passing from open land to forest.

The relation of forests in the Atlantic plain to the humidity of the Central States and prairie region, R. ZON (*Proc. Soc. Amer. Foresters*, 8 (1913), No. 2, pp. 139-153, pls. 2).—The author bases his conclusion that there is "a relation between the forests of the coastal plain and the southern Appalachians, on the one hand, and the humidity of the Central States and prairie region, on the other," on three fundamental considerations presents data upon these, as follows:

"(1) In the eastern half of the United States there is a marked periodicity in the wind direction. In winter the prevailing winds are from the north and northwest; in summer they are from the south. When the prevailing winds come from the south the entire eastern half of the United States is wet. When the prevailing winds are from the northwest and west the precipitation decreases. Therefore, the precipitation of the eastern half of the United States depends largely upon the prevailing southerly winds which come from the Gulf and penetrate far into the interior of the continent.

"(2) The evaporation from the ocean plays a comparatively unimportant part in the precipitation over the land; seven-ninths of the precipitation over land is supplied by evaporation over the land itself, and only two-ninths is furnished by the evaporation from the ocean. Therefore, the greater the evaporation from the land which is in the path of the prevailing southerly winds, the more moisture must be carried by them into the interior of the continent.

"(3) The forest evaporates more water than any vegetative cover and much more than free water surfaces. Therefore, forests enrich with moisture the winds that pass over them, and contribute to the humidity of the regions into which the prevailing air currents pass."

Restraining effect of forests on sudden melting of snow, J. E. CHURCH, JR. (*Engin. Rec.*, 69 (1914), No. 24, p. 674).—Measurements are referred to which indicated that the protection of snow against rain and sun is directly proportionate to the density of the forest growth, and that the melting of snow is most rapid in open areas.

A method of estimating rainfall by the growth of trees, A. E. DOUGLASS (*Bul. Amer. Geogr. Soc.*, 46 (1914), No. 5, pp. 321-335, figs. 5).—The results of studies of the rings of yellow pine trees near Flagstaff, Ariz., are correlated with past meteorological conditions, especially rainfall. The curves for the period of known rainfall show a close correlation with that for the tree growth. A certain correlation between tree growth, as shown by the rings, and climatic cycles is also indicated.

Distribution of drought, F. EREDIA (*Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, pp. 325-329).—Following the suggestion of Broounoff that a knowledge of the distribution of the rainfall of a given region during 10-day periods may be used to advantage in adapting crops

to meteorological conditions, especially with reference to the critical periods of growth, the author gives calculations for Sicily of the frequency of 10-day periods of rainfall between 0.1 and 5 mm. and of 10-day periods without rain, and discusses the bearing of these data upon rain distribution and plant growth in Sicily. He is of the opinion that in a region like Sicily, which has distinct rainy and dry seasons, it is more important to know the occurrence of the rainy periods than the dry periods.

"An examination of the 10-day periods with a total rainfall of 5 mm. (0.2 in.) shows that different values must be attached to them, according to the time of the year at which they occur; that is to say, during periods of regular rainfall a 10-day period with a total of 5 mm. is really a dry period comparable to one having no influence on vegetation, while, on the other hand, if it occurred in a period of extreme dryness, e. g., during the summer months in Sicily, such a period could exercise considerable influence. It would appear, therefore, that the rainfall measurements would be more profitable if the probability of the period with low rainfall greater than 5 mm. were known, and also those of absolute drought."

Is the earth drying up? (*Quart. Jour. Roy. Met. Soc.* [London], 40 (1914), No. 170, pp. 165, 166).—This is a brief discussion of a paper by J. W. Gregory already noted (*E. S. R.*, 30, p. 815), emphasizing especially the conflicting evidence and views upon this subject.

A study of the changes in the distribution of temperature in Europe and North America during the years 1900 to 1909, H. ARCTOWSKI (*Ann. N. Y. Acad. Sci.*, 24 (1914), pp. 39–113, figs. 61).—Following the procedure adopted in a previous paper dealing with temperature data for 1891 to 1900 (*E. S. R.*, 23, p. 712) and considering the means for that decade as quasi-normal values, the author calculates for each year from 1900 to 1909 and for each station the departures from these means. Curves are presented showing these annual departures, the positive departures being designated thermopleions, the negative departures antipleions.

These curves show that the year 1900 was one of predominant thermopleions while in 1893 the antipleions strongly predominated. It is estimated that the difference in temperature between these two years must have been at least 0.5° C.

For the purpose of making the necessary comparisons the temperature curve of the exceptionally undisturbed climate of Arequipa, Peru, for the years 1900 to 1910 was taken as the standard. This curve shows four characteristic crests and four depressions for the period named.

The paper presents data to show "that in far distant regions of the globe, simultaneously with the appearance of the Arequipa crests pleions are formed; that these pleions have a tendency to persist; that, in order to persist, one must displace another. Pleions and antipleions are correlated; if one moves, the other moves. In North America the displacements seem to be confined to the North American Continent. In consequence, the pleions must pendulate from one side to the other. Moreover, the differences between the pleionian crests and the antipleionian depressions of temperature change. These changes of amplitude seem to be in immediate correlation with the equatorial changes of temperature. . . .

"The existence of macropleionian variations, the close correlation of the pleionian phenomenon with the Arequipa variation, the compensating antipleions, and, finally, the dynamic character of these climatic changes, eliminate . . . the hypothesis attributing such changes exclusively to the presence of variable quantities of volcanic dust in the higher layers of our atmosphere.

"Variations of the solar radiation must be the real and most important cause producing the changes of our climates and keeping them in a dynamic state."

The climate of Duluth, Minnesota, H. W. RICHARDSON (*Duluth, 1914, pp. 47, figs. 14*).—This publication, compiled by the local forecaster of the U. S. Weather Bureau, presents briefly the principal facts concerning the climate in the vicinity of Duluth and discusses the relation of the climate to the agricultural possibilities of the region.

A summary of meteorological records, J. E. OSTRANDER (*Massachusetts Sta. Bul. 153 (1914), pp. 117-146*).—In addition to summaries of observations on pressure, temperature, precipitation, humidity, cloudiness, wind, and casual phenomena made at the Massachusetts Station during the period from 1889-1913, inclusive, this bulletin includes records of such available and apparently reliable precipitation and temperature records as were made in Amherst previous to 1889, viz, those made by the late Prof. E. S. Snell of Amherst College and his daughters (1836-1883) and those made at the state experiment station under the direction of Dr. C. A. Goessmann (1883-1888).

The summary for the 25 years (1889-1913) shows that the maximum pressure reduced to freezing and sea level was 30.65 in. February 26, 1889; the minimum 28.24 in. February 8, 1895; the mean 30.012. The highest temperature recorded was 104° F. July 4, 1911; the lowest -26° January 5, 1904; the mean 47.5°. The mean dew-point was 39; the mean relative humidity 74.6. The greatest annual precipitation was 57.05 in. in 1897; the lowest 30.63 in. in 1908; the mean 43.76 in. Using all of the available data for temperature (1837-1913) and precipitation (1836-1913) it was found that the mean temperature was 46.9° F.; the mean annual precipitation, 44.17 in.

Meteorological observations at the Massachusetts Agricultural Experiment Station, J. E. OSTRANDER and R. E. McLAIN (*Massachusetts Sta. Met. Buls. 307, 308 (1914), pp. 4 each*).—Summaries of observations at Amherst, Mass., on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during July and August, 1914, are presented. The data are briefly discussed in general notes on the weather of each month.

Weather report, W. H. DAY (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 39 (1913), pp. 64-70*).—Observations on temperature and precipitation and on the length of the growing season at Guelph and at fourteen other places in Ontario during 1913 are summarized. A wind record for Guelph is also given.

Notes on the water of cranberry bogs, F. W. MORSE (*Massachusetts Sta. Bul. 150, pp. 62-68*).—Studies of the composition of ditch water and seepage water from small experimental bogs previously described were continued. (E. S. R., 28, p. 324).

It is estimated that the seepage water of the experimental bogs in 1913 contained more than 21 lbs. of nitrogen, 10 lbs. of phosphoric acid, and 50 lbs. of potash per acre. There appeared to be no direct relation between varying applications of fertilizers the previous year and the composition of the drainage water. There was, however, found to be a direct relation between free circulation of water and drainage and vine growth.

Bacillus coli in water supply, J. RACE (*Municipal Engin., 47 (1914), No. 1, pp. 12-14, figs. 3*).—The author gives a warning against the present tendency to minimize the value of the indication given by the presence of the *Bacillus coli communis* in water supplies. He emphasizes the fact that the presence of that organism in a sample of water, although not certain evidence that it is dangerously polluted, is a definite warning, which can not be safely ignored, that the water is polluted and that the source of the pollution must be determined and kept under close observation at all times to insure that it does not become dangerous.

SOILS—FERTILIZERS.

Soil management, F. H. KING (*New York and London, 1914, pp. XII+311, pls. 17, figs. 8*).—For many years before his death Prof. King had been assembling material for the preparation of a book on soil management. In this volume his widow, Mrs. C. B. King, "has brought together such of his papers and lectures as contain materials that he would have worked into an organized form."

An introductory chapter discussing the influence of good and bad management of soils on their productive capacity and emphasizing the value of scientific soil management is followed by a chapter explaining the principles governing the productive capacity of fields. In these sections the factors making for fertility are considered, and emphasis placed on the importance of soil composition and structure and moisture regulation. Separate chapters deal with the functions, availability, and conservation of soil moisture in crop production, soil moisture and plant feeding, and the principles and practice of earth mulches. Keeping in mind the importance of the conservation of soil moisture the author discusses the relations of optimum soil moisture capacity and soil texture, and points out the value of the use, where practicable, of straw, grass, litter, and earth mulches in particular for the conservation of soil moisture.

A further chapter explaining the beneficial effects of lime in soils is followed by a discussion of the physical features of soils which influence their ability to feed crops. Other chapters deal somewhat at length with the functions, conservation, and application of water in crop production and reclamation of swamp lands. A final chapter dealing with agricultural conditions in China, Korea, and Japan describes the methods of tillage, fertilization, and crop rotation practiced in those countries.

Guide to the scientific study of soils, F. WAHNSCHAFFE and F. SCHUCHT (*Anleitung zur wissenschaftlichen Bodenuntersuchung. Berlin, 1914, 3. rev. ed., pp. VIII+216, figs. 57*).—This is the third revised edition of this work (E. S. R., 15, p. 659), in which the authors have endeavored to incorporate more recent developments in methods of soil investigation.

Types of soil formation, their classification and geological distribution, K. GLINKA (*Die Typen der Bodenbildung, ihre Klassifikation und geographische Verbreitung. Berlin, 1914, pp. 365, pl. 1, figs. 65*).—In this volume, translated from the Russian, the author describes field and laboratory methods of soil investigation, and discusses especially the observations and conclusions of Russian investigators regarding the problems of soil genesis and the geography and physical and chemical properties of soil types and varieties, more particularly those encountered in European, Asiatic, and mountainous Russia. He discusses the objects and results of soil study, and considers the influence of climate on the origin of soil types to be of basic importance.

Several methods of soil type classification according to mechanical, physical, and chemical properties, geographical distribution, etc., are described, and the author finally divides the types and their variations into two classes which are formed either by external or internal forces, viz, ectodynamorphic and endodynamorphic soils.

Quantitative mineralogical analysis of sandy soil, A. VENDL (*Földtani Közlemény, 43 (1913), No. 7-9, pp. 331-343; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, p. 337*).—The use of a combination of microscopic and chemical analysis on a special type of sandy soil is described.

The inorganic composition of some important American soils, W. O. ROBINSON (*U. S. Dept. Agr. Bul. 122 (1914), pp. 27*).—This bulletin reports chemical and mineralogical investigations of certain important types of soils.

Chromium, vanadium, rare earths, zirconium, barium, strontium, lithium, and rubidium were present in all the soils examined. Chromium ranged from a trace to 0.025 per cent; vanadium, from 0.01 per cent to 0.08 per cent; rare earths, from 0.01 per cent to 0.08 per cent; zirconium, from 0.003 per cent to 0.08 per cent; barium, from 0.004 per cent to 0.36 per cent; and strontium, from 0.01 per cent to 0.11 per cent. Lithium was found in spectroscopic traces only. Boron was indicated in 18 soils by the presence of tourmalin and fluorin in 24 soils by the presence of micas.

Molybdenum was found in the surface soils of only two types and caesium in only one soil. Neither the amounts nor even the presence of copper, nickel, and cobalt were established in the soils with certainty.

Silica, manganese, and phosphorus were found to concentrate in the surface soil, and aluminum, iron, potash, magnesium, and generally titanium, in the subsoil.

The sulphur content was low, ranging from 0.3 to 0.39 per cent of SO_2 , with an average of 0.13 per cent.

An abundance of potash minerals was found in the soil, the amount varying from 43 to 2,000 tons to the acre of soil to a depth of 3 feet.

The evidence that soils contain the more important rock-forming minerals is said to be strengthened by the mineralogical examinations.

A colluvial soil and its people, F. V. EMERSON (*Bul. Amer. Geogr. Soc.*, 46 (1914), No. 9, pp. 655-658, fig. 1).—An area in one of the Ozark counties of Missouri is described which consists of an old limestone plateau where the soil creep is said to cause accumulation of colluvial soils in a narrow belt near the foot of slopes. The colluvial soils vary from a clay loam to a silt loam and are said to be extremely important both because of their fertility and because of the scarcity of arable lands in the region. The possibility of increasing the area of very fertile soil by terracing is pointed out.

The occurrence of manganese in Kentucky soils and its possible significance, O. M. SHEDD (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 8, pp. 660-664).—An examination of a large number of Kentucky soils showed that in a large majority of the cases there was considerably less manganese in the cultivated soils than in corresponding virgin soils. In practically every case the surface soil contained more manganese than the subsoil. The majority of the soils contained considerably more manganese than phosphorus, but many samples contained much less, while the losses of manganese in the cultivated areas were usually greater than of phosphorus.

"There are large differences in the manganese content of the soils of the different geological areas and sometimes in those from the same area. The amounts found in the surface soils vary from 0.005 to 0.331 per cent, and in the subsoils from 0.002 to 0.264 per cent. As a rule, the better agricultural areas contain much larger amounts of manganese than the inferior areas."

Report of the state agricultural chemist, J. H. PHILLIPS (*Rpt. Dept. Agr. So. Aust.*, 1912-13, pp. 27-30).—Among a number of miscellaneous analyses are determinations of manganese in various soil samples, and of copper, lead, and arsenic in soil samples taken from under the drip area of fruit trees which have been sprayed for a number of years with various insecticides.

On osmosis in soils. The efficiency of the soil constituents as semipermeable membranes, C. J. LYNDE and H. A. DUPRÉ (*Proc. and Trans. Roy. Soc. Canada*, 3. ser., 7 (1913), Sect. III, pp. 105-117, figs. 4).—The investigations here reported have already been noted from another source (*E. S. R.*, 30, p. 23).

On a new method of measuring the capillary lift of soils, C. J. LYNDE and H. A. DUPRÉ (*Proc. and Trans. Roy. Soc. Canada*, 3. ser., 7 (1913), Sect. III, pp.

119-129, figs. 3).—The investigations here reported have already been noted from another source (E. S. R., 30, p. 22).

The theory of antagonism of salts and its significance in soil studies, C. B. LIPMAN (*Proc. Soc. Prom. Agr. Sci.*, 34 (1913), pp. 33-40).—A previous paper setting forth the same views has already been noted (E. S. R., 31, p. 317).

The deposits in drainpipes in drainage of swamp soil, B. TACKE (*Zentbl. Agr. Chem.*, 43 (1914), No. 5, pp. 308-311).—Investigations of the incrustations in drainpipes in swampy soil showed that the trouble was due mainly to fine sand and clay separations which penetrated the drain joints. The reddish-yellow color was due to iron oxid. Most of the incrustation was found at the joints. The trouble was best prevented by covering the joints with peat muck.

Some chemical and bacteriological effects of clearing grass land by burning, F. QUISUMBING and G. OCFEMIA (*Philippine Agr. and Forester*, 3 (1914), No. 4, pp. 76-78).—It is stated that grass lands in the Philippines are commonly cleared by burning, but experiments are referred to which show that this practice results in a large loss of nitrogen and humus in the surface soil. A study of the bacterial life of the soil showed that burning not only greatly reduced the number of organisms in it, but profoundly modified their character. The work did not go far enough to show whether this was an advantage or disadvantage.

Mobilization of the soil phosphoric acid under the influence of the life activity of bacteria, S. SEVERIN (*Věstník Bakt. Agron. Stantsii V. K. Ferreïn*, No. 18 (1911), pp. 156-246; *abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 13 (1912), No. 4, pp. 629, 630).—This is a detailed account of investigations more briefly reported elsewhere (E. S. R., 26, p. 817).

Enriching of soils in nitrogen in connection with the life activity of aerobic micro-organisms assimilating free nitrogen, A. V. KRAINSKIĬ (*Univ. Izv. [Kief]*, 52 (1912), Nos. 4, pt. 2, Art. 3, pp. 1-58; 8, pt. 2, Art. 3, pp. 59-131, figs. 7; 9, pt. 2, Art. 5, pp. 133-182, figs. 2; *abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 13 (1912), No. 4, pp. 625-629).—This elaborate report first reviews the literature, then describes the methods used by the author, and finally reports in detail the results of his investigations on the subject.

The biological nature of nitrogen fixation in soils was deduced from results of experiments with antiseptics (chloroform and thymol). The higher the humus content the larger the water content of the soil required for optimum nitrogen fixation. The mutual relations of different groups of organisms were affected by varying conditions of light. No nitrogen was fixed under strictly anaerobic conditions (in an atmosphere of nitrogen), although it occurred in a chernozem soil with high moisture content. There appeared to be a certain associative action of anaerobic and aerobic organisms.

Increasing the organic matter of the soil did not increase nitrogen fixation, but the organic matter was quickly decomposed. Nitrogen fixation was more active in naturally rich or well-fertilized soils than in poor soils. *Azotobacter* was shown to be capable of using carbohydrates, alcohol, and acids as sources of energy.

With an increase of aeration the amount of organic matter required to fix a unit of nitrogen diminished and the process of fixation was accelerated. In sand cultures the curve of respiration ran parallel with or lagged behind the curve of fixation. In water cultures it ran ahead. Ammonium sulphate depressed fixation of free nitrogen by *Azotobacter*. *Aspergillus niger* and *Penicillium glaucum* assimilated free nitrogen best in a 5 per cent sugar solution. The ratio of carbon consumed to free nitrogen assimilated was on the average about 10:1 in sand cultures. In soils with high contents of water

and organic matter it was much greater than this, while with soils with abundant aeration it was about the same as in sand cultures.

The influence of organic substances on nitrification and denitrification in cultivated soil, C. BARTHEL (*Meddel. Centralanst. Försöksv. Jordbruksområdet*, No. 83 (1913), pp. 36, fig. 1; *K. Landtbr. Akad. Handl. och Tidskr.*, 52 (1913), No. 8, pp. 599-632, fig. 1; *abs. in Zentbl. Agr. Chem.*, 43 (1914), No. 6, pp. 372, 373).—The author's experiments showed, in conformity with those of Winogradski and Omelianski (*E. S. R.*, 11, p. 711), that in the presence of easily soluble organic matter nitrification does not take place until the organic matter is completely mineralized. For example, a small amount of dextrose not only hindered nitrification to a marked extent but strongly promoted denitrification, and nitrification did not occur until the dextrose was completely mineralized. A very small amount (0.1 per cent) of dextrose, however, produced the opposite effect, due probably to stimulating action.

The danger from the harmful effect of organic matter upon nitrification is not considered as great as the investigations of Winogradski and Omelianski would indicate, because soluble organic substances seldom occur in soils in large amounts. The conditions, however, are different in the manure heap, and this accounts for the feebleness or failure of nitrification there.

The course of nitrification in fallow soil, B. VELBEL (*Khutorianin*, 1912, Nos. 10, pp. 12-18; 20, 22, 23, 24, pp. 26-28; *abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 13 (1912), No. 5, pp. 717, 718).—The experiments here reported indicated that the chief factor controlling nitrification in fallow soil was the humus and humus nitrogen content of the soil. Nitrification increased directly with the humus. The largest amount of nitrates observed in these experiments (2,137 lbs. per acre to a depth of 14 in.) was found at the beginning of August in a heavy clay chernozem containing from 8 to 10 per cent of humus in the surface soil. Nitrification was found to be greater in early fallow than in late. It was also increased by the cultivation of leguminous plants.

The first result of the application of manure was to produce a certain amount of denitrification, but later in the summer the nitrification was more rapid in manured soil than in unmanured soil, and the favorable effect of the manure was still noticeable after four years.

Green manuring experiment, 1912-13, C. M. HUTCHINSON and S. MILLIGAN (*Agr. Research Inst. Pusa Bul. 40 (1914)*, pp. 31, pl. 1, fig. 1).—Field and laboratory experiments to determine the best stage of growth and methods of turning under green manures, with a special study of the relation of various conditions of soil, rainfall, supplementary fertilization, bacterial activity, etc., to the character of decomposition which takes place, are reported. The experiments were confined to one plant, namely, *Crotalaria juncea*.

The results indicated that water was probably the controlling factor in the decomposition and nitrification of green manure in soil. It was found that three-eighths saturation of the soil was the optimum moisture content for nitrification of the green manure under the conditions prevailing in these experiments. The best results were obtained by turning under the plant while it was still green and succulent. With plants 4 weeks old 67 per cent of the nitrogen was nitrified, while with plants 10 weeks old only 34.5 per cent of the nitrogen was nitrified. The optimum depth of burying the green manure varied with the age of the plant and probably with the character of the soil and its subsequent treatment, but in general the more mature the plant the less the depth to which it should be plowed under in order to insure nitrification. The optimum moisture content, 16 per cent, for carbon dioxid formation was the same as that for nitrification of the green manure. The addition of superphosphate promoted the decomposition of the green manure.

How to improve our heavy clay soils, A. R. WHITSON, E. J. DELWICHE, and F. L. MUSBACK (*Wisconsin Sta. Bul. 202, rev. (1914), pp. 3-16, figs. 5*).—This is a revised edition of this bulletin (E. S. R., 25, p. 19).

Ways of improving our sandy soils, A. R. WHITSON, F. J. SIEVERS, and H. W. ULLSPERGER (*Wisconsin Sta. Bul. 204, rev. (1914), pp. 3-27, figs. 11*).—This is a revised edition of this bulletin (E. S. R., 25, p. 19).

Dry farming in Washington, C. C. THOM and H. F. HOLTZ (*Washington Sta. Popular Bul. 69 (1914), pp. 31, figs. 6*).—This is a popular bulletin for farmers and new settlers.

Soils, M. HOFFMANN (*Jahresber. Landw., 28 (1913), pp. 21-54*).—This is a classified review of recent reports of investigations on this subject.

Fertilizers and fertilizing, M. HOFFMANN (*Jahresber. Landw., 28 (1913), pp. 54-99*).—A classified review is given of recent reports of investigations.

Outline of the function and use of commercial fertilizers, E. O. FIPPIN (*New York Cornell Sta. Circ. 23 (1914), pp. 21-28*).—A brief popular discussion of the subject.

Fertilizers in Central America, J. E. VAN DER LAAT (*Los Abonos en Centro América. San Jose, Costa Rica, 1914, pp. 53, figs. 6*).—The need of fertilizers on tropical soils is emphasized, and information regarding the nature and use of fertilizers suited to the crops and soil of this region is given.

Fertilizer for south China, A. E. CARLETON (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 214, p. 1404*).—It is stated that the trade in fertilizers in China has not materially increased in recent years, but that the prospects favor an improvement in the future. The total value of manures and fertilizers of all kinds imported into China during 1913 was \$700,872. This included among other things various natural manures, bird guano, bean oil cake, sodium nitrate, and ammonium sulphate, the latter mainly for use on rice.

Absorption of fertilizer salts by Hawaiian soils, W. MCGEORGE (*Hawaii Sta. Bul. 35 (1914), pp. 32*).—A chemical study of the absorptive power of different types of Hawaiian soils for phosphoric acid, potash, and nitrogen in different forms is reported in this bulletin.

The fixation of phosphoric acid was found to be much higher than that of other elements, due to the highly basic character of the soil. Apparently the fixation of potash and ammonium nitrogen was controlled largely by the amounts of lime and magnesia present in the soil. The absorptive power of the soil for nitrate nitrogen was found to be almost negligible except in the case of highly organic soils. Drying the soil had but slight effect upon its fixing power. The results indicate that fertilizer salts are more strongly fixed when applied singly rather than in mixtures. The effect of heat and antiseptics on the absorptive power of soil was not very striking and the results were not very consistent. The removal of the absorbed elements approached a constant quite rapidly in the case of potash and ammonium salts, but more slowly in that of the phosphates.

Soil tank experiments, S. E. COLLISON (*Florida Sta. Rpt. 1913, pp. XCVIII-CII*).—Experiments with fertilizers for citrus trees were continued as in previous years (E. S. R., 29, p. 211) in two series of four tanks each, the data for composition of the drainage obtained from the tanks during the year being tabulated without comment. Brief notes are also given on the character of the season, especially the rainfall, and on the growth of the trees.

Nitrification of organic manures, J. W. PATERSON and P. R. SCOTT (*Jour. Dept. Agr. Victoria, 12 (1914), No. 6, pp. 321-329, figs. 2*).—In continuation of previous experiments on the relation of moisture and certain soil constituents to nitrification (E. S. R., 28, pp. 217, 720), a study was made of the

rate of nitrification of dried blood, ground bone, leather, oat straw, and alfalfa hay, each added at the rate of 0.1 gm. of nitrogen with 0.75 gm. of calcium carbonate to 300 gm. of sandy soil.

Two rates of moisture were maintained in different series, (1) 5.35 per cent calculated on the dry soil, or 20 per cent of the water-holding capacity of the soil, and (2) 16.05 per cent, or 60 per cent of the water capacity. The soils were placed in bottles which were kept in a dark cupboard. They were corked to prevent evaporation but were aspirated twice weekly to renew the air.

Determinations of ammonia and nitrate nitrogen were made at the beginning of the experiments and at the end of 34 and 123 days. The mean temperature of incubation was about 70° F.

The results showed that in the case of the more active fertilizers the nitrogen was promptly ammonified and passed readily into the form of nitrates. Taking the sum of the ammonia and nitrate nitrogen to represent available nitrogen, it was found that four-fifths of the nitrogen of blood and bone was converted into available form within four months under suitable conditions of moisture and temperature. About 50 per cent of the nitrogen of alfalfa was also made available in four months. Only 1.36 per cent of the nitrogen of leather became available in that time, and this occurred only under the more moist conditions of soil. There was an actual loss of available nitrogen in the case of oat straw.

On the composition and value of bat guano, C. F. MILLER (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 8, pp. 664, 665).—Analyses of samples of bat guano from various sources are reported and discussed.

In these samples the nitrogen varied from 0.5 to 11.84 per cent, phosphoric acid from 1.08 to 4.8, and potash from 0.21 to 1.61. The results show wide variations not only in the percentages of the fertilizer constituents but also in their ratios to one another. In general, in the more recent deposits nitrogen is the most valuable constituent, phosphoric acid and potash following in the order given, but on aging the nitrogen content decreases very rapidly. Over 90 per cent of the phosphoric acid present was found to be water soluble, as was also the greater part of the potash.

The origin of nitrate deposits, W. H. ROSS (*Pop. Sci. Mo.*, 85 (1914), No. 2, pp. 134-145; *Amer. Fert.* 41 (1914), No. 6, pp. 40-46).—The occurrence of nitrate deposits in different parts of the world is described and the various theories which have been advanced to explain their origin, particularly as found in Chile, are reviewed.

Among the theories to which attention is called are (1) that the nitrates have resulted from electric storms, (2) that the atmospheric nitrogen has been fixed by alkali carbonates in the presence of oxidizable matter, (3) that the nitrates have resulted from the action of radio-active emanations from the soil, (4) that the nitrates have been derived from seaweed, bird guano, or the manure of vicuñas and llamas, (5) that the deposits represent accumulations of nitrate formed by the oxidation of organic matter in the soil of the great plain lying between the nitrate beds and the Andes and washed down to their present location by periodic floods, and (6) that the nitrates have been formed by the direct fixation of the nitrogen of the air by *Azotobacter* and like organisms as suggested by Headden.

The author concludes, however, that not one of these theories "is adequate to account for all the conditions under which the deposits are found, and it seems most probable, as some have suggested, that instead of being formed in one way only, the nitrates owe their origin to several sources."

Growth in Chilean nitrate industry, A. A. WINSLOW (*Daily Cons. and Trade Rpts.* [U. S.], 17 (1914), No. 165, p. 305).—The industry is stated to be growing and prosperous.

Ammonium sulphate and sodium nitrate in 1913 (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 8, p. 693).—Statistics of production are briefly summarized.

It is stated that the world's production of ammonium sulphate in 1913 was 1,365,700 tons, of which Germany produced 549,000 tons, the United Kingdom 420,000 tons, the United States 177,000 tons, and France 75,400. The production of Chilean nitrate was 2,450,000 tons in 1913 as against 2,552,770 tons in 1912.

Recent increase in production of lime nitrogen, C. KUBIERSCHKY (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 8, p. 692).—Statistics of production since the beginning of the industry are briefly reported.

The estimated production of cyanamid in 1914 is 208,000 tons. It is stated that the average annual increase in the production of cyanamid from 1907 to 1912 was 212 per cent, of Norwegian nitrate from 1903 to 1911, 170 per cent, while the increase of Chilean nitrate from 1901 to 1911 was only 6.8 and of ammonium sulphate in the same period 10.5 per cent.

Lime nitrogen and its use, B. SCHULZE (*Deut. Landw. Presse*, 41 (1914), No. 62, p. 761).—In comparative tests of sodium nitrate and of oiled, granulated, and untreated lime nitrogen on white mustard grown in pots it was found that the oiled lime nitrogen was practically as efficient as the untreated, being from 85 to 91 per cent as efficient as sodium nitrate. The granulated lime nitrogen, however, was much less effective than the oiled or untreated material, being only 66 per cent as efficient as sodium nitrate.

The author urges the use of high-grade lime nitrogen as it is more likely to be free from dicyandiamid and to be more efficient than low-grade material.

Solubility of nitrogen compounds of lime nitrogen in water, C. MANUELLI (*Ann. Chim. Appl. [Rome]*, 1 (1914), pp. 412, 413; *abs. in Jour. Soc. Chem. Indus.*, 33 (1914), No. 13, p. 690).—It was found, as reported in this article, that about 80 per cent of the nitrogen of lime nitrogen was dissolved in water at 13 to 14° C. in one hour and 88 per cent in six hours. Beyond that point solution began to diminish.

Transformation of calcium cyanamid into ammonia, C. MANUELLI (*Ann. Chim. Appl. [Rome]*, 1 (1914), pp. 388–396; *abs. in Jour. Soc. Chem. Indus.*, 33 (1914), No. 13, pp. 690, 691).—When about 100 gm. of crude calcium cyanamid was heated in water in an autoclave for 6 to 8 hours at from 170 to 180° C. 90 per cent of the theoretical amount of the nitrogen was obtained, and this proportion could be increased by using one-tenth of the amount of cyanamid or repeating the treatment.

Commercial possibilities of the process are discussed.

The origin, mining, and preparation of phosphate rock, E. H. SELLARDS (*Bul. Amer. Inst. Mining Engin.*, No. 93 (1914), pp. 2379–2395, figs. 3).—This article deals with Florida and Tennessee phosphates. Substantially the same information in part has already been noted from other sources (*E. S. R.*, 25, p. 121; 30, p. 222).

The importance of the adoption of less wasteful methods of mining and preparing phosphate for market and of devising processes by which lower grades of phosphate may be used in the manufacture of superphosphate is especially emphasized.

Tennessee phosphate practice, J. A. BARR (*Bul. Amer. Inst. Mining Engin.*, No. 93 (1914), pp. 2397–2413, figs. 12).—Methods of mining the brown and blue phosphate rock and preparing it for the market, and manufacturing superphosphate, are described and discussed.

Coral phosphate islands of the Pacific Ocean and their products, C. ELSCHNER (*Corallogene Phosphat-Inseln Austral-Oceaniens und ihre Produkte. Lübeck, Germany, 1913*, pp. 120, pls. 31; *abs. in Bul. Amer. Geogr. Soc.*, 46 (1914), No. 9, p. 691).—This monograph deals particularly with the geology and chem-

istry of the phosphates of certain of the Pacific islands, especially Nauru and Paanapa but also of Angaur and Makatea of the Palau and Tuamotu groups. These are all islands of upheaval and the phosphate is more or less advanced in chemical and pressure changes. A chapter is also given on the following guano islands of recent formation: Baker, Howland, Phoenix group, Sydney, Malden, Starbuck, Christmas, Fanning, Flint, Jarvis, Browse, Laceyède, Laysan, Cornwallis, and Clipperton.

German potash supply (*Daily Cons. and Trade Rpts.* [U. S.], 17 (1914), No. 208, p. 1261).—The imports of potash salts into the United States during the fiscal year ended June 30, 1914, are stated to have been as follows: Kainit 541,846 tons, manure salts 261,342, muriate of potash 237,916, and sulphate of potash 45,139, the total being 1,086,243 tons valued at \$15,160,123, as compared with 882,562 tons valued at \$12,484,576 in 1913.

It is stated that the only outlet for German potash during the European war is through the Netherlands, which on August 31 temporarily lifted the embargo on the exportation of potash.

The deep boring at Spur, J. A. UDDEN (*Bul. Univ. Tex.*, No. 363 (1914), pp. 109, pls. 16, figs. 18).—The agricultural interest in this boring centers about the fact that analyses of water obtained at different depths indicate the presence of a potash-bearing stratum somewhere near 2,200 ft. below the surface. A sample of the water obtained at about this depth contained 324.1 gr. per gallon of potassium chlorid.

Experiments on the effect of liming agricultural soils, A. BOTTO and D. N. GUGLIEMMETTI (*Rev. Facult. Agron. y Vet. La Plata*, 2. ser., 10 (1914), No. 3, pp. 85-124).—It is demonstrated that the effects of liming on soils of Argentina which are poor in lime are to correct physical defects, to increase chemical decomposition, to favor the activity of soil organisms, to render plant food, particularly phosphoric acid, more soluble, and to further indirectly the assimilation of plant food by crops such as alfalfa.

The lime requirements of moor and similar soils which are poor in lime, B. TACKE (*Jahrb. Moork.*, 2 (1913), pp. 1-22).—The author reviews and discusses the results of a number of experiments by himself and others showing particularly the unfavorable effects of excessive liming on moor and similar soils under different conditions. He points out that upland moor soils growing hay and root crops need, and are able to endure, a much smaller quantity of lime than meadow and pasture soils, the quantity required depending on the condition of decomposition and acidity of the moor soil and the crop to be grown. For north German conditions it is considered inadvisable to apply lime in excess of 1,780 lbs. per acre to soil growing hay and root crops, while on meadows and pastures at least twice that amount is necessary.

The effectiveness of lime fertilizers when applied to acid soil is said to depend largely on its degree of fineness.

It is further concluded that on sand and moor soils, poor in lime, the effect of liming is usually very lasting, and that liming should be repeated only when the necessity for it is indicated by comparative tests.

The production of lime in 1913, R. W. STONE (*U. S. Geol. Survey, Mineral Resources of the United States Calendar Year 1913*, pt. 2, pp. 309-324).—"The lime manufactured in the United States in 1913 amounted to 3,595,390 short tons, valued at \$14,648,362. This was an increase of 65,928 tons, or 1.87 per cent, in quantity and of \$678,248, or 4.85 per cent, in value, when compared with the output for 1912, which was 3,529,462 short tons, valued at \$13,970,114. The production in 1913 was the largest in the history of the industry, both in the quantity manufactured and in the value of the output. . . . The total

number of plants reporting operations in 1913 was 1,023 as compared with 1,017 in 1912 and with 1,139 in 1911."

The influence of sulphur on soil acidity, H. C. LINT (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 9, pp. 747, 748).—Laboratory experiments on the rate of oxidation of sulphur in soil to which it had been added to the amount of 1,000 lbs. per acre-foot showed that the sulphur had practically all been oxidized within the first eight or nine weeks, there being little change in the acidity after the seventh week. The oxidation of sulphur was much more rapid with a heavy clay loam soil than with a sandy loam soil. Soils made up to 20 per cent water content once each week and allowed to dry did not give as rapid oxidation as those in which an optimum moisture content of 20 per cent was constantly maintained by keeping the soils covered to prevent drying out.

That the sulphur causes an increase in acidity under field conditions is verified by analyses of field soils to which sulphur had been applied the previous year. These showed the lime requirement to correspond to the rate of sulphur application.

Fertilizer and oils, B. W. EVERMANN (*U. S. Dept. Com., Bur. Fisheries Doc. 797, pp. 134, 135; abs. in Amer. Fert., 41 (1914), No. 6, p. 28*).—This is a short section in a larger report on the Alaska fisheries and fur industries in 1913. It deals briefly with the status of fish fertilizer and oil production in Alaska, which is stated to have been less extensive than during the previous year, emphasizes the great waste of valuable fertilizing material at the canning factories, and describes particularly a new plant for the manufacture of fertilizer and oil established at Klawak during the year.

Commercial fertilizers, J. S. BURD (*California Sta. Bul. 245 (1914), pp. 53*).—Guaranties, analyses, and valuations of 498 samples of fertilizers inspected by the California Fertilizer Control during the year ended June 30, 1914, are reported. Ninety-one of these fertilizers were deficient in one or more fertilizing constituents under the terms of the state fertilizer law which allows a deficiency of 0.25 per cent in nitrogen, 0.5 in potash, and 1 in available phosphoric acid. The sales of fertilizers in the State during the year are estimated at from 35,000 to 40,000 tons.

Fertilizer analyses, H. B. McDONNELL ET AL. (*Md. Agr. Col. Quart., No. 65 (1914), pp. 39*).—Analyses and valuations of fertilizers sold in Maryland examined from February to July, 1914, are reported.

AGRICULTURAL BOTANY.

[The evolutionary aspects of genetic research], W. BATESON (*Nature [London], 93 (1914), Nos. 2338, pp. 635-642; 2339, pp. 674-681; Science, n. ser., 40 (1914), Nos. 1026, pp. 287-302; 1027, pp. 319-333*).—This is the presidential address delivered before the British Association for the Advancement of Science at its Australian meeting in August, 1914, in which the author outlined his ideas regarding evolution in the light of recent research in genetics.

It is claimed that variation in a series must occur either by the addition or loss of a factor. Of the origin of new forms by the loss of a factor there is said to be abundant evidence, but there does not appear to be any clear evidence of the contemporary acquisition of new factors. The author summarizes his views as follows: "As the evidence stands at present all that can be safely added in amplification of the evolutionary creed may be summed up in the statement that variation occurs as a definite event often producing a sensibly discontinuous result; that the succession of varieties comes to pass by the elevation and establishment of sporadic groups of individuals owing their origin to

such isolated events; and that the change which we see as a nascent variation is often, perhaps always, one of loss."

The second part of the paper is devoted to the development of his conclusions in regard to man.

Physiological plant anatomy, G. HABERLANDT, trans. by M. DRUMMOND (*London, 1914, pp. XV+777, figs. 291*).—This work is a translation of the fourth German edition which appeared in 1909, and is considered as representing the mature views of the author. The scope of the work may be shown by the definition given to physiological plant anatomy: "It consists first, in the recognition of the physiological functions pertaining to the tissues of the plant and to the structural units, or cells, of which these tissues are composed; and secondly, in the discovery of the connection that exists between the several functions and the anatomical arrangements required for their proper performance."

Chapters are given on the cells and tissues of plants, meristematic tissues, and dermal, mechanical, absorbing, photosynthetic, vascular or conducting, storage, aerating or ventilating, secretory and excretory, motor, sensory, and stimulus transmitting systems. A chapter is also given on the secondary growth in thickness of stems and roots causing both the normal and anomalous forms.

By means of copious notes additional data are given to support various statements, and controverted points are discussed at some length. This book will undoubtedly be a noteworthy addition to the available literature in the English language relating to the general field of the physiology of plants.

On chlorophyll and leaf pigments and those of flowers and berries, R. WILLSTÄTTER (*Naturwissenschaften, 2 (1914), No. 19, pp. 468-470*).—This is a brief note of a paper read before the German Chemical Society.

It is stated that the composition of chlorophyll is largely independent of season, time of day, and illumination, also that the composition of the particular pigments involved varies but slightly. The characteristic coloring matter of the cornflower is thought to be identical with that of the rose and to have as a basis some potassium compound.

Winter as a factor in the xerophily of certain evergreen ericads, F. C. GATES (*Bot. Gaz., 57 (1914), No. 6, pp. 445-489, figs. 12*).—The author, giving results of work carried on from 1910 to 1912, states that the transpiration of all plants tested was very low in winter, often being imperceptible at night. A gain of weight occurring at low temperatures indicated absorption, in some cases sufficient to overbalance transpiration. Transpiration per unit surface of evergreen shrubs was from 4 to 30 times that of deciduous shrubs during cold winter weather, also under warm indoor conditions.

In case of peat bog plants in nature, light, particularly sunlight, seems to be the effective factor in causing stomatal movements. These appear to be less influential in regulating transpiration of peat bog plants than the evaporating power of the air.

Thermotropism in roots, H. D. HOOKER, JR. (*Plant World, 17 (1914), No. 5, pp. 135-153*).—Summarizing conclusions reached from details obtained in nine experiments on thermotropism as carried out with seedlings of *Ervum*, *Pisum*, *Phaseolus*, *Lupinus*, and *Zea* sprouting in agar, the author states that the use of a 1.25 per cent solution of agar as a medium for the roots effectually excludes all factors except the difference of temperature, but allows the roots to grow and bend; that no thermotropic reactions occur when such agar is used; that reactions occurring in such cases must be attributed to positive hydrotropism; and that traumatropism enters as a factor at higher temperatures.

The solvent action of roots, F. V. CHIRIKOV (*Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 15 (1914), No. 1, pp. 54-65).—As the result of experiments carried out with barley and buckwheat in nutritive media, the author concludes that the excretion of acids by roots is inadequate to explain a number of facts noted in connection with the nutrition of the higher green plants. Roots of such plants are surrounded by a solution which is in a certain state of equilibrium. Roots of different plants disturb the equilibrium in the medium in very unlike ways, absorbing predominately calcium oxid or phosphorous pentoxid, as the case may be, and the relations of these plants to phosphorus pentoxid must differ considerably. Barley does not take up phosphorus pentoxid in the presence of calcium nitrate or other calcium salt, but it may utilize phosphoric acid from phosphorite alone in considerable degree. Buckwheat behaves differently, taking up phosphorus pentoxid from phosphorite in either the presence or absence of calcium nitrate. This difference is explained on the supposition that buckwheat takes up, from the nutritive solution, calcium oxid more energetically than phosphorus pentoxid, while in case of barley, phosphorus pentoxid is much more energetically taken up than is calcium oxid.

Some factors which influence the water requirements of plants, P. КХАНКХОЈЕ (*Jour. Amer. Soc. Agron.*, 6 (1914), No. 1, pp. 1-23, fig. 1).—These experiments were carried out in order to ascertain more in detail some of the factors influencing the water requirements of cereals, standard methods being employed.

It is stated that different kinds of crops require different amounts of water to produce a unit of dry matter. Increased strength of soil solution decreases water requirement. A fertile soil with limited water supply will produce a larger crop than will an infertile soil under similar conditions. Young plants require more water than older plants. Plants furnished with excessive water come to require more water per unit of dry matter than do plants grown in drier soils.

The relation of atmospheric evaporating power to soil moisture content at permanent wilting in plants, J. W. SHIVE and B. E. LIVINGSTON (*Plant World*, 17 (1914), No. 4, pp. 81-121, figs. 5).—The authors, giving a detailed account of their investigations, state that these have substantiated the claim of Caldwell (E. S. R., 29, p. 523) to the effect that the amount of water left in any given soil at the time of permanent wilting of plants is a function of the intensity of atmospheric evaporating power for the period during which permanent wilting is attained. They further hold that the conclusion reached by Briggs and Shantz (E. S. R., 26, p. 628; 27, p. 223), to the effect that the atmospheric and environmental conditions that obtain during the process of wilting have little or no effect upon the residual water content here considered, and that this soil moisture residue for any given soil remains constant for all species of plants grown in it and for various stages of development, can not be considered as of general application but only as expressing a relation obtaining under some as yet undetermined range of external and internal conditions within which must have lain the experimental conditions employed by these workers.

Acidity of manures as related to germinability of seeds of leguminous weeds, O. MUNERATI and T. V. ZAPPAROLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 1, pp. 5-17).—Field and laboratory tests were made with seeds of *Vicia segetalis*, *V. hirta*, and *Lathyrus aphaca* from 2 to 6 years old in contact for different periods with acid phosphate of varying strength. It was found that long contact and strong solutions both corresponded with the progressive diminution of germinability of the seeds. This result is thought to be related to an increase in permeability of the seed coats.

The formation and regulation of enzymes by some mold fungi, H. KYLIN (*Jahrb. Wiss. Bot. [Pringsheim], 53 (1914), No. 4, pp. 465-501*).—The author, giving a detailed account with results of several series of studies involving the activity of *Aspergillus niger*, *Penicillium glaucum*, and *P. bifforme* as regards formation and regulation of diastase, invertase, and maltase, states that two sorts of regulation may be distinguished, namely a qualitative (in which an enzym is formed only when a particular substance is present in the nutritive solution) and a quantitative (when an enzym may be formed under different conditions, but most favorably and in increasing quantity when a component is present which is readily broken up by the enzym in question). A bibliography is appended.

Physical and chemical factors influencing the toxicity of inorganic salts to *Monilia sitophila*, L. O. KUNKEL (*Bul. Torrey Bot. Club, 41 (1914), No. 5, pp. 265-293, figs. 2*).—In extension of work previously reported (*E. S. R., 30, p. 227*), the author studied the influence of carbohydrates and peptones on the toxicity of 11 different chlorids in five different media, using as before cultures of the fungus *M. sitophila*.

The results are tabulated and discussed. It is claimed that in studies on toxicity the organic part of the medium must be taken into account.

A bibliography is appended.

The behavior of hydrocyanic acid when injected into plants, S. DEZANI (*Arch. Farmacol. Sper. e Sci. Aff., 16 (1913), No. 12, pp. 539-546*).—Claiming to have found previously that hydrocyanic acid injected into plants was probably broken up by reaction with substances in the plant juices, one of the products thereof being ammonia, the author experimented with minute doses of the acid in question injected into maize and hemp, and holds that direct proof of its utilization was indicated by the results observed.

Increase of heliotropic sensitivity of seedlings by narcotics, O. RICHTER (*Sitzber. K. Akad. Wiss. [Vienna], Math. Naturw. Kl., 121 (1912), I, No. 10, pp. 1183-1228, pl. 1, figs. 3*).—Describing experiments under varied conditions with seedlings of cereals, etc., the author claims that the heliotropic sensitivity of the plants employed was increased by exposure in a narcotic medium.

The harmful action of distilled water, R. H. TRUE (*Amer. Jour. Bot., 1 (1914), No. 6, pp. 255-273, fig. 1*).—Presenting details of studies with plants in distilled or tap water or in various solutions, previously noted (*E. S. R., 30, p. 825*), the author considers it probable that the problem of injury by distilled water to contained cells is not a simple one capable in all cases of the same explanation. Besides cases of toxic substances derived from containers, etc., other cases remain unaccounted for. Extraction of electrolytes by distilled water from the cells is regarded as but a special case of a type of injury done to cells by unbalanced solutions. Calcium salt added to distilled water to make it osmotically equivalent to tap water protects the chemical integrity of the cells in some way not yet known. Further work is now in progress.

A bibliography is appended.

Poisoning of trees on streets by gas, P. EHRENBERG (*Ztschr. Pflanzenkrankh., 24 (1914), No. 1, pp. 33-40, figs. 2*).—In the case of linden trees dying on both sides of a street in the middle of a block in Hanover, no parasites could be detected, but a break was found in the gas main in the center of the street. The gases seemed to have percolated beneath the asphalt and were thought to have produced the effects observed. Better ventilation of the space around the trees is suggested.

Studies on smoke injury, S. EICKE (*Naturw. Ztschr. Forst u. Landw., 12 (1914), No. 5, pp. 201-207, figs. 5*).—Presenting graphically the results of studies on the growth of pines up to 52 years old as affected by gases from

industrial works, the author states that pines, especially the younger ones in the neighborhood, showed a progressive diminution in growth, attributable to gas and smoke.

Soil bacteriology, C. M. HUTCHINSON (*Rpt. Agr. Research Inst. and Col. Pusa, 1912-13, pp. 85-90*).—This is a part of the more general report of the bacteriologist, and deals, as the principal subject of inquiry, with the nitrogen supply in the soil as affected by the intervention of bacteria.

Azotobacter was found in all Indian soils examined, pure cultures exhibiting nitrogen-fixing power very similar to that from European strains, and its physiological activity depending upon the supplies of water, air, lime, and especially of carbohydrate food. Successful use of a green manure crop was found to depend almost entirely upon the rainfall after turning under the crop. Field experiments with green manure in 1912-13 showed no increase from the plats tested, but in some cases a decided falling off. The nitrate formed from buried tissues increased for eight weeks provided the soil water supply was kept up to at least 16 per cent, but decreased thereafter.

A new medium for the quantitative determination of bacteria in soil, H. J. CONN (*Science, n. ser., 39 (1914), No. 1012, pp. 763, 764*).—As a result of comparative tests of an asparaginate agar containing chemicals of known composition, a soil extract gelatin, and three special media for soil work proposed by Fischer (*E. S. R., 22, p. 723*), and by Lipman and Brown (*E. S. R., 22, p. 723*), the asparaginate agar is highly recommended. "The only medium which seems better, either in respect to count or to the colony differentiation, is soil-extract gelatin; and because of the addition of soil extract this gelatin is not one that can be readily duplicated. The only one of the media investigated which gives a higher count than either of these is Fischer's soil-extract agar, which does not allow good colony differentiation."

Flora of southeastern Washington and adjacent Idaho, C. V. PIPER and R. K. BEATTIE (*Lancaster, Pa., 1914, pp. XI+296, pl. 1*).—This is an extension of the flora of the Palouse Region published by the authors in 1901 (*E. S. R., 13, p. 620*). The area covered by this new edition has been enlarged so as to include about a half dozen counties of eastern and southeastern Washington and parts of three counties in Idaho. The list of species given is 1,139, an increase of 476 over that of the previous publication.

Mistletoe in Great Britain and Ireland, C. VON TUBEUF (*Naturw. Ztschr. Forst u. Landw., 12 (1914), No. 5, pp. 211-214*).—This is a brief discussion with a list of occurrences of mistletoe on oaks in England from 1857 to the present time.

Mistletoe in England, W. SOMERVILLE (*Naturw. Ztschr. Forst u. Landw., 12 (1914), No. 5, pp. 207-211*).—This is a condensed account of observations by 15 persons reporting from as many places in England on cases of parasitism, natural or artificially induced, by mistletoe on various hosts named, with a list of trees which appear not to be attacked.

FIELD CROPS.

[Field experiments], J. M. SCOTT (*Florida Sta. Rpt. 1913, pp. XIX-XXVI*).—In a four-year fertilizer experiment with Japanese cane, the use of sulphate of potash gave an average increased yield of 0.9 ton per acre over that of muriate of potash; sulphate of ammonia an increased yield of 1.1 tons per acre over dried blood; dried blood and muriate of potash an increased yield of 1.56 tons per acre over muriate of potash and acid phosphate; ground limestone an increase of 2.99 tons per acre; and dried blood and muriate of potash an increase of 3.19 tons per acre over dried blood and acid phosphate. There was

a marked decrease in yield in all plats from the first to the fourth year. Similar results were obtained in another test.

The results of a three-year cultivation test showed a yield of 14.97 tons of green Japanese cane per acre with 2-in. depth of cultivation. This was an increase of 1.36 tons over that with 4-in. and 6-in. depths.

Velvet beans grown on the same land for six years showed an irregular decrease in yield of beans from 25.13 bu. per acre to 9.63 bu.

A variety test of sweet potatoes for 1912 showed Unknown to be the heaviest yielder of commercial potatoes, 148.75 bu. per acre, with Porto Rico Yam and Triumph closely following.

One year's test showed sweet potatoes to be a desirable silage crop, keeping in perfect condition and eaten by cattle and hogs readily. Cassava silage also gave good results. Both crops were ensiled in the ordinary way.

Culture experiments at the experiment field at Bromberg in 1913, G. RICHTER (*Mitt. Kaiser Wilhelms Inst. Landw. Bromberg*, 6 (1914), No. 3, pp. 143-191, pl. 1, figs. 6).—This reports weather conditions from 1907-1912 and irrigation results on sandy and on heavy soils with rye, grass, beans, cabbage, tomatoes, fruit, sugar beets, stock beets, and turnips, and data as to the water condition of the soils.

It is noted that irrigation proved satisfactory, that one application proved best, that with an application of 130 mm. of water an increased yield of 1,450 kg. of dry matter per hectare was obtained over no irrigation while an application of 180 mm. did not materially increase the yield, that none of the irrigation experiments were profitable, that the proportion of grain to straw was increased by irrigation, and that kernel weight increased with irrigation. A table showing the amount of water necessary to produce 1 kg. of winter rye on sandy soil follows:

Amount of water necessary to produce 1 kg. of winter rye on sandy soil.

Rain, April to June, per hectare.	Irrigation water applied per hectare.	Rain and irrigation water per hectare.	Yield of rye per hectare.	Water used to produce 1 kg. of crop.	
				As harvested, 15 per cent water.	Water-free.
<i>Cubic meters.</i>	<i>Cubic meters.</i>	<i>Cubic meters.</i>	<i>Kilograms.</i>	<i>Kilograms.</i>	<i>Kilograms.</i>
1,200	1,200	6,140	196	230
1,200	300	1,500	6,110	246	289
1,200	1,300	2,500	7,590	330	387
1,200	1,800	3,000	7,800	385	452

A brief résumé is given of the effect of adding humus to sandy soils in 1908-1912 with oats, potatoes, and rye.

Cultivation of east Prussian low moorlands.—I, Report of the experiment fields on the overflowed moors of the Bledau estate near Cranz, FELDT (*Veröffentl. Preuss. Landw. Kammern*, No. 1 (1914), pp. 90, pls. 12).—This discusses methods of drainage and cultivation suitable for such soils and gives some results of cultural and variety tests with cereals, beans, potatoes, and vegetables.

Report on the Cawnpore Agricultural Station in the United Provinces for the year ended June 30, 1913, B. C. BURT ET AL. (*Rpt. Cawnpore [India] Agr. Sta.*, 1913, pp. 33+6a, figs. 5).—This report includes results of experiments with artificial manures, calcium cyanamid, calcium nitrate, and green manures; variety tests with cotton, pigeon peas, great millet, sugar cane, peanuts, maize,

wheat, flax, and potatoes; and cultural experiments with cotton, wheat, sugar cane, indigo, peanuts, pigeon peas, millet, and crop rotations.

Report of the experimental work of the Coimbatore Agricultural Station, 1912-13, R. C. WOOD (*Dept. Agr. Madras, Rpt. Coimbatore Agr. Sta., 1912-13, pp. 40*).—This report gives results of cultural, manurial, and variety tests with rice, sorghum, wheat, cumbu (*Pennisetum typhoideum*), millet, cotton, tobacco, sugar cane, fiber and oil plants, and legumes.

Report of the experimental work of the Koilpatti Agricultural Station for 1912-13, H. C. SAMPSON (*Dept. Agr. Madras, Rpt. Koilpatti Agr. Sta., 1912-13, pp. 20*).—This report gives results of cultural and manurial tests of cereals, legumes, and cotton, and an account of the local agricultural conditions.

Experiments with different sized plats, SCHNEDEWIND (*Mitt. Deut. Landw. Gesell., 29 (1914), No. 21, pp. 298-300*).—This article gives first-year results of using plats of different sizes and shapes placed contiguous and with unused space between them in fertilizer tests with sugar beets.

Experiments on germinative ability and germinative force, GISEVIUS (*Fühling's Landw. Ztg., 63 (1914), No. 9, pp. 297-318*).—This article gives tabulated data on results of germinative tests with oats, barley, rye, and wheat.

A study of the root system of our agricultural plants, B. SCHULZE (*Festschrift 50. Jubiläum Agr. Chem. Versuchs u. Kontroll Stat., Breslau, pp. 67-95, pls. 10*).—Results obtained by washing out the roots of plants grown in concrete apartments in the field reaching to a depth of 2 meters below the surface of the soil are tabulated in detail.

The relation of tops to roots of plants taken at different stages of development is given in length and weight, respectively, as follows: Rye, young, 100:826 and 100:104; rye, in early spring, 100:321 and 100:48.6; rye, beginning to flower, 100:133 and 100:21.1; rye, in milk stage, 100:112 and 100:10.1; rye, mature, 100:135 and 100:4.7; wheat, young, 100:684 and 100:129; wheat, in early spring, 100:502 and 100:47.2; wheat, shooting, 100:369 and 100:27.8; wheat, milk stage, 100:188 and 100:10.5; wheat, mature, 100:159 and 100:9.2; barley, mature, 100:259 and 100:7.4; oats, mature, 100:173 and 100:9; peas, mature, 100:90 and 100:3.4; beans, mature, 100:100 and 100:38.9; lupines, at end of vegetative period, 100:404 and 100:41.3; serradella, in flower, 100:281 and 100:20.2; red clover, young, 100:444 and 100:37.5; vetch, 10:185 and 100:15.7; potatoes, 100:380 and 100:41.4; and sugar beets, length only, 100:461.

Serological study of Leguminosæ and Gramineæ, ZADE (*Ztschr. Pflanzenzücht., 2 (1914), No. 2, pp. 101-151, figs. 4*).—This article describes a method of distinguishing varieties of plants that involves a precipitin reaction (E. S. R., 29, p. 144) in which the serum of rabbits is used in connection with a liquid prepared from the meal of the grain to be tested and sodium chlorid (1:10).

Results obtained with varieties of peas, clovers, oats, and wheat, which were not altogether conclusive, are given.

The efficiency of leguminous plants in increasing the nitrogen content of the soil, V. C. BARTOLOME (*Philippine Agr. and Forester, 3 (1914), No. 1, pp. 9-14*).—This article reports results of comparative tests of peanuts, sincamas (*Pachyrrhizus erosus*), velvet bean, cowpea, sinay bean (*Phaseolus calcaratus*), soy bean, and Ami bean (*Glycine hispida*) as nitrogen gatherers. It is noted that sincamas gave the largest net profit, followed by sinay and cowpeas.

The behavior of oats and lupines toward different sources of phosphorus, T. PFEIFFER and E. BLANCK (*Landw. Vers. Stat., 84 (1914), No. 1-2, pp. 93-118*).—Results are here given of numerous experiments in which oats and lupines were fertilized with dicalcium phosphate, phosphate rock, superphosphate, Thomas slag, and bone meal in pots. The oats utilized dicalcium phos-

phate, superphosphate, and Thomas slag to better advantage than lupines. Phosphate rock seemed to be an equally good source for both oats and lupines, but bone meal seemed to furnish phosphoric acid to the lupines better than to the oats. Although oats apparently use more water than lupines, the appropriations of phosphorus by the plants could not be explained on that basis. The fact that the more difficultly soluble compounds were more readily used by the lupines seemed to indicate that the acids of the root sap played an important part in the assimilation. Applications of ammonium nitrate did not cause an increase in the phosphoric acid with the lupines, while the reverse was true with the oats.

Report of assistant botanist, J. BELLING (*Florida Sta. Rpt. 1913, pp. CIV-CXXXI, figs. 8*).—This reports work in continuation of that previously noted (E. S. R., 29, p. 228) on the selection of useful beans from the cross of Florida Velvet (*Stizolobium deeringianum*) and Lyon (*S. niveum*). Three selected constant strains are described, followed by discussions of precautions in breeding work, and general sources of error.

In a study of the inheritance of purple color four distinct parts of the plant are considered. On the lower epidermis of the first pair of apparently simple leaves; on the stem as a mark on the leaf axil; in the wings of the flower and to a less degree, in the standard; and on stems and petioles, on the sides exposed to sunlight. In several generations the purple and nonpurple colors were found to mendelize.

In regard to time of flowering it is noted that "a definite proof of segregation of some kind having occurred is found in the raising of constant strains of different degrees of earliness in F_2 and later generations. I have, in F_2 of the cross of the Florida Velvet by Lyon, several strains constant in flowering period, of which: (A) one flowers two months before the Florida Velvet or Lyon beans; (B) another flowers one month before; (C) a third flowers a week or two weeks before; while (D) a fourth flowers with the Florida Velvet bean; and (E) a fifth was over a month later in F_2 than the Florida Velvet or the Lyon bean. These strains (except the last) have been grown on a field scale in F_2 , and have proved uniformly constant to time of flowering. As only one F_2 plant later than the Velvet bean has been multiplied in F_2 (except in the elimination field), we might perhaps expect several constant grades of later plants also. The black plants (with black tomentum all over) which segregate in normal Mendelian manner, and from three-sixteenths of F_2 , are always later than the corresponding white plants (with white pubescence) in the F_2 families in which they occur in the normal proportion of three white to one black. Hence I regard the isolation of these five races constant to different degrees of earliness as a proof of the segregation of genetic factors affecting earliness and lateness in the microspores and megaspores of the F_1 hybrids." It was found that "the time of first flowering is in most cases a reliable indication of the climax of flowering and of the time of ripening pods."

A study of earliness and size of plant showed a strong correlation between time of flowering and size of plant, especially for the white plants, and purple plants with white shoots were slightly earlier than the nonpurple.

In regard to flower bunches the number of flower clusters (nodes) on a raceme is determined for any plant by the time of flowering (that is, indirectly by the factors for late flowering), and, independently of the time of flowering, by the presence or absence of a genetic factor. There was evidently a strong correlation between lateness of flowering and increased length of flower bunches.

Progress in crossing several varieties of corn is noted.

Alfalfa, W. P. BROOKS (*Massachusetts Sta. Bul. 154 (1914)*, pp. 143-171, pls. 2).—This bulletin considers alfalfa as a crop for Massachusetts farmers; gives results of experiments with manure and potash as fertilizers, a comparison of different methods of seeding, and a test of a commercial culture for inoculation; and discusses methods of the production and management of the crop.

In conclusion it is noted that "a heavy application of lime is in almost all cases necessary, usually, from 1½ to 2½ tons at least. On soils which are low in humus and relatively poor, one good application of manure plowed in is beneficial, but in general, fertilizers should be preferred to manure because less likely to bring in weeds, grasses, and clovers. The best source of potash for the crop is sulphate, and one of the best sources of phosphoric acid is basic-slag meal. The Grimm variety is superior.

"Among the principal obstacles to success are leaf spot or rust, which can be prevented by cutting when it first appears; dodder, which can be avoided by care in the purchase of seed; the competition of weeds, grasses, and clovers, which is reduced by avoiding manures or fertilizers rich in nitrogen; and winterkilling, which is due to poor drainage, formation of ice, and insufficient growth for protection.

"The method of seeding attended with least risk is sowing alone in late summer after most careful preparatory tillage. The crop should be cured with little exposure to direct sunshine and little handling to avoid loss of leaves. It is a mistake to sow alfalfa in fields infested with witch grass. The growth of weeds, grasses, and clovers can be largely prevented by harrowing after the first or second cutting of any season when they are first present in noticeable proportion. Annual top-dressing with slag meal and potash will in most cases be desirable."

Cultivation of carrots with cereals, E. GRABNER (*Wiener Landw. Ztg.*, 64 (1914), No. 23, pp. 208, 209, figs. 2; *abs. in Jour. Bd. Agr. [London]*, 21 (1914), No. 2, pp. 149).—The results here given show successful crops of carrots grown in 1912 and in 1913 when seed was planted in the winter wheat during April.

Lea's cotton book, compiled by J. J. LEA (*New Orleans, La., 1914 ed.*, pp. 124, figs. 6).—This book gives a record of climatological conditions affecting the growth and culture of the American cotton crop; a statistical history; a summary of the rules of the New Orleans Cotton Exchange; and data on the cotton milling industry, the cotton ginning industry, weights and values of lint cotton, seed cotton, cotton seed, and cotton picking.

The pollination and fertilization of hops and the characteristics of "seeded" and "seedless" hops, E. S. SALMON (*Jour. Bd. Agr. [London]*, 20 (1914), No. 11, pp. 953-966, pls. 3, figs. 7; 21 (1914), Nos. 1, pp. 22-31, pls. 4, fig. 1; 2, pp. 123-133, pls. 2; 3, pp. 23-220, fig. 1).—This article discusses the history of hop production and cultural and marketing methods, and presents evidence to show the value of planting male hops in the hop fields in order that the size and quality of the product may be improved by fertilization of the flower.

Hop manuring experiments.—Brief report for 1913, with summary of the eighteen years 1896-1913, B. DYER (*London, 1914*, pp. 4).—This leaflet briefly brings up to date the results of the continuous hop manuring experiments carried on at Golden Green, Hadlow, Tunbridge, showing the average of the results of 18 seasons, together with the detailed results of the crop of 1912-13.

A plat receiving, aside from a complete commercial fertilizer, additional applications of nitrate of soda consisting of 200 lbs. in January, 400 lbs. in February, and 200 lbs. in March, is recorded as giving the largest average yield, 16¾ cwt., of the best quality of hops.

Fertilizers for hops, W. CZERMAK (*Illus. Landw. Ztg.*, 34 (1914), No. 24, pp. 239, 240).—Experiments conducted during 1911–1913 in Posen in which equal quantities of potash and superphosphates were applied, and ammonium sulphate in ratios of 1, 2, 3, and 4, showed an increased yield of hops with each increase of the ammoniacal fertilizer.

The kapok tree, A. ZIMMERMANN (*Pflanzer*, 10 (1914), No. 3, pp. 123–133).—This article gives a botanical, cultural, and industrial discussion of *Ceiba pentandra*.

Botanical origin and usefulness of kapok fiber, GERTRUD TOBLER-WOLFF (*Pflanzer*, 10 (1914), No. 4, pp. 171–175).—This article includes a description of the kapok tree and its fiber. Among the uses to which this fiber has been put are mentioned the manufacture of paper, guncotton, fuses, tassels, fringes, and hats.

Market conditions of kapok, F. TOBLER (*Pflanzer*, 10 (1914), No. 4, pp. 175–180).—This article gives the exports of this fiber from Java as increasing from 5,750,000 kg. in 1906 to about 10,000,000 kg. in 1911. The market classification given comprises “extra clean,” “good clean,” and “clean.”

Valuations are given for the markets of Java, Calcutta, Bombay, Ceylon, Philippines, Ecuador, Venezuela, Mexico, and Togo, which range from 100 to 170 marks per 100 kg. (10.4 to 17.8 cts. per pound).

Potato development work in Wisconsin (*Wis. Potato Growers Assoc. Bul.*, 1914, pp. 62, figs. 46).—This bulletin gives reports on the progress of potato growing in the several sections of Wisconsin by different authors; the minutes of the 1913 meeting of the Wisconsin Potato Growers Association; and a summary of important addresses and papers presented at that meeting, with a plan of potato seed inspection for Wisconsin in 1914.

Potato storage work in Bihar and Orissa in 1912, E. J. WOODHOUSE and H. L. DUTT (*Agr. Jour. Bihar and Orissa [India]*, 1 (1913), No. 2, pp. 115–137, pl. 1).—This article notes the success of storing potatoes under a layer of sand to prevent the damage of the potato moth.

Report of the Hmawbi Agricultural Station for the year 1912–13, A. MCKERRAL (*Rpt. Hmawbi [India] Agr. Sta.*, 1912–13, pp. 8).—This report gives results of variety, cultural, and manurial tests with rice.

Variety test with stock beets, K. VON RÜMKER, J. ALEXANDROWITSCH, ET AL. (*Landw. Jahrb.* 45 (1913), No. 4, pp. 503–596, figs. 6).—Yields of dry matter and of sugar in numerous experiments with a large number of varieties are reported. Considerable space is also given to methods of computing comparative values.

The influence of fertilizers on the mineral and sugar content of beets, D. MEYER (*Illus. Landw. Ztg.*, 34 (1914), No. 8, pp. 59–61).—Some results of experiments at Halle are noted in which a complete fertilizer seemed to more than double the potash content of sugar beets, while the tops were considerably richer in potash than the tops of stock beets. Stock beets were shown to store large quantities of sodium in the roots, while the sodium of the sugar beets was found almost entirely in the tops. Chlorin was found in very small quantity in the roots of sugar beets while much was stored in the tops. The stock beet roots contained about 10 times as much chlorin as did the sugar beet roots, and the tops also contained more than the tops of the sugar beets. The ash content was found to be higher in the stock beets. The above-mentioned differences are attributed to the results of selection and breeding.

Among the effects of different fertilizer elements noted are that no noticeable increase of potash in beet roots through fertilization by potash or by barnyard manure had been observed, but large quantities have been found stored in

the tops. Sodium nitrate or barnyard manure as fertilizers did not appreciably increase the sodium content of the roots, but large quantities were found in the tops. No increase in the chlorin content of the roots could be detected whether it was furnished in potassium salts or in barnyard manure, but it was found in the tops. The ash content was not noticeably influenced by fertilizers.

Nitrogenous fertilizers are not deemed favorable to sugar production. Applications of nitrate of soda reduced the sugar content 0.14 per cent and ammonia salt 0.08 per cent, while lime nitrogen was without effect.

Experiment on the development of sugar in beets, M. LEVALLOIS (*Bul. Assoc. Chim. Sucr. et Distill.*, 31 (1914), No. 11, pp. 903-909).—Analyses of beets taken at intervals during the second season's growth (the seed producing stage) showed a general decline in sugar content from April 15 (18.7 per cent) to December 10 (2.37 per cent).

Handling and planting of seed cane, A. P. ADRIANO (*Philippine Agr. and Forester*, 3 (1914), No. 2, pp. 41-49).—This article gives results of experiments in cultural methods with some Philippine varieties of cane.

In comparing the methods of planting cane slanting or flat in the furrow it was found that flat planting gave the best results, being less subject to any injury and better withstanding drought. Cane planted 50 cm. (19.5 in.) in rows $1\frac{1}{2}$ meters (59 in.) apart gave heavier yields, 32,857 kg. per hectare (14.62 tons per acre) than when planted 30 cm. in rows 60 cm. apart (18,571 kg.).

A test in planting tops, middles, and butts of the cane showed that "tops may be grown successfully when planted at once after cutting even if not soaked at all. In all the tests made tops which were not soaked in water and those soaked in water did better than the other thirds of the cane. Butts may be planted to advantage if soaked in water for 48 hours."

A depth of 12 in. in planting gave better results than that of 6 in.

Report of experiment of the Banjumas division of the experiment station of the Java sugar industry for 1913 (*Arch. Suikerindus. Nederland. Indië*, 22 (1914), No. 13, pp. 441-498, pls. 3; *Meded. Proefstat. Java-Suikerindus.*, 4 (1914), No. 21, pp. 413-467, pls. 3).—This contains results with sugar cane as to yields and quality of sugar with different fertilizers on several classes of soil.

The cultivation of the sugar cane in southern Spain (*Roy. Bot. Gard. Kew, Bul. Misc. Inform.*, No. 4 (1914), pp. 147-150, fig. 1).—This article suggests variety and cultural methods for that region.

Queensland sugar industry (*Brisbane: Govt.*, 1913, new ed., pp. 172, pl. 1, figs. 109).—This book gives cultural methods and general notes on cost of production and manufacture, including statistics.

Sudan grass as a forage crop, H. N. VINALL (*U. S. Dept. Agr., Farmers' Bul.* 605 (1914), pp. 20, figs. 10).—This bulletin describes Sudan grass, discusses climatic and soil requirements, gives methods of culture and harvest, and notes its usefulness as a hay, soling, silage, and pasture crop, its value in irrigated sections and as a seed crop, enemies, and methods of breeding.

"The yields vary from 1 to 8 tons of cured hay per acre. Its seed habits are good, and large returns are now being secured from the seed produced. The seed of Sudan grass resembles very closely that of Johnson grass; therefore farmers should use seed only from regions free from Johnson grass. It promises to fill a long-felt want for a hay grass in the South, and will likely replace millets as a catch crop in the Central and Eastern States. It does not do well in sections having a high altitude, because the nights are generally cool. There seems to be a place for it in irrigated regions as a forage to mix with alfalfa hay. Chinch bugs and grasshoppers, among insects, and the red-spot disease are its greatest enemies."

Fertilizers for tobacco, TRICHEREAU (*Jour. Agr. Prat., n. ser., 27 (1914), No. 22, pp. 691-693*).—Results of two years' trials show the profitableness of using a potassic fertilizer (sulphate of potash) for tobacco.

Field experiments with wheat, M. H. REYNOLDS (*Agr. Gaz. N. S. Wales, 25 (1914), No. 1, pp. 1-20*).—In rotation experiments for the years 1907-1912, inclusive, wheat grown continuously produced an annual average yield of 16.8 bu. per acre, wheat alternated annually with bare fallow averaged 24.8 bu., and wheat alternated annually with a fodder crop averaged 26.4 bu. In testing the value of burning the straw, plowing the straw under, or removing the straw with the binder, average yields, respectively, of 23.5, 22.6, and 22 bu. per acre were obtained.

"In the continuous wheat section the application of manure is shown to be most beneficial, its relative value increasing as the yield from the unmanured portion decreases. The best return is obtained from the complete manure, followed closely by the combination of phosphoric acid with potash, and of phosphoric acid with nitrogen. Superphosphate alone gives a substantial increase of one-third over the six years of the test, while the results from potash alone and in conjunction with nitrogen, are slight. The use of nitrogen has resulted in a return lower than that of the check plats.

"In the 'wheat after bare fallow' section, the increases throughout are slight, the best return being given by phosphoric acid and potash, followed, a long way after, by the complete manure. Superphosphate alone has a slight influence for good, while potash and nitrogen alone both yield lower returns than the unmanured portion. In the 'wheat after fodder crop' the best returns are also given by phosphoric acid and potash, followed closely by phosphoric acid alone and the complete manure. Nitrogen, in combination with phosphoric acid, is also of considerable benefit, while the effects of the others may be considered negligible."

A case of correlation in wheat, W. H. PARKER (*Jour. Agr. Sci. [England], 6 (1914), No. 2, pp. 179-181*).—In this article the author notes a high correlation between the total length of the rachis and the average internode length (obtained by dividing the length of the rachis in millimeters by the number of internodes of the straw). The coefficient of correlation is given as +0.9099 in the case of a square head variety of wheat. A correlation table is given.

On various treatments for the disinfection of seeds, T. BOKORNY (*Biochem. Ztschr., 62 (1914), No. 1-2, pp. 58-88*).—Experiments testing the efficiency of various treatments of seeds of barley, lentils, white beans, cabbage, and cress are described.

The treatments considered effective were immersing the seed at the boiling point for one-half minute in 0.1 per cent solution of copper sulphate, 1 per cent acetic acid, or 1 per cent solution of soda (crystals); immersing for 1 minute in 96 per cent alcohol at either 15° C. or the boiling point; treatment with alcoholic solution of potash (50 cc. of 30 per cent potash solution and 50 cc. of 96 per cent alcohol) at 15°; and one-half minute treatment with alcohol solution of hydrochloric acid (50 cc. of 96 per cent alcohol and 50 cc. of crude HCl).

The treatments that the author considers inefficient were immersion at air temperature in copper sulphate solution, alcoholic solution of formaldehyde, alcoholic carbolic acid solution, alcoholic acetic acid, or acetic acid; treatment with 0.5 per cent of copper sulphate at 60°; one-half minute treatment at the boiling point with either 2 to 10 per cent copper sulphate or 0.1 per cent permanganate solution; or 2-minute treatment with boiling water.

Cooperative experiments in weed eradication, J. E. HOWITT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 39 (1913), pp. 46, 47*).—This notes successful methods employed by farmers under the direction of the college. The use of

rape destroyed perennial sow thistle and twitch grass. A method of cropping and cultivation also destroyed and exterminated twitch grass.

Destruction of chickweed in vineyards, P. Hoc (*Prog. Agr. et Vit. (Ed. l'Est-Centre)*, 35 (1914), No. 24, pp. 755-758).—This article records the successful treatment of chickweed (*Stellaria intermedia*) with a 5 per cent solution of copper sulphate, 5 per cent solution of sulphuric acid, 15 per cent solution of iron sulphate, and dehydrated iron sulphate. The last-named applied at the rate of from 400 to 500 kg. per hectare (356 to 445 lbs. per acre) was exceptionally efficient.

Wild garlic and its eradication, F. J. PIPAL (*Indiana Sta. Bul.* 176 (1914), pp. 43, pls. 8, figs. 17).—This bulletin describes a successful method of eradicating wild garlic (*Allium vineale*) from large areas by the use of orchard-heating oil, a by-product of the fractional distillation of rock oil. This oil was used as a mist spray at the rate of 75 gal. per acre in the absence of a growing crop, before the plants have begun to form heads (April 15 to May 1 in southern Indiana), and supplemented by cultivation in the fall to sprout the bulbs and grow the tops to the proper size for the spring spraying. The bulletin treats also of the distribution, description, propagation, life history, conditions of growth, and dissemination of wild garlic.

The cost of the oil is noted as varying from 2.1 cts. to 6.75 cts. per gallon. Of many sprays and other methods, the above described was the only one that was entirely effective.

Experiments to destroy the vitality of the garlic bulblets in seed wheat by soaking first in cold water then in hot water at 126 to 129° F. indicated that a large percentage of the garlic bulblets can be killed in this way. Treating seed wheat with the orchard heating oil and in some cases heating the oil indicated that the treated bulblets can be killed by heating them for three hours at 125° F., but there are difficulties in subsequently drying the grain.

Wild onion: Methods of eradication, H. R. Cox (*U. S. Dept. Agr., Farmers' Bul.* 610 (1914), pp. 8, figs. 7).—This describes this weed and suggests a method of eradication, consisting essentially of a late fall plowing of infested field followed in the spring by a cultivated crop to prevent the wild onion from growing.

On the destruction of wild mustard, HAAG (*Württemb. Wchnbl. Landw.*, No. 20 (1914), pp. 326-330).—The use of iron sulphate (800 liters of 20 per cent solution per hectare), calcium cyanamid 150 kg. per hectare, kainit 1,000 kg. per hectare, and a mixture of calcium cyanamid 50 kg. and kainit 500 kg. per hectare, is reported as successful in the destruction of wild mustard and related plants in fields of oats, barley, and wheat. It is noted that the liquids made a more satisfactory material, they being cheaper, easier to apply, and more uniformly applied than the salts.

HORTICULTURE.

Asparagus culture and exploitation, H. MIATELLO (*Bol. Min. Agr. [Buenos Aires]*, 17 (1914), No. 5, pp. 530-619, pl. 1, figs. 81).—A treatise on asparagus with reference to its history, botany, culture, exploitation, diseases and insect pests, and uses. A bibliography is appended.

Five oriental species of beans, C. V. PIPER and W. J. MORSE (*U. S. Dept. Agr. Bul.* 119 (1914), pp. 32, pls. 7).—In this bulletin the authors describe five annual species of Asiatic beans that at various times have been introduced into the United States but concerning which very little definite information has been published. They are the adsuki bean (*Phaseolus angularis*), the rice bean (*P.*

calcaratus), the mung bean (*P. aureus*), the urd (*P. mungo*), and the moth bean (*P. aconitifolius*). The beans are considered with reference to their botany and history, distinguishing characters, yields, and uses in their native countries. They are also compared with other similar legumes and notes are given on previous introductions into this country, together with chemical analyses of the hay and seeds.

A bibliography of cited literature is included.

Onion culture, O. M. MORRIS (*Washington Sta. Popular Bul. 66 (1914), pp. 4*).—A brief popular treatise on onion culture.

Recent investigations on solanaceous grafts, L. DANIEL (*Rev. Hort. [Paris], 86 (1914), No. 6, pp. 135-138, figs. 4*).—A study of direct and reciprocal grafts between various species of *Solanum*, such as the pepper, tomato, eggplant, etc., leads the author to conclude that many of the physiologic troubles of plants commonly considered as diseases are in reality due to the employment of antagonistic stocks and scions.

Top grafting of fruit trees, O. M. MORRIS and C. B. SPRAGUE (*Washington Sta. Popular Bul. 67 (1914), pp. 8, figs. 13*).—This contains popular directions for top grafting fruit trees by the following methods: Cleft grafting, saw kerf grafting, bark grafting, budding, and bridge grafting.

Winter sprays: Sulphur-lime wash and crude oil emulsions, A. L. MELANDER (*Washington Sta. Popular Bul. 64 (1914), pp. 8*).—This contains popular directions for the control of orchard pests by winter spraying with lime-sulphur washes and crude oil emulsions, including data as to their preparation.

Report on insecticides and fungicides licensed, inspected, and analyzed during the year 1913, S. K. JOHNSON (*Agr. Com. Ohio, Off. Rpt. Nursery and Orchard Insp., 1913, pp. 31-64*).—This comprises a report of the work for 1913 on the inspection and analysis of insecticides and fungicides under the Ohio insecticide and fungicide law, the text of which is given.

Reports on experimental work in connection with cranberries, H. J. FRANKLIN (*Massachusetts Sta. Bul. 150 (1914), pp. 37-62*).—The author here presents a full report on the work of the cranberry substation at Wareham for the year 1913 (E. S. R., 31, p. 441).

Weather records are being secured at the substation and at various other bogs with the ultimate aim of making more satisfactory frost predictions. Observations of barometric changes with respect to their influence on frost conditions in the Cape Cod region have shown a need of a more thorough knowledge of barometric conditions in the eastern Provinces of Canada. The U. S. Weather Bureau is planning to take such observations. An overhead irrigation system was tested on a small scale for drawing frost out of the cranberry vines by applications of cold water before sunrise. The sprayed areas afterward appeared to show more frost injury than did the surrounding unsprayed portions of the bog and such irrigation systems are also undesirable from the standpoint of expense. In lieu of a better method of frost protection, attention is directed to the practice of sanding the bogs as used with good results at the Wisconsin Station (E. S. R., 28, p. 838).

The work with fungus diseases was continued on the experimental plats in cooperation with the U. S. Department of Agriculture (E. S. R., 30, p. 143) and a number of spraying tests were carried on by growers. As in previous years the spray plats were treated in part with Bordeaux alone and in part with Bordeaux for early sprayings and neutral copper acetate for the last application. The tabulated results show a marked falling off in yield of the sprayed plats as compared with the surrounding untreated portions of the bog. It is suggested that the vigorous vines resulting from the control of fungus diseases in previous years may have seriously reduced the supply of available

plant food. A fertilizer test conducted on one of the sprayed plats resulted in an improved yield and indicates that vines which have borne a large crop through reduction of fungus diseases are in need of an extra supply of plant food the following year to maintain their vigor. Some evidence was obtained which indicates that the best time for applying fertilizers in order to increase the yield of fruit may be at about the blossoming period. An unexpected result of the spraying was the killing of the wood moss on all of the fungus plats. No marked difference in color was observed between the berries from the sprayed plats and their checks. The size of berries of the Howe variety was somewhat reduced on the sprayed plats as compared with berries from the check plats. Data on the keeping of berries from the sprayed plats and their checks indicate in a general way that the sprayed fruit holds up better under storage, although this result is more marked with some varieties than with others.

Three new fungus plats were started on the station bog in 1913. One of these plats was sprayed with lime-sulphur and the others with Bordeaux early in the season and with neutral copper acetate late in the season. One of the latter plats consisted of one-half of the fertilizer plat, in order to determine the combined effect of fertilizer and fungus spraying. As compared with the checks all of the sprayed plats gave a reduced yield of fruit. The fruit sprayed with Bordeaux and neutral copper acetate kept better in storage than the fruit from the check plats; whereas both the yield and keeping quality of fruit from the lime-sulphur plat was inferior to the fruit from the check plats. Thus far it appears that lime-sulphur is not a good cranberry fungicide and that Bordeaux may have an injurious effect on the setting of fruit if applied during the blooming period. The new disease "blossom end rot" (E. S. R., 30, p. 143) was prevalent in 1913, especially with the Howe variety.

In June tests were begun looking for the control of fungus diseases by applying copper sulphate in the flowage. As indicated by the yields and keeping quality of the fruit, the copper sulphate treatment was neither beneficial nor injurious. Investigations looking to the development of improved varieties were continued and samples of berries of most of the varieties grown in the Cape Cod region have been collected.

In the bee pollination experiments the plats from which bees were screened out during the blooming periods of 1911 and 1912 yielded fruit in 1913 at the same rate as the surrounding bog. A new exclusion plat, approximately 0.5 sq. rod in area, was established in 1913, and the yield on this plat was reduced to 2 $\frac{1}{4}$ qt. as compared with about 1 bu. on any equal unscreened adjoining plat.

On the cranberry fertilizer plats there was a general reduction in yield as compared with the check plats, but the decrease was slight except on the nitrate of soda plats where there was a marked drying up of the blossoms and small berries, which has thus far been unexplained. The fertilizers failed to show any marked effect on the keeping quality of the fruit except on one plat receiving the heaviest application of nitrate of soda. The berries from this plat showed poor keeping quality. The season's work with insects is noted on page 752.

An attempt was made to control the horsetail weed by pouring a solution of copper sulphate in holes in the soil spaced 1 ft. apart each way. One qt. of a solution as strong as 1 lb. to 25 gal. of water was poured in each hole. The solution appeared to cause the horsetail to thrive instead of affecting it injuriously. Spraying with a 20 per cent iron sulphate solution was fairly effective in killing back the tops of the weeds although there appears to be a possible danger connected with the continued use of this chemical on the same area.

Experiments in resanding were continued. The results indicate that the yield of berries is reduced by a prolonged lack of resanding. In general the berries from unsanded plats kept better than those from sanded plats. Some notes are given on a test of spray mixtures in which it was demonstrated that resin fish-oil soap and arsenate of lead can not safely be used together as a spray unless lime is added. As a result of three years' experience there appears to be no distinct advantage in hand picking cranberries.

Observations on the station bog crop have shown that the higher and better drained portions usually produce more fruit than the low portions. An examination of the root systems of plants on high and low areas indicates that the root systems on flowed bogs are confined for the most part to sand above the peat, while on dry bogs the roots run well down into the peat. The author calls attention to the need of a more thorough knowledge of the underground portions of the cranberry plant.

Selection and preparation of land for cranberry culture, C. L. LEWIS (*Minnesota Sta. Bul. 142 (1914), pp. 9-46, figs. 18*).—This bulletin deals primarily with the problems involved in the selection of suitable land for cranberry culture, its preparation, planting, and care up to the fifth year. Brief general consideration is also given to the problems of harvesting, marketing, and protection from diseases and insects. A short bibliography is appended.

[**Citrus experiments**], S. E. COLLISON (*Florida Sta. Rpt. 1913, pp. XCVI, XCVII*).—In continuation of previous reports (E. S. R., 29, p. 237) measurements are given showing the average gain in diameter of trees from June, 1909, to June, 1913, growing on various fertilizer plats in the citrus experimental grove. So far the factors which stand out as evidently influencing growth are clean culture and excessive fertilization, the former in increasing and the latter in retarding growth. The clean culture plats continue to show the largest gains. The plat receiving no fertilizer continues to show less new growth, but no fertilizer or combination of fertilizers shows a predominating influence on growth.

Sand cultures of citrus seedlings, B. F. FLOYD (*Florida Sta. Rpt. 1913, pp. XLIV-LIII, figs. 2*).—This report embodies the result of a preliminary experiment carried out in the greenhouse to determine the effect of varying sources of ammonia and phosphoric acid upon the growth of grapefruit seedlings.

Measurements made during the first season indicate that a combination of dried blood and acid phosphate gave the best growth. The addition of lime to this mixture was a hindrance, the growth being only slightly better than that where lime was used without any fertilizer. A mixture of sulphate of ammonia and acid phosphate gave the poorest growth of any of the combinations. The addition of lime to this mixture improved the growth somewhat but lime used alone gave a much better growth. Nitrate of soda and nitrate of potash gave growth measurements which were much alike. Basic slag appears to be the better source of phosphoric acid for use with sulphate of ammonia and nitrate of potash, but was inferior to acid phosphate for use with dried blood.

Coconuts: Experiments at Peradeniya, M. K. BAMBER (*Dept. Agr. Ceylon Buls. 2 (1912), pp. 37-51; 10 (1914), pp. 135-146*).—The first of these bulletins is a progress report on fertilizer experiments with old coconut trees, started at the Peradeniya station in 1911. The second presents the results of three years' experimental work.

Palm fruits and seeds (*Missouri Bot. Gard. Bul., 2 (1914), No. 9, pp. 107, 108, pls. 2*).—This comprises illustrations of some 45 species of palm fruits and seeds received by the Missouri Botanical Garden from the Botanical Garden at Rio de Janeiro, Brazil.

The perpetual flowering carnation and how to grow it indoors and out-of-doors, E. J. WOOTTEN (*London, 1914, pp. 55, pls. 13*).—A popular treatise on the culture of carnations under glass and in the open, including also information relative to hybridization and raising from seed and diseases and their treatment. A monthly calendar of operations is also given.

Growing bulbs for winter and spring blooming, M. FULD (*New York, 1914, pp. 78*).—A popular treatise on bulb culture both indoors and in the open, including also a descriptive list of the more important ornamental bulbs.

The small rock garden, E. H. JENKINS (*London and New York, 1913, pp. XII+139, pl. 1, figs. 52*).—A popular treatise on the construction of rock gardens, including lists of plants suitable for all purposes and seasons, together with cultural details.

Gardens in the making, W. H. GODFREY (*London, 1914, pp. XVII+207, figs. 63*).—A popular treatise on garden design in which the important problems considered are the layout and general effect of the garden and the proper relationship of all parts of the garden to the whole. The text is accompanied by a number of garden plans.

FORESTRY.

The timbers of British Guiana, H. STONE and W. G. FREEMAN (*London, 1914, pp. XI+110, pl. 1*).—The present report contains a descriptive account of the wood of a large number of species of trees collected in British Guiana under the direction of A. G. Bell. Each wood is treated with reference to its nomenclature, salient features, physical characters, bark, uses, qualities, etc.

Studies on the periodicity of the life processes of trees native to continually humid tropical districts, S. V. SIMON (*Jahrb. Wiss. Bot. [Pringsheim], 54 (1914), No. 1, pp. 71-187*).—The author here reports observations and investigations on the life history of a large number of Javenese tree species. The literature of the subject is reviewed and a bibliography appended.

The genus *Pinus*, G. R. SHAW (*Pubs. Arnold Arboretum, No. 5 (1914), pp. 96, figs. 332*).—In part 1 of this work the author discusses the characters of the genus *Pinus* with special reference to their taxonomic significance and their utility for determining the limits of the species. In part 2 a classification of the species is given which is based on the gradual evolution of cone structure.

The relation of crown space to the volume of present and future stands of western yellow pine, G. A. BRIGHT (*Forestry Quart., 12 (1914), No. 3, pp. 330-340*).—A preliminary study of yellow pine stands with special reference to the relation between stand density and wood volume.

Volume table for lodgepole pine, A. T. UPSON (*Forestry Quart., 12 (1914), No. 3, pp. 319-329*).—The author here presents and discusses a volume table for lodgepole pine which was compiled from measurements secured on some 2,015 trees on the Arapaho Forest, Colorado.

Relative resistance of various conifers to injection with creosote, C. H. TEESDALE (*U. S. Dept. Agr. Bul. 101 (1914), pp. 43, pls. 8, figs. 9*).—The author here reports creosote penetration tests conducted with various species of conifers at the Forest Products Laboratory maintained by the Forest Service in cooperation with the University of Wisconsin. Introductory considerations have to do briefly with the gross and microscopic structure of coniferous woods and the experimental methods employed. The results of the tests are presented in a series of graphic curves and tables and fully discussed.

Turpentine possibilities on the Pacific coast, C. S. SMITH (*Proc. Soc. Amer. Foresters, 9 (1914), No. 3, pp. 327-338*).—The author here briefly summarizes

his investigations relative to the possibilities of various western species of pine for turpentine production.

Some experiments conducted in California show a yield of oleoresin from western yellow pine about 12 per cent greater than that obtained from southern yellow pine in average operations in Florida, the comparison being made on the same period of time for both sections. It is believed that the turpentine produced in California will be satisfactory for industrial purposes.

The low yield from western yellow pine in Oregon precludes its use for turpentine at the present time. Jeffrey pine in California yields somewhat less oleoresin than western yellow pine and the principal constituent, heptane (abietene), can not be used as turpentine. Heptane is used to a considerable extent in the manufacture of various medicinal products and it is believed a further market may be developed for it as an extractive in place of petroleum hydrocarbon fractions now used. The rosin from both of these pines is of high grade. Thus far the commercial exploitation of oleoresin from digger pine, single leaf piñon, lodgepole, and sugar pine is considered to be impractical.

The administration of a National Forest for naval stores, I. F. ELDRIDGE (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 3, pp. 310-326).—A descriptive account of the administration of the Florida National Forest with special reference to the conservative exploitation of naval stores.

Tenth annual report of the shade tree commission, G. B. ASTLEY, J. J. MOONEY, and F. L. DRIVER (*Ann. Rpt. Shade Tree Com., Newark, N. J., 10 (1913), pp. 79, pl. 1, figs. 32*).—A progress report on the work of the Newark Shade Tree Commission, including a map showing the streets planted and the species used since 1904.

Joint annual report of the forestry branches for the year 1912-13 (*Bd. Agr. and Fisheries [London], Joint Ann. Rpt. Forestry Branches, 1912-13, pp. 82, pl. 1, figs. 2*).—This comprises the first annual report of the forestry branches recently constituted in the Board of Agriculture and Fisheries and the Office of Woods.

The introductory chapter deals with the general attitude toward forestry and afforestation in England and Wales. The work of the forestry branches is then briefly reviewed. A historical note is given on the management of the crown forests and woods, together with notes on the individual woods and information relative to the school for working foresters and the wood distillation works on the Forest of Dean. The report concludes with a statistical review of the timber trade of the United Kingdom. Information relative to technical advice in forestry and the area of woodlands in England and Wales for 1913 is appended.

Report of the director of forests, N. W. JOLLY (*Ann. Rpt. Dir. Forests [Queensland], 1913, pp. 7, pls. 3*).—This is the report for the year ended December 31, 1913, relative to the administration and management of the state forests in Queensland, including data relative to forest areas, revenues, expenditures, etc.

Forestation a success in the sand hills of Nebraska, S. D. SMITH (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 3, pp. 388-395, pl. 1).—A review of reforestation work in the sand hills on the Nebraska National Forest.

The sand dunes of Coos Bay, Oregon, H. D. HOUSE (*Plant World*, 17 (1914), No. 8, pp. 238-243, figs. 2).—In addition to a general descriptive account of the sand dunes information is given relative to the plants found growing on these dunes.

Study of protection finances and fire plans, J. F. PRESTON (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 3, pp. 342-355).—The author here presents the results of study of various fire protection factors, conducted with special reference

to determining methods for estimating protection funds and the formation of fire plans.

Forest taxation in Washington, F. G. MILLER (*Proc. Soc. Amer. Foresters*, 5 (1914), No. 3, pp. 407-447).—The author here reports the results of inquiries among timber owners in the State of Washington to determine the actual burden of taxation on forest land as compared with that borne by other classes of real estate, the effect of the present system of taxation on the management of forest property, and what remedial legislation should be enacted.

DISEASES OF PLANTS.

Bacteria in relation to plant diseases, III, E. F. SMITH (*Carnegie Inst. Washington Pub.* 27, vol. 3 (1914), pp. VIII+309, pls. 47, figs. 155).—Continuing the method adopted in the previous volume (E. S. R., 27, p. 44), the author describes a number of vascular diseases of plants due to bacteria. Among these are the following: Bacterial disease of sugar cane (*Bacterium vascularum*), sweet corn disease (*B. stewarti*), the Grand Rapids disease of tomato (*Aplanobacter michiganense*), bacterial disease of orchard grass (*A. rathayi*), Trinidad disease of banana (*Bacillus musæ*), and brown rot of solanaceous plants and wilt of tobacco (*Bacterium solanacearum*).

In addition to the above, notes and discussions are given of a number of diseases that have been attributed to bacteria, but which are considered too imperfectly known to be of definite classification or are of doubtful identity.

Phytopathological problems, J. ERIKSSON (*Inst. Internat. Agr. [Rome], Actes Conf. Internat. Phytopath.*, 1914, pp. 231-233).—This is a brief discussion of certain plant diseases considered as falling in two categories, those long known and those of more recent appearance as dangerous pests, each in connection with measures looking to its control.

Means for combating plant diseases, M. HOLLRUNG (*Die Mittel zur Bekämpfung der Pflanzenkrankheiten. Berlin*, 1914, 2. ed., rev. and enl., pp. VIII+340, figs. 30).—This work is a revised and enlarged edition of the author's handbook of chemical means for combating plant diseases (E. S. R., 10, p. 363). Chemical, physical, and mechanical means for combating fungus and insect injuries are described at length, the author making a very comprehensive review of the literature during the first half of 1913 and that appearing previously regarding the use of fungicides and insecticides. A chapter is included on the construction and use of spraying apparatus.

Cryptogamic review for 1912, G. BRIOSI (*Atti Ist. Bot. Univ. Pavia*, 2. ser., 15 (1912), pp. 242-273).—This is a brief account of studies carried out during 1912 on cryptogamic diseases of plants, listing diseases and causative agencies according to plants attacked.

Maryland plant diseases, 1913, J. B. S. NORTON (*Rpt. Md. State Hort. Soc.*, 16 (1913), pp. 164-168).—Notes are given on plant diseases observed in the State during the year, together with a brief discussion of the relation of weather to the prevalence of plant diseases.

Botany, H. S. HAMMOND (*New Mexico Sta. Rpt. 1913*, pp. 34-36).—The principal work of the plant pathologist is said to have been an investigation of the disease of chili peppers. The results indicate that the disease is of bacterial origin and that the organism is closely related to *Bacillus solanacearum*, which causes wilt of the tomato and other solanaceous plants. An experiment was carried on to test the value of treating seed for the prevention of the disease, but although various chemicals were used no benefit seemed to follow their application.

Notes are given on a number of other diseases, among them chlorosis of fruit trees, blight (*B. amylovorus*), cotton root rot (*Ozonium omnivorum*), bean rust (*Uromyces appendiculatus*), crown gall (*Pseudomonas tumefaciens*), potato blight (*Macrosporium solani*), and alfalfa leaf spot (*Pseudopeziza medicaginis*).

[Fungus diseases in Barbados], W. NOWELL (*Rpt. Dept. Agr. Barbados, 1912-13, pp. 44, 45; abs. in Agr. News [Barbados], 13 (1914), No. 314, p. 158*)—The author briefly reports on a number of diseases observed during the year.

Of the sugar cane diseases the root disease, caused by the fungus *Marasmius sacchari*, is said to have been the most important and injurious, while the rind disease (*Colletotrichum falcatum*) was rather unimportant. The author urges planters to exercise care in the selection of cane cuttings, using only the strongest and healthiest plants, in order that the injury due to the disease may be reduced as much as possible.

Attention is called to *Eutypa erumpens* on the evergreen *Ficus nitida* and other shade trees.

Brief notes are given on silver scurf on limes, which is considered probably due to *Coniothecium* sp. It is suggested that spraying with Bordeaux mixture might be useful in controlling it.

Brief notes are also given on the black spot of roses, rose mildew, and the powdery mildew of grapes, and suggestions are given for the control of these rather common diseases.

New fungus diseases of useful plants, E. PANTANELLI and U. CRISTOFOLETTI (*Staz. Sper. Agr. Ital., 46 (1913), No. 10, pp. 625-642, pls. 4*).—The authors report studies carried out by them on *Pleospora eriobotryæ* n. sp. (conidial form, *Macrosporium eriobotryæ* n. sp.), *Puccinia endiviæ*, *Psathyrella ampelina*, *Botryodiplodia chamæropis*, *Ascochyta pisi*, *Ovularia palmicola* n. sp., and *Macrosporium hesperidearum* n. sp., descriptions of the new forms being given.

New diseases and parasites noted and studied in the cryptogamic laboratory at Pavia, G. BRIOSI (*Atti R. Ist. Bot. Univ. Pavia, 2. ser., 16 (1914), pp. 72-75*).—The diseases here listed affect a great variety of plants, representing garden, field, forest, flower garden, etc.

Publications of the cryptogamic laboratory of Pavia, G. BRIOSI (*Atti R. Ist. Bot. Univ. Pavia, 2. ser., 16 (1914), pp. 75-102*).—The director gives lists, by years, of publications of the cryptogamic laboratory at Pavia from 1873 to 1912, inclusive.

A method of picking up single spores, C. W. EDGERTON (*Phytopathology, 4 (1914), No. 2, pp. 115-117, fig. 1*).—A description is given of a form of apparatus devised by the author, by which it is possible to secure single spores of any organism that is being studied.

The identity of the anthracnose of grasses in the United States, G. W. WILSON (*Phytopathology, 4 (1914), No. 2, pp. 106-112*).—The results of a study of all the available specimens of grass anthracnose are given, in which the author shows that the fungus causing this widespread disease has been described and specimens distributed under at least 14 different names. The data presented indicate that the proper name of the fungus should be *Colletotrichum graminicolum* n. n. In the course of his study he found this fungus present on species of 8 of the 12 tribes of the grass family.

Tylenchus dipsaci in the United States, E. A. BESSEY (*Phytopathology, 4 (1914), No. 2, p. 118*).—The author reports having found, in 1907, this nematode in rye grown at Edgerton, Kans.

Flag smut of wheat, G. P. DARNELL-SMITH (*Agr. Gaz. N. S. Wales, 25 (1914), No. 4, pp. 285-287, pl. 1*).—The best results obtained at the Cowra station from treating seed infected with *Urocystis tritici* followed dipping in 2 per cent

copper sulphate 5 minutes, then in lime water for 5 minutes. It is held that the lower infection rate resulting when the wheat is sown late in soil that has been moist for some time is usually due to the early germination and death of the spores. Pot experiments are claimed to show, however, that spores germinating in damp soil may produce germ tubes terminated by secondary spores, which may again produce elongated infection threads.

Head smut of sorghum and maize, A. A. POTTER (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 5, pp. 339-372, pls. 7, figs. 7).—An account is given of the head smut of sorghum due to *Sorosporium reilianum*.

This fungus, it is said, was first reported from Egypt in 1868 and has been found to be a destructive parasite of sorghum, and to occur also on maize. The author has made a study of the organism grown in artificial cultures, and a detailed account of its life history is given. It is stated that the work of other investigators pointed to the conclusion that infection was by means of seed-borne spores, but numerous floral inoculations failed to show that it could be produced intraseminally and carried over in the seed to the next crop. On the other hand, large percentages of infection were repeatedly produced by the inoculation of seedlings with dry spore material. The author thinks that it is clearly proved that the parasite is not carried with the seed, but is wind-distributed in the locality in which it occurs, doubtless infecting the seedling from the soil.

But little appears to be known regarding the prevention of the head smut, but as milo maize is immune, this could probably be grown in regions where the other species of sorghum are subject to attack.

A bibliography is appended.

Some important contributions concerning the diseases of sugar beet plants in 1913, A. STIFF (*Bl. Zuckerrübenbau*, 21 (1914), Nos. 5, pp. 72-75; 7, pp. 108-111).—The author reviews some of the more important contributions pertaining to the diseases of sugar beets due to nematodes, fungi, etc.

Resistance in tobacco to hydrocyanic acid gas injury, J. JOHNSON (*Phytopathology*, 4 (1914), No. 2, p. 118).—Attention is called to the fact that fumigation with hydrocyanic acid resulted in the discoloration and wilting of the leaves of three varieties of tobacco, namely, Little Dutch, Cuban, and White Burley, while Connecticut Broadleaf remained free from injury in all parts of the greenhouse.

Report of assistant plant pathologist, O. F. BURGER (*Florida Sta. Rpt. 1913*, pp. LXXXVII-XCV, figs. 3).—The bacterial rot of lettuce, first reported some years ago at this station (E. S. R., 21, p. 342), was present to some extent, and an investigation was carried on to determine the effect of aphids in the distribution of the disease. Aphids were collected from an infected field and placed on two healthy lettuce plants, and in about 12 days the infected plants were reduced to a black putrid mass, seeming to indicate that the disease might be carried in this manner.

Notes are given on the lettuce drop, due to *Sclerotinia libertiana*, and a discussion is given of the relation of the fungus to atmospheric conditions and particularly that of temperature.

A brief account is given of the bacterial rot of cucumbers, which has been previously described (E. S. R., 30, p. 149), and notes on a number of vegetable diseases, among them those of tomatoes, beets, celery, onion, and cantaloup.

Fruit rot, leaf spot, and stem blight of the eggplant caused by *Phomopsis vexans*, L. L. HARTER (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 5, pp. 331-338, pls. 5, fig. 1).—A report is given of a disease of eggplants that has been variously reported as due to *Phoma solani*, *Phyllosticta hortorum*, and *Ascochyta hortorum*. As a result of inoculation experiments and morphological

studies the author concludes that the above species are identical, but that the genus should be *Phomopsis*, and the name *P. vexans* n. comb., is given it.

Oxidases in healthy and in curly dwarf potatoes, H. H. BUNZEL (*U. S. Dept. Agr., Jour. Agr. Research*, 2 (1914), No. 5, pp. 373-404, figs. 21).—Summarizing his investigations on the oxidase in potatoes, the author states that the oxidase activity of the foliage of normally developed potato plants is greatest in the early stages of development. It falls off with the growth of the plants and rises again when the plant's growth about reaches a standstill. Curly dwarf potato plants show a greater oxidase activity than healthy ones of the same age, both in the juice of their tubers and in the juice of their foliage. The oxidative activity of the different parts of the potato plant has been established for 18 different reagents.

A brief bibliography is given.

A parasite of tomato (*Bol. Min. Agr., Indus. e Com. [Brazil]*, 2 (1913), No. 2, p. 165).—A disease of tomato, noted in April, 1912, in northern Italy, is said to be that due to *Cladosporium fulvum violaceum* (E. S. R., 30, p. 749).

The plaster cast apple specimen, L. E. MELCHERS (*Phytopathology*, 4 (1914), No. 2, pp. 113, 114, fig. 1).—The author describes a method for the preparation of diseased materials of apple, pear, quince, and other fruits, in which, it is claimed, the characteristics of the disease are completely retained and the material kept readily available for permanent use.

Apple powdery mildew and its control in the Pajaro Valley, W. S. BALLARD and W. H. VOLCK (*U. S. Dept. Agr. Bul.* 120 (1914), pp. 26, pls. 6, figs. 5).—The authors describe the powdery mildew of apples, which is caused by *Podosphæra leucotricha* and *P. oxycanthæ*.

In the Pajaro Valley, California, *P. leucotricha* is very common, attacking the foliage and current year's twig growth. It often makes such rapid progress during the spring and summer that by the end of the leaf-forming season it is said to be difficult to find normal, healthy leaves on certain unsprayed varieties. The fungus is described at some length and notes are given on the susceptibility of different varieties, after which accounts are given of spraying experiments for its control.

It is claimed that the apple powdery mildew may be controlled by foliage spraying with what the authors call iron-sulphid mixture (which consists of a solution of iron sulphate and lime-sulphur solution), precipitated sulphur, or sulphur in some other finely divided form. In addition winter pruning of the trees so as to obtain stimulating effects and removing mildewed twigs, together with winter spraying with some spray that has the effect of inducing vigorous foliage growth in the spring, should be employed.

The Jonathan spot rot, M. T. COOK and G. W. MARTIN (*Phytopathology*, 4 (1914), No. 2, pp. 102-105).—In a previous paper (E. S. R., 29, p. 847) the authors expressed the belief that the Jonathan spot rot was probably caused by species of *Alternaria*. Other investigators have claimed that it was a physiological trouble, due to gas, etc. The authors give a brief account of further investigations to determine, if possible, the cause of this trouble.

In 1913 a large number of apples were bagged during the growing season on the supposition that if the disease was due to an *Alternaria*, protection from infection would produce clean apples, while if it was due to physiological causes the apples would develop spots the same as those unprotected. The fruit matured and was examined in November and January.

It was found that the number of spots on the apples bagged previous to June 9 was much less than those bagged after that date. As a whole the bagged apples showed less spots than those which were not bagged. Two forms of spots were found, small nearly black Jonathan spots and rather large light

brown *Alternaria* spots. Many of the Jonathan spots were surrounded by a light brown area characteristic of *Alternaria* infections. Laboratory studies were made of these spots, and as high as 93 per cent of the large spots were found infected with *Alternaria*, while from the small spots a much lower percentage of the fungus was present, in one case as low as 30 per cent.

The authors believe that, having found two similar spots on the Jonathan, it is probable that different investigators may have been working with different spots. At present they do not consider the data sufficient for establishing any definite theory regarding the cause of this disease.

Fire blight, J. G. HALL (*Washington Sta. Popular Bul.* 65 (1914), *post card*).—A brief description is given of the fire blight of apples and pears, together with suggestions for treatment.

Brusone of pear, L. GABOTTO (*Agr. Mod.* [Milan], 19 (1913), No. 23, p. 269, *fig. 1*).—An illustrated description is given of injury done to the fruit, leaves, and branches of pear by *Fusicladium pirinum*, claimed to be the summer form of *Venturia pirina*.

Spraying with lime sulphur, A. MANARESI (*Agr. Mod.* [Milan], 19 (1913), No. 23, pp. 271, 272).—Experiments carried out on the control of *Exoascus deformans* and *Venturia* spp. during 1912 and 1913, employing several mixtures described, are said to confirm the high value of lime sulphur used in this connection.

A study of the brown rot fungus in the vicinity of Champaign and Urbana, Illinois, J. L. CONEL (*Phytopathology*, 4 (1914), No. 2, pp. 93-101).—On account of the differences of opinion regarding the specific identity of the fungus causing brown rot, the author carried on a series of experiments with material taken from plum mummies. The organism was isolated, cultivated in various media, and studied at length, after which inoculation experiments with plum, apple, crab apple, and cherry trees were made, the trees being infected with the organism.

From his experiments he concludes that the *Sclerotinia* occurring in that locality is *S. cinerea*. This fungus occurs predominantly on stone fruits, but as the result of inoculation tests he found that under laboratory conditions it may also infect pome fruits.

A brief bibliography is given.

The North American gooseberry mildew and its control, G. KÖCK (*Separate from Obstzüchter*, No. 8 (1913), pp. 4, *figs. 3*).—This is a brief account of the appearance, morphological development, and effects of *Sphaerotheca mors uva* as noted in Europe, together with a discussion of means for its prevention and control, including severe cutting back in autumn, also a heavy application of lime sulphur at that time and in the spring just before development of the foliage, and a liberal application of sulphur to any parts showing the disease after the appearance of the foliage.

A new disease of gooseberry twigs, G. KÖCK (*Separate from Obstzüchter*, No. 6 (1913), pp. 2, *figs. 2*).—The author found diseased gooseberry twigs sent for examination to show abundant mycelium in the inner portions of the bark, which were speedily killed, showing abundant fructifications of a fungus which proved to be *Botrytis cinerea*.

Report of plant physiologist, B. F. FLOYD (*Florida Sta. Rpt.* 1913, pp. XXVII-XXIV, *figs. 2*).—This report consists principally of an account of investigations on the use of Bordeaux mixture for the control of die-back of orange trees and of the gumming of citrus trees produced by chemicals.

In the experiments with Bordeaux mixture trees were sprayed with a 5:5:50 mixture twice during the spring of 1912. In January, 1913, an examination was made of the grove and it appeared that Bordeaux mixture was effective for the

control of die-back, but that its benefits were somewhat hidden by a decrease of of the disease due to natural causes.

In the investigations on the gumming of citrus trees the author carried on experiments with a large number of chemicals inserted either in small holes bored into the trunk, or under the bark or placed on the forming buds. An enzyme and 28 different organic and inorganic chemicals were used in the experiment, and of this number 13 induced the formation of gum. Most of these substances are classed as acids, alkalis, or salts of heavy metals. The production of gum was coincident with the injury caused by the chemicals. The most copious production of gum was caused by copper sulphate and the other salts of heavy metals, and the injury extended from the point of insertion in the bud or stock to the upper branches. The injury caused by the other compounds was confined to the region of insertion, and the amount of gum produced was relatively small. In all cases the gum was the same in character and appearance, being of a clear amber in color and completely soluble in water. A microscopical examination showed that in all cases the gum originated in the live embryonic xylem tissue outside the dead area produced by the chemical. Enlarged gum pockets were produced in the immature branches of the trees inoculated with copper sulphate and mercury bichlorid, and no differences in development, structure, or external appearance could be recognized between these and the pockets formed during the progress of the die-back disease. The author states that through the swelling of the gum collected in the gum cycle by the absorption of water, pressure is developed, and that if the covering tissue is inelastic a break will occur and the gum exudes. On the other hand, if the tissue is elastic, as in the immature branches, the covering tissue is raised and large gum pockets are formed in the stem.

Report of plant pathologist, H. E. STEVENS (*Florida Sta. Rpt. 1913, pp. LXXII-LXXXVI*).—The investigations reported upon consisted mostly of a study of melanose, stem-end rot, gummosis, and fruit rot of citrus trees.

Melanose, caused by *Phomopsis citri*, which has been previously described (E. S. R., 28, p. 651), is briefly discussed and results of inoculation experiments are given which confirm previous conclusions regarding this disease and also show that it is due to a specific organism and does not result from any soluble toxin in dead twigs. Experiments were conducted to test the effect of fungicides for the control of melanose, lime sulphur, Bordeaux mixture, and ammoniacal copper carbonate solutions being sprayed upon orange trees in pots in the greenhouse. Lime sulphur seemed to prevent infection completely, but caused more or less injury to the foliage by burning. Bordeaux mixture and ammoniacal solution of copper carbonate gave about the same degree of control, and the injury to the foliage attributed to Bordeaux mixture was practically negligible, while there was some slight burning in one experiment with the ammoniacal solution of copper. An experiment with pruning on the effect of melanose has been begun, but sufficient time has not elapsed to give exact data regarding it.

Brief accounts are given of the stem-end rot, fruit rot, and scab.

The Fusariums from cankered cacao bark and Nectria cancri n. sp., A. A. L. RUTGERS (*Ann. Jard. Bot. Buitenzorg, 2. ser., 12 (1913), pt. 1, pp. 59-63, pls. 4*).—A study was made of 15 apparent strains of *Fusarium* (six supposedly belonging to *F. colorans* and nine to *F. theobromæ*) on different substrata. Perithecia of one of the latter appeared to belong to the genus *Nectria*, but to coincide with no species yet listed. Accordingly this new species, which is here described, received the name *N. cancri*.

A trunk disease of the lilac, H. VON SCHRENK (*Ann. Missouri Bot. Gard., 1 (1914), No. 2, pp. 253-262, pls. 2*).—A destructive trunk disease noted during recent years in and around St. Louis, Mo., is described. It is said to be caused

by *Polyporus versicolor*, gaining entrance through holes made by borers. These may be killed by the insertion of a wire, after which the holes are to be given an antiseptic treatment and plugged. Diseased trunks are to be burned.

Endothia canker of chestnut, P. J. ANDERSON and W. H. RANKIN (*New York Cornell Sta. Bul.* 347 (1914), pp. 531-618, pls. 5, figs. 25).—The authors give the results of an extended investigation on the disease of chestnut due to *E. parasitica*.

After giving an account of the economic value of the chestnut, its soil requirements, and natural reproduction, the disease is described, its origin, spread, symptoms, and pathology being considered at length, and suggestions are given for its control. Under the last topic the authors state that there is nothing now known that will prevent the extermination of the American chestnut tree from this cause and that every measure of control that has been tried has been abandoned north of West Virginia and the Potomac River.

An extensive bibliography is appended.

Two trunk diseases of the mesquite, H. VON SCHRENK (*Ann. Missouri Bot. Gards.*, 1 (1914), No. 2, pp. 243-252, pls. 2).—The author gives a description of the effects produced by *Polyporus texanus* on mesquite near San Antonio, Tex., with a description of the fungus. *Fomes rimosus* was also found in one instance on a mesquite in the same locality.

A bibliography is appended.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Bird houses and how to build them, N. DEARBORN (*U. S. Dept. Agr., Farmers' Bul.* 609 (1914), pp. 19, figs. 48).—This publication, prepared with a view to encouraging the protection and study of birds, gives plans for the construction of various forms of bird houses.

Physiological investigations of insect pests, J. DEWITZ (*Naturw. Ztschr. Forst u. Landw.*, 11 (1913), Nos. 3, pp. 129-143; 9, pp. 431-440).—The first part of this paper has been noted from another source (*E. S. R.*, 28, p. 752); the second part deals with the arrest of the growth of insect larvæ.

The compatibility of insecticides and fungicides, G. P. GRAY (*Better Fruit*, 9 (1914), No. 2, pp. 9, 10, 35-42; *Mo. Bul. Com. Hort. Cal.*, 3 (1914), No. 7, pp. 265-275).—This discussion includes a classification of the various mixtures and gives a compatibility table.

Report of entomologist, J. R. WATSON (*Florida Sta. Rpt.* 1913, pp. LIV-LXXI, figs. 4).—The author first reports upon spraying experiments with *Microcera* in continuation of those previously noted (*E. S. R.*, 29, p. 251), the general results of which were about the same as those tabulated in the previous report.

In a discussion of white fly conditions in various groves the author states that during the past two years in the groves under observation the fungi, especially the brown fungus, have done excellent execution, amounting in most cases to practical control so far as the summer brood is concerned and often the fall brood as well. The woolly white fly (*Aleyrodes howardi*) spread rapidly during the year, at the close of which it was found in groves as far east as Orlando. In some groves it is becoming so abundant as to be fully as serious a pest as *A. citri* and is much more resistant to parasitic fungi than either *A. citri* or *A. nubifera*. Two chalcidid species are said to parasitize it, one of which is quite common.

Observations of other citrus insects, including *Icerya purchasi*, *Leptothrips floridensis*, *Heliothrips hæmorrhoides*, *Pachnæus opalus*, and *Trirhabda bevicollis*, are briefly reported. Under the heading of destructive insects for the

year mention is made of injury to velvet beans by *Anticarsia gemmatilis*; the the attack of camphor buds by *Cryptothrips floridensis* (see E. S. R., 30, p. 357); defoliation of bay (*Persea* sp.) by *Trichostibas parvula*; etc.

Insect records.—Miscellaneous notes by officers of the division of entomology (*Agr. Jour. Union So. Africa*, 8 (1914), No. 1, pp. 70-78, figs. 3).—The several papers here presented include one on the gall on *Aloe transvaalensis*, caused by an Eriophyes mite, by B. B. Hardenberg (pp. 70-72); The False Codling Moth (*Enarmonia batrachopa*) with Particular Reference to Its Attack upon Acorns, by A. Kelly (pp. 72-75); An Interesting Larval Habit of the Pepper Tree Caterpillar (*Bombycomorpha bifascia*), by J. C. Faure (pp. 75, 76); etc.

Notes on the Hymenoptera Trichogrammatidæ and Mymaridæ, A. A. GIRAULT (*Canad. Ent.*, 46 (1914), No. 9, pp. 327-330).—Mention is made of *Anagrus armatus* as having been reared from egg clusters of *Delphax saccharivora* in sugar cane leaves, *Aphelinoidea semifuscipennis* from egg clusters of a leafhopper, and *Ufens niger* from leafhopper eggs in sugar cane, all at Rio Piedras, P. R. *Trichogramma minutum* is reported to have been reared from eggs of the sugar cane borer at Santa Lucrecia, Vera Cruz; Donna, Tex.; New Orleans, La.; Bridgetown, Barbados; Georgetown, British Guiana; in Trinidad; and in Porto Rico.

[Work with cranberry insects in 1913], H. J. FRANKLIN (*Massachusetts Sta. Bul.* 150 (1914), pp. 49-58).—This is a more detailed report of the work than that previously noted (E. S. R., 31, p. 453).

The spanworm previously referred to has been determined as *Epelis truncataria faxonii*. In addition to the cranberry it has been found feeding on the bearberry (*Arctostaphylos uva-ursi*). The parasitic enemies of cranberry pests thus far identified are *Carcelia (Exorista) pyste*, *Phytodietus vulgaris*, and *Pimpla conquisitor*, which attack the dry bog fireworm (*Peronea minuta*); *Phanerotoma tibialis* and *Microbracon dorsator*, which attack the cranberry fruit worm; *Ichneumon extrematatis* and *Phorocera (Euphorocera) claripennis*, which attack the spanworm (*Cymatophora sulphurea*); *Winthemia quadripustulata*, which attacks the false army worm (*Calocampa nupera*); and *Exorista (Tachina) robusta*, which attacks the bud worm.

Cockroaches and ants as carriers of the vibrios of Asiatic cholera, M. A. BARBER (*Philippine Jour. Sci.*, Sect. B, 9 (1914), No. 1, pp. 1-4).—Experimental evidence of the transmission, vitality, retention of virulence, and longevity of the vibrio in the alimentary canal of the common cockroach (*Periplaneta americana*) is here presented. Feces containing cultures were exposed to starved roaches which devoured them greedily and the organisms were demonstrated in the feces from 6 to 79 hours after ingestion. "Cholera vibrios in cockroach feces will survive on human food at least 16 hours after discharge from the insect, and cholera vibrios in human feces will survive, in competition with numerous other bacteria, on food at least four days. There is no loss of virulence for guinea pigs in cholera vibrios after 29 hours in the intestine of the cockroach."

In experiments in which ordinary red ants (*Monomorium latinode*) were fed cholera cultures the organisms were recovered from their crushed bodies eight hours afterwards.

The coccobacillus of the locust, F. D'HERELLE (*Ann. Inst. Pasteur*, 28 (1914), Nos. 3, pp. 280-328, figs. 4; 4, pp. 387-407, fig. 1).—The first part of this paper (pp. 280-296) consists of a somewhat detailed account of migratory locusts and their geographical distribution. The second part (pp. 296-301) gives a technical description of the coccobacillus (*Coccobacillus acridiorum*) affecting them. The third part (pp. 301-328) describes the work with the coccobacillus

in combating the locust. Part 4 (pp. 387-398) discusses the results which have been obtained in Argentina, Colombia, Cyprus, and Algeria. Part 5 (pp. 399-407) deals with the organization of the work.

The destruction of locusts in Algeria by *Coccobacillus acridiorum*, E. SERGENT and A. LHÉRITIER (*Ann. Inst. Pasteur*, 28 (1914), No. 4, pp. 408-419, figs. 2).—The authors report having succeeded in increasing the virulence of cultures of *C. acridiorum* for the Algerian locust (*Stauronotus maroccanus*) until the virus will cause death in about four hours. There appears to be some doubt as to whether the disease will spread sufficiently rapidly to produce results of practical value and further experiments will be carried on.

The oat aphid, J. J. DAVIS (*U. S. Dept. Agr. Bul.* 112 (1914), pp. 16, figs. 9).—The oat aphid (*Aphis avenæ*) is said to be the most widely distributed and most common over its area of distribution of the three important plant lice attacking wheat and oats above ground, and second only to the so-called green bug (*Toxoptera graminum*) in importance as a wheat pest. This aphid was introduced into the United States previous to 1851 in which year it was recorded by Fitch. While it has never been considered a pest of great importance, observations would lead to the belief that it is worthy of more serious consideration.

It is found in all parts of Europe as well as in most of the States in this country and has been recorded from a large number of plants, particularly the grasses. The author presents a summary of its life history, habits, natural checks, remedial and preventive measures, etc., based upon the literature and experiments and observations by agents of the Bureau of Entomology of this Department.

The winter is passed in the egg stage on apple and related trees or as wingless females. In the spring the progeny from the eggs hatching on apple migrate to grasses and grains. From September to November the migrants return to the apple where several forms are produced and eggs laid; others remain on grasses or migrate to fresh grass hosts, passing the winter as viviparous females.

The species is freely attacked by various parasitic and predaceous enemies which doubtless are responsible for the usual control of this pest. As in the case with the spring grain aphid or green bug, it is practically impossible to control the oat aphid after it has once gained much headway in numbers and diffusion, but by proper precautions it is possible to prevent serious outbreaks.

Walnut aphids in California, W. M. DAVIDSON (*U. S. Dept. Agr. Bul.* 100 (1914), pp. 48, pls. 4, figs. 18).—This is a detailed report of studies of the life history and habits of aphidids commenced early in the year 1911 and continued until the summer of 1913, largely at Walnut Creek, Cal. The studies relate to the European walnut aphid (*Chromaphis juglandicola*) which alone infests walnuts of commercial value grown in California, and two native species found to be pests on native walnuts that are much used for stock on which to graft the European or Persian nut, namely, the American walnut aphid (*Monellia caryæ*) which attacks the eastern black walnut (*Juglans nigra*), and the little hickory aphid (*M. caryella*) which attacks the California black walnut (*J. californica*).

"In general the aphidids inhabit the underside of the leaves, but those of the second, third, and fourth generations often attack the nuts, sometimes seriously dwarfing them. . . . When infestation on the leaves and nuts is severe the vitality of the infested tree is impaired. The aphidids excrete a sweet, gummy, transparent substance much sought after by ants, and in this thrives a black sooty fungus. This black fungus often covers the upper sides of the lower leaves and the upper part of the nuts, thereby interfering with the

respiratory action of the plant tissues." Attacks on the tree from year to year also materially reduce its vitality.

The life history of the walnut aphidids in California in brief is summarized by the author as follows: "A week or so before the buds open on the trees in the spring the aphidids begin to hatch from the winter eggs. As soon as the young foliage appears the 'lice' settle on it, and after feeding for a month or so become adults. These stem mothers are always winged and like plant lice of later generations are capable of migrating to other trees and orchards. As soon as they are fully developed they produce young parthenogenetically. These second-generation young become mature in three weeks and in turn produce young. The individuals of the third and subsequent generations of summer mature in about 16 days. On early-leaving varieties there are 10 or 11 viviparous generations in the year while on late varieties there are 8 or 9. The production of the sexual generations is prolonged over four months, these forms first appearing in July. After the sexes (comprised of the winged male and the wingless female) mate, the female repairs to the twigs and limbs of the tree, there to deposit her eggs. Winter is passed in the egg stage only."

Of the many predatory enemies of the walnut plant lice the ashy-gray lady beetle (*Olla abdominalis*) is said to be the most important. As regards remedial measures the author finds that winter spraying directed against the eggs is the easiest to apply, and that high trees can be reached by a winter wash with ease. "Lime-sulphur and crude-oil emulsions are effective, especially the first named. The spray should be directed all over limbs and twigs so as to cover every part. If it is necessary to spray in spring or summer, a combination of 2 per cent distillate-oil emulsion and commercial tobacco extract No. 2 (1:1,500) will prove effective provided it be applied under a pressure of at least 150 lbs. and the spray directed on the nuts and underside of the leaves."

A bibliography of literature relating to these aphids is appended.

New or little-known species of Aphididæ, J. J. DAVIS (*Canad. Ent.*, 46 (1914), Nos. 2, pp. 41-51, figs. 13; 3, pp. 77-87, figs. 22; 4, pp. 121-134, figs. 19; 5, pp. 165-173, fig. 1; 7, pp. 226-236, figs. 12).—Species here described as new include *Macrosiphum creelii* from alfalfa in Utah, Nevada, and Washington; *M. coryli*, which lives gregariously on the underside of the leaves and tender terminal shoots of hazel (*Corylus americana*), collected at La Fayette, Ind., and Chicago, Ill.; *M. venæfusca* from crested wild buckwheat (*Polygonum cristatum*) and curled leaf dock (*Rumex crispus*) in Indiana, from *Rumex* and *P. cristatum* in Wisconsin, and from *Rumex* in Missouri; *Symdobius albasiphus* from white oak in Illinois, Indiana, Missouri, and Virginia; and *Aphis pseudo-brassicæ* from cabbage in New York, radish, turnips, kale, rape, and mustard in Indiana, and turnips in Texas.

Contribution to the study of the biology of the black aphid of the beet root, L. GAUMONT (*Compt. Rend. Acad. Sci. [Paris]*, 157 (1913), No. 22, pp. 1092-1094; *Rev. Phytopath. Appl.*, 1 (1914), No. 16-17, pp. 4, 5; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 236, 237).—*Aphis euonymi* causes considerable damage to beets in north and central France nearly every year. This aphidid passes the winter in the egg stage on Japanese spindle-trees, which are very numerous in parks and public gardens, as well as on the European spindle-tree (*Euonymus europæus*) and guelder-rose (*Viburnum opulus*).

The author observed at the end of October a field of beet roots in which the aphid was still present, both in parthenogenetic and sexual forms, and in which females were laying eggs at the bases of the leaves. Attention is called to the fact that the eggs which remain in the collar hatch in the cellar after the roots are stored and in the spring spread to *Rumex*, *Chenopodium*, and other wild plants.

Aphidid enemies of sorghum in the French Sudan, J. and A. VUILLET (*Agron. Colon.*, 1 (1914), Nos. 11, pp. 137-143; 12, pp. 161-165; 2 (1914), No. 13, pp. 17-23, figs. 8).—This brief account deals with *Aphis sorghi*, *A. maidis*, and *Siphonophora leptadeniæ* n. sp., their natural enemies, and means of control.

Classification of the Aleyrodidæ, II, A. L. QUAINANCE and A. C. BAKER (*U. S. Dept. Agr., Bur. Ent. Bul. 27, pt. 2, tech. ser. (1914), pp. 95-109, pls. 14*).—This second part of the work previously noted (*E. S. R.*, 29, p. 54) completes the classification of the family. It deals with the genera of the subfamily Aleyrodinæ, of which 14 are erected as new, and lists the species belonging to each. The species *Aleurotithius timberlakel* n. g. and n. sp. from California is characterized.

A list of unplaced species of the old genus *Aleyrodes* is appended.

The life history of *Psylla isitis* (*Psyllopa punctipennis*, Crawford), the "psylla" disease of indigo, A. J. GROVE and C. C. GHOSH (*Mem. Dept. Agr. India, Ent. Ser.*, 4 (1914), No. 6, pp. 329-357, pls. 6).—The author presents the details of studies of *P. isitis* made during the course of investigations of enemies of indigo in Behar.

A general account of this pest and its relation to other diseases of indigo by Maxwell-Lefroy has been previously noted (*E. S. R.*, 29, p. 854).

The lesser bud moth, E. W. SCOTT and J. H. PAINE (*U. S. Dept. Agr. Bul. 113 (1914), pp. 16, pls. 2, fig. 1*).—This bulletin presents the results of studies of the life history and habits and means of control of *Recurvaria nanella* which were carried on during 1913 at Benton Harbor, Mich. A preliminary account of this pest by the authors has been previously noted (*E. S. R.*, 31, p. 252).

This insect has attained quite wide distribution throughout the Northeastern and North Central States, having been collected in New Hampshire, New York, Pennsylvania, Ohio, Maryland, and the District of Columbia. Its food plants include apple, pear, peach, plum, cherry, wild plum, and hawthorn.

In rearing cages at Benton Harbor the first moths issued on June 22, the maximum emergence taking place on June 30 and the last moths appearing on July 10. Eggs were loosely deposited among the hairs on the underside of apple leaves, singly or several sticking together, for the most part along the veins; others were deposited on a twig under the edge of a small scale. They commenced hatching about July 15. The larvæ at once commence boring through the epidermis of the leaf on the underside and the construction of a mine in the inner tissues. On arrival of the first cold days of fall they begin leaving the mines to construct small silken hibernacula in which they pass the winter on the trees. After a few warm days in the spring they commence to appear in great numbers. At Benton Harbor the first larvæ were observed working in the buds in considerable numbers on April 15, at which time the buds were just beginning to swell. By April 23 all had apparently entered buds. On boring into a bud the larva makes its way directly to the center, there feeding on the tender ovary, stamens, and pistils of the unopened flower, provided the insect has entered the flower bud, as the majority do. After consuming the inner portions the larva feeds upon the leafy tissue of the bud, remaining within until the bud expands and the leaves begin to unfold. As the first leaves open out, it fastens them together by spinning a silken thread about them and constructs a shelter for itself, often rolling over the edge of a leaf and constructing it from within, or bringing the tips of several leaves together. It then greatly deforms and hinders the succeeding leaves as they develop.

On May 15 the caterpillars were observed to have left some of the nests in the leaves and to be constructing cocoons beneath loose bits of bark on the limbs and trunk in which to pupate. The larval stage was found to cover an average period of 10 months, the last crawling larva in the orchard having been found on June 19. The first pupa was observed on May 18 and the last larva pupating in rearing cages did so on June 16. The average time spent in the pupal stage was about 15 days, varying, however, from 15 to 30 days.

Hymenopterous parasites representing six families and seven genera were reared from material collected in the larval and pupal stages and confined in breeding cages. Experiments carried on and observations made throughout the infested section at Benton Harbor show that this pest can be controlled by thoroughly spraying the trees with lime-sulphur at 32° Baumé, used at the rate of 1 gal. to 8 gals. of water just before the buds swell or preferably when the buds are swelling.

A list of the more important literature cited is appended.

The insensitivity of the life forms of the potato moth to various poisons, F. STOWARD (*Reprint from Rpt. Austral. Assoc. Adv. Sci.*, 14 (1913), pp. 326-329; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, p. 377).—*Phthorimæa operculella*, which defoliates the potato plant and infests the tubers, is one of the most troublesome enemies of this crop in Australia. The most satisfactory manner of dealing with this pest is said to have been through fumigation with carbon bisulphid. In experimental work the larva, whether in the tuber or exposed, succumbs after 15 or 16 hours' exposure to an atmosphere containing carbon bisulphid in the proportion of 1 to 2 lbs. per 1,000 cu. ft. of air. Forty-eight hours are required to destroy the pupa and a single application under these conditions does not invariably suffice. In the majority of the experiments the eggs succumb to a single fumigation of 48 hours' duration but a second fumigation should follow from 6 to 8 days after the first.

Investigation has shown that commercially sound unsprouted tubers may be subjected to an intermittent fumigation with carbon bisulphid at the strength above mentioned, two, three, or even four times without producing serious damage to the tuber buds if each fumigation is limited to a period of 48 hours' duration.

An outbreak of the Forleule (*Panolis griseovariegata*) in northern Bohemia in 1913, W. SEDLACZEK (*Mitt. Forstl. Versuchsw. Österr.*, No. 38 (1914), pp. 65-75).—*P. griseovariegata* was a source of considerable injury in 1913 to forests in the vicinity of Weisswasser where from 1907 to 1910 the nun moth had caused great damage.

How war has been waged in Mexico against the mosquito, E. LICEAGA (*Amer. Jour. Trop. Diseases and Prev. Med.*, 2 (1914), No. 2, pp. 118-123).—A paper presented before the American Society of Tropical Medicine, held at Boston in May, 1914.

What the farmer can do to prevent malaria, R. H. VON EZDORF (*Pub. Health Rpts.* [U. S.], *Sup.* 11 (1914), pp. 6).—This paper calls attention to the importance of screening and use of mosquito bars, destruction of breeding places of mosquitoes, use of quinin as a prophylactic measure, etc.

Breeding and colonizing the syrphid, P. L. GUPPY (*Dept. Agr. Trinidad and Tobago Bul.*, 13 (1914), No. 82, pp. 217-226, pls. 2).—This paper presents information which supplements that previously noted (E. S. R., 30, p. 457), and reports the results of investigations which show how this predator can be bred and colonized. A pairing cage 6 by 6 by 6 ft. was used, also lamp chimneys 9 by 4 in. in which to place the females to lay after having paired.

A review of the work on the poisoned bait spray, dry method, and mixed treatment of controlling fruit flies (*Trypetidæ*), H. H. P. SEVERIN (*Canad.*

Ent., 46 (1914), Nos. 7, pp. 243-246; 8, pp. 277-284, figs. 3; 9, pp. 309-314).—A review is given of the methods employed and the results obtained, taken up under the headings of the Mediterranean fruit fly (*Ceratitis capitata*), melon fly or bitter gourd fruit fly (*Dacus cucurbitæ*), olive fly (*D. oleæ*), Mexican fruit fly (*Anastrepha ludens*), apple maggot, cherry fruit flies (*Rhagoletis cingulata* and *R. fausta*), currant fruit fly, and imported onion fly (*Pegomya cepetorum*). The work by Italian entomologists has been left for a later paper. References are given to the literature reviewed.

Report of investigation of the fruit fly situation in the Territory of Hawaii, F. MASKEW (*Mo. Bul. Com. Hort. Cal.*, 3 (1914), No. 6, pp. 227-238).—"The clean culture campaign has not controlled the Mediterranean fruit fly even in the policed district, nor has it reduced the amount of infested material recorded as reaching the mainland. The value or not of the clean culture campaign is purely a local problem, and the desirability of a continuance, also provision for its maintenance, is in my opinion a matter for the local authorities to decide. The melon fly (*Dacus cucurbitæ*) is the source of great financial loss to the producers, and all of its hosts should be included in the list of material covered by the United States quarantine order.

"The horticultural interests of the mainland would be far better protected by a federal supervision of horticultural exports similar to the system in force in the gipsy moth area, than by continuing the clean up of house yards in Honolulu and its environs. Every article of commerce between the islands and the mainland, including vessels and persons, constitute a potential danger of introducing the fruit fly at all times, and the commercial shipments of bananas under the present system of federal inspection do not constitute a greater danger of infestation than other articles of general commerce. The question of mail, sealed baggage, and passengers' clothing as avenues of entrance open at present to various hosts of the Mediterranean fruit fly is one of grave importance, and measures looking to the complete control of the same should be devised in such a manner as will withstand any attempt to defeat their legality, and authority given to the horticultural quarantine officers for their prompt enforcement."

Narcissus flies (*Jour. Bd. Agr. [London]*, 21 (1914), No. 2, pp. 136-141, pl. 1; *Bd. Agr. and Fisheries [London] Leaflet* 286 (1914), pp. 7, figs. 9).—This is a general account of *Merodon equestris* and *Eumerus strigatus*. See also a previous note (E. S. R., 30, p. 458).

The dusty surface beetle (*Opatrum æquale*), R. W. JACK (*Rhodesia Agr. Jour.*, 11 (1914), No. 6, pp. 894-901, pls. 2, fig. 1).—This beetle is a source of injury through its habit of devouring maize seed when planted in dry soil.

In the present paper the author presents the results of field and laboratory studies of the pest which have extended over a period of two years. The experiments have shown the poison-bait method to be effective in dealing with this beetle.

Hymenopterous parasites of *Aphis euonymi*, A. MALAQUIN and A. MOITIÉ (*Compt. Rend. Soc. Biol. [Paris]*, 76 (1914), No. 16, pp. 803-805).—The authors have found no less than 17 different species of Hymenoptera to parasitize the black beet aphid of which *Trioxys auctus* and *Aphidius crepidis* are the most abundant. Preliminary studies of the biology of these two species and their utilization are reported.

Some notes on parasitism of chrysopids in South Carolina, E. A. MCGREGOR (*Canad. Ent.*, 46 (1914), No. 9, pp. 306-308, fig. 1).—Of 99 chrysopid cocoons collected and observed daily 48 yielded parasites and 51 chrysopids. The parasites reared, in order of relative abundance, are *Chrysophagus compressicornis*, *Perilampus* sp., *Goniocerus* sp., *Isodromus iceryæ*, *Orthizema atriceps*, and

Helorus sp. *C. compressicornis*, in addition to having been reared frequently from chrysopids, was reared on one occasion from an undetermined syrphid pupa. *Pachyneuron allograptæ* and *Syrphophagus mesograptæ* were also reared from the same syrphid species.

The economic importance of wood lice, W. E. COLLINGE (*Jour. Bd. Agr. [London]*, 21 (1914), No. 3, pp. 206-212, pl. 1).—Of 35 species found in the British Isles not more than nine or ten are sufficiently common to be of economic importance. The commonest and most numerous of these species, which are here discussed, are *Trichoniscus roseus*, *Oniscus asellus*, *Porcellio scaber*, *P. pictus*, *P. lævis*, *Porcellionides pruinosus*, and *Armadillidium vulgare*.

The rust mite and its control, W. W. YOTHERS (*Proc. Fla. State Hort. Soc.*, 27 (1914), pp. 115-119).—A brief account is first given of the life history of this mite, which is known to occur in California, Hawaii, Mexico, Jamaica, Cuba, and Australia, as well as Florida. It is said to have been recorded also from Philadelphia and New York, where it undoubtedly infested citrus trees growing in greenhouses. While citrus fruits and trees are given in the literature as the only food plants, the author reports having found a mite on roses which resembles the rust mite of the orange.

The author's investigations lead him to conclude that a reduction in the size of oranges close to 25 per cent of the total crop is caused by this mite. He states that a sulphur soda solution consisting of sulphur 30 lbs., caustic soda (98 per cent) 20 lbs., and water 20 gal. applied at the rate of 1:60 or 1:66 will kill the mites and that a dilution of 1:40 will destroy the egg.

The data relating to lime-sulphur have been noted from another source (*E. S. R.*, 31, p. 549).

A mixture consisting of 1 lb. flowers of sulphur and 2 lbs. of hydrated lime applied frequently with a dusting machine is also reported to have given satisfactory results.

New observations on the biology of *Fasciola hepatica*, D. SSINITZIN (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 74 (1914), No. 3-4, pp. 280-285, figs. 3).—The author reports that he was unable to find young distomes in the liver of rabbits during the first four days following infection but that they were always found in the abdominal cavity.

FOODS—HUMAN NUTRITION.

Studies on chicken fat.—VI, The factors influencing the acid value of the crude fat, MARY E. PENNINGTON, J. S. HEPBURN, and E. L. CONNOLLY (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, p. 38).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., December, 1913, and continuing previous work (*E. S. R.*, 28, p. 63).

According to the authors, "low temperatures tend to retard the hydrolysis of the fat. The acidity is influenced to some extent by the quantity of fat, expressed as percentage of the body weight; other conditions being equal, a large quantity of fat is usually accompanied by a low acid value and vice versa. The acidity is also dependent on the degree of activity of the lipase. The degree of saturation of the fatty acids, measured by the iodine number, and the titer of the insoluble fatty acids, apparently, are without influence on the acidity.

"The study reported would tend to confirm the reliability of the acidity of crude chicken fat as an index of decomposition. The influence exerted by the various factors, just enumerated, while of interest from the viewpoint of acquiring knowledge of biochemical processes and especially of those relating to

the decomposition of fat, does not vitiate the practical usage of this method as it has been applied [in the authors'] laboratory."

The relation between spoiling and the age of hen's eggs, H. KÜHL (*Hyg. Rundschau*, 24 (1914), No. 5, pp. 253-259).—From an examination of a large number of sorts of commercial eggs, the author concludes that the following would be a good classification for trade purposes: Fresh eggs, those from 8 to 10 days old; eggs, those not over 4 weeks old; and cooking eggs, any offered for sale which are not spoiled.

The occurrence of fumeric acid in fresh beef, H. EINBECK (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 90 (1914), No. 3, pp. 301-308).—The experimental data reported led the author to conclude that fumeric acid is a constituent of the extract of fresh beef and furnished additional evidence of the occurrence of succinic acid.

Bacteriological findings in Baltimore oysters, M. JOSEPH (*Bul. Johns Hopkins Hosp.*, 25 (1914), No. 278, pp. 128-131).—This study was undertaken to ascertain whether the oysters sold in Baltimore contained organisms derived from the human intestinal tract and whether or not their bacterial content varied with the season of the year. The results of the examination indicate the quality of the oysters at the time they were sold and not when collected. The methods of examination were those adopted by the committee of the American Public Health Association on standard methods of shellfish examinations. The method of procedure is fully described and the results are presented in tabular form.

The results indicated that the oysters sold in Baltimore are as a rule free from sewage contamination. It was found that in the early fall and in the spring the bacteriological content of the oysters was high, while in the cold winter months the bacterial content was low.

Fish sausage as a general article of diet, L. BITTER (*Umschau*, 18 (1914), No. 18, pp. 365-367).—The author summarizes data and states that fish sausage is a palatable, nutritious, and economical foodstuff. See also a previous note (*E. S. R.*, 25, p. 163).

The chemical effects of polarized light, E. G. BRYANT (*Chem. News*, 108 (1913), No. 2811, pp. 177, 178; *abs. in Chem. Abs.*, 8 (1914), No. 9, p. 1626).—The author discusses the widespread belief as to the harmful effects of moonlight upon fish and meat intended for food. Moonlight, it is pointed out, is more or less polarized, and investigations showed that slices of fish exposed to strong polarized light decomposed much sooner than those exposed to direct light from the same source.

Report on chemical composition of wheat, G. A. OLSON (*Washington Sta. Popular Bul.* 68 (1914), pp. 4).—A popular review and summary of some of the material published in Bulletin 111 of the station, previously noted (*E. S. R.*, 29, p. 833).

Milling of wheat and testing of flour, H. McCORMACK (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 5, pp. 423-428).—Data are summarized and discussed in this address, delivered in Rochester, September, 1913.

Edible and nonedible mushrooms, BERTRAND and A. SARTORY (*Bul. Soc. Sci. Nancy*, 3. ser., 14 (1913), No. 2, pp. 82-92).—Extended data are given regarding the numerous varieties of mushrooms found in the vicinity of Nancy, France, with reference to their nature, domestic use, and the toxic properties of some varieties together with their antidotes.

"Zipangu," a new coffee compound containing ivory nuts, and its evaluation, J. GORBING (*Ztschr. Öffentl. Chem.*, 19 (1913), No. 14, pp. 266-277; *Chem. Zentbl.*, 1913, II, No. 10, pp. 893, 894).—An analysis is reported.

Food and drug examinations, C. D. HOWARD (*Quart. Bul. Bd. Health N. H.*, 3 (1914), No. 2, pp. 47-58).—Data are given regarding the examination of a large number of samples of drugs and food materials, including among others baking powders and egg substitutes, coffee and cocoa, and breakfast cereals.

[Food inspection and analyses] (*Penn. Dept. Agr., Mo. Bul. Dairy and Food Div.*, 11 (1913), No. 2-3, pp. 41-117).—General and analytical data are given regarding the inspection and analysis of a large number of samples of milk and dairy products and proprietary foods.

Results of slaughterhouse and meat inspection in the German Empire for the year 1911 (*Die Ergebnisse der Schlachtvieh und Fleischschau im Deutschen Reiche im Jahre 1911. Bearbeitet im Kaiserlichen Gesundheitsamte. Berlin, 1913, pp. IV+139*).—This report, which was prepared by the Imperial Bureau of Health, consists chiefly of statistical data.

Ceylon's food supply, C. K. MOSER (*Daily Cons. and Trade Rpts. [U. S.]*, 17 (1914), No. 114, pp. 891-893).—A brief summary of data regarding the kind and quantities of food used in Ceylon.

The dietary of the civilian employees at the cartridge factory of Vincennes, A. DEJOUANY (*Bul. Soc. Sci. Hyg. Aliment.*, 4 (1914), No. 3, pp. 103-121).—A study of family budgets is reported, which contains tabulated data regarding the amounts of food eaten, income, expenditures, and ratio of income to expenditures.

The author concludes that the diet supplies sufficient amounts of fat, carbohydrates, and energy, and that in some instances the amount of these substances is more than is necessary. It is pointed out that some money is wasted in the purchase of too much meat and wine, by purchasing the more expensive cuts of meat, by buying food already cooked from restaurants and delicatessen stores, etc. A plea is made for instruction in home economics.

Menus for children (*Boston Cooking-School Mag.*, 18 (1914), No. 10, pp. 790, 791).—Menus are suggested for children in an institution having a "home table."

Foodstuff—a digest (*Schenectady, N. Y.*, 1914, pp. 32).—Nutrition and the composition of common foods are considered in this summary and there is a special section on sandwiches of different sorts. The publication is designed for extension work among wage-earners through mothers' clubs.

Scientific suggestions regarding home management, R. LEBLANC (*Notions scientifiques d'Enseignement ménager. Paris, 1913, pp. 324, pls. 3, figs. 115*).—Food, clothing, shelter, and household management are considered in this handbook.

Creatin- and creatinin-free foods, RITA K. CHESNUT (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, p. 35).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., December, 1913.

According to the results of the author's analytical studies "creatin and creatinin [are] absent in crabs, lobster, shrimps, clams, oysters, scallops, caviar, calves' brains, sweetbreads, and milk. In bloater paste total creatinin is 0.12 per cent, in anchovy paste 0.085 per cent, in whitefish 0.19, and in halibut 0.36 per cent."

Further studies in the comparative biochemistry of purin metabolism, A. HUNTER and M. H. GIVENS (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, pp. 17-19).—In a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., in December, 1913, the authors' experiments are briefly summarized together with the results of some other investigators. Though some of the results are only preliminary, the

authors are of the opinion that the following conclusions may be safely drawn:

"In all species except man and the higher apes . . . allantoin is quantitatively by far the most important product of purin metabolism. In carnivora and rodents 'uricolysis' is always practically complete; in the monkey it is slightly, in the opossum decidedly, less so; among ungulates there is no definite rule. While in the majority of species uric acid is excreted in greater abundance than purin bases, there are instances, especially frequent among the ungulates, where the reverse is true; the precise relation between the two is, even for the species, not so constant as the uricolytic index. The total endogenous purin metabolism per unit of weight is in a general way inversely related to the size of the animal; but there are notable exceptions."

The specific rôle of foods in relation to the composition of the urine, N. R. BLATHERWICK (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, pp. 34, 35).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., in December, 1913. Experiments were made with healthy men on a uniform diet, to which single foods were added during the experimental period after normal values had been established.

According to the author, the results showed that "some vegetables and fruits, because of their content of bases, are markedly efficient in reducing $\left(\frac{+}{H}\right)$ and ammonia excretion. They also produce conditions which enable the urines to dissolve uric acid. Potatoes, oranges, bananas, apples, raisins, cantaloups, and tomatoes caused such effects. The presence of certain organic acids in fruits leads to an increased acid production due to their incombustibility in the body. Cranberries, plums, and prunes are examples. Benzoic acid, which is found in them, was also shown to produce like results. All urines of $\left(\frac{+}{H}\right)$ less than 7.00 were capable of dissolving uric acid when opportunity offered. When the $\left(\frac{+}{H}\right)$ was greater than 1×10^{-7} , uric acid precipitated, i. e., the urines were supersaturated. The average $\left(\frac{+}{H}\right)$ of 30 vegetarian urines was found to be 6.63 as compared with the higher value of 6.03 obtained for normal urines by Henderson and Palmer."

Concerning the theory of the constancy of uric acid excretion in individuals, O. FAUSTKA (*Pflüger's Arch. Physiol.*, 155 (1914), No. 10-12, pp. 523-546, fig. 1).—From his investigations the author concludes that in the case of adults the excretion of uric acid is a physiological constant under like conditions.

Studies on enzym action.—X, The lipolytic properties of human duodenal contents, K. G. FALK (*Jour. Amer. Chem. Soc.*, 36 (1914), No. 5, pp. 1047-1057).—In a number of cases, under varying conditions, the lipolytic activity of human duodenal contents was tested.

Two lipases were found to be present. "One of these, found as a rule after ingestion of food, was, under certain definite experimental conditions, more active toward triacetin than toward ethyl butyrate; the other, present when no food had been taken, was more active toward ethyl butyrate than toward triacetin. The importance of these two lipases in diagnostic work was pointed out. . . .

"The effect of a number of neutral salts and alcohols in different concentrations on the activity of the duodenal contents on the two esters was studied."

Concerning lipid-free diet and its relation to beri-beri and scurvy, W. STEPP (*Deut. Med. Wchnschr.*, 40 (1914), No. 18, pp. 892-895).—A summary and

digest of data which led to some general conclusions and the suggestion that both vitamin and certain definite lipoids are necessary for life.

On the protective and curative properties of certain foodstuffs against polyneuritis induced in birds by a diet of polished rice, II, E. A. COOPER (*Jour. Hyg. [Cambridge]*, 14 (1914), No. 1, pp. 12-22).—Continuing previous work (E. S. R., 28, p. 760), experiments are reported with pigeons in which the protective power of various substances was studied to prevent polyneuritis following a diet of polished rice. The author's general conclusions follow.

"Nuts (husked filberts) are very efficient in preventing polyneuritis, being even superior to lentils and husked barley. Cheddar cheese, on the other hand, even in considerable amount, has no preventive effect.

"Malt extract taken from two different samples readily cured polyneuritis in pigeons. A third sample, however, even in large doses had no curative action.

"For the prevention of beri-beri, egg yolk, heart muscle, liver, nuts, barley, and lentils can be recommended as suitable foodstuffs with which to supplement the polished rice diet. As meat (voluntary muscle) has been frequently found to be ineffective in preventing epidemics of beri-beri, its replacement by heart and liver in mixed diets would be a considerable improvement, because not only are these tissues when suitably prepared as nutritious as voluntary muscle but they also contain the antineuritic substances in much higher concentration."

Phosphates and wheat bran in animal nutrition, P. CARLES (*Répert. Pharm. et Jour. Chim. Méd.*, 3. ser., 25 (1913), No. 3, pp. 97-99).—The relative values of mineral phosphates, animal phosphates such as dried and powdered bones, and wheat bran are discussed.

The author regards mineral phosphates as worthless, while animal phosphates show a marked beneficial effect upon animals. Wheat bran is superior to animal phosphates, because of its stability and good keeping quality.

Data are given regarding the amount of phosphates present in the materials which the author discusses.

Behavior and effect of sugars of different sorts in the body, P. ALBERTONI (*Ergeb. Physiol.*, 14 (1914), pp. 431-473).—An exhaustive digest of experimental data.

The effect of sugars on the secretions, D. LO MONACO (*Arch. Farmacol. Sper. e Sci. Aff.*, 17 (1914), Nos. 3, pp. 127-144; 4, pp. 145-177).—This is a progress report of experiments in which are being studied the effects of sugars upon the salivary, intestinal, and renal secretions. The sugars were taken into the body in part via the stomach and in some cases by means of intravenous or subcutaneous injections. A digest of the work done by others along this line is given. Extended data of the experiments are presented, but no general conclusions are drawn, as further work is to be reported on the subject.

The comparative value of various sugars in the feeding of infants, C. C. HASKELL (*Arch. Ped.*, 30 (1913), No. 8, pp. 572-587; *Lilly Sci. Bul.*, 1. ser., No. 4 (1914), pp. 136-150).—The data obtained in tests with infants, either convalescent or suffering with more or less chronic conditions, indicate, according to the author, that the best results were obtained with a diet containing "malt-soup extract," with lactose and a mixture of dextrans with maltose following in the order named. He points out that the conclusions have nothing to do with the selection of sugar for normal infants, and states that he has "seen nothing in the literature to prove nor have we made any observations in support of the contention that the maltose-dextrin mixtures are in any way superior to lactose for addition to the food of the average sound infant."

Industrial maltose, C. B. DUBYEA (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 5, pp. 419-423).—In this general discussion of data the author summarizes

the results of some experiments in candy making, by himself and others, which he believes indicate that such products stand cooking heats "as well or better than the best glucoses" and have other good properties. As a whole the article is a polemic comparison of glucose and maltose.

The effect of glucose on autolysis—a possible explanation of the protein-sparing action of carbohydrates, P. A. SHAFFER (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, pp. 36, 37).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., in December, 1913.

The results of a series of antiseptic autolysis experiments (made with hashed dog liver) seem to indicate that the addition of 1 per cent of glucose under some conditions slightly inhibits the action of proteolytic enzymes. The author believes this may be a confirmation of the hypothesis that "the 'protein-sparing action of carbohydrates' is exerted through the influence of the concentration of glucose or of glycogen upon the enzymes of the cells.

"The explanation of the 'sparing action' on the supposition that sugar when present is merely burned by preference and thereby makes unnecessary the catabolism of (body) protein, is wholly inadequate. Food protein is not thus spared. . . . It seems to the writer that instead of supposing with Landergren that body protein (in carbohydrate starvation) is catabolized to supply the essential sugar, it is more likely that so long as a normal concentration of sugar (or glycogen) is present in the cell the proteolytic enzymes are somewhat held in check and the strictly endogenous catabolism is restricted to its normal low value, but that when carbohydrate food is lacking and the sugar (or glycogen) concentration in the cells falls, an inhibition is removed, the proteolytic enzymes become correspondingly more active, a larger amount of cell protein is digested, and the products like the products from food protein are in part converted into glucose.

"It is believed that the autolysis experiments support this point of view."

Origin of glycogen—rôle of proteins and fats, N. C. PAULESCO (*Compt. Rend. Soc. Biol. [Paris]*, 76 (1914), No. 1, pp. 50-52).—From the results of experiments here reported it is concluded that albuminoid substances like fibrin, meat, or gelatin are important sources of glycogen, peptones are to be regarded as only mediocre sources, albuminoid substances like casein, egg white, and egg yolk are of little importance, and fats such as butter, lard, and beef fat, and olive, cottonseed, and linseed oils are not sources of glycogen.

Concerning pentosans as a source of energy in the animal body, P. SCHIBOKICH (*Biochem. Ztschr.*, 55 (1913), No. 5-6, pp. 370-392).—According to the author's observations, oxygen consumption was somewhat lower when arabinose was fed to laboratory animals (dogs) than was the case during fasting. Since it apparently plays no part in the oxidative processes, one may assume that it is stored or used to form other substances, in a way analogous to the formation of glycogen from hexoses.

Some metabolic effects of bathing in the Great Salt Lake, HELEN I. and H. A. MATTILL (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, p. 25).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., in December, 1913.

Two subjects kept on uniform diets were studied. Analysis of the urine showed no variations in total nitrogen attributable to the experimental conditions. Observed variations in the uric acid and ammonia excretion were small. The maximum ammonia nitrogen excretion was observed on the days of longest baths. Creatinin excretion showed a slight rise during the bathing periods, perhaps related to the increased muscular tonus. "Chlorid elimination was considerably increased during the bathing periods, 25 per cent in one case and

28 per cent in the other, and since these variations have no parallel in those of any other metabolic products determined, the possibility of absorption through the skin seems evident."

A new respiratory chamber, A. C. KOLLS and A. S. LOEVENHART (*Proc. Amer. Soc. Biol. Chem.*, 3 (1913), No. 1, pp. 32, 33).—A summary of a paper presented at the eighth annual meeting of the American Society of Biological Chemists at Philadelphia, Pa., in December, 1913. A respiratory chamber designed for the purpose of determining the effect of reducing the oxygen of the respired air on the erythrocyte and hemoglobin content of the blood is described.

A self-recording calorimeter for large animals, A. V. and A. M. HILL (*Jour. Physiol.*, 48 (1914), No. 1, pp. XIII, XIV).—The authors describe a calorimeter constructed according to the same principle employed in a smaller one previously noted (E. S. R., 29, p. 569). The apparatus consists essentially of two horizontal co-axial iron cylinders separated by an insulating medium of sawdust and kapok wool and is of a size suitable for experiments with a sheep or dog.

A simple and convenient form of bicycle ergometer, C. J. MARTIN (*Jour. Physiol.*, 48 (1914), No. 1, pp. XV, XVI, fig. 1).—An ergometer of the brake type is described in which the work done in foot-pounds is calculated from the frictional pull, the circumference of the wheel, and the number of its revolutions.

For the rear wheel of the bicycle is substituted a cast-iron one weighing 22 kg., the friction being supplied by means of a stout linen band passing around the circumference of the wheel, the ends of the band being so attached to spring balances that the friction may be easily adjusted. The advantages claimed for this piece of apparatus are that the subject of the experiment may make all the necessary observations; that "it has an error of less than 1 per cent"; that "the frictional pull is steady and is nearly independent of the velocity, so that it is not necessary to pedal always at a constant rate"; that "the instrument can be adjusted for any rate of work at any pedal revolution desired"; and that "the friction band is quite thin and so does not get hot and vary the pull during the experiment."

ANIMAL PRODUCTION.

Bibliography of physiology (*Bibliographia Physiol.*, 3. ser., 8 (1912), Nos. 1, pp. 112; 2-3, pp. 113-384; 4, pp. 385-500; Index, pp. 501-613).—A bibliography of American and foreign works and articles on physiology and biochemistry received during 1912.

On the correlation between the number of mammæ of the dam and size of litter in mammals, R. PEARL (*Proc. Soc. Expt. Biol. and Med.*, 11 (1913), No. 1, pp. 27-32).—This includes two papers.

I. *Interracial correlation* (pp. 27-30).—Biometrical methods are applied to an extensive series of statistics regarding size of litter and number of mammæ for many different species of wild and domestic mammals as collected by C. F. Bellingeri in 1849. It is found that "interracially the mean size of litter is approximately two individuals below the mean number of mammæ possessed by the mother. This may be taken as a rough measure of the evolutionary 'factor of safety' in regard to these characters. There is relatively . . . somewhat more variation exhibited in size of litter than in number of mammæ. The correlation between these two characters, as measured by the coefficient r , is surprisingly low. This result certainly can not be said to furnish particularly strong evidence that natural selection has had anything to do with fixing the relationship between number of mammæ and size of litter."

II. *Intraracial correlation in swine* (pp. 31, 32).—Biometrical methods are applied to statistics collected by E. N. Wentworth in 1913 on the correlation between number of mammæ and size of litter in Duroc Jersey swine (E. S. R., 29, p. 470). It is shown that "there are approximately 2.5 more mammæ in the dam, on the average, than number of young in the litter in these swine. This is a slightly larger 'factor of safety' than is found interracially. The intraracial correlation between these variables in swine is not only absolutely low but is relatively much lower than the interracial correlation. Again it is not apparent here that natural selection has operated in the expected manner.

"Intraracially, just as interracially, size of litter is relatively a more variable character than number of mammæ in the dam. There is, as would be expected, a very considerable reduction in variability, in respect of both characters, in the single species (intraracial) as compared with the composite group of 90 different species (interracial)."

A note on sex determination, G. H. PARKER (*Science, n. ser.*, 39 (1914), No. 997, pp. 215, 216).—In collecting data to show the relation of the size of litters to the number of nipples in swine, observations were made on the position that the young pigs occupied in the uterus and their sex, and it was therefore possible to make a comparison of the products of one ovary with those of the other. A tabulation was made of the frequency of occurrence of pairs of unborn pigs of various combinations of sex at the division of the horns of the uterus next the right ovary and next the left ovary, the observations extending over 2,600 pairs of pigs. In all three positions the frequencies of the pairs were approximately in the ratio of 25 per cent males: 25 per cent females: 50 per cent males and females, showing that in the pig the ovaries exert no influence on the sex of the offspring by virtue of their position in the maternal body.

On the atavistic long stripe of the new-born young of certain breeds of domestic swine, E. A. GOELDI (*9. Cong. Internat. Zool.*, 1913, pp. 369, 370).—The author comments on a phenomenon of the atavism of coloration, a long stripe, sometimes found in the young of some of our domestic breeds of swine, as the Berkshire and Yorkshire, and which evidently traces back to the early types of wild swine.

Rudimentary parthenogenesis in the golden pheasant, LÉCAILLON (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 1, pp. 55-57; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 4, pp. 502, 503).—The author made a study of the unfertilized eggs from a golden pheasant (*Chrysolophus pictus*) to determine whether rudimentary parthenogenesis applies to this species as it does in the case of the hen.

It was found that the cicatricula shows blastomeres of varying size and that these are composed of cytoplasm and deutoplasm and contain normal nuclei. The degeneration of the blastomeres is often characterized by hypertrophy of the nuclei, which form numerous fresh nuclei of various sizes by budding. It is concluded from these observations that unfertilized eggs always show a tendency to develop like fertilized ones.

The distribution of creatin in the bodies of mammals, J. C. BEKER (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 87 (1913), No. 1, pp. 21-37).—Analyses made to determine the creatin and creatinin content of the organs of the cow, goat, pig, rabbit, and dog showed the largest amount of creatinin present in the voluntary muscles and the least in the thymus gland. The fetus shows a low creatin content. The creatinin content increases in animals in advanced pregnancy.

The digestibility of cattle foods, J. B. LINDSEY and P. H. SMITH (*Massachusetts Sta. Bul.* 152 (1914), pp. 79-120).—This bulletin contains the results of 47 single digestion experiments with a variety of cattle feeds. The basal ration consisted of hay, corn, and gluten. The experiments were conducted with sheep.

The average coefficients of the several feeds are given as follows:

Average coefficients of feeding stuffs.

Feed.	Dry matter.	Protein.	Fat.	Nitrogen free extract.	Crude fiber.	Ash.
English hay, June grass (<i>Poa pratensis</i>) predominating (late cut).....	<i>P. ct.</i> 61.68	<i>P. ct.</i> 54.43	<i>P. ct.</i> 51.12	<i>P. ct.</i> 64.87	<i>P. ct.</i> 66.89	<i>P. ct.</i> 31.78
English hay (early cut).....	65.14	62.82	49.30	67.14	68.85	38.43
Dried beef pulp.....	74.58	51.86	83.48	83.45	25.58
Molasses dried beet pulp.....	82.34	61.20	90.54	76.99	51.01
Coconut meal.....	81.94	89.81	102.74	87.24	23.36	64.04
Cotton-seed feed meal.....	58.23	75.31	100.61	61.20	26.10	49.37
Wheat screenings.....	66.76	62.64	90.09	81.83
Wheat screenings (contain more fiber).....	59.11	80.93	86.80	64.55	26.73
Flax shives.....	45.38	81.03	92.68	43.45	25.79	22.78
Cacao shells.....	57.52	11.47	100.48	73.46	50.66	13.64
English hay and corn meal (5½:1).....	70.09	63.00	58.69	74.18	70.76	42.68
Timothy, red top, and clover mixed.....	59.06	50.38	39.93	58.81	64.85	42.61
Fish meal.....	67.72	75.14	101.32	28.58
Fish guano.....	74.58	81.10	108.03	32.06
Molasses meal and sphagnum moss.....	61.98	41.74	71.90	79.48
English hay and gluten feed (550:150).....	66.37	68.35	56.33	70.02	65.64	30.81

The utilization of Para rubber seed (*Bul. Imp. Inst. [So. Kensington], 11 (1913), No. 4, pp. 551-559; abs. in Agr. Bul. Fed. Malay States, 2 (1914), No. 8, pp. 213-215*).—Sheep and cattle feeding experiments with Para rubber seed cake are reported.

All attempts at feeding sheep with the cake failed. Cattle ate it readily but when the quantity was increased to 8 lbs. per head daily scouring occurred. With dairy cattle fed on Para rubber seed cake the yield of milk rose, but the percentage of milk fat remained unchanged.

The composition of the cake is given as follows: Moisture 8.75 per cent, protein 30.19, fat 8.71, carbohydrates 41.71, crude fiber 5.01, ash 5.6 per cent, and feed units 139. A small quantity of cyanogenetic glucosid was present, yielding approximately 0.02 per cent prussic acid, a negligible quantity.

Studies on the nutritive requirements for fattening mature cattle and sheep.—Feeding experiments with heated liquid potato distillery refuse and with dried refuse in comparison with palm-nut cake, W. VÖLTZ, J. PAECHTNER, A. BAUDREXEL, W. DIETRICH, and A. DEUTSCHLAND (*Landw. Jahrb., 45 (1913), No. 3, pp. 325-437, pls. 8, fig. 1*).—Analyses of malt sprouts, dried brewers' grains, potato flakes, potato refuse from distilleries, and palm-nut cake are reported. The water-free potato refuse contained 25.47 per cent of protein, 0.68 fat, 53.15 nitrogen-free extract, 6.94 crude fiber, and 13.76 ash.

Two lots of 5 head each of yearling Hampshire wethers were fed during a 164-day feeding period on a basal ration consisting of millet hay, oat straw, malt sprouts, brewers' grains, and potato flakes; lot 1 receiving potato refuse and lot 2 palm-nut cake. During the last 45 days of the period molasses was added to both rations. The total increase in weight per head for lot 1 was 15.26 kg. and for lot 2, 18.16 kg.; the dry substance consumed per head per day by lot 1, 1,072.2 gm. and lot 2, 1,075.1 gm.; and the estimated starch value required per kilogram of grain 5.22 kg. for lot 1, and 4.59 kg. for lot 2. The dressing percentage was 51.2 and 50.2 per cent, and the intestinal fat 2.3 and 1.85 per cent, respectively.

It is concluded that feeding stuffs have a specific value independent of their starch value, and that molasses added to the ration has a specific value in increasing the nutritive value of the ration for sheep and cattle.

Comparing the digestibility of feeds for ewes and wethers it was found that on the potato refuse ration the ewe utilized 4 per cent more organic matter than the wether, while on the palm-nut cake ration the utilization of organic matter, protein, and nitrogen-free extract was practically the same for both ewe and wether. The digestibility of the potato refuse was 54.7 per cent for the ewe and 59.8 per cent for the wether; for the palm-nut cake 58.7 and 58.3 per cent.

Complete digestion trials were made with one bull and two sheep. It was found that a 2- to 3-year-old bull required per day per 1,000 kg. live weight, 21 kg. dry substance, 1.9 kg. digestible protein, and 10 kg. digestible nitrogen-free extract, or the equivalent of 45,000 usable calories of energy or 8.5 kg. starch value; a yearling wether 28.5 kg. dry substance, 2.9 kg. digestible protein, and 14 kg. nitrogen-free extract, or the equivalent of 70,000 usable calories or 13.5 kg. starch value. On the potato refuse ration the value of the feed was greater for the bull than for the sheep, 29 per cent less digestible protein and 26 per cent less starch value being required. On the palm-nut ration the differences were less marked; on the palm-nut molasses ration the value of the feed was higher for sheep than for cattle. Cattle showed a higher resorption of protein fats and fiber. The physiological value of the control-mixed feed, the potato refuse ration, and the palm-nut cake ration was higher for the sheep than for cattle, and the potato refuse molasses higher for the cattle.

The heated liquid refuse had a slightly higher nutritive value than the dried refuse and cold water. The addition of lactic acid to the ration lowered the nutritive value and hastened the protein transformation.

It is concluded that the actual starch value of feeds is a very variable quantity, depending upon the individuality of the animals. From these trials it is estimated that the gains made by cattle from 100 kg. starch value of potato refuse were 30.9 kg., of potato refuse and molasses 21.7, palm-nut cake 31.2, and palm-nut cake and molasses 22.4 kg.; and for sheep on these feeds 16.7, 20.5, 19.9, and 25 kg., respectively.

Proceedings of the American National Live Stock Association, 1914 (*Proc. Amer. Nat. Live Stock Assoc.*, 17 (1914), pp. 156, pls. 12).—This reports the proceedings of the seventeenth annual convention of this association, held at Denver, Colo., in January, 1914, and includes addresses on the future cattle supply of the United States, effect of free trade in live stock and meats on prices, railway rates and service, grazing on national forests, etc.

The breeds of pure-bred live stock (*Montana Sta. Spec. Circ.* [1] (1913), pp. 9).—This includes a list of the breeds of pure bred live stock, their American record association, and the secretary of the association.

A list of breeders of pure-bred live stock in Montana (*Montana Sta. Spec. Circ.* 2 (1914), pp. 23).—This circular gives a list of breeders of pure bred live stock of the several counties of Montana.

On the growth of pasture animals, K. G. BRUCHHOLZ (*Deut. Landw. Tierzucht*, 18 (1914), No. 16, pp. 185-187).—This reports studies made of the increase in breast measurement and increase in weight of calves on pasture.

Dung making experiment, 1912-13, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England*, 74 (1913), pp. 410, 411).—Four bullocks were placed in special stalls and fed a mixed ration of bean meal and crushed oats, together with roots, oat straw, and chaff for a period of 130 days. During the time two of the bullocks received in addition 1 ton of hay.

It is estimated that the animals in stall 1, receiving no hay, produced 204.69 cu. ft. of manure, weighing 10,595 lbs., those of stall 2 receiving hay, 259.87 cu. ft., weighing 13,564 lbs. The moisture content of the former was 75.82 per cent, of the latter 74.21; the nitrogen contents 0.489 and 0.615 per cent, respec-

tively. A distinctly better grade of manure was thus procured from the hay-fed animals.

Cattle and carabao in the Philippines, G. E. ANDERSON (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 125, p. 1166*).—It is stated that the shipment of cattle to the Philippines from Hongkong and from Australia has been one of the chief items of trade. However, the rate at which cattle and carabaos in the Philippines are increasing indicates that the islands are soon to be at least self supporting.

Individual variation in musk oxen, J. A. ALLEN (*9. Cong. Internat. Zool., 1913, pp. 210-215*).—A discussion of the skeletal measurements and weights of musk oxen.

It is concluded that "the range of individual variation in cranial characters in musk oxen, in both males and females, is greater during the period from 5 to 8 years of age than later. It is much greater in males than in females. The length of the tooth row is more variable than is the relative breadth of the skull (at given points) to the basal length. The nasal bones, in respect to length, breadth, and convexity, are among the most variable elements of the skull, and the most untrustworthy for use in diagnosis. The lacrymal bones are also subject to great variation in size and form, and especially in respect to the depth of the lacrymal depression ('fossa' or 'pit')."

"Naturally the highest ratio of variability is shown in the horns—in their curvature, length, breadth at base, and general massiveness. The weight of the skull in animals of the same age and sex is subject to great variation, amounting to 80 per cent of the mean weight in a comparable series of 26 male skulls, and about 45 per cent in 22 skulls of females. The range of individual variation often exceeds the average differentiation between well-marked subspecies, or even the average differentiation between closely allied congeneric species."

Management and feeding of sheep, T. SHAW (*New York and London, 1914, pp. XXXIX+471, figs. 24*).—This book treats of the feeding, care, and management of sheep and the classification and characteristics of wool.

Breeds of Scottish sheep.—I, Cheviots, W. BARBER (*Trans. Highland and Agr. Soc. Scot., 5. ser., 26 (1914), pp. 102-146, pls. 4*).—The origin and early development of the Cheviot breed of sheep in England and Scotland, their present status, and utility value are discussed.

Breeds of Scottish sheep.—II, Half-bred sheep, R. MACMILLAN (*Trans. Highland and Agr. Soc. Scot., 5. ser., 26 (1914), pp. 146-150, figs. 3*).—In this article the author treats of the so-called "half-bred" sheep of South Scotland and North England. These sheep are a cross between the Cheviot and Border Leicester and through years of selection have become a distinct breed. The sheep are of great size and hardiness and are deemed of distinct value to the general purpose farmer.

Domestic sheep and their wild ancestors.—II, Wild sheep of the Argali type, J. C. EWART (*Trans. Highland and Agr. Soc. Scot., 5. ser., 26 (1914), pp. 74-101, pls. 8*).—In this paper, which is a continuation of work previously noted (*E. S. R., 29, p. 469*) the author presents further evidence showing the relation between the wild sheep of the Argali type and the present-day domestic sheep, and concludes that "even before the coming of the Romans, Britain had sheep which included the Argali as well as the Urial and Mouflon amongst their ancestors."

Some early references to four-horned sheep in Scotland, J. RITCHIE (*Scot. Nat., No. 29 (1914), pp. 100-106*).—From a review of early references to four-horned sheep it is concluded "that an early breed of Scottish sheep was distinguished by its small size of body, by the fineness of its wool and the shortness

of its tall, by its horned ewes, and the frequent occurrence, especially among the rams, of horns in groups of 4 or more. These characters have persisted in common since at latest the middle of the sixteenth century till the present day."

It is presumed that improved breeds by a process of selection have gradually usurped the place of the more primitive race.

[Pig-feeding experiments], J. M. SCOTT (*Florida Sta. Rpt. 1913*, pp. XVII-XIX).—Two lots of four 75-lb. pigs each were fed during 46 days as follows: Lot 1, shelled corn and green cowpeas; lot 2, corn and green sorghum, equal amounts by weight being fed so that for each pound of corn a pound of green feed was given. Lot 1 made an average daily gain per head of 0.43 lb., costing 12.2 cts. per pound of gain; lot 2, 0.36 lb., costing 14.7 cts. per pound.

Three lots of pigs were fed during 43 days as follows: Lot 1, shelled corn and green rape; lot 2, shelled corn and peanuts 3:1, with green rape; lot 3, shelled corn and peanuts 1:1 with green rape. Lot 1 made an average daily gain per head of 0.686 lb. costing 13.9 cts. per pound of gain; lot 2, 0.72 lb., costing 14.6 cts. per pound; and lot 3, 0.774 lb., costing 15.6 cts. per pound of gain. It is noted that as the amount of the peanuts in the ration was increased there was a noticeable increase in the average daily gains, but likewise an increase in the cost, and indicating that for pork production peanuts are worth only about 30 or 40 cts. per bushel.

Growing hogs in Mississippi, E. M. RANCK (*Mississippi Sta. Circ., 1914, June 20, pp. 17*).—General directions for the breeding, feeding, care, and management of hogs under Mississippi conditions, including hog diseases and a text of a new state law relating to the quarantine and burial of diseased animals, are given. A table showing rotations of forage crops, supplemental feed, etc., is included.

Swine husbandry in Washington, R. C. ASHBY and C. F. MONROE (*Washington Sta. Popular Bul. 63 (1914), pp. 36, fig. 1*).—A popular bulletin on swine husbandry, including methods of feeding, breeding, diseases, and general management.

Forty years' experience of a practical hog man, A. J. LOVEJOY (*Springfield, Ill., 1914, pp. 170, figs. 29*).—This is a practical treatise on the care, feeding, and management of swine.

Studies on the proportions of the horse, L. VAN MELDERT (*Ann. Gembloux, 24 (1914), Nos. 3, pp. 121-151, figs. 2; 5, pp. 249-274, figs. 4*).—This article reviews the history and development of the horse and the origin of the different types and classes. Various body measurements of the several types of horses are given and comparisons made in their slope and measurement of shoulder. formation of croup, and other points of conformation.

Comparative digestion experiments on Equidæ, O. FRANK (*Kühn Arch., 3 (1913), pt. 2, pp. 363-396; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 2, pp. 241, 242*).—In 10-day feeding experiments with horses, asses, and their hybrids notable differences were noted in their relative power to utilize feed. Of the horses, the mare, belonging to a thrifty country breed (Belgian), digested the feed, with the exception of protein, better than a Mongolian gelding. In the utilization of crude fiber, fat, and nitrogen-free extract the mules and hinnies were superior to the gelding and inferior to the mare.

It is concluded from these observations that thrifty breeds of horses can compete in thriftiness with mules. The author has also calculated how much feed each animal consumed per unit of body surface and found that the smaller animal requires the greater energy to keep up its vital processes.

Poultry culture, W. H. DAVENPORT, J. H. ROBINSON, H. D. SMITH, J. C. GRAHAM, and J. E. RICE (*Mass. Bd. Agr. Bul. 1 (1914), 4. ed. rev., pp. 158,*

pls. 11, figs. 26).—This bulletin is a compilation of articles treating of general poultry topics, including breeds for the farm, poultry housing, hatching and rearing chicks, feeding and management for egg production, and other related subjects.

Relation between the rotting and age of hens' eggs, H. KÜHL (*Hyg. Rundschau*, 24 (1914), No. 5, pp. 253-259).—The author advocates the control of market eggs and the establishment of grades based upon specific weight. The specific weight of absolutely fresh eggs is found to range between 1.035 and 1.06 and that of comparatively fresh eggs not older than 8 to 10 days between 1.015 and 1.035. Among the factors influencing the rotting of eggs are bacterial infection from packing, as in hay, and the temperature and condition of the room in which eggs are kept.

Practical rabbit keeping, G. A. TOWNSEND (*London, New York, Toronto, and Melbourne*, 1912, pp. XIV+299, pls. 20, figs. 13).—This book treats of the breeding, feed, care, and management of the various breeds of domestic rabbits.

The culture of black and silver foxes, R. B. and L. V. CROFT (*Woodstock, Ontario*, 1913, pp. 83, figs. 29).—This pamphlet relates to the breeding, feed, care, and management of black and silver foxes for commercial purposes.

DAIRY FARMING—DAIRYING.

Evolution in judging dairy cattle in Denmark, J. J. DUNNE (*Hoard's Dairyman*, 48 (1914), Nos. 3, p. 52, figs. 8; 7, pp. 166-168).—The author reviews the development of judging of dairy cattle in Denmark. In 1847, during the Guenon period, the "indications" (milk mirror largely) outweighed all other considerations, counting 67 per cent, with build and size 12.5 and milk appearance (frame, skin, etc.) 20.5. In 1852, when the Guenon storm had partially subsided, the build and size quadrupled in importance, the milk appearance increased to 25, and the indications (milk mirror) came down to 25 per cent. In 1869 there occurred a reaction in favor of the indications at the expense mainly of the "appearance," these being rated at 40 and 15, respectively.

In 1887 the appearance came back into favor (33.3) and a new consideration (ancestry) was created (11.2) at the expense of the build and the milk indications (33.3 and 22.2, respectively). In 1890, the commissioners of the state-animal shows attached more importance to the ancestry of bulls, while the same body, in 1906, added additional points to ancestry and offspring (28) and equalized the points awarded to the other three groups (24 each), and giving, for the first time, some consideration to the performance. In 1908, build and size reasserted their importance (40), while appearance and indications dropped to 10 each, ancestry to 20, and individual performance was set down at 20 per cent for the first time. Another slight change in 1913 reduced ancestry to 15, and increased performance to 25.

Comparison of milk yield of cows calving fall and spring, E. J. WOODWARD (*Hoard's Dairyman*, 48 (1914), No. 7, p. 165, fig. 1).—The records of 18 pure-bred dairy cows calving in September and October were compared with those of 18 cows calving in April and May, the cows of both groups being quite uniform as far as breeding and individuality were concerned.

It is shown that for the first few months the decline in milk flow for the two groups was quite constant, but that seven or eight months after calving, or at the opening of spring, the group calving in the fall showed decidedly less decline than did the spring-calving group when equally advanced in lactation. "During the tenth month as platted, the average milk yield of the cows in the fall-calving group was 58 per cent of their yield for the first complete calendar month as against 35 per cent for the group which calved in the spring. The

production for the first complete calendar month for the spring-calving group was 1,104 lbs., for the fall-calving group 1,017 lbs. Yet the group calving in the fall gave an average total milk yield of 8,149 in the 10 months, while the group calving in the spring averaged for the same time 7,364 lbs."

The most profitable calving time, J. J. DUNNE (*Dept. Agr. and Tech. Instr. Ireland Jour.*, 14 (1914), No. 4, pp. 725-728).—Summarizing the results of four competitions between entire herds of Red Danish dairy cows, each competition covering a period of two years, it was found that cows that calved during the quarter, October, November, and December, gave an average of 160 gal. more milk during the period of lactation than did those that calved during the quarter, April, May, and June, but comparing the average of the winter half-year, October to March, with that of the summer half-year, April to September, 96 gal. more milk. This is thought to be due to the uniformity of the nutrient values of the daily feed during the winter in contrast to the variability of those of summer feeds. It is shown that two-thirds of the 34,217 cows belonging to cow-testing associations in 1912-13 calved during the winter half of the year.

[Feeding experiments with silver beet], A. MACPHERSON (*Jour. Agr. [New Zeal.]*, 8 (1914), No. 4, pp. 379-387, figs. 7).—Milch cows foraged during the morning and afternoon on silver-beet, or Swiss chard, ate it greedily, did not scour, and maintained their milk flow throughout a 12-day feeding period.

Production of clean milk (*U. S. Dept. Agr., Farmers' Bul. 602 (1914), pp. 18, figs. 6*).—This gives general information on the essential factors in producing clean milk.

Removal of garlic flavor from milk and cream, S. H. AYERS and W. T. JOHNSON, JR. (*U. S. Dept. Agr., Farmers' Bul. 608 (1914), pp. 4, fig. 1*).—A process of removing garlic flavor from milk which proves successful consists in blowing air through milk which is heated to at least 145° F. The flavor was removed in from 30 to 60 minutes from milk from a cow fed 0.75 lb. wild garlic 20 minutes before milking. It was found to require a slightly longer blowing period to remove the flavor from cream. While the flavor was more quickly removed at 160°, a cooked taste was produced.

The apparatus used in this process is described and its adaptation for commercial use discussed.

A home pasteurizer (*Ill. State Food Com. Bul. 31 (1914), pp. 4, figs. 4*).—A description of the construction of a pasteurizer for home purposes.

Milk cans should be jacketed (*Milk Dealer, 3 (1914), No. 12, pp. 38*).—In experiments conducted by this Department in shipping milk at 50° F., hauling a distance of 13 miles in an open truck and exposing to the direct rays of the sun at a temperature of approximately 83°, it was found that the milk in cans that were hair-quilt jacketed showed a raise of only 5½° temperature in three hours. The milk in cans that were wrapped with wet burlap showed a raise of 8½°, and the milk in unjacketed cans rose 28½°.

The cytology and bacteriology of condensed milks, F. W. ANDREWES (*Jour. Path. and Bact.*, 18 (1913), No. 2, pp. 169-178).—From cell counts made of condensed milk it is concluded that none of the samples examined contained, in spite of the questionable appearance of the stained sediment of some specimens, pus cells in sufficient quantity to cause suspicion.

As regards bacteriology, it is plain that a machine-skimmed, sweetened, condensed milk can not be expected to be sterile. The author regards "the presence, in reasonable number, of the bacteria commonly found in fresh milk—*Bacillus coli*, streptococci, a few staphylococci, and *B. enteritidis sporogenes*—and of such ordinary air contaminations as *B. subtilis* and *mesentericus*," as

comparatively unobjectionable. A large proportion of the bacteria of milk seem to be destroyed in the process of condensation. It was demonstrated that "condensed milk is almost a differential medium for the growth of staphylococci. It would appear that if only a few *Staphylococcus pyogenes aureus* were present, and escaped destruction in the process of condensation, there is no limit to the number which, later, may be found on opening the tin. [However, their presence] in large numbers in a condensed milk is objectionable and should probably constitute a ground for condemnation, even though the potential harmfulness of such a product is unproven. Efficient pasteurization, before condensation and before the addition of sugar, should prevent the presence of such organisms in the final product, however difficult it may be to destroy them afterwards, for in the majority of condensed milks they are absent or but scantily present."

Condensed milk (*Food and Drugs, n. ser., 2 (1914), No. 3, pp. 133-142*).—This article deals with the various types of sweetened and unsweetened condensed milk, their composition, nutritive value, and bacterial content.

Kefir, J. C. LANDIN (*Bul. Sci. Pharmacol., 21 (1914), Nos. 6, pp. 356-363, figs. 5; 7, pp. 400-409*).—A treatise on the bacteriological characteristics of kefir, a fermented-milk food, and the importance in pathological conditions of the various bacteria and acids in the digestive processes.

Fermented-milk product and process of making the same, A. H. THOUMAIAN (*U. S. Patent, 1,101,044, June 23, 1914; abs. in Jour. Soc. Chem. Indus., 33 (1914), No. 15, p. 803*).—"A mixture of egg albumin, milk, and cream is submitted to the action of a culture of the lactic acid bacillus and *Bacillus bulgaricus*."

The normal bacteria of Swiss cheese, E. E. ELDRIDGE and L. A. ROGERS (*Abs. in Science, n. ser., 38 (1913), No. 976, pp. 377, 378*).—Studies were made in this Department of a large number of cultures isolated from various cheeses, particularly in relation to their fermentative abilities. Three morphological groups were separated, short rods which predominated at the beginning of the ripening, long rods which appeared in the early ripening stages and increased steadily, and cocci which appeared in small numbers in the cheese at an age of five or six weeks. It is stated that "the essential bacteria of Emmental cheese are evidently not ubiquitous. In two widely separated localities cheeses made without inoculation have invariably failed to give the normal fermentation. Cheese made from milk inoculated with a mixture of a large number of pure cultures, or from special culture media inoculated with good cheese, have given uniformly a normal ripening."

The action of *Bacillus bulgaricus* in suppressing gassy fermentations in cheese making, C. F. DOANE (*Abs. in Science, n. ser., 38 (1913), No. 976, p. 377*).—From studies conducted in this Department, "it was found that pure cultures of *B. bulgaricus* could be used with perfect results in suppressing the undesirable fermentations, principally gas, which have worried Swiss cheese makers in the past. There seems to be a difference in the efficiency of different strains of *B. bulgaricus* for this purpose without respect to their activity in forming acid. One per cent of a whey starter made from one culture was sufficient, while it requires three per cent of another. The *B. bulgaricus* starters could not be seen to have any effect on the formation of the eyes or interfere with the flavor or texture. It is believed that the proper use of *B. bulgaricus* starters will go far toward making a more uniform cheese during the summer months and will make it possible to produce good Swiss cheese during the entire year."

Notes on yeast-like organisms in whey, S. F. EDWARDS (*Abs. in Science, n. ser., 38 (1913), No. 976, pp. 376, 377*).—In studies made at the Ontario Agricul-

tural College, 12 varieties of yeast-like organisms were isolated from samples of whey coming from cheese having a fruity or sweet flavor. Three lots of experimental cheese were made up, using a starter of these organisms, and the flavors typical of different factories were produced. It is stated that the term yeast as applied to these organisms is a misnomer, for with but one exception spore production was not demonstrated. A table is given showing the cultural and biological characters of these organisms.

The preparation of dried cultures, L. A. ROGERS (*Abs. in Science, n. ser.*, 38 (1913), No. 976, p. 377).—A method of drying cultures of lactic acid bacteria, *Bacillus bulgaricus*, and other organisms is described. It is stated that the activity of a dried culture diminishes more or less rapidly, depending upon moisture content, temperature, and presence of air or oxygen.

Purification and disposal of waste water from dairies, DOBNIK, DAIRE, and VIGNEROT (*Ann. Sci. Agron.*, 4. ser., 3 (1914), No. 4, pp. 150-170, figs. 3).—The chief object in the purification of waste water from dairies is the reduction of the casein, and the three methods of purification are the chemical, the biological, and the filter-bed. The last-named is deemed the most satisfactory in the majority of cases.

Reduction by chemical means of the nitrogenous matter in the waste water from dairies has been obtained with reagents as follows: Aluminum sulphate and lime 67.5 and 69.6 per cent; perchlorid of iron and lime 25.8 per cent; ferrous sulphate and lime 67.5 per cent; and ferric sulphate, aluminum sulphate, and lime 75.3 per cent. Daire's new chemical process, which is in operation, is described and declared to have given complete satisfaction. In plants where the water is not too rich in serum, anaerobic fermentation in septic pits may be employed. Irrigation of forage and vegetable crops may be employed where the water outflow is of sufficient quantity.

Purification of the residuary waters of the creamery, CALMETTE and E. ROLANTS (*Min. Agr. [France], Ann. Forêts, Hydraul. [etc.]*, No. 44 (1912), pp. 131-137).—An account of methods of purifying creamery-waste water by neutralizing the acids in the water and precipitating the organic material with ferric sulphate.

VETERINARY MEDICINE.

Lipoid anaphylaxis, F. P. WILSON (*Jour. Path. and Bact.*, 18 (1913), No. 2, pp. 163-168).—Attempts to sensitize guinea pigs to lipoids having various properties and extracted from the livers of rabbits gave negative results. "Lipoids extracted from egg yolk in a similar manner, and which differed considerably from the liver lipoids, also failed to produce anaphylaxis. Some doubtful evidence was obtained that a pure lipid from one source might sensitize an animal to a lipid of different origin.

"Dried liver substance and dried egg yolk do not sensitize to lipoids derived from these substances. Lipoids from yolk of egg sensitize animals to dried liver substance, but liver lipoids will not sensitize to dried egg yolk. Pure lipoids from any substance will sensitize an animal to a crude extract of the substance, but repeated injections of pure lipoids do not produce anaphylaxis."

Some further contributions to the knowledge of vegetable hemagglutinins, I. L. WAKULENKO (*Landw. Vers. Stat.*, 32 (1913), No. 5-6, pp. 313-391).—The lipases prepared by Jalander's and Falk and Nelson's (*E. S. R.*, 27, p. 712) methods have both lipolytic and blood agglutinating properties. The lipase is also capable of cleaving esters, glucosids, and high molecular carbohydrates hydrolytically. The reactions upon the blood caused by ricin are said to be due to the presence of enzymes. This view has already been put forth by Neuberg. Whether a universal enzym accounts for all of the above phenomena and

whether the reactions are identical with those brought about by a purified enzym (ricin), prepared according to Osborne's method, must be the subject of further investigation.

In nontoxic agglutinins, e. g., robin, robin-seed phasin, and robin-seed urease, various enzymes are present and consequently the agglutinating properties possessed by phasin are similar to those possessed by enzymes. No urease was noted in castor-bean lipase, nor was sinigrin cleavage, as observed by Power, noted with filtered and aseptic robin-bark enzym preparations. Kobert on a previous occasion has shown that the robin obtained from the bark of *Robinia pseudacacia* and that of robin-seed phasin were not identical. The preparation from the bark contained amylase and invertase while robin urease contained only amylase. Glucosid- and salol (ester)-cleaving enzymes were absent. Tannigen was cleaved but the most intense cleavage was with the urease prepared from robin seeds.

Enzymes were also noted in soy-bean phasin obtained from three varieties of beans. These were hydrolytic for certain carbohydrates, glucosids, esters, and urea. The blue lupine seed phasin contained diastatic enzymes and glucosid- and urea-cleaving enzymes in addition to the agglutinins. *Phaseolus mungo* did not agglutinate calf, adult bovine, horse, sheep, or goat corpuscles, but cat, rabbit, dog, pigeon, and human blood were agglutinated. The strongest action was on pigeon blood. The phasin from *P. maximus* agglutinated human, hog, horse, cat, and pigeon blood but not rabbit, dog, calf, adult bovine, sheep, or goat blood. *P. mungo* seeds contained invertase, amygdalase, helicase, and tannigenase. The seeds of *Sphenostylis stenocarpa*, which according to Kobert contain an agglutinating phasin, also had saccharose-, glucosid-, and tannigen-cleaving enzymes. Starch, glycogen, inulin, lactose, salol, and urea were not hydrolyzed by this seed.

Other plants studied in the above respects were *Voandzeia subterranea*, *Arachis hypogaea*, *Datura stramonium*, *Digitalis purpurea*, *Delphinium consolida*, *Atriplex hortensis*, *Strophanthus gratus*, *S. hispidus*, *S. combé*, sesame cake, apple seed, lemon seed, China orange seed, canary grass seed, and alder seed. The common feed cakes, namely, coconut, linseed, palm-nut, cotton-seed, and mowrah cakes, pea flour, and *P. erectus* gave negative results.

The poisonous constituent of the bark of *Robinia pseudacacia*, F. B. POWER (*Amer. Jour. Pharm.*, 85 (1913), No. 8, pp. 339-344).—A polemic in regard to statements made by Kobert (*E. S. R.*, 30, p. 204) with reference to the toxicity of robin.

A recent retest of the protein isolated in 1904 showed it to be very toxic; consequently Kobert's assertion that robin is a nonpoisonous phasin is deemed inaccurate. Other statements made by Kobert are also criticized.

In regard to the chemical nature and biological properties of ricin, G. REID (*Landw. Vers. Stat.*, 82 (1913), No. 5-6, pp. 393-414).—A. Cushny and F. Muller, working independently, as a result of their researches came to the conclusion that ricin is not a definite substance but is a mixture made up of an agglutinin and a toxin. Lau,^a on the other hand, showed that ricin was capable of combining with red blood cells and also with other body cells rich in lipoids. In this work the author attempted to prove Lau's contention that ricin is a unit substance which has both toxic and agglutinating properties.

The tests were made with isolated brain, liver, spleen, and kidney cells, small intestinal cells, and thymus cells. Ricin became anchored to these cells and agglutinated them (macroscopically) in much the same manner as blood cells are agglutinated by this substance. When the ricinized cells were treated with

^a Über Vegetabilische Blutagglutinine. Inaug. Diss., Univ. Rostock, 1901.

dilute hydrochloric acid the ricin which had become absorbed was liberated and again capable of agglutinating red blood cells of cats. Similar results were obtained with ricin and bean phasin (Merck) purchased on the market. Lecithin and cholesterol did not hinder agglutination of organ or blood cells by ricin.

Digestion experiments with pepsin-hydrochloric acid solution did not weaken the agglutinating properties of ricin but the presence of peptone seemed to delay its action. Vicarious elimination into the stomach of frogs and turtles could not be detected with the agglutination test in these experiments, but it is believed that it may take place if ricin is injected subcutaneously in large doses.

A short contribution to our knowledge of the action of abrin, A. SOMMERFELD (*Landw. Vers. Stat.*, 82 (1913), No. 5-6, pp. 415-426).—Abrin, from *Abrus precatorius*, like ricin is fixed by brain and similar cells and can not be washed from the cells with physiological salt solution. It is also considered a unit substance which has both toxic and agglutinating properties. Seeds 30 years old were still found to possess some of the agglutinating property. Formaldehyde in all concentrations is not inhibitory for abrin action.

The white blood cells (formalinized and nonformalinized) from the thymus of a calf also fixed abrin and the addition of hydrochloric acid to these cells freed the abrin, which in turn will agglutinate the red blood cells of man. Agglutination could also be induced with pus cells obtained from a cold abscess.

The hydropic degeneration of the fibers of heart muscle of guinea pigs and rabbits as noted by Schmorl could not be produced even though large quantities were used. The macroscopical findings with rabbits and guinea pigs after poisoning with abrin resembled those of ricin poisoning very closely. The lymph nodules in the abdominal cavity were swollen and there was often evidence of hemorrhage present. The microscopical examination of the abdominal organs showed a degeneration in the lymph nodules and in the lymph follicles of the digestive tract. Hemorrhagic areas were noted in the kidneys but in most instances the uriniferous tubules were intact.

About the poisonous substances in the seeds of *Jatropha curcas*, J. FELKE (*Landw. Vers. Stat.*, 82 (1913), No. 5-6, pp. 427-463).—This work is along the same lines as that noted in the abstract above. The seeds also contain a toxalbumin, curcin, which does not affect the red blood cells in vitro, but in vivo it has a marked effect upon these cells.

The oil owes its toxicity to an acid which is called curanolic acid and which is prepared in the same manner as the crotonic acid from croton seeds. It is a drastic and produces a marked gastrointestinal inflammation in both man and beast. The probability exists that curcin is destroyed in the gastrointestinal tract and is consequently robbed of its toxicity.

The use of salvarsan in nonsyphilitic diseases, W. H. BEST (*Jour. Amer. Med. Assoc.*, 63 (1914), No. 5, pp. 375-380).—From the study reported the following conclusions are drawn:

Salvarsan is specific in diseases caused by any variety of spirillum. It has curative properties in those diseases in which the infecting organisms are found in the blood or lymph, or in other locations where they can be easily reached. It has great therapeutic value in those diseases in which arsenic has been successfully used, and if used with caution in repeated doses over a long period has a therapeutic value in those diseases in which previously arsenic gave indifferent results. Salvarsan, used as an adjuvant to some other drug or drugs, is useful in those diseases in which a decided and quick tonic, stimulating, and alterative effect is desired, depending on the other drug or drugs for the ultimate result.

"The mode of administration is important, and should be as follows: Intravenous in those diseases in which a specific action is desired; full dose intramuscular injections, repeated once or twice at long intervals (eight weeks), in those cases in which the tonic, stimulating, and alterative effect is desired, as well as a certain specific action; small oft-repeated (week or ten days) doses, intramuscularly, over a long period of time, in those chronic diseases in which a purely tonic, stimulating, and alterative effect is desired."

The control of fluid in cattle dipping tanks, C. WILLIAMS (*Agr. Jour. Union So. Africa*, 8 (1914), No. 1, pp. 12-17).—In this paper the author presents a short review of the work hitherto published on the subject and gives the results of investigations that have been continued since publication of the article previously noted (*E. S. R.*, 29, p. 585). It is stated that the conclusions drawn in the previous article have been fully confirmed by the subsequent investigations.

"During the winter season the amount of arsenite in the tank only fell from 0.144 per cent to 0.134 per cent in 2½ months, whereas during an equal period of time in the summer the proportion of arsenite dropped from 0.138 per cent to 0.109 per cent, thus showing that oxidation takes place to a greater extent in the hot summer months than in the winter. . . . [In the winter] . . . bacterial activity was only apparent during the first month (May 22 to June 22), for after the latter date no signs of oxidation were detected. It may be also pointed out that very little dipping was taking place during the winter months, which circumstance in itself would favor oxidation than otherwise."

The investigations show that 10 gm. of sodium sulphite per 2,000 cc. of dip fluid has very little effect in arresting oxidation, and that the same is true of 1 gm. of either carbolic acid or one of the more common coal tar disinfectants. "By increasing the amounts of these two latter disinfectants to 10 gm. per 2,000 cc. of dip fluid the oxidation was very largely arrested. Under ordinary conditions this proportion could be materially lessened, seeing that the oxidizing action is much more powerful in vessels standing in the laboratory than in dipping tanks, even when the latter are used only at comparatively long intervals."

Oxidation of arsenical dipping fluids, A. G. HOLBOROW (*Rhodesia Agr. Jour.*, 11 (1914), No. 4, pp. 579-581).—Analyses made of the contents of three dipping tanks that were in constant use show that the amount of oxidation of sodium arsenite to sodium arsenate is neither constant nor regular but varies somewhat at different times. The author concludes "that there is no necessity to renew a dip in which a fair number of cattle are constantly dipped at short intervals until it has become too dirty for use."

Arsenical cattle dips: Methods of preparation and directions for use, R. M. CHAPIN (*U. S. Dept. Agr., Farmers' Bul.* 603 (1914), pp. 16, fig. 1).—This publication, which is intended to be a handbook for the user of arsenical cattle dips, includes general information, formulas, tables, and practical hints bearing on the preparation and management of arsenical dipping solutions.

Summary of experiments in the transmission of anthrax by biting flies, M. B. MITZMAIN (*Pub. Health Serv. U. S., Hyg. Lab. Bul.* 94 (1914), pp. 41-48).—The author states that the stable fly (*Stomoxys calcitrans*) as well as *Tabanus striatus* can be induced to feed on animals dying of anthrax and also upon their bodies a short time after death. It has been observed in the Philippines, however, that the stable fly does not, except under artificial conditions, attack the carcass of an animal whether recently dead or opened and exposed for some time.

In experiments conducted with a view to settling the question of fecal contamination it was found that only the vegetative form of the anthrax bacillus could be demonstrated throughout the entire series, either in the body of the

insect or in the fecal deposits. The virulence of the organisms present was demonstrated by the results with the animals inoculated from suspensions of agar cultures, there being a uniform fatality from the material used beginning with the three hours up to and including nine days. "Beginning with the cultures of feces made after the ninth day following the infective meal, all proved avirulent as far as animal inoculation was concerned. All of the ordinary cultural and morphological tests were positive from the ninth day to the twentieth day with the material obtained from *S. calcitrans*, and from the sixth to the tenth day with material obtained from *T. striatus*."

See also a previous note (E. S. R., 30, p. 780).

A case of myiasis aurium accompanying the radical mastoid operation, G. M. COATES (*Jour. Amer. Med. Assoc.*, 63 (1914), No. 6, pp. 479, 480).—The screw-worm (*Comptosmyia macellaria*) is thought to have been the parasite concerned.

Collected studies on the insect transmission of *Trypanosoma evansi*, M. B. MITZMAIN (*Pub. Health Serv. U. S., Hyg. Lab. Bul.* 94 (1914), pp. 7-39, pls. 5).—This collection consists of the following articles: (1) The Relation of *Tabanus striatus* to Surra Dissemination (pp. 7-19), previously noted (E. S. R., 30, p. 253); (2) The Relation of Mosquitoes to Surra (pp. 20-23); (3) Notes on the Blonomics of *Lyperosia exigua* and the Relation of this Fly to Experimental Trypanosomiasis (pp. 24-30); (4) Mechanical Transmission Experiments with *Phlebotomyia crassirostris* (pp. 31, 32); (5) Experiments with *Hippobosca maculata* in the Transmission of Surra (pp. 33, 34); (6) Experiments with Bloodsucking Gnats (p. 35); and (7) The Rôle of *Musca domestica* in Surra Conveyance (pp. 36-39).

A new staining method for preparing granulated tubercle bacilli, T. ISHIWARA (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 68 (1913), No. 1, pp. 113-117).—The following method is recommended for this purpose:

(a) Stain for 2 minutes with a petroleum ether water-fuchsin solution prepared by filling the conical portion of a test tube with petroleum ether, adding sufficient distilled water to fill three-fourths of the tube, filtering through moistened filter paper, and add one-fourth of the volume of carbol-fuchsin solution (100 cc. of 5 per cent carbolic acid and 10 cc. of a saturated solution of fuchsin); (b) decolorize for 2 minutes in a 25 per cent solution of nitric acid and follow by rinsing with 70 per cent alcohol until the preparation appears colorless; (c) stain with a saturated aqueous solution of methylene blue. After staining wash well with water to prevent a precipitation of the coloring matter.

The modified Gram staining method was also simplified by utilizing a petroleum ether water-carbol-gentian violet solution. In addition to this a simplified method for staining the Much granules and the granular form of the tubercle bacillus is described.

About the occurrence of tubercle bacilli in apparently healthy mammary gland tissues of cows destined for slaughter, T. ISHIWARA (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 70 (1913), No. 1-2, pp. 1-10).—Mammary glands macroscopically free from tubercular changes but from cows having organs affected with tuberculosis were found in 5 out of 26 cases to contain tubercle bacilli. Most of the udders came from animals which had the severest form of the disease.

Study of the pathological changes which occur in the organs of tubercular pigs and the detection of granulated tubercle bacilli, T. ISHIWARA (*Berlin. Tierärztl. Wchnschr.*, 29 (1913), No. 37, pp. 657, 658).—In this work the organs of 217 pigs were examined for the presence of tubercle bacilli. The lungs were tubercular in 181 instances, the bronchial lymph glands in 173, the mesenteric lymph nodes in 147, the spleen in 132, the tracheal nodes in 126, the liver in

83, the shoulder glands in 82, the kidneys in 55, the kneefold nodes in 21, the bones in 12, the joints in 8, and the muscles in 2 cases. A table is given which shows the pathologic appearance of the various organs.

In a previous paper the author pointed out that the tubercle bacilli present in hog tuberculosis are very hard to detect, as stainable forms are only sparingly present. The presence of much fat in and about the organisms is not the cause for not detecting the stain. Using Much's method it was found that as a rule the granulated bacilli from the purulent and calcified areas are harder to detect than the organisms present in the compact nodules and caseated areas.

Contribution to the biology of the tubercle bacillus, I, G. LOCKEMANN (*Deut. Med. Wchnschr.*, 39 (1913), No. 50, pp. 2458, 2459).—Weighing the cultures of the tubercle bacillus from time to time is considered a good procedure for obtaining a clew to the state of the growing process. Tubercle bacilli cultures, after having reached their maximum of growth, lose weight, undoubtedly because of an autolytic process going on in the culture. There was no difference in the rate of growth when different culture media (glycerin bouillon, or asparagin solution) were used. However, the acid titer obtained with the two cultures was different, and the curve with the glycerin bouillon took a middle position between the titers set down for the human and bovine types of organism.

During the growth of the tubercle bacillus in asparagin solutions, i. e., protein-free media, substances were liberated which gave reactions characteristic of the proteins.

Serologic investigations of the antigen content of the cultures of tubercle bacilli, B. MÖLLERS (*Deut. Med. Wchnschr.*, 39 (1913), No. 50, pp. 2460, 2461).—The antigens noted by the complement fixation method in cultures of tubercle bacilli increased up to the sixth week of growth. A diminution of antigen took place at the eighth week.

Theobald Smith's reaction curve as an aid for differentiating human and bovine tubercle bacilli, J. WANKEL (*Deut. Med. Wchnschr.*, 39 (1913), No. 50, p. 2461).—The value of this method (*E. S. R.*, 17, p. 294) for diagnosing the kind of culture in hand was investigated with 45 cultures. With 25 cultures of the human type only 11 gave a characteristic Smith curve, and 6 formed no acid at all but otherwise behaved like bovine bacilli. Out of 20 cultures which were adjudged by the animal experiments to be of the bovine type, 15 behaved as bovine cultures with the reaction curve, 4 formed acid which, according to Smith would be classed with the human type, and the remaining culture could not be classified.

See also a previous note by Grund (*E. S. R.*, 26, p. 582).

Intraperitoneal lysis of tubercle bacilli, W. H. MANWARING and J. BRONFENBRENNER (*Jour. Expt. Med.*, 18 (1913), No. 6, pp. 601-617, figs. 4; *abs. in Science, n. ser.*, 38 (1913), No. 978, pp. 453, 454; *Proc. Soc. Expt. Biol. and Med.*, 10 (1913), No. 3, pp. 67, 68).—"If suspensions of tubercle bacilli are injected into the peritoneal cavities of tuberculous guinea pigs, there takes place a rapid disappearance of the bacilli from the peritoneal fluids, as determined by subsequent examinations by the Ziehl-Neelsen method. Nine-tenths of the bacilli may disappear within an hour, and all but an occasional bacillus within five hours. This disappearance is paralleled by the appearance of atypical, nonstaining, and granular forms. After the disappearance numerous granules can be demonstrated in the peritoneal fluids and peritoneal scrapings by the Much method.

"Before the conclusion can be drawn, however, that the disappearance of the tubercle bacilli is due wholly to their destruction by the peritoneal fluids,

such factors as a possible removal of the bacilli by the rapid formation and absorption of peritoneal transudate must be ruled out, as well as the possibility of a spontaneous metamorphosis of the bacilli into nonstaining and therefore invisible forms, as described by Much. A similar rapid disappearance is brought about in the peritoneal cavities of tuberculous rats, rabbits, and dogs. The mechanism of the disappearance is now under investigation."

Does the subcutaneous injection of antiphymatol (Klimmer) protect bovines against artificial and natural infections with bovine tubercle bacilli? A. EBER (*Ztschr. Infektionskrank. u. Hyg. Haustiere*, 14 (1913), No. 4-5, pp. 203-230).—Antiphymatol is a preparation made from tubercle bacilli which has been passed through cold-blooded animals to render them avirulent (E. S. R., 20, p. 480). The injection of a trade package (5 cc.) of the vaccine into guinea pigs produced no tuberculosis.

The results reported considered 16 bovines, 9 of which were treated and 7 which were kept as controls, and the experiments were made especially for the purpose of determining whether the subcutaneous injection of antiphymatol will in reality protect against an artificial or natural infection with the bovine type of tubercle bacilli. It was also decided to note whether the protection given lasted for any length of time.

Six animals vaccinated 3, 6, or 8 months before intravenous or subcutaneous infection passed through the cycle of the disease at the same rate as unvaccinated animals. Three vaccinated animals exposed to natural infection became tubercular as quickly as the control animals. All animals infected by the artificial method were treated with the same culture.

The prevention of human tuberculosis of bovine origin (particularly from the point of view of the Tuberculosis Order, 1913), W. G. SAVAGE (*Vet. Jour.*, 69 (1913), No. 461, pp. 513-521).—This is a discussion of the occurrence of tuberculosis among bovines, with special reference to its being a source of danger to man. The whole discussion is in the light of the English Tuberculosis Order of 1913.

"In the words of the covering circular of the board, the order 'aims at securing the destruction of every cow found to be suffering from tuberculosis of the udder, or to be giving tuberculous milk, as well as of all bovine animals which are suffering from tuberculosis with emaciation.' . . .

"It is clear that the prevention of human tuberculosis of bovine origin can not be separated from the prevention of tuberculosis among bovine animals, and that no steps can be permanently satisfactory unless they definitely aim at a diminution of the total bulk of bovine tuberculosis."

Notes on some parasites of live stock in the West Indies, P. T. SAUNDERS (*West Indian Bul.*, 14 (1914), No. 2, pp. 132-138).—A general account of the more important parasites.

The granular venereal disease and abortion in cattle, W. L. WILLIAMS (*U. S. Dept. Agr. Bul.* 106 (1914), pp. 57).—During the course of the investigations here reported post-mortem observations were made on the killing floors of abattoirs at some of the principal slaughtering centers, including Chicago, Omaha, Kansas City, Denver, and Fort Worth, with a view to determining how widely and extensively the granular venereal disease exists among cattle in this country. Records of 3,250 cases of granular venereal disease, here summarized in tabular form, show nodules or granules macroscopically visible in the vulvar mucosa of 2,806.

Records kept for a period covering 22 years of a dairy herd consisting of a total of 217 cows with a total of 645 pregnancies, the details of which are here presented in tabular form, show an average annual rate of 12 per cent of abortions. Records kept from May, 1909, to December, 1911, of another herd in

which there were a total of 1,206 pregnancies show 17 per cent to have been the annual rate of abortions.

The investigations have led the author to the following general conclusions: "Abortion in cattle is essentially always the result of a chronic infection within the utero-chorionic space, revealing itself post-mortem by the presence of the so-called abortion exudate, which contains generally, if not always, the abortion bacilli. The granular venereal disease of cattle is, so far as known, universally distributed. From clinical observation it has a vital relation to contagious abortion. It is incurable in the present state of our knowledge, but may be greatly decreased in virulence. Contagious abortion of cattle has attained an essentially universal distribution, frequently present merely as an unrecognized infection of the genital organs, not inducing actual abortion but causing premature birth, retained afterbirth, and sterility.

"The ordinary if not sole avenue of the entrance of the infection of contagious abortion is the genital canal, and the invasion antedates the sealing of the uterus, which ordinarily occurs within 30 days after conception. When conception has occurred and the cervical canal has been sealed, the fate of the fetus is settled. If a sufficiently virulent and voluminous infection exists in the utero-chorionic space, abortion may result; if such infection does not exist within the sealed utero-chorionic space when the formation of the seal is completed, it will not enter thereafter during pregnancy.

"In the present state of our knowledge little or nothing can be done to prevent abortion once the pregnant uterus is sealed and the infection of contagious abortion exists within the hermetically sealed cavity. By systematic disinfection of the genitalia immediately following abortion or premature birth, and also in retained afterbirth and kindred infections of the uterus, the affected animals may be largely guarded against future sterility and abortion. It is even more important that the vaginae of heifers, whether virgin or previously bred, and cows shall be systematically disinfected for a period before and after breeding, until conception is assured. It is equally important that the genital organs of breeding bulls be kept clean by regular disinfection, including washing immediately prior to and after service. Most important of all, breeders of valuable cattle should institute definite, energetic, and permanent efforts to guard new-born calves simultaneously against the three great dairy scourges—calf scours and pneumonia, abortion and sterility, and tuberculosis."

The curative treatment of hemorrhagic septicemia in cattle by the administration of iodine, J. D. E. HOLMES (*Vet. Jour.*, 70 (1914), No. 468, pp. 277-280).—Of a large number of drugs tested in the laboratory, iodine was the only one found to have any action on the course of this disease. When administered either by mouth or subcutaneously as late as 16 hours after the inoculation of the virus, about one-half of the cases so treated recovered. At 16 hours after inoculation susceptible animals generally show a rise in temperature, uneasiness, and loss of appetite, and death follows in from 24 to 36 hours after inoculation.

"In laboratory experiments when an animal inoculated with hemorrhagic septicemia shows a decided rise of temperature or other symptoms of disturbance he rarely survives, unless he has received antiserum treatment. In many of the cases treated with iodine the animals passed through a fairly severe attack of the disease and recovered. In other cases which ended fatally death was delayed by one to two days."

Warble flies, a danger with imported cattle, C. P. LOUNSBURY (*Agr. Jour. Union So. Africa*, 8 (1914), No. 1, pp. 61-64, fig. 1).—The author calls attention to the fact that since warble flies do not occur in South Africa it is of considerable importance that the maggots in imported cattle be destroyed.

Ascaris suum in sheep, D. C. MOTE (*Science, n. ser., 40 (1914), No. 1023, p. 216*).—During the course of a post-mortem examination of an 8-month-old lamb two female ascarids were found which were identified as *A. ovis*. This lamb had been fed and kept in a pen previously occupied by hogs known to be infested by ascarids, and the author thinks it probable that the ascarids may represent *A. suum*, since it is still questionable whether *A. ovis* is a distinct species.

A summary of studies of loco weed disease of sheep, H. T. MARSHALL (*Bul. Johns Hopkins Hosp., 25 (1914), No. 282, pp. 234-236*).—This is a brief review of a detailed report to be published later of the results of investigations conducted in Montana for this Department during the summers of 1903 and 1904. Some 80 sheep were used in feeding experiments with *Aragallus spicatus*.

The experiments have led the author to conclude that none of the abnormalities encountered in the sheep could be attributed to the poisonous action of the loco weed. He states that none of the sheep gave the slightest evidence of having suffered any ill effects from eating the weed. On the other hand, the experiments seemed to confirm the view that the animals were suffering chiefly from starvation combined with one type or more of parasitic infection.

“My investigations have convinced me that there are several diseases of western live stock masquerading under the general name ‘loco disease.’ One hundred per cent of the severely ‘locoed’ sheep which I studied were not suffering from locoism, but from underfeeding combined with parasitic infection. I therefore think there is reason to be doubtful as to the existence of pure, bona fide loco weed poisoning, and I hold that it is perfectly certain that the heavy losses attributed to loco weed disease are at least in large measure due to other causes, which can usually be ascertained by careful study.”

The prevention of hog cholera in Indiana, C. G. STARR (*Indiana Sta. Circ. 44 (1914), pp. 7, figs. 2*).—The data here presented relate largely to antihog cholera serum and its use.

Canine babesiasis in Porto Rico, I. GONZALEZ MARTINEZ (*Jour. Trop. Med. and Hyg. [London], 17 (1914), No. 13, p. 194*).—During the course of routine examination of dogs for epizootic diseases and for hydrophobia the author detected two cases of canine piroplasmosis in Porto Rico.

Hygiene and diseases of poultry, LIÉNAUX (*Min. Agr. et Trav. Pub. [Belgium], Off. Rural Raps. et Communs., No. 9 (1914), pp. 245-266*).—A general account.

Studies on fowl cholera.—IV, The reciprocal relations of virulent and avirulent cultures in active immunization, P. B. HADLEY (*Rhode Island Sta. Bul. 159 (1914), pp. 383-403*).—“The present paper presents the results of a study conducted to ascertain (1) the protective power of certain avirulent cultures of the fowl cholera organism against a highly virulent culture (culture 48); (2) the extent and degree of protective power exercised by a certain immunizing culture (culture 52) against twelve, heretofore untested, virulent strains; (3) the protective power of combinations of cultures. The results, briefly stated, are as follows:

“Among 17 strains of the actual fowl cholera bacterium which have now been tested for their resistance-producing power toward a highly virulent culture, only one (culture 52) was found which produced any resistance whatever; and this culture, upon subcutaneous inoculation, invariably gave perfect immunity against the most virulent culture in the laboratory collection (culture 48). This immunizing culture has now been tested (alone) against five other virulent strains, toward three of which it is also protective. In the other two cases, it is irregularly protective. In the two instances in which culture 52 alone failed to protect, or protected irregularly, complete protection was

afforded by inoculation with culture 52, followed after one week, or more, by inoculation with culture 48. In all cases in which culture 52 alone was not tested against virulent cultures (seven) the inoculation with both cultures 52 and 48 in the sequence and under the conditions stated, yielded complete immunity.

"The results obtained in the investigation, thus far reported, are such as to afford, for the first time, complete control over infection in rabbits with probably any virulent strain of the fowl cholera bacterium. The method thus found successful for the active immunization of rabbits will now be employed, perhaps with modifications, in an attempt to produce a corresponding active immunity in birds."

See also previous work (E. S. R., 31, p. 485.)

Spirochetosis of fowls, S. VON RÁTZ (*Berlin. Tierärztl. Wchnschr.*, 30 (1914), No. 7, pp. 117-119).—The author has demonstrated the occurrence in Hungary of a spirochetosis of poultry, which affects chickens, geese, and ducks. He finds that the spirochetes may remain alive in the blood during a period of from 36 to 48 hours after death, during which time they are virulent.

A disease of the wattles of fowls, H. R. SEDDON (*Jour. Dept. Agr. Victoria*, 12 (1914), No. 7, pp. 426-428, figs. 2).—A so-called wattle disease investigated by the author at the Melbourne University Veterinary School appears to be a localized form of fowl cholera in which the causal microbe gains entrance into the wattles and remains there, giving rise to two very marked symptoms, namely, (1) enlargement, due to the presence of inflammatory fluid, and later (2) distortion, with the formation of hard nodules of cheesy material in the wattle.

RURAL ENGINEERING.

Irrigation, F. L. BIXBY (*New Mexico Sta. Rpt. 1913*, pp. 41-47).—Brief descriptions of the calibration of a submerged orifice, measurements of water on the mesa flats, a study of end contractions in Cippoletti weirs, duty of water investigations in orchard irrigation, and irrigation of onions and tomatoes are given.

In the duty of water investigations in orchards it was found that in comparing the flooding method by checks and the furrow method the different amounts of water produced very little difference in the material growth of the tree. The 4-in. irrigation appeared to be the best amount to use. In connection with the furrow irrigation it was impracticable to irrigate with large streams of water.

Loss of water in irrigation systems, P. M. FOGG (*Engin. and Contract.*, 41 (1914), No. 25, pp. 720-724).—Considerable data gathered by the Irrigation Investigations of this Office and by the U. S. Reclamation Service on evaporation losses, field evaporation, percolation losses, methods of loss prevention, waste water, etc., are reviewed and discussed.

Irrigation by "zaaidams," C. J. v. ZYL (*Agr. Jour. Union So. Africa*, 7 (1914), No. 4, pp. 493-495).—A method by which moisture is conserved in the soil by the construction of walls of earth, or ordinary earthen embankments, in which flood water is impounded and allowed to soak thoroughly into the soil is described.

Gate structures for irrigation canals, F. C. SCOBEEY (*U. S. Dept. Agr. Bul.* 115 (1914), pp. 61, pls. 12, figs. 18).—This bulletin describes and illustrates a large number of designs of small and medium-sized gate structures adapted to many localities for controlling the flow of water in ditches and canal systems. These include headgates and floodgates to regulate the water entering the system from the source of supply, check gates to regulate the water while within the

canal, sand and waste gates to control the water which is to be turned out and wasted, branch canal lateral and delivery gates to regulate the water turned out to branches of the system or to users, and bifurcation works and division gates to regulate the flow of water in the main canal and that passing into branches or laterals.

The author does not attempt to treat the subject fully, but gives examples of structures which are said to serve the purpose for which they are intended better than many others in common use. Since local conditions control many features of gate structures the descriptions given relate to existing structures in actual use which it is believed will prove suggestive and can be readily adapted to other conditions by local engineers and ditch owners.

The drainage of irrigated land, J. P. MARAIS (*Agr. Jour. Union So. Africa*, 7 (1914), No. 3, pp. 353-356).—The author briefly relates the results of his experience in the drainage of irrigated land, particularly referring to methods of removing injurious alkali salts.

Drainage and reclamation of swamp and overflowed lands, C. KETTLEBOROUGH (*Ind. Bur. Leg. Inform. Bul. 2* (1914), pp. 68).—It is the purpose of this pamphlet to present briefly the evolution, progress, and present status of drainage and drainage legislation in Indiana; to enumerate and discuss the most significant results achieved in other States; to point out the inadequacy of the present system in the State, the magnitude and economic importance of the question, and to suggest plans to bring the drainage laws of the State into harmony with those of the other States and thus promote the rapid and permanent reclamation of nonarable swamp lands.

Drainage investigations on the northeast Missouri prairie, M. F. MILLER, C. B. HUTCHISON, T. R. DOUGLASS, and R. R. HUDELSON (*Missouri Sta. Bul. 118* (1914), pp. 445-497, figs. 5).—Tile drainage experiments to determine the actual economic gain in crop yields and to determine the relation of under-drainage to fertilization are reported, together with a summary of data secured from farmers who have had experience with tile drainage.

It is concluded in general that for the wet sloughs and sags found in the region the use of tile is a very paying proposition. "On the tight level prairie where the water passes to the tile more slowly it is necessary to lay the tile from 4 to 6 rods apart for satisfactory work, thus greatly increasing the cost. . . . However, where the land is very level and where the tile are properly put in, the tiling of this land will pay. On the prairie land that drains well naturally . . . while tiling may pay, this will depend upon the crops grown and the particular character of the land in question. The return in such cases is therefore doubtful."

The fertilizer experiments indicated that when large supplies of available fertilizers are added there is less need for tiling and the profit from it is reduced. Drainage without any fertilizer treatment gave a total increase per acre on all crops for six years after laying the tile of \$26.55, or within \$1.33 of the cost of tiling. As an investment it seems profitable to apply manure and rock phosphate on this soil, even more profitable to use bone meal and turn under an occasional crop of cowpeas, while lime returns a good percentage on the investment where the land is not drained. Upon tiling, the plant food in the soil becomes more available and the detrimental effects of the acid are removed, so that the only profitable soil treatment seems to be the use of a legume green manure crop to supply nitrogen and organic matter which are decidedly lacking."

In addition to general suggestions as to the laying of tile it is further concluded not to be advisable to use a smaller size of tile than 4-in. in any case, and in systems draining more than 30 acres an 8-in. main is usually more

satisfactory. As regards distance apart of laterals it is concluded that 6 rods is about the maximum width for the level prairie. The proper depth on the prairie seems to be around $2\frac{1}{2}$ to $2\frac{3}{4}$ ft. on the average, although the actual depth varies from 2 to $3\frac{1}{2}$ ft.

Drainage problems in the Ganges delta, C. ADDAMS-WILLIAMS (*Calcutta, 1913, pp. 35, pls. 19*).—This book comprises a series of six lectures in which it is proposed to illustrate the practical application of mathematical principles in the design of the drainage works for delta lands. The discussion is confined to actual problems encountered by the author in the Ganges delta near Calcutta. The formation of the Ganges delta and the reclamation in the tidal portions of the delta are discussed in some detail, followed by a discussion of the practical design of the necessary drainage works. Maps and detailed drawings of drainage works and specific structures are included.

Some interesting experiments in hydraulics (Dom. Engin., 68 (1914), No. 2, p. 33, figs. 2).—Experimental data are given in tabular form showing the actual quantity of water which bibbs of sizes from $\frac{1}{4}$ in. to $1\frac{1}{2}$ in. will discharge.

A proportional-flow weir, E. W. RETTGER (*Engin. News, 71 (1914), No. 26, pp. 1409, 1410, figs. 2*).—By means of mathematical analysis the author points out that a weir whose width at any point is inversely proportional to the square root of the height of that point above the crest will have a theoretical discharge exactly proportional to the head. By means of further mathematical analysis he outlines a process for slightly modifying the theoretical shape of such a weir so that the coefficient of discharge will be constant for different heads.

Modern pumping machinery, R. W. ALLEN (*Sci. Amer. Sup., 78 (1914), No. 2009, pp. 8-11, figs. 10*).—The author deals chiefly with the mechanism of pumping outfits as used for the drainage of the fens in England, which employ vertical steam and horizontal oil engines driving horizontal spindle centrifugal pumps. The description is confined to outfits representing some of the more recent works in the district. Diagrammatic and other illustrations of important features are given.

Some tests on pipe reinforcing (Cement Era, 12 (1914), No. 7, pp. 44, 45, figs. 8).—Tests are reported on 6-in. sections of concrete pipe 22 in. in diameter and 2.2 in. thick, reinforced with 2 circular bands of No. 7 bright wire placed 3 in. apart on centers, thus bringing them $1\frac{1}{2}$ in. from the outside edges. Each band consisted of an inner and outer hoop, the inner hoop being placed $\frac{5}{8}$ in. from the inner wall and the outer $\frac{1}{2}$ in. from the outer wall. The two hoops were fastened together by (1) 6 radial ties, (2) 12 radial ties, (3) 6 radial ties and 6 tangential ties, and (4) 6 radial ties and ties in truss form.

The average load at failure of four unreinforced specimens was 328 lbs. The respective average loads at first crack for four specimens with each type of reinforcing were 465, 577, 835, and 1,047 lbs.; and at failure 1,413, 1,490, 1,645, and 1,770 lbs., thus showing the truss tied reinforcing to be much the strongest type.

The use of paint films as protective coatings for concrete, E. E. WARE and S. M. SCHOTT (*Concrete-Cement Age, 4 (1914), No. 4, pp. 177-181, figs. 5*).—This paper discusses the basic principles of successfully coating concrete surfaces and reports investigations on the relative merits of various concrete coating materials. The materials were applied to the surfaces of concrete and stucco panels and given an exposure test extending over about two years. To indicate the leaching out of lime, one-half the surface of each panel was painted after one year's exposure with a green paint, the pigment in which was a mixture of chrome yellow and Prussian blue. Conclusions from the test are as follows:

“Assuming water to be an important agent in the disintegration of concrete and stucco, there is a necessity for a system of waterproofing that will prevent

absorption. . . . No coating compound can be successful that will disintegrate under the influence of the weather. . . . Although linoxyn is readily saponifiable in the cold, there is not, under ordinary conditions, enough lime carried out by the small amount of water that may penetrate a paint film in good condition, to cause disintegration of the film. . . . The absence of stains on the green test paint film in the cases of some of the panels, the coats of which showed disintegration at the time of application of the green, would indicate that the lime at the surface of the panels had become pretty well carbonated within the first year. Any stucco exposed to the weather for a year's time can be coated satisfactorily with a good outside paint. A successful concrete coating material should be compounded on the same basis as is used for a satisfactory outside paint for wood, with only such adjustments in composition as tend to make it more nearly impervious, and these must not be made at the expense of the elasticity and general durability of the film."

An analysis of worn out and ravelled macadam surfaces with suggestions as to treatment, E. A. STEVENS (*Engin. and Contract.*, 42 (1914), No. 1, pp. 14, 15).—The author points out that raveling of macadam surfaces is due to (1) improper construction, (2) overload, or (3) neglect. Reconstruction of defective sections is the remedy suggested for the first cause of raveling, resurfacing with a better type of surface for the second, and repair of the old surface for the third. It is pointed out in this connection that a road structure may be so maintained as to increase its carrying capacity greatly, thus making the problem largely one of economics and administration.

The prevention of the subcrust movement in roads, E. S. SINNOTT (*Surveyor*, 46 (1914), No. 1172, pp. 9-11, figs. 7).—A means for preventing the lateral and longitudinal movement of material forming the subcrust of highways under heavy traffic is described and illustrated. The essential feature is that longitudinal and cross members are placed at a suitable depth below the surface to preclude any movement of the subcrust and at the same time to provide a means of constructing an impervious arch of tarred macadam to carry the traffic. It is thought best to construct the frames of reinforced concrete.

Carburation in theory and practice, R. W. A. BREWER (*New York*, 1913, pp. VIII+253, figs. 70).—It is the purpose of this book to provide in convenient form information upon the properties of various fuels, what treatment these fuels require for use in an engine, and what has been done in the past in order to obtain the necessary data upon which to base the theory. Chapter 1 gives a general outline of the subject, explaining terms used, describing early carburetting devices, and discussing the general principles of carburation and modern requirements. The succeeding chapters deal with the following subjects: Vaporization and evaporation; limits of combustion—air and heat required; inlet pipes and inertia; the flow of fuel through small orifices; the annulus; Brewer's fuel orifice; special jets; moving parts; float chambers; petrol substitutes; exhaust gas analyses; and carburetors. The closing chapters consist of descriptions of some of the best-known carburetors with criticisms thereon. Appendixes give tabular data as to equivalents, conversion from degrees Baumé to specific gravity, and properties of gases.

Simple water testing, P. EDELMAN (*Chicago*, 1913, pp. 50, figs. 20).—This pamphlet outlines quick, cheap, and practical methods of analyzing boiler feed-water, and for regulating the ill effects of impurities.

Steam plowing experiments in the Aira estate, Kheri, United Provinces, B. C. BURT (*Agr. Jour. India*, 9 (1914), No. 1, pp. 1-6, pls. 2).—Plowing experiments on heavy grass land with an alluvial soil very sandy in places, using a single-cylinder oil-burning steam tractor of about 25 brake horsepower, dragging two sets of 3-disk plows, and cutting furrows 10 in. wide and about

8 in. deep, showed that for this class of work the single-cylinder tractor was hardly powerful enough as even on the best land it was imposible to plow at top speed. It is stated that the cost of plowing per acre will vary enormously with the land to be plowed, and the amount to be charged for interest and depreciation will always be a matter of opinion, but that the cost of plowing virgin land is reasonable and much less than that of hand digging.

Buildings for small holdings in England and Wales (*Bd. Agr. and Fisheries [London], Rpt. on Buildings for Small Holdings, 1913, pp. 122, pls. 37*).—This report describes and discusses what are considered to be the most suitable buildings and equipment for small farms from the English viewpoint. The main points considered are the small holder's house, farm buildings, unusual materials and methods of construction, building by-laws, and the rural laborer's cottage. Appendixes to the main report deal with such subjects as particulars of houses, farm buildings and fencing erected in connection with small holdings, the increase in rent per acre attributable to the cost of erecting farm buildings of brick and timber, and the creosoting of timber.

It is concluded that as regards the cost of equipment generally some saving may be effected if houses and farm buildings are erected either in pairs or groups within a limited area, thus allowing reductions (1) in the quantity of necessary materials and (2) in the cost of supervision; by standardizing fittings; and by the provision of common roads and water supply. Other more specific conclusions are given regarding the design and materials of construction of houses and farm buildings and health regulations. A number of detail plans of buildings and equipment accompany the report.

Silo building, W. D. NICHOLLS (*Kentucky Sta. Ext. Circ. 18 (1914), pp. 24, figs. 8*).—This circular gives general information regarding silos and silage and the construction of stave and concrete silos.

How to build a Gurler silo, P. M. BRANDT (*Missouri Sta. Circ. 67 (1914), pp. 247-257, figs. 10*).—This circular is mainly a reprint of a previous one on the same subject (*E. S. R., 25, p. 891*).

Mississippi poultry house, D. SCOTES (*Mississippi Sta. Circ., 1914, Mar., pp. 8, figs. 7*).—The poultry house is described and diagrammatically illustrated. The essential features are as follows: (1) It has an open front, (2) is raised 2 ft. off the ground, (3) it can be opened on all sides, and (4) it is inexpensive. This poultry house "is designed especially for the Mississippi farmer, . . . should not cost over \$35, and where lumber can be bought very cheap, and the work done by farm hands at leisure times, it can be put up much cheaper."

Sheep-dipping tanks, B. G. L. ENSLIN (*Agr. Jour. Union So. Africa, 7 (1914), No. 3, pp. 360-371, figs. 11*).—In this article are given detailed plans, specifications, and descriptive and other information for the construction of an improved design for a circular sheep-dipping tank. The circular tank is recommended in preference to any other form because of its cheapness of construction, economy in the consumption of dipping material, and the better results obtained with less labor in dipping operations because the sheep can be kept swimming the full period of its immersion. The tank is supplied with a receiving yard, forcing pen, entrance race, inslide, outslope, dripping pens, and a drying yard. The maximum diameter is 6 ft., which decreases toward the bottom, and the approximate capacity is 505 gal. The tank itself and the outslope are built of bricks laid in ordinary blue hydraulic lime mortar with the inside plastered with cement mortar.

Sewage disposal for country homes, H. W. RILEY (*Cornell Reading Courses, 3 (1914), No. 59, pp. 149-187, figs. 27*).—The purpose of this pamphlet "is to suggest to persons in country homes better methods of disposing of household wastes than by means of the slop-pail and the outdoor privy." Although in-

tended to be of popular interest, the treatment is such as make it also of considerable technical value. Sanitation, particularly with regard to water supplies, is the main feature of the introduction, and is kept in mind throughout the entire discussion. Different sections describe and discuss types of sewage disposal systems; the septic tank and its proper design; the tile purifying system, its design, location, and construction; and types of septic tank systems, including the sink and barrel septic tank; sink, direct closet and barrel, or concrete, septic tanks; direct closet and chemical tank; and the type Y and metal septic tanks.

The most important of these appears to be the Y septic tank, which is a single-chamber, continuous-discharge tank of standard depth and variable length and width. The tank is of concrete, and inclined baffle boards are placed before the inlet and outlet, with a vertical bottom baffle near the outlet. New features of the purification system are the so-called sewage switch and sewage divider. The switch is designed to divert the sewage from one section of the system to another, and the divider to effect thorough distribution.

The L. R. S. sanitary privy (E. S. R., 25, p. 891), and the Kentucky sanitary privy are also described.

A number of illustrations accompany the text.

Sanitary sewage disposal without sewers (*Mo. Bul. Ind. Bd. Health, 17 (1914), No. 4, pp. 42, 43, figs. 2*).—A recent development in septic tanks for residential sewage disposal, which is composed mainly of Imhoff features, is described and diagrammatically illustrated.

Screening as an antimalarial measure, H. R. CARTER (*Pub. Health Rpts: [U. S.], Reprint 183 (1914), pp. 12*).—This paper discusses some of the more important points regarding the use of screens in houses and mosquito bars for beds.

RURAL ECONOMICS.

The business of farming, W. C. SMITH (*Cincinnati, Ohio, 1914, pp. 292, pls. 39*).—The author believes that for farming to be successful the soil should be plowed deep and thoroughly prepared, the best quality and variety of seed and live stock should be used, crop rotation should be followed in such a way that the soil should be supplied with an ample amount of plant food, all by-products should be utilized in a business-like way, the best machinery should be purchased and properly handled, the housewife should know how to prepare properly the right kind of foods to make the farmer and his family efficient in their work, the farmer should keep sufficient accounts or records to be able to determine whether any part of his business pays, and that he should be given sufficient credit to carry on his farm operations to the greatest advantage.

Some suggestions for city persons who desire to farm, G. F. WARREN (*New York Cornell Sta. Circ. 24 (1914), pp. 29-40*).—This circular was prepared for inexperienced persons making farm investments. It points out that farming is a complicated business, requires considerable experience for success, and while for one who knows how to farm it offers a wholesome living and a modest profit, it requires a considerable amount of capital, the returns from some investments do not even come in the farmer's lifetime, and aside from increases in land values it very rarely results in even small fortunes. The fact that food and housing are cheaper on the farm makes it more attractive for persons with a large family.

The way suggested to begin farming is to raise crops, as if one can not make a profit at this he has no need for buildings. The beginner should follow the practices of the best farmers of the region. The way for the young man to

prepare for farming is by working as a hired man on a farm, and unless the mature man can earn good farm wages for some one else he is not ready to direct a farm himself.

Social life in the country, MARY W. KEYES (*Home Prog.*, 3 (1914), No. 10, pp. 472-475).—The author suggests that to improve the social life of the farm woman, every woman should know how to harness and drive a horse and should have one at her disposal. Among other means suggested are the use of the school house or church parlor, both of which should be supplied with a cooking stove. Entertainment should be encouraged in the form of good music, amateur plays, and the serious study of some elevating topic.

Report of the Pennsylvania Rural Progress Association, 1914 (*Rpt. Penn. Rural Prog. Assoc.*, 1914, pp. 24, figs. 11).—The purpose of this association is to promote a wider study and consideration of the relation of rural problems to the welfare of the State. This report describes various means that have been used toward this end, and gives the constitution of the association and the programs of various country life conferences in which it took a part.

Scottish Agricultural Organization Society (*Scot. Agr. Organ. Soc. Rpt.* 1913, pp. 161).—This report contains a statement of the year's work, a list of the leaflets issued by the society, outlines of meetings held, and accounts and reports of affiliated societies.

An analysis of rural banking conditions in Illinois, C. L. STEWART (*Champaign, Ill.*, 1914, pp. 38, figs. 11).—By means of a questionnaire sent to rural bankers and to county institute officials the Illinois Bankers Association undertook to determine the "ability with which and the conditions under which Illinois farmers secure personal and mortgage credit and to define the relation between banks and farmers within the State."

The returns indicate that the farmers comprise 75 per cent of the customers and 45 per cent of the stockholders and own 40 per cent of the stock. The average rate paid the farmer depositors was 3 to 4 per cent. Sixty-three per cent of the loans were to farmers, and it was maintained that they receive as good or better treatment than any other class. The average rate of interest on long-term loans was 6.27 and on short-term loans 6.68 per cent. The usual period for short-term loans was 6 months. Of the farms mortgaged, it is estimated that the mortgages were for 48 per cent of their value.

The bankers also reported that 75 per cent of the tenants were satisfactory persons to whom to loan money. They were opposed to loaning money for more than from 10 to 20 years, and favored the Torrens system of land title.

The purpose of the law concerning long and short time credit in France, B. NOGARO (*Rev. Econ. Internat.*, 11 (1914), II, No. 3, pp. 438-459).—This article discusses the organization of credit in France and its weak points, the function of the large banking companies, renewal of local banks, and establishment of district banks. It calls attention to the scarcity of people's banks in towns in contrast with their frequency in rural districts and the recent proposals for utilizing the 20,000,000 francs of the Bank of France to aid the development of the people's banks in towns. It also discusses the new laws that have been proposed concerning banks and banking combinations.

The shifting of labor in agriculture, S. SCHULTZ (*Neue Zeit*, 32 (1913), I, Nos. 11-12, pp. 411-417; 12-19, pp. 447-456).—Prior to 1890 the number of shifting laborers in Germany was so small as to attract but little attention. In 1890 about 17,000 came from the surrounding countries, but in 1910-11 there were 696,000, of which 388,000 were employed in agriculture. The larger part of them came from Russia and Austria. The author also discusses the influence of this element in the international labor market and the necessity for it where agriculture is extensive rather than intensive.

Lure of the land (*Missouri Red Book, 1913, pt. 1, pp. VII+613, pls. 181, figs. 6*).—This volume sets forth the resources, advantages, and opportunities along the line of agriculture, manufacturing, and mining in the State of Missouri. Various phases of the agricultural industries of the State are fully described and illustrated.

A practical treatise on the agriculture of northern Africa, C. RIVIÈRE and H. LECQ (*Traité Pratique D'Agriculture pour le Nord de L'Afrique. Paris, 1914, pp. III+1090, figs. 31*).—This report contains detailed information concerning climate, soil, agricultural machinery, forage plants, cereals, industrial crops, live stock, diseases of plants and animals, colonization, and legislation concerning agriculture.

The agriculture of Belgian Kongo (*Min. Colon. Belg., Rap. Agr. Congo Belge, 1911-12, pp. 548, pls. 3, figs. 269*).—This annual report describes the organization and administration of the work for the advancement of agriculture, and methods that are being employed to improve the native crops and farm animals, and to introduce new plants and pure-bred live stock. A large part of the report is devoted to conditions in Katanga. The report is fully illustrated.

The agricultural outlook (*U. S. Dept. Agr., Farmers' Bul. 604 (1914), pp. 24*).—This report contains a general review of crop conditions on June 1, 1914, and gives statistical tables showing the acreage conditions, estimated production, and prices for wheat, oats, and barley, and the condition and prices of many other farm crops and products. The condition of the principal crops was found to be about 2.2 per cent above the average of the last ten years.

The outlook for the 1914 foreign wheat crops was found to be fully normal except in a few countries. The proportion of the world's wheat crops harvested each month was estimated as follows: January 5, February 1, March 3, April 7, May 4, June 15, July 35, August 25, September 2, October and November practically none, and December 3 per cent.

The prices of farm products during May indicated that the increase this year was less than the average increase during the last five years. The condition of cotton on May 25 was estimated as 74.3 per cent of normal, as compared with 80.4 as the average for the last ten years.

The quantities of apples shipped by rail and water during the past season amounted to only 64 per cent of the shipments for the previous year. The greatest falling off was in the North Central States west of the Mississippi River.

The agricultural outlook (*U. S. Dept. Agr., Farmers' Bul. 611 (1914), pp. 39, figs. 2*).—The composite condition of all crops of the United States on July 1, 1914, was about 1.4 per cent above the 10-year average condition on that date, indicating conditions about 8.7 per cent better than the outturn of crops last year. The forecast for the domestic wheat crop is 930,000,000 bushels, or the largest ever produced, but the condition of the foreign wheat crop indicates a considerable deficiency.

Statistical data are included showing for cotton and tobacco the acreage and condition on July 1, and for sugar beets the area planted in 1913-14 and area harvested in 1913. The condition of practically all farm crops, the prices paid to producers of agricultural products on June 15, and the range of prices of agricultural products at market centers are shown by statistical tables.

In addition, C. J. Brand discusses marketing by parcel post (pp. 16-22) and reports as to trial shipments of several commodities. He concludes that there are many conditions and circumstances under which the use of parcel post for marketing will not prove economical, but that there are many others, especially for particular products and under particular conditions, for which parcel post

transportation would seem the only reasonable and economical method. "It is not expected that parcel post marketing will supplant usual methods, but its proper use should certainly make it a valuable supplement to these under all conditions and a check upon other methods when they are not being applied with fairness either to the producer or the consumer, or to both."

G. C. White discusses the car supply in relation to the marketing of the wheat crop in 1914 (pp. 23-26). One of the greatest drawbacks has been failure to load and unload promptly and too frequent reconsigning of shipments. Indications are that shippers and carriers are cooperating this year more closely than ever before in their efforts to avert a car shortage in the movement of the wheat crop.

A popular article by F. M. Webster on the Hessian fly (pp. 12-16) is also included.

Prices and supplies of corn, live stock, and other agricultural produce in England and Wales (*Bd. Agr. and Fisheries [London], Agr. Statist.*, 48 (1913), No. 3, pp. 187-277, figs. 3).—This annual report contains statistical data showing for 1913 the prices of agricultural products when sold off of farms and at certain markets and the quantity entering various markets by months. Comparative data for the average annual prices are given for earlier years. The trade in live stock between Great Britain and Ireland is shown for 1876-1913.

Agricultural statistics of Germany (*Statis. Jahrb. Deut. Reich.* 35 (1914), pp. 37-58).—This yearbook gives statistical data showing for 1895-1907 the number of farms by sizes, and the total area devoted to different agricultural purposes for each size; the area, production, and average yield of the principal farm crops for 1903-1913; the number and value of live stock for 1873-1912; and the number of live stock slaughtered from 1905-1913.

[Agricultural] statistics of New Zealand, 1912 (*Statis. New Zeal.*, 1912, vol. 2, pp. 489-545).—This annual report contains statistical data concerning land settlement, the number of agricultural holdings by sizes, land tenure, the number of live stock, and the areas devoted to different agricultural purposes.

International statistics relating to agriculture (*Statis. Jahrb. Deut. Reich.* 35 (1914), pp. 18*-27*).—This section contains statistical data showing the number of persons employed in agriculture; total land area; area devoted to agriculture and forestry; area, production, and average yield of wheat, rye, barley, and potatoes; number of live stock; prices of agricultural products at the principal markets; and production of sugar, cotton, silk, and cocoa in the more important countries.

International statistics of agriculture (*Ann. Statist. [France]*, 32 (1912), pp. 185*-193*).—This section contains statistical tables showing the area and production of wheat, oats, potatoes, and vineyards for 1850-1913, and the number of live stock for 1835-1910.

AGRICULTURAL EDUCATION.

The training of agricultural chemists and the organization of agricultural chemical institutions, O. LEMMERMANN (*Landw. Vers. Statist.*, 83 (1913), No. 3-4, pp. 317-335).—Among the reasons discussed by the author for the lack of adequately trained officials for experiment stations and related institutions are the need of a special training course, but more particularly the unsatisfactory remuneration, conditions of tenure, and future prospects of such positions. A suggested course of study is outlined, together with examinations for chemists training for the position of agricultural chemist in agricultural experiment stations, control stations, and related institutions. The training of agriculturists

desiring to become agricultural chemists in experiment stations and problems of station organization are also discussed, the author recommending that all control work be separated from the experiment station.

Popular agricultural instruction and its methods, P. DE VUYST (*Vie Agr. et Rurale*, 3 (1914), No. 24, pp. 656-658).—The author discusses the object of the popularization of agricultural science, general and professional agricultural instruction and the influence of the former, and methods of popularizing agricultural instruction.

A plan for the introduction of the teaching of elementary agriculture (*Trenton, N. J.: Dept. Pub. Instr., 1914, 2. ed. rev., pp. 19*).—This is a revised edition of the bulletin previously noted (E. S. R., 28, p. 598). Suggestions for rating the agricultural work of schools adopting this plan, estimating credits, and examinations in elementary agriculture have been added.

School and home exercises in elementary agriculture, B. M. DAVIS (*Columbus, Ohio, 1914, pp. 96, figs. 12*).—This loose-leaf manual is an extension and revision of a series of exercises on *The Soil and its Relation to Plants*, previously noted (E. S. R., 19, p. 390), and is intended as a supplement to a text-book. Each exercise consists of an explanation and directions for carrying out a project or problem by the pupil, together with a brief statement of familiar facts and practices which the observed results help to explain, and a list of references to literature on the subject.

Suggestions for teaching household arts and agriculture (*Atlanta, Ga.: Dept. Ed., 1913, pp. 67, figs. 29*).—Directions are given for making a hotbed and children's home gardens, corn club work, housekeeping and sanitation in the rural school, and suggestions as to where, what, why, and how cooking should be taught in rural schools, serving, canning and preserving, sewing, darning, patching, and manual training.

A plan for the development of home economics along the line of practical education, CORNELIA PALMER (*Timely Helps for Farmers [Col. Agr. Univ. Me.], 7 (1914), No. 10, pp. 77-84; Rural Educator, 4 (1914), No. 3, pp. 54-56*).—A general scheme of home economics education from kindergarten to university is suggested as well as some of the possibilities of home economics training in schools.

Field crop production, G. LIVINGSTON (*New York, 1914, pp. XIX+424, figs. 135*).—This book is intended for use in agricultural schools and in elementary courses in colleges, but in no sense as a complete or exhaustive treatise on the subject such as would be desired for regular college courses in field crops. It describes the various field crops, discusses their history, types, uses, production, cultural methods, diseases and insect enemies, etc., and includes a chapter each on crop rotation and on the marketing of grain. A brief list of references, a list of the agricultural experiment stations in this country, a table showing the composition of field crops, and review questions are appended.

Corn growing (*N. J. Dept. Pub. Instr., El. Agr. Leaflet 3, rev. (1914), pp. 23*).—This is a revised edition of the leaflet previously noted (E. S. R., 28, p. 598), in which many additions, including references to books and bulletins, suggestions to teachers, etc., have been made.

Papers set at the examinations in horticulture, 1893 to 1913 (*London: Roy. Hort. Soc., 1913, pp. 33*).—This publication contains lists of the examination questions for the years 1893-1913, inclusive, for the general, school teachers', and public parks examinations in horticulture.

The beginner's garden book, A. FRENCH (*New York, 1914, pp. VIII+402, figs. 211*).—This text-book for the use of upper grammar grades with beginners in gardening is arranged in four sections, namely, autumn work, winter work,

gardening under glass, and the real garden, thus completing the garden cycle. Each chapter is followed by review questions and each section by general review questions. A planting list and table, directions for the draining of a garden and for trenching, and a table of the length of life and the space values of vegetable seeds are appended.

Project study outlines for vegetable growing (*Bul. Bd. Ed. Mass., No. 9 (1913), pp. 127*).—This bulletin consists of project study outlines, incorporating questions and references prepared by agricultural instructors, for producing and disposing of 16 of the more common vegetables.

Trees and forests (*N. J. Dept. Pub. Instr., El. Agr. Leaflet 9 (1913), pp. 15, pls. 4*).—A discussion of the relations of instruction in forestry to other school subjects is followed by an article on trees and forests, the object of which is to show the relation of tree life to human life and something of the methods of physiology and arboriculture. It contains many suggestions for the guidance of teachers and pupils.

Collection and preservation of insects and other material for use in the study of agriculture, C. H. LANE and N. BANKS (*U. S. Dept. Agr., Farmers' Bul. 606 (1914), pp. 18, figs. 15*).—This publication was prepared for use by teachers in rural schools, and suggests methods of collecting, preparing, mounting, and preserving insect specimens and similar illustrative materials.

A dairy laboratory guide, H. E. ROSS (*New York, 1914, pp. VI+84*).—"This manual is designed as a guide to students in dairy laboratory work, with just enough explanation given to supplement the exercises which are outlined in the manual. It is not intended for a text-book and should not be used in the place of one."

Bench and tools for the farm mechanics shop, E. L. USEY (*Rural Educator, 3 (1914), No. 4, pp. 68, 69, 67*).—In this article the author shows how a shop or work room may be equipped satisfactorily for a moderate sum. Directions for making a 5-ft. bench, material for which would not exceed \$2.50, are given; also a list of tools based on a 6-bench outfit which can be obtained for not to exceed \$70.

Simple lessons in nature study, J. O'NEILL (*London, Glasgow, Bombay, pp. X+11-122, figs. 82*).—The author outlines simple lessons in plant and bird life for the assistance of teachers.

The study of flowers in the first grade, IDA V. FLOWERS (*Atlantic Ed. Jour., 9 (1914), No. 10, pp. 19-23, fig. 1*).—A working plan for a series of three lessons dealing with one flower—the dandelion—is presented.

Tree study in the first grade, IDA V. FLOWERS (*Atlantic Ed. Jour., 9 (1913), Nos. 2, pp. 70, 71; 3, pp. 116, 117; 9 (1914), No. 6, pp. 212-215*).—This series of suggestive lessons for use in the fall, winter, and spring is intended to teach some of the values of trees, to increase and train observation and as an attractive center for the study of seasonal changes.

For Arbor Day and Bird Day (*Atlantic Ed. Jour., 9 (1914), No. 7, pp. 250-259, figs. 2*).—This collection of timely material and suggestions for the observation of Arbor and Bird Days includes The Significance of Arbor Day, by A. S. Draper; Suggestions to Teachers and Some Common Birds, by K. C. Davis; Wild Flowers, by R. E. Wagner; suggested program for Arbor Day; suggestions for the observation of Bird Day, by the Illinois Audubon Society; and poems.

Preparing normal students to teach children about birds, G. H. TRAFTON (*Nature-Study Rev., 10 (1914), No. 3, pp. 84-93*).—The work with birds at the Mankato (Minn.) State Normal School, which may be divided into laboratory work, field trips, and class discussions, is outlined as well as the bird study.

extending through the eight grammar grades, carried out in the training schools.

The nests of some common birds, R. E. WAGER (*Nature-Study Rev.*, 10 (1914), No. 4, pp. 137-151, figs. 11).—This is a study of the nests and eggs of some of the more common birds.

Some insect studies, ALICE J. PATTERSON (*Nature-Study Rev.*, 10 (1914), No. 3, pp. 108-113).—The author describes a study of insects taken up in the fall in a nature study course in the Illinois State Normal University.

Industrial and commercial geography, J. R. SMITH (*New York*, 1913, pp. XI+914, pls. 2, figs. 242).—The author has divided his book into two parts, the first treating geography from the point of view of specific industries and the second from the point of view of commerce. Under the first part he has chapters on the place and nature of agriculture; the cereals; starchy foods; animal industry; the vegetable, fruit, and wine industries; sugar; and condiments and tobacco.

Making practical use of the decimal point, K. L. HATCH (*Rural Educator*, 3 (1914), No. 6, pp. 119, 118).—A home project with resulting problems in the keeping of feed and production records of dairy herds by school children is described to illustrate the practical use of the decimal point.

Corn arithmetic, C. W. STONE (*Atlantic Ed. Jour.*, 9 (1913), Nos. 1, pp. 7, 8; 2, pp. 53, 54; 3, pp. 87, 88, 90; 4, pp. 148, 149; 10 (1914), Nos. 5, pp. 180-183, figs. 3; 6, pp. 207-210, figs. 2; 7, pp. 260-262, figs. 2).—It is the purpose of these articles to offer suggestions to teachers for vitalizing the teaching of arithmetic, agriculture, composition, and country life manual training in the upper grammar and lower high school grades. Problems in arithmetic are used to help decide whether it pays to select and care for seed corn properly, how much difference the variety may make in the corn crop, to help determine the importance of crop rotation in corn raising, the relative value of various means of maintaining the fertility of the soil, the waste of harvesting corn—advantages of the silo, how well it pays to test seed corn, and the possibilities of corn breeding.

The agricultural demonstration field, G. A. BRICKER (*Rural Educator*, 3 (1914), No. 4, pp. 65, 66, figs. 2).—The practical phases of planning and making school demonstration fields using one-eightieth of an acre as a unit are discussed. In the author's opinion it makes little difference from the educational standpoint whether a school or a home demonstration field is used; but where feasible the school field is to be recommended.

School gardens, P. ESSER (In *Handbuch der naturgeschichtlichen Technik. Leipsic and Berlin*, 1914, pp. 319-339).—This article, in the Handbook of the Technique of the Natural Sciences issued by Prof. Bastian Schmid, discusses the selection of a site, cultivation, planting, care, etc., of school gardens in general, the central propagating garden, the community school garden, and the individual school garden in particular.

School agriculture exhibit, C. E. WYLIE (*Agr. Student*, 20 (1914), No. 8, pp. 601, 602).—The author offers suggestions for the preparation of exhibits which include work of all classes above the second grade.

Boys' and girls' contests and clubs (*Agr. Ed. [Kans. Agr. Col.]*, 6 (1914), No. 3, pp. 30, figs. 10).—Suggestions and rules are given for conducting contests along various lines for boys and girls, as well as directions for organizing agricultural, manual training, high school demonstration (for poultry raising, dairying, growing tomatoes and corn, and potato seed selection), and rural life clubs.

Suggestions on organizing boys' and girls' clubs, Z. M. SMITH (*Purdue Univ. Dept. Agr. Ext. Leaflet 47* (1914), pp. 4).

Rules and regulations for the corn clubs and potato clubs for boys and canning clubs and poultry clubs for girls, 1914 (*Ky. Dept. Agr., Labor and Statis. Bul. 15, pp. 11*).—Rules and regulations for club work among the boys and girls of the common schools are given.

Boys' pig clubs, C. S. JONES (*Alabama Col. Sta. Circ. 21 (1913), pp. 4*).—This circular outlines the purpose of the boys' pig club and gives directions for joining it, rules governing it, and the basis for determining the winners in club contests.

Corn club catechism with introductory stories, W. H. BARTON (*Clemson Agr. Col. Bul., 1 (1914), No. 1, pp. 24*).—The object of this bulletin is to teach children the fundamental principles of soil building and production. It includes accounts of the legume family, corn, etc., told in story form for children, followed by corn club resolutions for South Carolina and a catechism for corn club members.

Suggestive programs for canning clubs, SUSIE V. POWELL (*Prog. Farmer, 29 (1914), No. 17, p. 536, fig. 1*).—Eight programs for local canning clubs are outlined.

MISCELLANEOUS.

Annual Report of Florida Station, 1913 (*Florida Sta. Rpt. 1913, pp. XXXI+XII, figs. 21*).—This contains the organization list, a financial statement for the fiscal year ended June 30, 1913, a list of the publications of the year, a general review of the work of the station during the year, and departmental reports, the experimental features of which are for the most part abstracted elsewhere in this issue.

Twenty-fourth Annual Report of New Mexico Station, 1913 (*New Mexico Sta. Rpt. 1913, pp. 58, figs. 2*).—This contains the organization list, a report of the director on the work, publications, and exchanges of the station, including reports of heads of departments, the experimental features of which have been for the most part previously noted or are abstracted elsewhere in this issue, and a financial statement for the fiscal year ended June 30, 1913.

NOTES.

Arizona University.—Rufus B. von Kleinsmid, since 1909 professor of education and psychology at DePauw University, has been appointed president. The registration in the college of agriculture is 30 per cent larger than that of the previous year.

California University and Station.—Elaborate tests of various kinds of sorghums and corn for silage purposes are contemplated by the animal husbandry department.

Dr. Walter P. Kelley of the Hawaii Federal Station has been appointed professor of agricultural chemistry in the Graduate School of Tropical Agriculture and the citrus substation. Woodbridge Metcalf has been appointed assistant professor of forestry. R. F. Miller, formerly assistant animal husbandman at the Montana Station, has been appointed assistant professor of animal husbandry to have charge of the experimental work with sheep, and with headquarters at Davis. Dr. M. B. Kurtz has been appointed assistant veterinarian in connection with the hog-cholera immunization work.

Hawaii Federal Station.—Dr. E. V. Wilcox, special agent in charge since 1908, has returned to this Office as scientific and administrative assistant in connection with its relations with the experiment stations. J. M. Westgate, agronomist in Forage-Crop Investigations of this Department, has been appointed agronomist in charge to take effect January 1, 1915.

Idaho University and Station.—W. L. Carlyle resigned as dean and director in September and is now secretary of the Northwestern Live Stock Association, with offices in Moscow, Idaho. J. S. Jones, vice director of the station, is serving as acting director. O. D. Center, of North Dakota, has been appointed director of agricultural extension, with offices in Boise, and began his duties in October. Stephen A. Regan has resigned as state seed commissioner to accept a position with the grain standardization work of this Department and will be stationed at Portland, Oreg. R. B. Coglean, state leader of county agents, has resigned to engage in teaching in Oregon. E. M. Strate began work in October as creameryman for the department of dairying.

Illinois University and Station.—W. F. Handschin has been appointed state leader in charge of county advisory work, both under the Smith-Lever Act and in cooperative relations with this Department, with the title of vice director of demonstration work. Other appointments include the following instructors: Clyde R. Newell, farm mechanics; James B. Andrews, animal husbandman; Frederick N. Evans, landscape gardening; and Margaret B. Stanton, Mamie Bunch (extension), Greta Gray, and Anna Williams, household science. Assistants have also been appointed as follows: Claude Harper and James W. Whisenand, animal husbandry; Anton Prasil, animal chemistry; Mary H. Keith, animal nutrition; P. W. Allen, dairy bacteriology; William B. Nevens and Frank Turner, dairy husbandry; Howard D. Brown, olericulture; Edwin Deal, Herbert W. Blaney, and John R. Van Kleek, landscape extension; D. T. Englis, floricultural chemistry; August G. Hecht and L. E. Miles, floriculture; Roy Hansen,

nitrogen fixation research; and Edward F. Torgerson and Henry DeWerff, soil physics.

Iowa College.—C. E. Brashear, assistant in animal husbandry at the Missouri University and Station, has been appointed assistant to the dean of the college of agriculture.

Kansas College and Station.—A bequest of \$20,000 in memory of Davies Wilson, who took a prominent part in the location of the college at Manhattan, has recently become available through the death of the donor, Mrs. Wilson. The money may be used either for the erection of a building bearing his name or for the establishment of a permanent endowment "for the promotion of education in the arts and sciences."

Over 100 inmates of the Federal penitentiary at Leavenworth and the state penitentiary at Lansing are enrolled in the correspondence courses of the college.

Recent appointments include the following: Miss Margaret H. Haggart, formerly of the New Mexico College, as professor of domestic science; E. N. Wentworth, of the *Breeders' Gazette*, as assistant professor of animal breeding and assistant in nutrition investigations; Mrs. Rebecca Bartholomew and Miss Nellie McClurg, assistants in domestic science; Miss Marion P. Broughten, assistant in movable schools in home economics; Alfred L. Clapp, superintendent, agronomy farm; P. L. Gainey, of the Missouri University and Station, assistant in bacteriology in the station; Miss Marian Harrison and Miss Florence Hunt, assistants in domestic art; William P. Hayes, assistant in zoology; Miss Stella Mather, assistant in home economics in farmers' institutes; Frank E. Mixa, assistant in poultry husbandry; R. E. Wiseman, assistant in farm machinery; E. M. Tiffany, correspondence assistant in extension; Miss Olive Sheets, instructor in domestic art; Miss Addie Root and Miss Louise Caldwell, assistants in farmers' institutes; and Ross M. Sherwood, assistant professor of poultry husbandry at the Iowa College, extension lecturer in poultry work.

Kentucky University and Station.—S. C. Jones, assistant professor of soil physics and assistant agronomist, resigned November 15 to become assistant in soils in the Indiana Station, and has been succeeded by P. E. Karraker, research assistant in soil physics at the Michigan Station.

Maine University.—Alexander W. Lurie (Cornell, 1914) has been appointed instructor in horticulture.

Massachusetts College.—A steam-operated wax-rendering apparatus has been installed for the service of beekeepers. A nominal charge of 5 cents per pound of rendered product is made, and considerable interest is being manifested in the undertaking.

Missouri University and Station.—The stock-judging pavilion provided by the last legislature is now in use. The outside dimensions are 90 by 160 feet, with an arena 50 by 120 feet, and a seating capacity of 1,500. It is also equipped with offices, practicum rooms, locker rooms, and shower baths, and will be utilized for short-course gymnasium work. It is said to be the best lighted pavilion of its kind in this country and cost about \$25,000.

The enrollment in the summer school of agriculture exceeded 200, or double that of the previous year. Many of the students were teachers desirous of qualifying under the Wilson law, which went into effect in September and provides state aid to high schools maintaining agricultural courses given by teachers of approved preparation. The enrollment in the four-year winter course of the college of agriculture is 535 and that of the first term of the two-year winter course in agriculture 199.

The department of agronomy has been divided into departments of soils and farm crops with M. F. Miller in charge of the soils work and C. B. Hutchison in charge of that of farm crops.

An agricultural-extension service was established July 1 under the direction of A. J. Meyer, formerly assistant to the dean and director and superintendent of short courses. The organization in the extension service includes L. F. Childers, in soils and farm crops; S. T. Simpson, in animal husbandry; D. H. Doane, state leader of farm advisers; May C. McDonald, in home economics; R. H. Emberson, boys' and girls' clubs; E. R. Spence, hog cholera eradication; and R. S. Besse, assistant to the state leader.

Farm advisers have now been located in 13 counties and branch short courses were held at 11 towns last year. Other lines which are to receive special attention are the hog cholera eradication campaign, dairy development, poultry extension, and movable schools of home economics. About 1,200 members are enrolled in boys' and girls' clubs.

Recent resignations include the following: H. H. Laude as farm adviser to Marion County, O. C. Smith as assistant in agricultural chemistry, T. J. Talbert as assistant in entomology, and W. I. Watkins as assistant in the soil survey. Appointments have been made including Frederick Dunlap as forester in the station, P. M. Brandt, formerly assistant professor of dairy husbandry, as assistant to the dean and director and superintendent of short courses, and the following assistants: H. C. Heaton, in veterinary science, vice Talmadge T. Tucker resigned to take up further studies in the New York State Veterinary College of Cornell University; C. E. Neff (1914), in farm crops; W. E. Thrun and B. E. Sive, in agricultural chemistry; H. K. Thatcher, in the soil survey; F. L. Bentley, in animal husbandry; A. H. Hollinger, in entomology; and C. E. Mangels, in agricultural chemistry in the station. Paul V. Maris has been appointed farm adviser for Saline County; I. F. Gilmore, farm adviser for Marion County; and R. M. Green, cooperative field agent in the project known as the demonstrations of the business of farming, which is being conducted in cooperation with the Bureau of Plant Industry of this Department.

Nebraska University and Station.—Robert F. Howard, assistant professor of horticulture and assistant horticulturist in the Wisconsin University and Station, has been appointed professor of horticulture and horticulturist and has entered upon his duties.

New Hampshire College.—J. B. Abbott, associate in soil improvement in the Indiana Station, has been appointed state leader of the county agents.

Rutgers College.—Director J. G. Lipman of the station has been appointed dean of agriculture.

Cornell University.—Prizes have recently been offered by James A. D. S. Findlay, of Salisbury Mills, for the best discussions by students of the college of agriculture of some phase of drainage improvement.

O. W. Dynes, associate professor of agronomy and connected with the plant-breeding work of the North Dakota College and Station, has been appointed instructor in farm crops. Earl L. Overholser has been appointed instructor in pomology. Recent promotions include the following: As professors, M. F. Barrus, plant pathology; L. J. Cross, agricultural chemistry; O. A. Johannsen, biologist; C. H. Myers, plant breeding; and as assistant professors, A. L. Thompson, farm management; Royal Gilkey, extension teaching; C. T. Gregory, L. R. Hesler, I. C. Jagger, and M. H. Rankin, plant pathology; E. W. Benjamin, poultry; A. J. Eames, botany; J. K. Wilson, soil technology; E. E. Barker, plant breeding; E. M. Tuttle, rural education; and Robert Matheson, economic entomologist.

Ohio State University.—J. E. McClintock for the past four years agricultural editor of the International Correspondence Schools, has been appointed supervisor of publications of the extension service of the college of agriculture and

entered upon his duties September 1. Other appointments include the following: V. C. Smith, secretary of the college, vice H. C. Ramsower, head of the newly organized department of agricultural engineering; John I. Falconer, Ph. D. (Wisconsin, 1914), assistant professor of rural economics; C. L. Long, extension department in horticulture and poultry husbandry; J. S. Coffey, of Purdue University, assistant professor in animal husbandry; T. C. Stone (Illinois, 1914), assistant in animal husbandry; J. L. Hutchison and F. J. Salter, instructors in agricultural chemistry; and G. M. McClure, assistant in agricultural chemistry. Max F. Abell (Cornell, 1914) has been appointed assistant in farm crops.

Oregon College.—The horticultural show, in which apples of standard varieties from many parts of the United States were exhibited, was held in the horticultural building November 7. Fruits of the kinds best adapted to Oregon conditions were displayed in educational forms, and contests in judging and identification of varieties were features of the show. An exhibit of Oregon nuts was made by a nursery company, and former students of the college provided three subtropical exhibits of fruits and nuts from southern California and Florida. Demonstration potting and pruning were also done by the specialists.

Farmers' Week has been postponed to February 1-6, 1915, inclusive, and the exercises assigned to the extension division. A number of conventions of the leading agricultural and rural interests will be held at that time, and problems of rural community life will receive consideration.

Pennsylvania College and Station.—The new stock judging pavilion is practically completed. It is a concrete, brick, and steel structure with an arena 120 feet long by 30 feet wide and with seating accommodations for about 800. The basement also contains rooms for instruction in methods of butchering and handling meats, and a modern refrigeration plant is to be installed. The cost of the pavilion and equipment is about \$30,000.

The new dairy barn consists of a center or main feed barn, 100 feet long by 36 feet wide, for the storage of hay and grain, to which are attached a cattle barn 129 feet long by 14 feet wide, and an experimental cattle barn 80 by 36 feet. There are also two silos 18 feet in diameter and 40 feet high, and a series of sheds, 168 feet in length, for bulls, young stock, etc. The barns are constructed of hollow brick on a concrete foundation, the walls finished in stucco, and roofed with red asbestos shingles. Their total cost with equipment is about \$125,000.

Miss Pearl MacDonald has been appointed home economics worker in connection with the extension department; H. N. Cobb and L. J. Obold, both 1914 graduates of the college, assistants in agronomy; F. D. Crooks, assistant in animal husbandry, vice D. E. Warner, resigned to accept a position with the Connecticut Storrs Station; M. F. Grimes, assistant in animal husbandry, vice C. W. Hickman, resigned to become assistant professor of animal husbandry at the University of Idaho; James M. Sherman, instructor in bacteriology at the college and bacteriologist at the station; T. L. Hills, assistant in bacteriology; and W. C. Gillespie (1914), assistant in experimental pomology, vice R. H. Bell, resigned.

Texas College and Station.—J. D. Blackwell, a 1914 graduate of the University of Missouri, has been appointed associate professor of agricultural education, and W. T. Magee, instructor in animal husbandry.

I. S. York, superintendent of the Spur substation, has resigned, and was succeeded by R. E. Dickson, formerly assistant agronomist of the main station, June 1. Thomas J. Conway (Cornell, 1914) has been appointed poultry husbandman, and entered upon his duties October 1. J. M. Jones, instructor in animal husbandry and animal husbandman in the New Hampshire College and

Station, has been appointed animal husbandman in charge of breeding investigations beginning August 1, and is conducting experiments with sheep. William Levin and J. B. Rather have resigned as assistant chemists, and the former has been succeeded by J. W. Chewning, and he in turn by R. H. Ridgell.

Virginia College and Station.—Glancy Sherman Ralston, research assistant in horticulture at the Oregon Station, has been appointed assistant in the extension department of the college. Dr. M. T. Smulyan, a graduate of the Massachusetts College, has accepted a research position in entomology.

Washington College.—F. L. Pickett, Ph. D., research fellow in botany in Indiana University, has been appointed associate professor in plant physiology. R. J. Barnett has been made professor of pomology.

West Virginia University.—The enrollment in the college of agriculture is 100 per cent greater than that of last year.

Wisconsin University and Station.—Of the 1914 graduates of the college of agriculture, R. V. Gunn has been appointed assistant in farm management, George B. Mortimer instructor in agronomy, and J. C. Walker assistant in plant pathology. W. A. Schoenfeld has resigned as executive secretary to become specialist in farm accounting in the department of extension of the University of Texas.

American Association for the Advancement of Agricultural Teaching.—The fifth annual meeting of this association was held in Washington, D. C., November 10.

A report of the standing committee on the use of land in connection with agricultural teaching, prepared by this Office, indicated that distinct problems are presented in different sections. In the New England States the majority of the pupils are living at home and have easy access to the school; the school farms are small and the home project is more or less closely supervised, so that the need of the school farm is less felt. In the Northern and Central States the school farms are small, but the pupils are drawn from greater distances than those in the New England States and have not access to as good means of transportation. There are also a larger number of boys from towns and cities and of girls desiring to become teachers in the classes studying agriculture.

In the South the majority of the schools have a boarding department and a large farm, so that the agricultural pupils have a better opportunity to participate in farm operations, and home projects have not been developed. Even in these schools, where the pupils carry on the farm operations under the direct supervision of the instructor, it is claimed too much attention has sometimes been given to getting the farm work done and not enough to making the pupils efficient in the ordinary farm operations. The report indicated that all schools having farms, however, can aid the more readily in the distribution of pure-bred seed, the introduction of new varieties of plants, fruits, and shrubs, and the extending of the services of pure-bred animals in the community.

The standing committee on cooperative use of equipment and illustrative material reported that little progress has been made in the preparation and use of such material during the past year. This Department is the only agency at the present time producing motion-picture films for agricultural instruction. It is urged that colleges provide prints or miniature drawings of all available charts for the purpose of cooperative exchange. The motion picture is not regarded as psychologically adapted to purposes of instruction, while, on the other hand, lantern slides and charts are not so attractive and do serve as valuable aids in the work of effective instruction.

K. L. Hatch, in a paper on What Constitutes Suitable Extension Work for Secondary Schools, advocated that the teacher of agriculture in the secondary

school before attempting other extension work should make a survey of agricultural conditions, organize extension efforts around home projects of his pupils, give individual assistance to farmers, and provide for rural organization. The extension service of the high schools should not be in the beginning an announced function, but rather a process of evolution.

How to Improve the Quality of Teaching the Technical Subjects in Agricultural Colleges was the subject of a paper read by A. V. Storm. He believed that administrative officers must be brought to realize how necessary is professional preparation along pedagogical lines for those who are to teach in colleges of agriculture. Courses of study should be so arranged that the student who expects to teach will obtain a broad preparation, including the fundamental sciences. Large classes must be made smaller, as by employing more teachers, abandoning some of the highly differentiated advanced courses which enroll only a small number of students, or reducing the number of courses offered by omitting nonessentials or duplicated material.

A better sequence of courses would, he believed, improve the quality of teaching. Poor organization of subject matter must be overcome, the examination must be made a part of the educative process, the students' judgment of the quality of the teaching of certain courses must be given consideration, and the teaching force must make greater use of the experiment station and extension results.

In a paper by A. B. Graham, entitled *The Relation Between the State Department of Education and the Agricultural College in the Supervision of Secondary Agriculture*, the present system of vesting the administrative work in the hands of the state department was indorsed, the college of agriculture being regarded as the source of information.

The officers elected for the ensuing year are A. V. Storm, University of Minnesota, president; W. H. French, Michigan Agricultural College, vice president, and A. C. Monahan, United States Bureau of Education, secretary.

Agricultural Education in Prince Edward Island.—The increased appropriation under the Agricultural Instruction Act (E. S. R., 29, p. 198) has enabled the government to make progress in organizing a complete system of agricultural education correlated with the general system. Provision has been made for short courses in household science in Prince of Wales College, long and short courses in agriculture, practical instruction in agriculture for those qualifying for teachers of the public schools, a science course for teachers now in charge of schools, and women's institutes. A very successful 2-weeks school for teachers was held during the summer vacation at the Prince of Wales College attended by nearly half the teachers of the Province.

Agricultural Education and Research in Greece.—The *Daily Consular and Trade Reports* announce that the Greek Government has established eight agricultural experiment stations, which are under the control of the ministry of agriculture, one of these being near Athens; an agricultural school known as Cassavetios at Halmyrios, with three professors and about 35 pupils; and two model farms, one at Astros and the other at Trichonis.

Agricultural Instruction in Mauritius.—Arrangements have been made for the training of a limited number, not to exceed six, of young men in agricultural science with special reference to the sugar industry in the laboratories of the department of agriculture. They must agree to pursue for three years a course of study in the general principles of agriculture, agricultural botany and biology, agricultural chemistry, agricultural entomology, and meteorology. A diploma will be awarded and a research scholarship will be available once in every three years.

EXPERIMENT STATION RECORD.

VOL. XXXI.

ABSTRACT NUMBER.

No. 9.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY—AGROTECHNY.

Ammonia-soluble inorganic soil colloids, G. S. FRAPS (*Texas Sta. Bul. 165 (1914)*, pp. 3-8).—It is pointed out that the indirect methods do not really estimate the colloidal constituents of soils but only compare them with regard to certain properties which may be partly dependent on other soil constituents. "The only method as yet proposed for approximately estimating the total colloids is by staining the colloidal particles, and estimating their number or quantity by means of a microscopic examination."

The work reported in this bulletin deals with the soluble colloidal soil substances and not with the total, or insoluble, colloids. The method used is based on observations made in the laboratory of the Texas Station, that when ammonium carbonate is added to the clear ammoniacal filtrate obtained in digesting soils with ammonium hydroxid a precipitate consisting chiefly of inorganic material is obtained. "The use of ammonium carbonate for precipitating the clay is the method proposed by Rather [E. S. R., 25, p. 614] for purifying the ammoniacal humus filtrate." The method is as follows:

"Digest 100 gm. of the soil with 2,000 cc. of fifth-normal hydrochloric acid at room temperature for 24 hours. Filter and wash thoroughly. Wash back into the bottle with 2,000 cc. of 4 per cent ammonia and let digest at room temperature for 24 hours, shaking every half hour for 4 hours. Filter on a large folded filter, getting as much of the soil as possible on the filter, and continue to pour back the filtrate until it comes through clear, as per the Smith method. Discard the residue. Take 1,500 cc. of the filtrate, coagulate with the ammonium carbonate (and heat, if necessary), let settle, collect on ash-free filter, ignite, and weigh.

"Fuse the precipitate with sodium and potassium carbonate, dissolve in hydrochloric acid, and evaporate to render silica insoluble. Filter off and weigh silica, if pure; if contaminated with iron, purify. Precipitate the iron and alumina in the filtrate with ammonia, ignite, and weigh precipitate. Fuse with potassium acid sulphate, and dissolve, reduce the iron with zinc, and titrate with permanganate."

If the soil contains much lime several extractions must be made with the hydrochloric acid or with stronger hydrochloric acid for the purpose of removing it.

The soils to be examined are divided into four groups, arranged according to their total content of ammonia-soluble colloids, viz, "(1) 0 to 0.05 per cent; (2) 0.051 to 0.101 per cent; (3) 0.101 to 0.2 per cent; (4) 0.201 to 0.6

per cent. For the purposes of comparison, the total nitrogen, the acid-soluble iron and alumina, and the acid-soluble lime, are also given." "The maximum quantity present in the soils examined was 0.59 per cent. The average of seven soils rich in colloidal matter was 0.299 per cent inorganic colloidal material."

The average percentage composition of the inorganic colloids of the four groups was as follows: Silica 59.7, 53.3, 51.5, and 47.5 per cent; iron oxid 24.3, 12.6, 11, and 12.6 per cent; alumina 8.7, 16.9, 29.9, and 36.9 per cent; and difference 7.3, 17.2, 7.6, and 3 per cent, respectively. "The most striking fact about these averages is the decrease in percentage of silica, and the increase in percentage of alumina, as the soluble colloid content of the soil increases."

The molecular ratio of the constituents is: "0 to 0.05 per cent colloids— $12\text{SiO}_2 : 2\text{Fe}_2\text{O}_3 : \text{Al}_2\text{O}_3$; 0.051 to 0.1 per cent colloids— $11\text{SiO}_2 : 2\text{Fe}_2\text{O}_3 : 2\text{Al}_2\text{O}_3$; 0.101 to 0.2 per cent colloids— $12\text{SiO}_2 : \text{Fe}_2\text{O}_3 : 4\text{Al}_2\text{O}_3$; 0.201 to 0.6 per cent colloids— $10\text{SiO}_2 : \text{Fe}_2\text{O}_3 : 4\text{Al}_2\text{O}_3$."

"In kaolin the ratio of silica to alumina is $2\text{SiO}_2 : \text{Al}_2\text{O}_3 : 2\text{H}_2\text{O}$. If we assume that all the alumina is present as kaolin, then there is an excess of five-sixths of the silica in the first group, seven-elevenths in the second group, one-third of the silica in the third group, and one-fifth of the silica in the fourth group. However, there were other bases present in the precipitate which were not estimated. It appears probable that the soluble colloidal material [extracted by ammonia] consists of hydrated silica, hydrated oxids of iron, hydrated silicates of alumina with other bases, and possibly hydrated silicate of alumina."

Bordeaux mixture.—I, Physico-chemical studies, O. BUTLER (*New Hampshire Sta. Tech. Bul. 8 (1914), pp. 125-180, pls. 2, figs. 3; Phytopathology, 4 (1914), No. 3, pp. 125-180, pls. 2, figs. 3*).—There is apparently a marked divergence of opinion regarding the composition of Bordeaux mixture, and according to the literature it is clear that no agreement exists as regards the chemical and physical properties (especially the latter). In consequence its toxic and biological properties are also imperfectly understood. This paper deals with the chemistry and physics of Bordeaux mixture.

"Bordeaux mixture may be composed of one or several basic cupric sulphates or mixtures of basic cupric sulphates depending on the ratio of cupric sulphate to calcic oxid employed. The copper precipitate of Bordeaux mixtures in which the ratio of cupric sulphate to calcic oxid is 1 : 1 or 1 : 0.5 becomes crystalline on standing when the washes contain more than 0.125 per cent cupric sulphate. The rate at which the copper precipitate becomes crystalline depends on the temperature and concentration in cupric sulphate of the mixtures. The crystallization of Bordeaux mixtures 1 : 1 and 1 : 0.5 is retarded by the presence of such impurities as ferrous sulphate, calcic carbonate, magnesian oxid, and magnesian carbonate; but this retardation is not due to the diluent action of the salts in question.

"The crystallization of Bordeaux mixtures 1 : 1 and 1 : 0.5 may also be delayed by various inorganic salts and organic substances, saccharose being particularly effective. Bordeaux mixtures after carbonization are slightly soluble in pure water, and dissolve readily in water containing carbon dioxide in solution. Bordeaux mixtures are soluble in water containing ammoniac salts in solution. Alkaline Bordeaux mixtures are soluble in dextrose, saccharose, and other organic substances giving the biuret reaction. The physical state of the copper precipitate found in Bordeaux mixture is affected, irrespective of the ratio of cupric sulphate to calcic oxid, by (a) the dilution of the salts and the manner in which they are brought together; (b) the temperature of the water.

"After the cupric sulphate and calcic oxid have been brought together, a slight delay in stirring the mixture does not materially affect the physical state of the precipitate. Long continued stirring of Bordeaux mixture does not materially affect the physical state of the precipitate. The Bordeaux mixtures employed in practice fall into one or another of three types: (a) 'neutral' Bordeaux mixtures of which Woburn Bordeaux mixture is a true type and 'acid' Bordeaux mixture a proximate type; (b) slightly alkaline Bordeaux mixtures—neutral Bordeaux mixture is a good example of this class; (c) strongly alkaline, or basic Bordeaux mixtures; in this class belong those Bordeaux mixtures in which the ratio of cupric sulphate to calcic oxid is not greater than 2 to 1."

An introduction to the chemistry of plant products, P. HAAS and T. G. HILL (*New York, London, and Bombay, 1913, pp. XII+401, figs. 5*).—This work is an attempt to provide the botanist and students of botany having some acquaintance with chemistry with an introductory account of the chemistry and biological significance of the more important chemical substances occurring in plants. In some instances micro-chemical, qualitative, and quantitative methods are included.

Its contents include fats, oils, waxes, phosphatids, carbohydrates, glucosids, tannins, pigments, nitrogen bases, colloids, proteins, and enzymes.

On the demonstration of carotinoids in plants, C. VAN WISSELINGH (*K. Akad. Wetensch. Amsterdam, Proc. Sect. Sci., 15 (1912), pt. 1, pp. 511-526, 686-692, 693-700; K. Akad. Wetensch. Amsterdam, Versl. Wis en Natuurk. Afdeel., 21 (1912), No. 1, pp. 370-386, 565-572, 572-579*).—This article is in three parts.

I. *Separation of carotinoids in crystalline form*.—The results obtained by various investigators in regard to the carotins, or carotinoids, of plants are far from uniform. The microscopical findings are especially divergent and they conflict with those shown by the chemical and physical methods. Some investigators believe all carotinoids to be identical. On this account a study was made of the various micro-chemical methods, including the potash, dilute acid, and resorcinol methods.

"The results of the above crystallization experiments point strongly to the frequent occurrence of several distinct carotinoids in a plant."

II. *Behavior of carotinoids with regard to reagents and solvents*.—"The reagents by means of which coloration is brought about in carotinoids are the following: Concentrated sulphuric, sulphurous, and concentrated nitric acids, bromin water, concentrated hydrochloric acid with a little phenol or thymol, and iodin in potassium iodid or chloral hydrate solution. All these reagents cause blue coloration except the iodin reagent, which generally produces a green color.

"In this paper the use of sulphuric acid, bromin water, and iodin in potassium iodid solution is dealt with as well as two new reagents for carotinoids, namely, concentrated solutions of antimony trichlorid and of zinc chlorid both in 25 per cent hydrochloric acid."

The list of the organs and plants on which the new reagents were tested were (1) flowers of *Trollius caucasicus*, *Chelidonium majus*, *Isatis tinctoria*, *Spartium junceum*, *Thermopsis lanceolata*, *Cucurbita melanosperma*, *Ferula* sp., *Asclepias curassavica*, *Calceolaria rugosa*, *Dendrobium thyrsiflorum*, *Iris pseudacorus*, *Narcissus pseudonarcissus*, and *Lilium croceum*; (2) green leaves of *Chelidonium majus* and *Urtica dioica*; (3) fruits of *Sorbus aucuparia* and *Solanum lycopersicum*; (4) the root of *Daucus carota*; and (5) algæ, viz, *Cladophora* sp., and *Hæmatococcus pluvialis*.

III. *The leaf of Urtica dioica, the flower of Dendrobium thyrsiflorum and Hæmatococcus pluvialis*.—In the foregoing communication stress was laid on the fact that the carotinoids present differences in the color and shape of the

crystals and in their behavior toward reagents and solvents. Working on this basis it is shown that in the leaves of *U. dioica* two coloring matters were noted, namely, carotin and xanthophyll. This finding has been previously noted by Willstätter and Mieg.

D. thyrsoiflorum contains two carotinoids. One of these is reddish orange in color and does not grow commonly in plants. The author believes that this substance is not a true carotinoid and belongs to the xanthophylls.

In *H. pluvialis* two carotinoids occur. This finding was previously made by Zopf but the procedures used by the two investigators were different.

The sugars and their simple derivatives, J. E. MACKENZIE (*London and Edinburgh, 1913, pp. XVI+242, figs. 17*).—The contents of this book are based on a course of lectures given at Birkbeck College, London, in 1903 and subsequently at the University of Edinburgh before students of pure chemistry, medicine, brewing and distilling, and sugar manufacture. The book is intended as a companion to works on physiological chemistry and to chemo-technological works.

Its contents include sugars; synthetic methods of preparation; manufacture of sucrose from the sugar cane and sugar beet; physical and chemical properties of sucrose; maltose; lactose; glucose; glucosamin; configuration; pentoses; methyl pentoses; aldohexoses; ketohexoses; disaccharids, trisaccharids, and tetrasaccharids; glucosids; fermentation; and metabolism.

The differentiation and specificity of starches in relation to genera, species, etc., E. T. REICHERT (*Carnegie Inst. Washington Pub. 173, 1913, pts. 1, pp. XVII+342+20, pls. 102; 2, pp. XVII+343-900+18, figs. 400*).—This is a preliminary report of an attempt to apply stereo-chemical principles to protoplasmic processes and products and to serve as a strictly scientific basis for the classification of plants and animals. It is a supplement to the report on the crystallography of hemoglobins by the same author (*E. S. R., 22, p. 701*).

The work deals with the literature pertaining to the starch grain, and also gives the histological appearance and behavior of the starches from many sources. Among the methods used were tests with iodine, aniline dyes, swelling reagents, the polariscope with and without the selenite plate, and gelatinization. In addition to this, curves of the reaction intensities and the histology of different starches were noted. Six hundred and twelve micro-photographs of starches are shown and the applicability of the results of the research to pharmacognosy, pharmacodynamics, systematic botany, and commercial pursuits is discussed.

Glycerids of butter fat, C. AMBERGER (*Ztschr. Untersuch. Nahr. u. Genussmittel, 26 (1913), No. 2, pp. 65-85*).—By fractional solution and crystallization pure individual glycerids can be obtained from butter fat. The least soluble glycerid, i. e., in ether, obtained from one fat consisted of tristearin (not quite pure), and from two others, palmityl-distearin. From another sample of butter a stearyl-dipalmitin was obtained.

The density and solution volume of some proteins, HARRIETTE CHICK and C. J. MARTIN (*Biochem. Jour., 7 (1913), No. 1, pp. 92-96*).—“A comparison has been instituted in case of four proteins, viz, caseinogen, egg and serum albumins, and serum globulin, between the density directly determined with dry specimens and that calculated from the specific gravity of concentrated solutions. The latter is found to be 5 to 8 per cent in excess of the former, showing the extent of shrinkage in volume taking place when these proteins enter colloidal solution.”

For previous work see other notes (*E. S. R., 29, p. 501*).

The factors concerned in the solution and precipitation of euglobulin, HARRIETTE CHICK (*Biochem. Jour., 7 (1913), No. 3, pp. 318-340*).—“The isoelectric point for euglobulin has been redetermined and found to coincide with

the point of most rapid agglutination, viz, at a hydrogen ion concentration of about 3×16^{-6} normal, a figure which agrees with that obtained by Michaelis and Rona.

“The solution or dispersion of euglobulin by electrolytes is shown to be much influenced by the nature (especially as regards valency) of the constituent ions and to be of two general types: (a) ‘Electrical’ type of solution in which the euglobulin dispersion is accompanied by the acquisition of an electric charge by the protein particles, the sign of which is similar to that of the more potent ion of the electrolyte employed; (b) ‘molecular’ type of solution, in which the dissolved euglobulin is electrically neutral.

“In type (a) the dispersion is considered to result from a specific adsorption of the ion possessing the higher valency, in (b) from a molecular union with (Hardy) or adsorption of (Schryver) the salt as a whole. Both types of solution are accompanied by loss of electrical conductivity in the liquid.

“The electrical type of solution is well seen in case of dispersion by such salts as sodium citrate and lanthanum nitrate in low concentration; in case of the more ordinary salts, containing mono- or divalent ions only, the electric forces concerned are not powerful enough to disperse globulin until the concentration is raised to a point where molecular solution takes place. In the case of sodium citrate, the electrical type of solution was found to change to the molecular type as the concentration of the salt was increased.

“Euglobulin, when denatured by heat, no longer possesses the property of forming the molecular type of solution with electrolytes. On heating the latter, in some cases the degree of dispersion is merely diminished, and the protein particles acquire an electric charge, whose sign is determined by the more potent ion of the electrolyte employed; in other cases agglutination takes place.

“The reaction of acid and alkaline solutions of euglobulin is greatly influenced by the addition of electrolytes, the hydrogen and hydroxyl ion concentration being reduced respectively. In case of the former the effect is much increased with rising valency of the anion, and in alkaline solution the result is determined by the valency of the cation. The influence of electrolytes in causing precipitation of globulin dissolved in acid and alkali may, in some instances, be adequately explained by the alteration in reaction; in this way solutions too acid or too alkaline for agglutination of the globulin may be adjusted to the isoelectric point by the addition of an appropriate electrolyte.

“Precipitation by electrolytes may, however, also take place in solutions whose reaction is still far removed from that of the iso-electric point. In these instances it is attributed to neutralization of the electric charge originally carried by the protein particles by means of a specific adsorption of the oppositely charged ion of the electrolyte; the effect is related to valency.

“In the properties regarding solution and precipitation . . . euglobulin, in common with caseinogen and the vegetable globulins, presents a very interesting analogy with heat-denatured proteins. Euglobulin differs from heat-denatured protein in its capacity to form solutions with electrolytes in which the protein particles are electrically neutral.”

The hydrolysis of organic phosphorus compounds by dilute acid and by dilute alkali, R. H. A. PLIMMER (*Biochem. Jour.*, 7 (1913), No. 1, pp. 72-80).—In these experiments it was found that ethyl phosphoric acid, glycerophosphoric acid, and phytic acid are hydrolyzed by acid but are not affected by alkali. Stability to alkali is consequently considered a property of phosphoric acid esters.

“It is not known how the phosphoric acid is combined in phosphoprotein, but it is probably united with one of the amino acids. Hexosephosphoric acid

reduces Fehling's solution, which points to the presence of the functional aldehyde or ketone group in the molecule."

Suggestions in regard to the possible atomic grouping of the above are appended.

Action of hydrogen chlorid upon diastase, I, T. PANZER (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 82 (1912), No. 3-4, pp. 276-325; *abs. in Centbl. Bakt. [etc.]*, 2. Abt., 37 (1913), No. 11-13, p. 281).—After studying the effects of dry hydrogen chlorid gas upon diastase, the author concludes that a chemical combination of the ferment and gas is necessary for amylolytic activity.

Action of hydrogen chlorid upon invertase, II, T. PANZER (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 82 (1912), No. 5, pp. 377-390; *abs. in Centbl. Bakt. [etc.]*, 2. Abt., 37 (1913), No. 11-13, p. 281).—Invertase absorbs much hydrogen chlorid but loses its activity as a result. There is probably a difference between the chemical constitution of diastase and invertase.

Saccharifying diastase of malt and the reaction of the medium, H. VAN LAER (*Orig. Commun. 8. Internat. Cong. Appl. Chem. [Washington and New York]*, 14 (1912), Sect. VIb, pp. 203-213).—This is a study of the influence of various amounts of acid and alkali on diastase obtained from malt extracts of different kinds.

The inhibition produced by an excess of either an acid or an alkali is deemed due to the formation of an inactive compound between the enzyme and the acid or alkali. The loss in acidity in the presence of hydrogen ions and hydroxyl ions is due to three principal causes, (1) the destruction of a part of the enzyme which is not reversible, (2) the temporary mobilization of a portion of the enzyme, and (3) an increase in the activity caused by a loss in ions and due to the influence of stabilization.

Book of methods (Methodenbuch. Vienna, 1913, pp. XVI+307, figs. 9).—This is the first edition of a treatise on methods compiled by the Association of Austrian Experiment Stations. The methods are for soils (general and special methods), moor soils, artificial fertilizers, peat straw and peat mull, commercial feeding stuffs, feed lime, condition powders, seeds, fats, waxes, oils and varnishes, cane sugar, molasses, sugar beets, bone charcoal, starch, alcohol, wine residues, sulphur, water, sewage, vegetable tanning materials, and foods.

Winkler's method for the determination of carbon dioxid in water, J. CASARES and S. PINA DE RUBIES (*Ann. Chim. Analyt.*, 18 (1913), No. 4, pp. 133-136; *abs. in Chem. Abs.*, 7 (1913), No. 19, p. 3377).—In these experiments, which were made with pure sodium carbonate in solution, an average error of 2.5 per cent was noted. This was about six times the error found by the originator of the method. The results were inconstant even with identical amounts of sodium carbonate, and the error did not depend upon the amount of hydrogen passed through the apparatus. It increased rapidly as the amount of carbon dioxid decreased.

Colorimetric determination of small amounts of manganese in drinking water, E. SCHOWALTER (*Ztschr. Untersuch. Nahr. u. Genussmitl.*, 26 (1913), No. 2, pp. 104-108).—When estimating manganese by conversion into permanganate with nitric acid and ammonium persulphate it is of importance first to remove any chlorids which may be present. This is done by the addition of silver nitrate, but the turbidity produced interferes with the subsequent colorimetric estimation. It is not possible to remove the hydrochloric acid by heating the water with sulphuric acid and ammonium persulphate.

Silver nitrate seems to be active in the reaction when permanganate is being formed and consequently the author prefers the following procedure for determining manganese: One hundred cc. of water is evaporated with 10 cc. of

nitric acid to dryness and then taken up with 10 cc. of water and 5 cc. of nitric acid. The solution is filtered through a small filter into an Erlenmeyer flask. The dish and filter are then washed with a measured amount of water until 35 cc. of filtrate is obtained. After adding 5 cc. of nitric acid and 1 gm. of ammonium persulphate (In most cases 0.5 gm. is sufficient), the solution is heated to boiling point. Then 10 drops of silver nitrate 1:20 is added, and from the time a reddish color appears, boiled for 1 to 1½ minutes. After cooling, the solution is transferred to a clean, dry cylinder, made up to 50 cc. with water, and compared with a standard solution of permanganate contained in an identical cylinder.

An iron content of 10 mg. per 1,000 cc. does not affect the results.

A note on the Hopkins and Cole modification of the Adamkiewicz test for protein, V. H. MOTTRAM (*Biochem. Jour.*, 7 (1913), No. 3, pp. 249-259).—The Hopkins and Cole modification of this reaction fails in the presence of small amounts of oxidizing agents. "The following method of carrying out the test yields excellent results:

"One cc. of strong 'reduced oxalic' acid (Benedict's reduced oxalic will do just as well) is mixed with 1 cc. of 1 per cent Witte peptone, and then 2 cc. of sulphuric acid is run down the side of the test tube which is held as near horizontal as convenient. The fluids are then rapidly mixed by shaking from side to side with the test tube vertical. The quantities given are for a test tube 1.5 cm. in diameter (the usual laboratory size). Subsequent addition of one drop of 1 per cent ferric chlorid solution usually increases the density and the blueness of the coloration.

"The quantities given may be varied greatly and yet a good coloration be obtained. One cc. or 5 cc. of sulphuric acid to 2 cc. of the mixture yields an unmistakable result and the quantities may be guessed and not measured. More sulphuric acid gives a bluer result than less."

The estimation of tyrosin in proteins by bromination, R. H. A. PLIMMER and ELIZABETH C. EAVES (*Biochem. Jour.*, 7 (1913), No. 3, pp. 297-310).—"The estimation of small quantities of tyrosin—0.01 to 0.04 gm.—can be effected by J. H. Millar's^a method of bromination when a more dilute solution of sodium bromate is used, but it is preferable to modify his procedure by adding excess of the reagent and titrating the nonabsorbed halogen with thiosulphate solution, using potassium iodid and starch as indicator.

"Tyrosin can not be directly estimated by bromination in the presence of protein and its decomposition products, since histidin and tryptophan also absorb bromin. Histidin can be removed by precipitation with phosphotungstic acid. The absorption of bromin by tryptophan is not completely eliminated after boiling with acids, so that tyrosin can not be estimated by this method in solutions containing the products of acid hydrolysis of proteins which contain tryptophan. Values for the tyrosin content of proteins, agreeing with those obtained by isolation and weighing, are obtained when the bromin absorption of a tryptic digest is measured after an interval of about six hours."

The separation of cystin and tyrosin, R. H. A. PLIMMER (*Biochem. Jour.*, 7 (1913), No. 3, pp. 311-317).—This work shows that cystin and tyrosin can be separated from one another by a precipitation with phosphotungstic acid. Practically all of the tyrosin can be determined in the filtrate and washings. The two amino acids may also be separated by a precipitation with mercuric sulphate in 5 per cent sulphuric acid, but the cystin is incompletely precipitated and the tyrosin which is recovered is impure.

^a Trans. Guinness Research Lab., 1 (1903), pt. 1, pp. 40-44.

"Cystin and tyrosin can be completely and quantitatively separated by means of absolute alcohol saturated with hydrogen chlorid. The tyrosin is rapidly converted into tyrosin ester and goes into solution. It can be recovered by boiling the solution when diluted with water for eight hours and then neutralizing with ammonia. Almost the whole of the cystin is insoluble; the portion which goes into solution (perhaps cystin hydrochlorid) is precipitated by adding an equal volume of absolute alcohol. The cystin is not converted into its ethyl ester since on dissolving the insoluble portion in dilute hydrochloric acid and neutralizing with ammonia the cystin is precipitated in the typical hexagonal plates."

Determination of amino nitrogen in the tissues, D. D. VAN SLYKE (*Jour. Biol. Chem.*, 16 (1913), No. 2, pp. 187-195).—"The amino acids are extracted from the tissues with hot water. Uncoagulated proteins in the extract are precipitated by alcohol. Alcohol and the slight amount of ammonia present in the extract are removed by concentration in vacuum, and the amino nitrogen in the residue is determined by the nitrous acid method. The rapidity with which the amino nitrogen reacts with nitrous acid, and the relatively small increase which it shows as the result of hydrolysis of the extract with hydrochloric acid, indicate that the amino nitrogen determined by the method outlined represents approximately the free *a*-amino acids. Only a few per cent of the amino nitrogen appears due to proteins or their intermediate products and to amines not of protein origin. The correction for the latter can, when desirable, be readily determined."

Testing animal fat for phytosterol, M. FRITZSCHE (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 26 (1913), No. 11, pp. 644-648).—The digitonin method of Marcusson and Schilling, while very satisfactory, requires 24 hours for its execution. The method has now been modified so as to require only two hours, as follows:

Fifty gm. of the melted and clear filtered fat is heated in a 150-cc. beaker with 20 cc. of a 1 per cent digitonin solution to from 60 to 70° C., and stirred at this temperature for five minutes with a mechanical stirring device. Fluid and semisolid fats are filtered, with the aid of suction, through an easily permeable Büchner funnel holding a 50-mm. diameter filter disk. The residue is then washed with ether six successive times with the aid of gentle suction.

While still warm the solid fats are treated, after the stirring process, with 20 cc. of chloroform, filtered under pressure, and washed twice with 5 cc. of warm chloroform and six successive times with 5 cc. of ether aided by slight suction. The fat-free residue (digitonin) with the filter disk is dried for five minutes on a watch glass at from 30 to 40°, and after the removal of the filter. The residue is transferred to a dry test tube provided with a cooling tube and heated with 2 cc. of acetic acid anhydrid to liquefaction with a small flame and then heated five minutes longer. The hot fluid is filtered through cotton into a crystallizing dish and the test tube and funnel washed twice with 0.5 cc. of warm absolute alcohol. The residue is then dried upon the water bath aided by a current of air, 1 cc. or less of absolute alcohol is added, covered with a watch glass, heated to solution, cooled, and the solution, etc., poured after crystallization has set in, upon a porous clay plate. When the mother liquor has been absorbed, the crystals are transferred to a crystallization dish.

A small portion of the crystalline mass is heated on a watch glass ten minutes at 70° and then employed for the melting point determination. The remainder of the residue is dissolved in absolute alcohol and used for a second, third, and possibly a fourth determination. Paraffin when present does not affect the results.

Some tests with beef tallow, oleomargarin, lard, and butter are included.

Estimation of sugar by the biological method, A. J. KLUYVER (*Abs. in Centbl. Bakt. [etc.]*, 2. Abt., 38 (1913), No. 21-25, pp. 648, 649).—In contradistinction to other workers (Prior, König and Hörmann, and Geelmuyden), the author introduces large quantities of yeast into relatively small amounts (1 to 2 cc.) of sugar solution held in a special form of fermentation saccharometer. Within 40 hours the fermentation is finished and from the amount of carbon dioxide produced the amount of sugar fermented is calculated.

The method is deemed useful for studying carbohydrate metabolism in plants and animals.

Estimation of iron in presence of organic substances, E. SALKOWSKI (*Hoppe-Seyler's Ztschr. Physiol. Chem.*, 83 (1913), No. 2, pp. 159-164; *abs. in Jour. Chem. Soc. [London]*, 104 (1913), No. 605, II, pp. 248, 249).—This is a critical study of the difficulty experienced in the estimation of iron in organic substances. "The iron is converted by fusion with a mixture of alkali nitrate and carbonate into oxide, the fused mass dissolved in water, and the iron oxide collected on an ash-free filter. It is advantageous to carry out the washing with a 10 to 15 per cent solution of ammonium nitrate, and finally to fill the filter with alcohol. A further difficulty is often experienced in removing all traces of iron oxide from the platinum dish."

The method of estimation of iron as ferric phosphate was examined and found to be very unsatisfactory. Washing the ferric phosphate precipitate with ammonium acetate did not remove the difficulties.

The soluble nitrogenous substances as a factor for judging flours, E. ROUSSEAU and M. SIROT (*Ann. Chim. Analyt.*, 18 (1913), No. 6, pp. 224-228).—It sometimes occurs that the results obtained by analyzing flours according to the usual methods (moisture, ash, fat, dry gluten, acidity, and fineness) indicate a good flour, but when the flour is submitted to a practical baking test, it furnishes a bread, etc., of inferior quality. The author therefore deems it advisable to take into account the total and soluble nitrogenous substances contained in the flour.

A flour suitable for baking purposes contains a ratio of total to soluble nitrogen of 5.72:1 (data obtained from 26 analyses of satisfactory and unsatisfactory flours). The total nitrogenous substances were determined by Kjeldahl's method in a 2-gm. sample of flour.

For estimating the soluble nitrogenous substances, mix 10 gm. of flour with 150 cc. of water in a 200-cc. flask and then place in a boiling water bath for from 2 to 5 minutes, shaking frequently during the interval. Take away the burner from the water bath, remove the flask, cool, shake, filter, and determine the nitrogen in 50 cc. of the filtrate (2.5 gm. of flour) by Kjeldahl's method.

The polarimetric determination of starch in rye and wheat flours, MACH (*Abs. in Österr. Ungar. Ztschr. Zuckerindus. u. Landw.*, 42 (1913), No. 6, pp. 1011, 1012).—The purpose of this work was to determine especially the starch content of feeds, and furthermore, whether typical samples of rye and wheat by-products can be used as a basis for judging the by-products of the industries dealing with these commodities. Seven samples of material were studied in this connection and the Lintner, Lintner-Wenglein, and Ewers methods were used for determining the starch.

The conclusions reached were that the polarimetric methods are not so refined that they can be called exact and reliable. On the other hand, these methods, especially Ewers' (*E. S. R.*, 21, p. 108) do furnish results which will aid in judging rye and wheat by-products.

A new method for examining baked goods, A. SCHMID (*Chem. Ztg.*, 36 (1912), No. 83, p. 796; *Mitt. Lebensm. Untersuch. u. Hyg., Schweiz. Gsndtsamt.*,

3 (1912), No. 3, pp. 193-199).—A method recommended for noting whether eggs (yolk or the entire egg) have been used in the preparation of baked goods is to determine the soluble proteins present. The procedure, which is provisional, is as follows:

Thirty gm. of material is powdered and passed through a No. 5 universal sieve into a 200 cc. flat-walled medicine bottle with 150 cc. of water and the mixture shaken for 30 minutes. The solution is then set aside, and if it does not clear it is centrifuged; 20 cc. of the clear solution is placed in a tube graduated in 0.1 cc. at its lower (tapered) end which is immersed in a water bath at 50° C. and the temperature raised to 80 to 85°. It is held at the latter point for ten minutes when 2 cc. of a 10 per cent nitric acid solution is added. After ten minutes the tube with its contents is centrifuged at 1,400 revolutions per minute and the volume of the precipitate read off. A comparison is made with a solution containing a known amount of eggs.

Determination of saccharin in foods, J. KARAS (Ztschr. Untersuch. Nahr. u. Genussmtl., 25 (1913), No. 9, pp. 559, 560).—It is often difficult to extract saccharin from solutions containing substances like starch, dextrin, etc., owing to emulsion formation with the solvent, or, when examining cordials, substances are often present which mask the taste of saccharin or prevent its crystallization.

A method suggested is as follows: Remove by evaporation the alcohol present in the sample or in a water extract thereof, and concentrate until it has a definite sweet taste; cool, add an aqueous solution of tannin (for 100 cc. of fluid add about 10 to 15 cc. of a 10 per cent tannin solution), shake, add 5 to 8 cc. of lead subacetate solution, and filter. Acidify the filtrate with phosphoric acid, filter off the lead precipitate, and shake the filtrate with a mixture of equal parts of ethyl and petroleum ethers. After evaporating off the ethers, a residue of pure saccharin is obtained.

It is not necessary to convert the saccharin into salicylic or sulphuric acid. When much fat is present, make alkaline with sodium hydroxid before clarification and extract with ethyl alcohol.

Examination of altered milk, L. VUAFIART (Ann. Falsif., 6 (1913), No. 53, pp. 148, 149).—The method of Kling and Roy (E. S. R., 22, p. 414) and the modification thereof proposed by Ronnet were studied and the difficulties experienced are pointed out. The greatest difficulty was with the quantitative extraction of fat from the coagulum. The procedure now followed consists of placing the coagulated milk in a Schleicher and Schull thimble, and, after removal of the serum by filtration, drying the coagulum at from 100 to 105° C. and extracting for an hour with ether. The extraction is then stopped, the coagulum rubbed up in a mortar and placed again in the thimble, and extracted for from one to two hours longer.

For estimating the protein, 250 cc. of the clear serum is evaporated in an 800-cc. flask to sirupy consistency; 150 cc. of sulphuric acid and a little mercury are added and the solution heated until nearly clear, when the coagulum in the thimble, thimble and all, is added and the process continued until completion.

In contradistinction to Kling, who considers that 1.033 gm. equals 1 liter of milk and who takes 32 gm. of fat and 33 gm. of protein as a minimum, the author takes Ronnet's figures, namely, 1,030 gm. for 1 liter of milk, 30 gm. for fat, and 29 gm. for protein. The latter figures are deemed more closely representative of the milks occurring in the north of France.

Analysis of altered milk, A. GASCARD (Ann. Falsif., 6 (1913), No. 60, pp. 525-530).—A review and study of methods for examining decomposed milk.

The calculation of the coconut-fat content of butter according to the Polenske method, T. SUNDBERG (Ztschr. Untersuch. Nahr. u. Genussmtl., 26

(1913), No. 8, pp. 422-424).—High results for coconut fat were obtained by the Polenske method of calculation (E. S. R., 15, p. 850). The method of calculation is deemed faulty on account of the figure which is taken as a standard for butter, and which does not represent the original butter.

The estimation of the Reichert-Meissl and Polenske numbers, A. GOSKE (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 26 (1913), No. 11, pp. 651, 652, fig. 1).—Many of the nonconcordant results obtained from these determinations are attributed to improper saponification. The chief requirement for proper saponification is a definite end temperature. This has been determined and a special form of apparatus for the work is suggested and illustrated.

Testing butter for preservative, W. E. GWILLIM (*Jour. Agr. [New Zeal.]*, 8 (1914), No. 1, pp. 64-67, fig. 1).—The fact that butter designed for shipment to the United States must be free of preservatives is pointed out. As most butter preservatives consist of a mixture containing boron compounds, methods are described for detecting these substances in butter, milk, or cream.

Contribution to the examination of cheese, E. REUCHLIN and F. RACHEL (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 26 (1913), No. 1, pp. 20-38).—These studies, which were made with a large variety of cheeses, emphasize the fact that the Siegfeld method for determining moisture (E. S. R., 24, p. 14) gives in a short time figures which compare well with those furnished by other methods. The Buttenberg and Koenig dry method (E. S. R., 23, p. 182), without the use of distributing agents, often yields low results.

The direct method of Mai and Rheinberger (E. S. R., 28, p. 612), when compared with other figures obtained by the same method, gives results which are fairly comparable, but are higher or lower than the indirect method. The alkaline distillate obtained in this method allows a determination of ammonia at the same time, which may possibly serve as a criterion for judging the ripeness of cheese.

Farnsteiner's method^a yields results for fat which are comparable with the figures obtained from the Bondzynski and Ratzlaff method (E. S. R., 16, p. 440).

The article also discusses many of the other methods proposed for the estimation of moisture and fat in cheese.

Short notes from practice, W. ARNOLD (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 26 (1913), No. 11, pp. 654-656).—This consists of methods for detecting (1) coloring matters in edible fats, (2) sesame oil in margarin which contains hydrochloric acid and reddening substances, and (3) butter with a suspiciously low olein content.

Short notes from practice, A. GOSKE (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 26 (1913), No. 11, pp. 652-654, figs. 2).—A description of a special water bath, a universal pycnometer, and a sedimentation glass with a glass stopcock at its lower end.

METEOROLOGY—WATER.

Weather fallacies, A. O. WALKER (*Bot. Jour. [London]*, 2 (1914), No. 9, pp. 232-235).—This article indicates certain respects in which meteorological observations as ordinarily reported fail to meet the requirements of the farmer. For example, monthly and annual summaries of rainfall are considered to be of little practical value, as more detailed information regarding the distribution of rainfall is necessary.

^a *Ztschr. Untersuch. Nahr. u. Genussmtl.*, 7 (1904), No. 2, pp. 105, 106, fig. 1.

It is suggested that in order that temperature observations may be of practical value the means of all important periods of heat and cold, irrespective of the calendar, ought to be published in an easily accessible form. Mean minima are also useless. It is only the extreme range of temperature and the absolute minimum that is deemed of significance in relation to plant growth.

Meteorological observations at the Hamburg Observatory, 1912, R. SCHORR (*Jahrb. Hamburg. Wiss. Anst.*, 30 (1912), *Beiheft 4*, pp. 50).—Detailed observations on temperature of the air and soil, pressure, moisture, precipitation, cloudiness, and wind for each month of the year are reported in tables.

Annual report of the director of the [Philippine] Weather Bureau for the year 1911, J. ALGUÉ (*Ann. Rpt. [Philippine] Weather Bur.*, 1911, *pt. 3*, pp. 266).—This contains a record of hourly meteorological observations made at the secondary stations during the calendar year 1911.

The influence of weather conditions upon the amounts of nitric acid and of nitrous acid in the rainfall near Melbourne, Australia, V. G. ANDERSON (*Chem. News*, 110 (1914), *No. 2859*, p. 127).—The results of determinations of nitric and nitrous acids in rain water at Canterbury from November 1, 1912, to February 28, 1914, are reported and discussed in connection with similar data from other sources.

The data indicate that these acids are formed in rain water in equal molecular proportions and this points to nitrogen peroxid in the atmosphere as their source. These proportions are maintained for some time in cold weather but in hot weather the nitrous acid is rapidly converted into nitric acid. As a result the ratio of nitric nitrogen to nitrous nitrogen is highest in summer and lowest in winter.

It was found that "the concentration of nitric acid reached a maximum in summer, a minimum in winter, and an intermediate position during autumn and spring. The concentration of nitrous acid reached a maximum in winter and a minimum in summer." The amount of oxidized nitrogen per acre carried down by rain falling on any day appears to be a function of a type of weather and within certain limits is independent of the amount of rainfall. The oxidized nitrogen content of the rainfall corresponding to nine well defined recurring types of weather is computed from various observations which have been made in different parts of the world. This content is shown to be much higher in the tropical than in the temperate and antarctic types.

Artesian water in Missouri, A. W. MCCOY (*Univ. Mo. Engin. Expt. Sta. Bul.*, 4 (1913), *No. 3*, pp. 72, *figs. 10*).—It is the purpose of this bulletin to outline the general artesian conditions in Missouri. It is attempted to furnish data as to what depths water may be reached, how high it will rise in the well, through what formations the drill must pass, what compounds the water is liable to contain, amount of discharge from the ordinary well, and the general economic conditions as compared with other sources.

The waters of Russian Turkestan and the future for the cultivation of the soil, WOEIKOF (*Ztschr. Gesell. Erdk. Berlin*, *No. 5* (1914), pp. 341-355).—Data on the surface water supplies and precipitation in Russian Turkestan are given, and discussed with reference to the possibilities of irrigation farming in that territory.

The climate of Turkestan is said to be warm and arid for six months of the year, with plenty of sunshine. The precipitation is relatively small but the streams are well supplied with water from mountain snow and ice. Floods in these streams are said to follow usually extremely warm weather. Such floods are said to occur at times when they will be most useful to such crops as cotton, rice, forage, etc., but owing to the imperfect native contrivances for storing and utilizing water approximately 3,500 cubic meters (123,550 cu. ft.) per second is

wasted during the six warm months. One cubic meter per second is said to be sufficient to irrigate 1,000 hectares (2,470 acres). The area at present irrigated is about 9,880,000 acres, but much of this area receives water for so short a time that cotton can not be grown.

The influence of ocean spindrift and blown spray on the chlorin content of inland ground waters, W. BARR (*Jour. Hyg. [Cambridge], 14 (1914), No. 1, pp. 119-128, figs. 3*).—Studies of the ground waters of that part of Scotland lying south of the river Forth, an area which shows appreciable differences in its meteorological conditions, led to the conclusions that the ocean, through the agencies of ocean spindrift and blown spray deposited on the land by all forms of precipitation, has an influence on the chlorin content of inland ground waters which is not limited to waters near the seaboard only but varies in intensity with the distance from the seaboard. This influence is also modified by the configuration of the land surface and to some extent depends on the direction of the prevailing winds from seaward.

Except where beds of salt occur, chlorin in inland ground waters is not due to the geological character of the water-bearing strata but is derived from the sea. It is further concluded that the chlorin figure may be utilized as a preliminary means of gaging the purity, or otherwise, of water samples from a district where the normal chlorin content has been established.

The location of water by means of the divining rod and automatic water finder, G. B. BROOKS (*Queensland Agr. Jour., n. ser., 2 (1914), No. 3, pp. 183-193, figs. 8*).—The author defends the divining rod and the automatic water finder, claims the ability of locating underground water by them, and gives experimental data to substantiate his claims. He states that the factors affecting the results obtained by a divining rod are thunderstorms, atmospheric moisture, and other weather conditions, proximity to growing timber, heavy clay subsoil, and ironstone or other minerals, the time of day, and the physical condition of the diviner.

Rural water supplies, E. BARTOW (*Univ. Ill. Bul., 10 (1913), No. 36, pp. 79-84, figs. 2*).—A classification of rural water-supply samples examined by the State Water Survey during the years 1907-1912, on the basis of their analyses considered in conjunction with their source and the surroundings of the well, is reported. The average number condemned decreased with the depth of the well. This was true but to a less extent with samples collected from typical wells. Many of the deepest wells were condemned owing to their mineral content. Three-fourths of the shallow wells examined were contaminated and 45 per cent of the samples of unknown origin were condemned.

Information is given regarding the protection of shallow wells.

SOILS—FERTILIZERS.

Soil survey of Ashley County, Arkansas, E. S. VANATTA ET AL. (*U. S. Dept. Agr., Advance Sheets Field Operations of the Bureau of Soils, 1913, pp. 5-39, fig. 1, map 1*).—This survey was issued March 13, 1914. It deals with soil characteristics and crop adaptabilities of an area of 596,480 acres in south-eastern Arkansas which is broadly divided into uplands and bottom lands. The upland soils are both loessial and sedimentary. Although drainage is poor in many cases, it is stated that "topographically practically the entire area of the county is easily tillable." Twelve soil types are mapped, the Richland silt loam being by far the most extensive. Agriculture is stated to be growing in importance, but it is not yet well developed in the county.

Soil survey of Bradford County, Florida, W. C. BYERS ET AL. (*U. S. Dept. Agr., Advance Sheets Field Operations of the Bureau of Soils, 1913, pp. 36,*

fig. 1, map 1).—This survey, made in cooperation with the Florida State Geological Survey, was issued July 24, 1914. It deals with soil characteristics and crop adaptabilities of an area of 344,960 acres in northeastern Florida, the topography of which varies from flat to hilly. The soils of the area are broadly grouped into sedimentary, alluvial, and cumulose soils, and their greatest general requirement is said to be drainage, which should be followed by liming. Fourteen soil types of six series are mapped, with Portsmouth fine sand predominating. Although only a small part of the county is under cultivation, agriculture is said to be entering a period of development.

Soil survey of Gordon County, Georgia, J. O. VEATCH (*U. S. Dept. Agr., Advance Sheets Field Operations of the Bureau of Soils, 1913, pp. 70, fig. 1, map 1*).—This survey, made in cooperation with the Georgia State College of Agriculture, was issued July 10, 1914. It deals with soil characteristics and crop adaptabilities of an area of 238,080 acres in northwestern Georgia, which consists of three principal topographic divisions, viz, a narrow mountainous area extending practically the entire width of the western boundary of the county, a mountainous area occupying the extreme eastern part, and a great valley approximately 20 miles in width lying between. There is a diversity of soils which are principally residual in origin. Thirty-nine soil types of 21 series are mapped, the loam and silt loam classes predominating. It is stated that the agricultural possibilities of the county have hardly been realized.

Soil survey of Miller County, Georgia, R. T. ALLEN and E. J. GRIMES (*U. S. Dept. Agr., Advance Sheets Field Operations of the Bureau of Soils, 1913, pp. 34, fig. 1, map 1*).—This survey, made in cooperation with the Georgia State College of Agriculture, was issued August 22, 1914. It deals with soil characteristics and crop adaptabilities of an area of 176,000 acres in southwestern Georgia, the topography of which is flat to gently rolling, varied here and there by limestone sinks. The soils of the area are derived from the Coastal Plain deposits and are consolidated and unconsolidated. Drainage is for the most part good and practically all of the upland portion of the county is said to be well suited to tillage operations and to the use of labor-saving machinery. Seventeen soil types of nine series are mapped, the Norfolk sandy loam with its two phases being the most extensive and important.

Agrology of Sahel, I. POUGET, F. LÉONARDON, and D. CHOUGHAK (*Agrologie du Sahel.—I, Sahel d'Alger. Algiers, 1913, pp. 84; abs. in Rev. Gén. Sci., 25 (1914), No. 10, pp. 531, 532*).—The results of physical, mechanical, and chemical analyses of soils of the region are reported and discussed with reference to the ease with which the soils may be cultivated and with reference to plant nutrition. A geological chart of the region is also given.

Study of Hungarian soils by means of their water solutions, R. BALLENEGGER (*Földtani Közlöny, 43 (1913), No. 7-9, pp. 317-324; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, pp. 336, 337*).—Analyses of water solutions, as well as determinations of moisture, electrical conductivity at 18° C., and alkalinity were made on samples of 75 typical Hungarian soils. See also a previous note (*E. S. R., 30, p. 516*).

The author concludes from the results that the water solutions may be used to characterize the various types of soils. Thus the water solutions of the poor, gray forest soils were found to contain the least soluble matter. On the other hand, the very fertile Alföld soils were found to be rich in soluble matter. The distribution of the soluble matter also varied in the different types of soil.

Some adsorption phenomena in soils and kaolin, J. E. HARRIS (*Jour. Phys. Chem., 18 (1914), No. 4, pp. 355-372; abs. in Jour. Chem. Soc. [London], 106 (1914), No. 619, I, pp. 643, 644; Chem. Abs., 8 (1914), No. 12, p. 2209*).—Investigations are reported which show that the liberation of acid when soils are

shaken up with solutions of sodium chlorid, potassium nitrate, and sodium acetate is not due to double decomposition in which insoluble humic acids are involved but to adsorption of the base of the salt.

Acid was set free by similar reactions when solutions of the salts named were shaken up with kaolin.

“That the acid is not adsorbed by the soil and kaolin and liberated again when treated with a salt solution was shown by treating samples of soil and kaolin with sulphuric acid, washing out the acid, and treating with potassium nitrate solution. Although a soluble acid was set free in the potassium nitrate solution, no evidence of the presence of the sulphate radical could be found. This showed that there had been no adsorption of the acid.

“To show that the base of the salt is actually adsorbed by the soil and kaolin, samples of these substances were treated with dilute hydrochloric acid, and then with a barium chlorid solution, the amount of acid that was set free in the solution being determined. The soil and kaolin after being thoroughly washed were treated again with hydrochloric acid and the amount of barium recovered by this process determined. It was found that the barium recovered in the case of the soil corresponded to 95 per cent of the acid liberated in the barium chlorid solution and to 89 per cent in the case of the kaolin. The soil was found after this second treatment with hydrochloric acid to have regained all its original capacity for liberating an acid from a salt solution.

“Finally it was found that a soil which had been boiled for six or seven hours with concentrated sulphuric acid to remove the organic matter, after being washed to remove the soluble acid, had the power of setting free almost exactly the same quantity of acid from a salt solution as a sample of the same soil which had been treated with twentieth-normal or fortieth-normal acid and in which all the organic matter was present. This would indicate that acid soils of the sort investigated (sandy loams) owe their acidity not to organic matter but to inorganic matter, probably to hydrated silicates.”

The nonexistence of magnesium carbonate in humid soils, W. H. MACINTIRE, L. G. WILLIS, and J. I. HARDY (*Tennessee Sta. Bul. 107 (1914), pp. 151-202, figs. 4*).—This is a full account of investigations more briefly noted elsewhere (*E. S. R., 31, p. 25*).

In basket and pot experiments magnesium carbonate equivalent to applications of 8 tons per acre of calcium carbonate in excess of the lime requirement, as shown by the Veitch method, was entirely decomposed after contact, without leaching, with fallow soils of three distinct types for a period of one year. Similar experiments under field conditions showed that magnesium carbonate equivalent to 28,180 lbs. of calcium carbonate per acre (2,000,000 lbs.) of soil had been entirely decomposed at the end of 8 weeks without leaching, while in soils treated with equivalent amounts of precipitated calcium carbonate the carbonate was still plainly discernible.

It was found in laboratory experiments that sand, both coarse and fine, clay, silt, opal, kaolin, kaolinite, bauxite, hornblend, rutile, soapstone, serpentine, and aluminum silicate, as well as the three different types of soils experimented with, decomposed precipitated magnesium carbonate and dolomite, with evolution of carbon dioxide, by moist contact at room temperatures both with and without the presence of precipitated calcium carbonate. Pure alkaline silicon dioxide, hydrated and dehydrated, decomposed precipitated calcium and magnesium carbonates and dolomite at room temperatures. The magnesia of precipitated magnesium carbonate also showed a strong affinity for alkaline titanium oxide at room temperatures. In all cases the magnesium compounds showed a greater affinity for the substances named and underwent more rapid decomposition than did the calcium compounds. The great affinity of mag-

nesium carbonate for silicon dioxide, hydrated silicates, and titanium oxide is thought to account for the decomposition and rapid disappearance of magnesium carbonate in the pot and field experiments.

The general conclusion is reached that "except for the minute quantities in soil moisture, resulting from hydrolyzation of silicates, or immediately after carbonate treatment, before decomposition has been effected, magnesium is not to be found in the carbonate form in surface soils."

While it is shown that the large applications of magnesium carbonate were decidedly toxic to wheat, it is thought "that ground dolomite might be used even in excessive amounts without any immediate toxic effect upon plant growth. However, the greater loss of lime by leaching of carbonate and hydrolyzed silicates would produce at some future time conditions which would necessitate extensive liming to overcome magnesia poisoning."

A bibliography of 55 references to literature bearing on the subject is given.

The effect of strongly calcareous soils on the growth and ash composition of certain plants, P. L. GILE and C. N. AGETON (*Porto Rico Sta. Bul. 16 (1914), pp. 45, pls. 4*).—The plan of the investigations reported in this bulletin was to grow several species of plants in adjacent field plats containing varying amounts (5, 18, and 35 per cent) of calcium carbonate and then measure the yield and determine the composition of the ash of the plants from the different plats.

The plats were prepared by digging holes 10 ft. wide by 20 ft. long and 2 ft. deep in a clay soil, leaving a bank 3 ft wide between each plat. These holes were filled with clay, sand, and disintegrated limestone in proportions to furnish soils of the desired texture and composition. Eight species of plants representing six families were grown in the plats, namely, rice, soy beans, bush beans, radishes, sunflowers, sweet cassava, sugar cane, and pineapples.

The results showed that "the growths of bush beans and radishes were unaffected even by 35 per cent of CaCO_3 . The growths of sunflowers, soy beans, and sugar cane were somewhat depressed by 18 per cent of CaCO_3 ; the growth of sweet cassava was somewhat depressed by 5 per cent of CaCO_3 and markedly by 35 per cent of CaCO_3 ; the growths of rice and pineapples were markedly depressed with the appearance of chlorosis, by 5, 18, and 35 per cent of CaCO_3 .

"The carbonate of lime apparently had no effect on the amount of nitrogen, potash, and phosphoric acid contained in the various plants, but did increase slightly the total carbon-free ash in all the plants except rice, and modified either the amount of lime, magnesia, or iron in the ash of all the plants.

"On the calcareous soils the lime in the ash of bush beans was not increased, but there was a slight increase in the amount of lime in the ash of soy beans, sunflowers, and sugar cane. On the plat with 5 per cent of carbonate of lime, the lime in the ash of radishes was increased about 17 per cent, but on the plats with 18 and 35 per cent of carbonate of lime the increases of lime in the ash of this plant were progressively less. On the plat with 35 per cent of carbonate of lime the amount of lime in the ash and dry substance of sweet cassava was markedly increased. On all the calcareous soils the amount of lime in the ash and dry substance of rice and pineapples was greatly increased.

"Some plants whose growth was little affected by the carbonate of lime (bush beans, soy beans, radishes, and sunflowers) showed marked decreases in the amount of iron or noticeable decreases in the amount of magnesia in the ash, when grown on the calcareous soils.

"The plants whose growths were most depressed on the calcareous soils (rice and pineapples) showed the greatest increases in the amount of lime in the ash and dry substance of the plant, and also a marked decrease in the amount of iron in the ash."

Apparently the most significant changes in the composition of the ash of the plants showing the greatest injury from the calcareous soils were an increase in lime and a decrease in iron. The results, however, "do not warrant a decisive conclusion that the diminished growth of all those plants which are affected by the carbonate of lime is due to the same change in ash composition. In fact, some quite marked changes in ash composition, as the decrease of iron in bush beans, occurred without affecting the growth. And some depressions in growth occurred, as [in case of] sugar cane, with practically no change in ash composition."

Sulphur in plant nutrition (*Wisconsin Sta. Bul. 240 (1914), pp. 18, 19, fig. 1*).—A brief note is given on pot experiments in which W. H. Peterson found that where no sulphate had been applied the plants contained absolutely no circulating sulphates. On the other hand, clover on soil which had been supplied with gypsum contained an abundance of sulphates in the sap. "This suggests that the determination of the amount of sulphates in growing plants may be of value in showing whether or not a crop on a given soil is being limited in growth by a scarcity of sulphates."

In a study of the form and distribution of sulphur in crops it was found that such plants as June grass and red clover contained volatile sulphur compounds, as is known to be the case with plants of the mustard family.

Forms of sulphur in plant materials and their variation with the soil supply, W. H. PETERSON (*Jour. Amer. Chem. Soc., 36 (1914), No. 6, pp. 1290-1300; abs. in Jour. Chem. Soc. [London], 106 (1914), No. 621, I, p. 914*).—This is a more complete account of investigations briefly noted above. It reports in detail the results of determinations of volatile sulphur, sulphates, soluble nonoxidized sulphur, and insoluble nonoxidized sulphur in ruta-bagas, cabbage, sugar beet, alfalfa, rape, radishes, clover, June grass, milk, oats, and wheat.

The method used in determining the volatile sulphur in plants was in brief as follows: Dry the material at 95 to 100° C. in a tube through which purified air is drawn; lead the gases over heated copper oxid and into an absorption bottle containing glass beads and a concentrated solution of potassium hydroxid; when this operation is completed boil the copper oxid in water to dissolve the copper sulphate formed; combine the solution in the absorption bottle with the washings from the copper oxid and concentrate the mixture on the water bath; cool and carefully neutralize with hydrochloric acid; pour the neutral solution slowly into bromin water; heat the oxidized sulphates; and precipitate the resulting sulphates with barium chlorid.

It was found that when only small quantities of sulphur were present in the material it was all fixed as copper sulphate. In case of ruta-bagas and cabbage the volatile sulphur amounted to about 10 per cent of the total sulphur. In case of radishes and clover grown in the greenhouse, the amount present depended upon the supply of sulphates in the soil, being four times as great with an abundant supply of sulphates in the soil as without. A considerable proportion (10 to 20 per cent) of the volatile sulphur in ruta-bagas was lost on drying the green material in the steam oven.

"Volatile sulphur was obtained from red clover, alfalfa, June grass, and sugar beet tops not known to contain any bodies yielding such compounds. The volatile sulphur in milk was also determined. The nature of this compound is not known. In ruta-bagas it is evidently of a sulphid form, as silver sulphid is obtained when silver nitrate is added to the distillate from ruta-bagas.

"The sulphates in the field samples examined varied from 10 to 50 per cent. Where large quantities of sulphates were added to the soil, there was a corresponding increase of sulphates in the plant tissue. Rape, radishes, and clover

grown in the greenhouse on soils low in sulphur, but supplied with an abundance of nitrogen, phosphorus, and potassium contained no sulphates.

"Where no sulphates were added to the soil, 90 per cent or more of the total sulphur was found in the form of unoxidized sulphur, probably in proteins. In the normally grown plants examined this was from 50 to 65 per cent of the total. The plant was evidently very economical of its supply and made healthy, vigorous growth where no sulphates could be found in the tissue."

A bibliography of 24 references to literature on the subject is given.

Some soil changes produced by micro-organisms, W. G. SACKETT (*Colorado Sta. Bul. 196 (1914), pp. 3-39, pls. 3*).—This is a popular discussion of the nature and activities of soil bacteria, yeasts, and molds, with particular reference to the decomposition of organic matter, the transformation of carbon and nitrogen, and the changes in mineral substances. The most space is devoted to the transformation of nitrogen, under which are discussed ammonification, nitrification, denitrification, and symbiotic and nonsymbiotic fixation of atmospheric nitrogen. In this connection data previously reported (E. S. R., 30, p. 818) are reviewed.

Ammonification and nitrification studies of certain types of Oregon soils, T. D. BECKWITH, A. F. VASS, and R. H. ROBINSON (*Oregon Sta. Bul. 118 (1914), pp. 40, figs. 30*).—This bulletin reports a study of the number and kinds of bacteria in certain widely different types of Oregon soils and of the effect of moisture, soil acidity, and lime upon the numbers and activities of these organisms, an attempt being made especially to correlate the number of bacteria present in the soil and the amounts of ammonia and nitrate nitrogen produced.

The soils used were of two main groups, namely, those of western Oregon which are generally acid and deficient in lime and those of eastern Oregon which are neutral or slightly alkaline and abundantly supplied with lime. It was found that the number of bacteria in soils low in organic matter was small as compared with the number in peat and muck soils. The application of lime was without effect upon the number of bacteria except in acid soils or when large amounts of organic matter were added. There was a direct correlation between amounts of ammonia formed and the number of bacteria.

The ammonifying and nitrifying powers of the soils of western Oregon were favorably influenced by the application of lime. The ammonifying powers of the soils varied greatly, the light soils producing the greatest amount of ammonia when nitrogenous substances were added.

The unit ammonifying power of the organism also varied greatly, the organisms in some types of soils being much more active than those in others. It was found that the greater the number of bacteria to a gram of soil the less the amount of ammonia produced per unit number.

On the influence of soils and of the water content on nitrogen changes, W. P. ROBSON (*Über den Einfluss der Böden und des Wassergehaltes auf die Stickstoffumsetzungen. Inaug. Diss., Univ. Halle-Wittenberg, 1913, pp. 91*).—Studies were made of changes in nitrogen compounds in the natural organic matter of soils and in ammonium sulphate and horn meal in sandy loam and clay soils with varying amounts of water (6, 12, and 18 per cent in sandy soil; 8, 16, and 24 per cent in loam, and 8, 18, and 28 per cent in clay). The effect of the addition of sulphur on these changes was also studied.

With low moisture content the transformation of organic nitrogen was more rapid in sandy soils than in the heavy soils, while with higher moisture content there was very little difference. In all cases the nitrification of ammonium sulphate was more rapid the higher the water content. In sandy soils 97 per cent and in loam and clay soils 100 per cent of the ammonium sulphate applied had been transformed into nitrate at the end of the experiment. In the sandy soils

the nitrification of organic nitrogen was at first more rapid than that of ammonium sulphate. In general, the most rapid nitrification was observed in all soils between the third and the sixth week after the addition of ammonium sulphate. Only in the case of the clay soil with the highest moisture content was the most rapid nitrification observed during the first three weeks. Appreciable denitrification was observed without the addition of organic matter only with the highest water content. Ammonium sulphate in loam soil showed a loss of 19.8 per cent of the applied nitrogen at the end of the experiment. With horn meal furnishing an abundant supply of carbonaceous food there was a greater loss (32.2 per cent in loam and 32.7 per cent in clay soils) in the heavier soils but a very small loss in sandy soils (9 per cent).

The addition of organic matter, as for example in the form of sugar, reduced the amount of soluble nitrogen compounds in the soil. In all soils the addition of sugar increased this fixation of ammonium sulphate nitrogen but did not affect the nitrate nitrogen. The amount of nitrogen fixed was increased by the addition of sugar from 18.18 to 26.18 per cent in sandy soils, from 22.32 to 43.2 per cent in loam soils, and from 29.08 to 38.38 per cent in clay soils.

The danger of bacterial destruction of nitrate in the field, H. FISCHER (*Fühling's Landw. Ztg.*, 63 (1914), No. 7, pp. 244-252).—Reviewing various investigations on this subject, the author concludes that under normal conditions, particularly of drainage and aeration, the danger of denitrification in the field is not great.

Hurtful actors on cultivated plants, T. JAMIESON (*Agr. Research Assoc. [Scot.] Rpt. 1913*, pp. 15-37).—Summarizing the results of experiments on the subject, the author concludes that the increased productiveness following the heating of the soil or treatment with substances inimical to life is "due simply to the riddance, in varied degree, of the varied forms of animal life in soil that prey on plants," and not to any influence upon the bacterial activity of the soil.

Barren spots, A. HUTIN (*Bul. Assoc. Chim. Sucr. et Distill.*, 31 (1914), No. 12, pp. 968-978).—A study of the causes of barren spots in sugar cane fields is reported.

Faulty soil aeration due to various causes is indicated as at least partly responsible for barrenness in certain cases. A study of the organic matter of certain of the barren soils which were apparently greatly benefited by liming showed the presence of a very large amount of soluble organic matter of a mucilaginous nature (pectates and parapectates). It is suggested that the unproductive character of the soil in such cases may be due to faulty aeration resulting from the presence of excessive amounts of the organic matter, and that liming coagulates this matter and thereby improves the aeration and drainage of the soil.

The fertility of the soil, M. F. MILLER (*Missouri Sta. Circ. 69* (1914), pp. 19, figs. 3).—This is a popular discussion of the problem and means of maintaining soil fertility, particularly under Missouri conditions. Emphasis is laid upon the fact that under present methods of management Missouri soils are not, on the whole, maintaining their fertility. It is pointed out that the extensive agriculture which prevails does not lend itself well to the profitable use of large quantities of commercial fertilizers. They can not be depended upon alone to maintain soil fertility and should therefore be used only in connection with good systems of crop rotation, manuring, and legume growing.

Fertilizer experiments (*Ver slag. en Meded. Dir. Landb. Dept. Landb., Nijv. en Handel*, No. 3 (1914), pp. 1-39).—The results of a number of fertilizer experiments completed during the years 1910 to 1912 at different Dutch experiment stations are briefly reported.

In comparative tests of stable manure, a complete fertilizer, and a half and half mixture of the two, on different soils with different crops the best results generally were obtained with the complete fertilizer, followed closely by the half and half mixture. In comparative tests of sodium nitrate, ammonium sulphate, lime nitrogen, and calcium nitrate on alluvial, sand, and clay soils sodium nitrate and ammonium sulphate were apparently on the average about equally as good sources of nitrogen for potatoes, and were followed in order by calcium nitrate and lime nitrogen. Sodium nitrate was on the average the best for grains and sugar beets, followed in order by ammonium sulphate, lime nitrogen, and calcium nitrate. Ammonium sulphate was better than sodium nitrate for potatoes on sandy and alluvial soils, as was also calcium nitrate on sandy soils. Further tests of sodium nitrate and ammonium sulphate showed the former to be generally better for potatoes and the latter better for oats and rye, although the differences were on the average small. Castor-bean meal was not as desirable for potatoes, oats, and rye as were sodium nitrate and ammonium sulphate.

Potash fertilizers were, on the whole, used with profit on clay soil for potatoes, particularly when applied by means of a seeder or planter. In experiments to determine the best manner of potash fertilization on sand and peat soils equally good results were obtained with kainit and a patented artificial potash fertilizer as regards crop yield when applied in the spring or in the fall. The quality of potatoes was poorer, however, in some cases where kainit was applied in the spring. Both fertilizers were used with profit on clay soil with potatoes and sugar beets, and the favorable effects on the average increased with the application to a certain limit. In further experiments with potatoes and grain there was little difference in the results obtained with the two types of potash fertilizers, each being used with some benefit. The experiments as a whole indicate that kainit may be used with some benefit for potatoes and grain on peat soils, even when applied in the spring shortly before planting.

Tests of a potassium silicate containing 25 per cent clay, 50 per cent silica, 8 per cent sodium, and 9 to 10 per cent potash, using kainit, potassium chlorid, and a patented artificial potash fertilizer for comparison, showed that although the yield of potatoes was increased the potash of the potassium silicate was much less available than that of the other potash fertilizers.

Six years' tests of slag meal, superphosphate, bone meal, and Algerian phosphate on a new alluvial soil indicated that the superphosphate was the most desirable for oats, slag meal for rye, and bone meal and Algerian phosphate for potatoes. Two years' tests on a sand soil of superphosphate, agricultural phosphate, Bernard phosphate, and slag meal favored the superphosphate for potatoes and oats, while the two new phosphorus fertilizers were better for oats and poorer for potatoes than the slag meal. A comparison of slag meal and Bernard phosphate showed the former to be the more favorable for rye. Two years' tests on sand soil of slag meal, agricultural phosphate, bone meal, and superphosphate showed the superphosphate to be the least favorable for peas and beets, slag meal the most favorable for peas, and bone meal the most favorable for beets. Slag meal was the most favorable for potatoes on sand soil and superphosphate the least favorable.

On a heavy clay soil 8 years' liming experiments, using crushed limestone, marl, and burnt lime, gave favorable results with sugar beets, potatoes, oats, clover, mangel-wurzels, and onions.

Fertilizer experiments, M. VAN DEN BURGT ET AL. (*Verlag Rijkstuinbouw-proefvelden Zuid-Gelderland en Utrecht, 1913, pp. 1-40*).—Cooperative fertilizer experiments with different crops on farms in various parts of Holland are briefly reported.

Five years' fertilizer experiments in East Prussia, A. STUTZER ET AL. (*Arch. Deut. Landw. Gesell.*, No. 258 (1914), pp. IV+236; *abs. in Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 7, pp. 873, 874).—In cooperative fertilizer experiments made during the years 1909 to 1913 on farms in different parts of East Prussia it was found that 40 per cent potash salt was better than kainit as a winter top-dressing, and that potash was especially necessary on permanent pastures and meadows.

The results indicate that small applications of nitrogen may be beneficial to grass lands, but are not conclusive as to the conditions under which this is the case. Calcium nitrate proved to be a very effective source of nitrogen. Cyanamid was considerably inferior to sodium or calcium nitrates. The ease of application and efficiency of the cyanamid was increased by mixing it with ground bog iron ore, which assists in the transformation of the cyanamid into urea. Cyanamid freed from carbid by treatment with steam gave higher yields of oats than ordinary cyanamid. A mixture of ammonium sulphate and salt gave better results with sugar beets than sodium nitrate in a good season but poorer results in a bad (dry) year. Urea obtained from atmospheric nitrogen and urea nitrate gave good results in field and pot experiments, the recovery of nitrogen by oats being higher for these substances than for sodium nitrate. In case of tobacco urea nitrate was the most effective nitrogenous fertilizer used. Calcium nitrite, aluminum nitrogen, and silicon nitrogen, all atmospheric nitrogen compounds, were of little or no value as fertilizers.

The stimulating or catalytic effect of various metallic oxids and salts of metals was studied with inconclusive results.

The action of mineral fertilizers on the activity of certain soil bacteria, C. LUMIA (*Atti R. Accad. Lincei, Rend. Cl. Sci. Fis., Mat. e Nat.*, 5. ser., 23 (1914), I, No. 9, pp. 738-746; *abs. in Chem. Zentbl.*, 1914, II, No. 3, p. 261; *Jour. Soc. Chem. Indus.*, 33 (1914), No. 14, p. 759).—It was found that the alcoholic ferment remained practically inactive in culture media deficient in phosphoric acid and potash. Various phosphates, especially Thomas slag, promoted the activity of the ferment, but perphosphate checked it on account of the free sulphuric acid present. This retarding effect was overcome by adding calcium carbonate. Potassium sulphate and chlorid were almost as effective as phosphates in promoting the activity of the ferment, but leucite was without effect.

The author suggests that the behavior of the bacteria indicated in these results may be used as a means of differentiating between easily assimilable and difficultly assimilable fertilizers. See also a previous note (*E. S. R.*, 31, p. 27).

Radio-active fertilizers, J. STOKLASA (*Chem. Ztg.*, 38 (1914), No. 79, pp. 841-844).—Tests of the effect of radium emanations on bacteria, germinating seeds, and various crops are reported.

It was found that treatment with the radium emanations increased fixation of nitrogen by bacteria, promoted germination of seeds, and increased the growth of plants to a marked extent. A chemical analysis and pot test of a so-called radioactive fertilizer indicated that whatever fertilizing value this material may possess is not due to its radio-active properties.

The bacterial treatment of peat, W. B. BOTTOMLEY (*Bot. Jour. [London]*, 3 (1914), No. 2, pp. 49-53).—A brief account is given of the author's method of treating peat to make it more active as a fertilizer and as a medium for the growth of *Azotobacter*. The results of tests of the material with various garden crops are also reported. These results indicated "that bacterized peat, in addition to being an excellent medium for the growth and distribution of nitrogen-fixing bacteria, possessed special manurial properties of its own."

See also a previous note (*E. S. R.*, 30, p. 721).

Experiments with bacterized peat (*Gard. Chron.*, 3. ser., 56 (1914), No. 1436, pp. 12-14).—A brief preliminary account is given of tests of this material in the open ground and in greenhouse experiments.

The results are stated to indicate that while the bacterized peat does not appear to have a beneficial effect upon the water-holding capacity of the soil it has valuable fertilizing properties which apparently are not limited to providing nitrogen. It gave the best results, as compared with manure, when used under conditions of an abundant supply of moisture.

On the influence of straw on the availability of organically combined nitrogenous fertilizers, F. VON MAY (*Mitt. Landw. Lehrkanz. K. K. Hochsch. Bodenkul. Wien*, 2 (1914), No. 3, pp. 433-454).—In this paper previous literature along this line is briefly reviewed and results of experiments by the author are given in which rye straw, red clover hay, and cotton-seed meal were used as fertilizers for potatoes.

The potatoes were planted immediately after plowing under the fertilizing materials, singly and in combinations. The results showed that the availability of the organically combined nitrogen was depressed by the presence of a nitrogen-free organic substance (as in case of rye straw). The magnitude of this depression seemed to depend upon the relation of the nitrogen and nitrogen-free organic substance.

The author suggests that the depression of available nitrogen under these circumstances is due to appropriation of the soluble nitrogen by micro-organisms which use the nitrogen-free substance as a source of energy.

Experiments on the fertilizing action of guanidin and urea nitrates in comparison with sodium and ammonium nitrates, P. WAGNER (*Mitt. Deut. Landw. Gesell.*, 29 (1914), No. 29, pp. 417-421).—In pot experiments with oats and rye grass, urea and guanidin nitrates were less effective fertilizers than ammonium or sodium nitrates. With oats the guanidin nitrate was positively injurious.

The conversion of ammonia into nitric acid or ammonium nitrate from an economic standpoint, O. DIEFFENBACH (*Chem. Indus.*, [Berlin], 37 (1914), No. 10, pp. 265-269; *abs. in Jour. Soc. Chem. Indus.*, 33 (1914), No. 11, p. 590; *Chem. Ztg.*, 38 (1914), No. 77, *Repert.*, pp. 360, 361).—It is concluded that the conversion of ammonia into nitric acid and ammonium nitrate is likely to be less profitable than conversion into sulphate except in factories producing calcium nitrate as a fertilizer from synthetic nitric acid. In this case the absorption of ammonia by nitric acid is shown to be more economical than by sulphuric acid, and it is suggested that the production of ammonia from calcium cyanamid or aluminum nitrid can be profitably combined with the manufacture of nitric acid by the Birkeland-Eyde process.

The fixation of atmospheric nitrogen, J. KNOX (*London*, 1914, pp. VII+112, figs. 7).—This is the fourth of a series of chemical monographs intended primarily for advanced students. It deals with theories of methods of (1) fixation of atmospheric nitrogen as nitric and nitrous acids, or as their salts, (2) synthesis of ammonia and ammonium compounds from atmospheric nitrogen, and (3) conversion of atmospheric nitrogen into compounds which readily yield ammonia. Attention is given only "to those methods which are either in actual operation, or which show promise of assuming technical importance in the near future." Information regarding the purely technical part of the subject is drawn from the report of Norton (*E. S. R.*, 27, p. 623).

A bibliography of 153 references to the literature of the subject is given.

Lime nitrogen-superphosphate, H. KOPPEN (*Illus. Landw. Ztg.*, 34 (1914), No. 18, pp. 181, 182; *abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 5, pp. 629, 630).—Experiments are reported

which indicate that mixing lime nitrogen with superphosphate does not decrease the availability of the nitrogen but causes a decided reversion of soluble phosphoric acid. The author, therefore, advises against the use of mixtures of cyanamid and superphosphate.

Available phosphates by furnace treatment, J. H. PAYNE (*Amer. Fert.*, 41 (1914), No. 7, pp. 44-46).—Various processes proposed for obtaining available phosphoric acid by heat treatment of phosphate rock are briefly described. The prospect of successful commercial use of some of these processes is thought to be good.

Availability of phosphate to various crops (*Wisconsin Sta. Bul.* 240 (1914), pp. 22, 23, fig. 1).—In experiments which are here briefly noted, E. Truog found in a comparison of ten different kinds of plants grown under greenhouse conditions with acid phosphate, rock phosphate, precipitated calcium phosphate, aluminum phosphate, iron phosphate (both ferric and ferrous), magnesium phosphate, or manganese phosphate as sources of phosphorus that "contrary to the general belief that aluminum and iron phosphates are relatively unavailable to plants, nine of the ten plants tested made better growth on aluminum phosphate than on calcium phosphate, and six better growth on iron (ferric) phosphate." This clearly indicates the inadequacy of chemical solvents as means of determining the availability of different phosphates.

Notes on kelp and its potash contents, G. SURR (*Mining and Engin. World*, 38 (1913), No. 10, p. 488).—An analysis of *Macrocystis pyrifera* showing 1.65 per cent of potash in the fresh plant (87.02 per cent of water) is reported and the fertilizing value and commercial possibilities of kelp are discussed.

Commercial fertilizers and their use, G. S. FRAPS (*Texas Sta. Bul.* 167 (1914), pp. 3-45).—This is a popular discussion of the subject, dealing particularly with the plant food requirements of different crops and how fertilizers supply these requirements, the principal sources and nature of fertilizing materials, the preparation of fertilizers, the valuation and purchase of fertilizers, methods of experimenting with fertilizers, and methods of using fertilizers on different crops and soils, particularly those of Texas.

Chemical analyses of licensed commercial fertilizers, 1913, F. W. WOLL and W. H. STROWD (*Wisconsin Sta. Circ.* 49 (1914), pp. 17, fig. 1).—Guaranteed and actual analyses of fertilizers, including ground limestone and rock phosphate, offered for sale in Wisconsin during the year are reported and discussed.

AGRICULTURAL BOTANY.

Spore conditions in hybrids and the mutation hypothesis of De Vries, E. C. JEFFREY (*Bot. Gaz.*, 58 (1914), No. 4, pp. 322-336, pls. 4).—The author reports examining a large number of spore-bearing plants as well as numerous higher plants, and found that spontaneous hybridization, while comparatively rare among lower plants, is very common among the angiosperms. In such families as the Rosaceæ and the Onagraceæ there are found to be grading into each other recognized species and recognized hybrids, having in common the character of partial or complete reproductive sterility, which is easily recognized in the organization of the pollen. This is said to point to the hybrid origin of these abnormal species. Species of this type, the author proposes, should be called cryptohybrids and include species of *Oenothera*, many species of *Epilobium*, and probably those of *Fuchsia*. This addition, it is claimed, must be recognized in connection with any investigation on the origin of species based on such material as *OE. lamarckiana*, *OE. biennis*, etc.

In conclusion the author states that although there appears to be good evidence that hybridism has been an important cause of the multiplication of species, there seems to be no logical support for the view that it has to do with their actual origin.

Some wild tuberiferous Solanums, L. WITTMACK (*Ber. Deut. Bot. Gesell.*, 31 (1913), *Gen. Versamml. Heft*, pp. (10)–(34), figs. 4).—Descriptions and illustrations are given of several specimens of Solanum sent to the author for study following the appearance of his articles, formerly noted (E. S. R., 31, p. 425), also a proposed systematic arrangement of several forms with reference to the views in this connection of several other authors.

The relationship between the weight of the seed planted and the characteristics of the plant produced, II, J. A. HARRIS (*Biometrika*, 10 (1914), No. 1, pp. 72–84, figs. 4).—In continuation of investigations previously reported (E. S. R., 29, p. 522), the author reports on the constants measuring the influence of the weight of the seed planted upon the number of ovules formed and the number of seeds developing in the pods of mature plants of *Phaseolus vulgaris*.

There was found to be a sensible relationship between the weight of the seed planted and the number of pods on the plant developing from it. There was also a positive correlation between the weight of the seed planted and the number of ovules and the number of seeds in the pods produced. The correlations between weight and ovules and weight and seeds are said to be regarded as the resultant of two other correlations, namely, that between the weight of the seed planted and the number of pods per plant and that between the number of pods on the plant and the characteristics of these pods.

The conservation of vitality of seeds in soil periodically cultivated, O. MUNERATI and T. V. ZAPPAROLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 5, pp. 347–371, fig. 1).—Experiments carried out with seeds of about 18 species of common plants, buried at various depths up to 45 cm. in soil and examined at varying intervals, are claimed to show that seeds of many cultivated or wild plants having coverings more or less permeable by water show a power of conserving vitality when buried in soil that is in close relation to their germinability at the time when they are planted.

Effects of disinfectants on germinability of grain, A. FRASSI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 1, pp. 25–56).—Germination tests were made with wheat seed after exposure to the action of different disinfectants in solution or in gaseous form during periods of varying length. The results given in connection with each test show the various degrees of injury inflicted, which is generally greater in case of moistened seeds than of those exposed only to vapors, and still greater in case of seeds in solutions, length of time always playing an important part. A bibliography is appended.

Delayed germination in seed of *Alisma plantago*, W. CROCKER and W. E. DAVIS (*Bot. Gaz.*, 58 (1914), No. 4, pp. 285–321, figs. 8).—A study is reported of the delayed germination of the water plantain, which is said to be due to the mechanical resistance of the seed coat. The seed coat was found to be composed almost entirely of pectic substances, which acids and bases so weakened that imbibitional and osmotic swelling of the embryo was capable of breaking away the coat cap. The authors state that the seeds of *Alisma*, as well as water plants in general, are capable of lying in water for years in an imbibed condition without losing their vitality.

A bibliography is appended.

Vegetation experiments on the evaporation of pine seedlings, A. TOL'SKII (*Abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 13 (1912), No. 4, pp. 651, 652).—The author describes the method and gives the results of his investigations conducted during several years with reference to the amount of

moisture given off by pine seedlings at the age of one to three years and to the influence of the weather on their evaporation.

To determine the limits of the fluctuations in the amount of evaporation by the seedlings in strict relation to age, in case of plants in vessels watered daily, proved impossible since only year-old plants gave more or less homogeneous magnitudes, while in the case of plants two and three years old the fluctuations in the evaporation by individual pines were very considerable. The evaporation considerably increases as the young needles attain normal dimensions, but before the needles develop the evaporation is feeble even at high temperatures. The pines were found to evaporate in the spring considerably less than in corresponding weather toward the end of the summer of the preceding year, and this continues to be noticeable until the new young shoots complete their development.

In an experiment with gradually decreasing humidity of the soil, when the pots were watered from two to five times during the summer it was found that the seedlings which were watered and those which were not watered dried the soil to a like degree nearly to the limit of minimum capacity for humidity: also that the introduction of water into the soil caused a large rise in the evaporation in young birches, while in pines the growth and evaporation were affected only by the first watering in the beginning of the spring, watering in the summer only slightly increasing the evaporation. The last mentioned fact is explained by the development of the pine being completed by the middle of the summer, in consequence whereof the water supplied later goes only to maintain the life activity of the developed needles. In young birches, on the other hand, each watering induces the appearance of new leaves with a consequent new increase of evaporation.

As to the influence of the weather on evaporation, the importance of the temperature and solar radiation was accentuated. Observations on the course of the daily evaporation in clear days showed the existence of two maxima, the larger before midday and the other after midday.

The effects of surface films on the rate of transpiration: Experiments with potted potatoes, B. M. DUGGAR and J. S. COOLEY (*Ann. Missouri Bot. Gard.*, 1 (1914), No. 3, pp. 351-356, pl. 1).—In a previous report (*E. S. R.*, 30, p. 726) the authors presented data concerning the application of a film of Bordeaux mixture to the leaves of castor bean and tomatoes. In the present paper experiments have been extended to potatoes to determine the effect of sprays upon the transpiration of this plant. Potted potatoes in good growing condition were arranged in series of 10 plants each, the different series receiving strong Bordeaux mixture, weak Bordeaux mixture, lime wash, lime-sulphur solution, strong Bordeaux mixture and lampblack, and lime wash and lampblack. The water loss from the different plants was determined for 5-day periods.

The results obtained corroborated those previously announced, showing that there was a marked acceleration of transpiration induced by spraying with Bordeaux mixture, as also with some other films. The experiments not only indicate that Bordeaux mixture facilitates water loss, but that treatment with a fairly thick lime wash or lime wash and lampblack also increases transpiration. Lampblack added to Bordeaux mixture seemed to give a greater transpiration than Bordeaux mixture alone. This seems to indicate that the additional quality of color is a factor requiring investigation. The fact that injury might result from the accelerated transpiration under the conditions of the experiment does not indicate that a benefit might not accrue under field conditions.

On the formation of hydrocyanic acid in plants, A. JORISSEN (*Acad. Roy. Belg., Bul. Cl. Sci., No. 3 (1914), pp. 130-137; abs. in Nature [London], 94 (1914), No. 2340, p. 7*).—Attention is called to the fact that citric acid in the presence of oxidizing agents and a trace of nitrate gives rise to hydrocyanic acid, and that in dilute solution in sunlight small quantities of ferrous or ferric salts can bring about the preliminary oxidation of the citric acid. As citric acid is widely distributed in plants, the author considers that hydrocyanic acid may possibly be produced in them through the action of sunlight on citric acid in the presence of traces of iron salts.

The oxidases of acid tissues, G. B. REED (*Bot. Gaz., 57 (1914), No. 6, pp. 528-530*).—Results of work done by the author are said to suggest that the apparent absence of oxidases in some organisms as reported by some authors may be due to faulty methods of observation. Having obtained results comparable with those reported by Clark (*E. S. R., 30, p. 203*), who noted a relation between apparent absence of oxidases and acid reaction, the author made special tests with citrus fruits, from which it appeared that these have normal oxidases in their acid tissues, also that these oxidases are protected in some manner from the action of the acid, which at the usual concentration inhibits the action of the oxidases.

The author thinks this protection may be afforded by a semipermeable surface (plasma membrane or cell walls similar to the cell walls of barley seed), through which the acid is unable to pass. When the tissue is ground, previous to expressing the juice, the structure which separates the acid from the ferment is destroyed so that the action of the latter is inhibited. It is thought probable that this condition is a general one in acid tissues. The general effects of acids and alkalis on oxidase ferments are now under investigation.

Some accessory factors in plant growth and nutrition, W. B. BOTTOMLEY (*Proc. Roy. Soc. [London], Ser. B, 88 (1914), No. B 602, pp. 237-247, figs. 2*).—Experiments are reported in which the manurial value of sphagnum peat which had been incubated with a mixed culture of aerobic soil organisms was tested. The results obtained indicated that the growth-stimulating action of the bacterized peat might be due to the presence of a substance or substances similar in nature to the accessory food bodies concerned in animal nutrition.

In another series of experiments extracts of bacterized peat were tested on the growth and fixation of nitrogen by *Azotobacter chroococcum*, and the results obtained indicated that there is present a substance which stimulates plant growth, and that it is of a fairly stable nature. Further investigations showed that this active stimulant could not be obtained directly from raw peat, but was evidently the result of bacterial action.

In another series of experiments a solution was tested on wheat seedlings deprived of their endosperms, but furnished with a nutrient solution and the same solution containing the extract from peat. After 17 days the weights of the plants were obtained, showing a decided increase where the bacterized peat solution has been employed.

Bioreactions of tellurium and their applicability to the study of vegetable physiology and pathology, G. POLLACCI (*Atti Ist. Bot. R. Univ. Pavia, 2. ser., 15 (1914), pp. 281-284, fig. 1*).—This is a brief report on the effects produced by tellurium on plants and their parasites, as shown by experiments with roots of *Brassica* attacked by *Plasmodiophora brassicæ*. The effects produced when these were kept 48 hours in a solution containing a very small proportion of a tellurium salt indicate that this fungus is able to reduce the salt.

The effect of the soot in smoke on vegetation, J. F. CLEVINGER (*Mellon Inst. Indus. Research, Smoke Invest. Bul. 7 (1913), pp. 26, pls. 8, figs. 2*).—The results are given of an investigation to determine the effect of soot in smoke

and other included materials upon plants, the observations being made in the public parks of Chicago, in Pittsburgh and vicinity, along the railroad between Tyrone and Pittsburgh, and at State College, Pa., the work being carried on cooperatively between the botanical department of the Pennsylvania State College and the Institute of Industrial Research.

The experiments show that especially in the case of pines, when soot is applied in small quantities over a considerable interval of time measurable injury follows. The soot is found to be a mixture of finely divided carbon, ash, tar, and gases, which may have a mechanical effect and also cause injury through their chemical properties. The injury done by soot is considered chiefly due to the accompanying ash, tar, and gases. Of the gases, sulphur dioxide and sulphur trioxide were said to cause considerable injury to vegetation.

The injurious effects of tarring roads on neighboring plants and remedies therefor, C. L. GATIN (*1. Cong. Internat. Pathol. Comparée [Paris], 1912, vol. 2, Comp. Rend., pp. 914-924*).—This work has already been partly reported (*E. S. R., 27, p. 333*). Strong insolation is said to favor injury to plants by gases from tarred roads, while frequent rains or strong winds decrease its severity.

Bacterial digestion of fiber or cellulose (*Wisconsin Sta. Bul. 240 (1914), pp. 21, 22, fig. 1*).—In an investigation conducted by R. R. Primm, a method was perfected whereby bacteria capable of digesting fiber or cellulose are readily isolated and studied. It is claimed that bacteria have been isolated which actively digest cellulose at a temperature of 149° F., and that they have been kept in pure cultures for a number of generations at this temperature without the loss of their cellulose digesting power.

Influence of soil bacteria on plant growth (*Wisconsin Sta. Bul. 240 (1914), pp. 19-21, fig. 1*).—In a study of the injurious effect of certain soil compounds on plant growth, C. Hoffmann found that when pure cultures of various soil bacteria were grown in extracts from marsh soil in which corn, oats, or clover had been previously grown, the bacterial content was considerably increased. When, however, the organisms were grown in extracts from cropped loam or sandy soils, the bacterial development was retarded. The action of corn grown in such solutions was especially notable in its root development. It was also found that different kinds of bacteria behaved differently in previously sterilized soil, showing apparently that the resulting compounds of bacterial activity in soils have an important bearing on plant nutrition and that various crops stimulate or retard others through this means, as in crop rotation.

Physiological investigation of the respiration of denitrifying microorganisms, A. F. LEBEDEV (*Zap. Nov. Obshch. Yest., Vol. 39; abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.), 13 (1912), No. 4, pp. 632, 633*).—The process of denitrification was studied in the case of *Bacillus pyocyaneus* under anaerobic conditions.

The examination of the gaseous exchange in old cultures showed the ratio of carbon dioxide to nitrogen to be equal to the theoretical one or very near to it. Thus the denitrification process is a true respiratory process. However, in young cultures this ratio is always greater than the theoretical one, being in some cases even 1½ times as great.

A contribution to our knowledge of the relation of certain species of grass-green algae to elementary nitrogen, J. R. SCHRAMM (*Ann. Missouri Bot. Gard., 1 (1914), No. 2, pp. 157-184, pl. 1, fig. 1*).—In the present series of experiments it was the author's aim to extend the observations over a greater variety of algal forms than has been dealt with heretofore in pure culture and under unexceptionable conditions. It is claimed that in seven forms named complete results have been obtained, none of these forms being able to fix free atmos-

pheric nitrogen in the complete absence of combined nitrogen under the conditions here employed.

Indications regarding the source of combined nitrogen for *Ulva lactuca*, G. L. FOSTER (*Ann. Missouri Bot. Gard.*, 1 (1914), No. 2, pp. 229-235).—Working on the general question as to the sources of nitrogen for marine algæ, the author carried out some preliminary experiments to determine the sources of available nitrogen for *U. lactuca*.

From the growth and appearance of this alga in natural and in artificial sea water with ammonium, urea, acetamid, etc., it was found that the first two of these nitrogen sources named are considerably better nutrients for *Ulva* than the others, in either natural or artificial sea water. It is thought probable that *Ulva* is not limited to an inorganic nitrogen supply and that for this alga the amount of available nitrogen in the water is a limiting factor in growth.

Concerning a plurality of starches, C. TANRET (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 19, pp. 1353-1356).—From a study of starches from oats, bananas, wheat, chestnuts, beans, lentils, maize, barley, peas, apples, rice, buckwheat, rye, and potatoes, the author claims to have found that they not only have different proportions of amylopectin and amylose, but that they react quite differently to physical and other agents, indicating that starches are not all alike.

FIELD CROPS.

The work of the Huntley reclamation project experiment farm in 1913, D. HANSEN (*U. S. Dept. Agr., Bur. Plant Indus., Work Huntley Expt. Farm, 1913, pp. 14, figs. 5*).—This describes the climatic and agricultural conditions of the Huntley, Mont., project and reports experimental work, which includes crop rotation, time and methods of planting alfalfa, time of harvesting alfalfa, tests of pasture grasses, variety tests of corn, irrigation of flax, fertilizer tests with wheat, oats, and barley, and test of orchard trees and small fruits, and pasturing corn and alfalfa with hogs.

“The chief results from the rotation experiments in 1913 are the following: Decidedly better yields were produced with crops grown in rotation than with the same crops grown continuously on the same land. The yields indicate that the practice of plowing under alfalfa and of applying barnyard manure greatly increases the productivity of the soil. The beneficial effect on the soil of growing cultivated crops, particularly sugar beets and potatoes, was strongly indicated.”

The results of the time-of-cutting experiment “indicate that delaying the harvest of the first crop did not have the effect of reducing the yield of the second crop. There was, on the contrary, a consistent increase in the yield of the second crop as the growing period of the first crop increased. The yields obtained in 1913 indicate that three cuttings a year will be more profitable than four cuttings.”

Of several methods employed in the reclamation of the Worden tract it is noted that “determinations of the total salt content of the soil indicate that the practice of plowing under rye as a green-manure crop has been more effective than either of the other methods in reducing the salt content. This method has also been found to be much less expensive.”

The work of the Truckee-Carson reclamation project experiment farm in 1913, F. B. HEADLEY (*U. S. Dept. Agr., Bur. Plant Indus., Work Truckee-Carson Expt. Farm, 1913, pp. 1-8, 10, 11*).—These pages record the soil and climatic conditions at the Truckee-Carson experiment farm and include data showing acreage, yields, and farm values of crops grown on this project in 1913.

The results of various tests with alfalfa grown for soil-improvement and forage purposes as noted show Grimm, Peruvian, Western Grown, Caucasus, and Montana to have been the best five. Data show that three cuttings a year secure a larger yield than two cuttings, but the author concludes not sufficiently large to cover the expense of the third cutting. Irrigation experiments on a small scale showed weekly irrigations to be more productive with alfalfa than at two-, three-, four-, five- or six-week periods. It is noted, however, that these conclusions are drawn from only one year's work.

Various tests with potatoes showed Early Rose, Colorado, Mammoth Pearl, and Burbank to be the best yielders out of 12 varieties.

The cause of the spotted character and general nonproductivity of soils in portions of the project was found to be the presence of excessive alkali salts.

Forage and silage crops for Oklahoma, O. O. CHURCHILL (*Oklahoma Sta. Circ. 34 (1914), pp. 3-15, fig. 1*).—For Oklahoma conditions the following forage and silage crops are discussed: Bermuda, brome, Colorado, Sudan, and Johnson grasses, timothy, orchard grass, reedtop, blue grass, fescue, curly mesquite, and native grasses, alfalfa, cowpea, sweet Japan, burr, medium red, mammoth, alsike, and white clovers, and vetches. As coarse fodders are mentioned grain sorghums, canes, corn, teosinte, pearl millet, millets, and rape, and as silage crops, grain crops, peanuts, alfalfa, cowpeas, corn, cane, and grain sorghums.

Grains and forage crops (*Wisconsin Sta. Bul. 240 (1914), pp. 26-30, figs. 4*).—This consists of brief notes referring to the work in progress by R. A. Moore and E. J. Delwich in regard to testing varieties, and breeding and selection of rye, wheat, soy beans, clover, and field and canning peas, and methods of curing seed corn at the station and elsewhere in the State.

Yields per acre of different classes of farm crops, C. A. ZAVITZ (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 39 (1913), pp. 120-188, figs. 6*).—Notes on the year's work as to the effect of change of seed, rotations, seed selection, plant selection and hybridization, cooperative experiments, oat smuts, and different combinations for grain productions, and variety tests of cereals, buckwheat, legumes, flax, millet, sunflowers, sorghum, potatoes, roots, sugar beets, rape, cow cabbage, and kale are reported.

[Field crop experiments], L. SMITH (*Rpt. Agr. Expt. Sta. St. Croix, 1912-13, pp. 4-39, 46-53, 60-65, 71, 72*).—Results of manurial, cultural, and variety tests are given with sugar cane, cotton, sweet potatoes, potatoes, maize, sorghum, Lyon beans, Canada beans, cowpeas, pigeon peas, horse beans, guar, woolly pyrol, Porto Rico beans, peanuts, spineless cactus, and analyses of cotton and some legumes.

[Manurial, variety, and cultural experiments], D. A. GILCHRIST (*County Northumb. Ed. Com. Guide to Expts. 1914, pp. 9-84, fig. 1*).—This gives some results of manurial treatments of meadows and pastures in terms of pounds of gain of cattle or sheep, and of variety tests with cereals and potatoes, mangels, cabbages, sugar beets, thousand-headed kale, swedes, and turnips.

Field experiments, 1913 (*Dept. Agr. and Tech. Instr. Ireland Jour., 14 (1914), No. 2, pp. 252-303*).—This paper gives results of variety tests of barley, potatoes, mangels, oats, turnips, and wheat, and manurial tests with barley, hay, pasture, potatoes, mangels, oats, and turnips which involved the use of nitrate of soda, superphosphates, kainit, basic slag, barnyard manure, liquid manure, sulphate of ammonia, muriate of potash, and seaweed and salt on both upland and peaty soils.

On peaty soils containing from 17.5 to 32.9 per cent organic matter and in preliminary experiments, each of the manurial applications (1) 1 cwt. nitrate of soda, 2 cwt. superphosphate, and 2 cwt. kainit per acre, (2) 1 cwt. nitrate of soda, 2 cwt. basic slag (high grade), and 2 cwt. kainit, and (3) one-half

cwt. nitrate of soda, 4 cwt. basic slag (high grade), and 2 cwt. kainit produced practically the same increase in yield of hay and at almost the same cost. In using seaweed for potatoes it was shown that "weight for weight, seaweed seldom produces as heavy a crop of potatoes as does farmyard manure; muriate of potash generally has less effect when used with seaweed than when applied with dung; seaweed gives the best results on light soils and, possibly, in a dry season."

In experiments with mangels the use of 20 tons of barnyard manure per acre was more profitable than a dressing of 15 tons. Adding 4 cwt. superphosphate resulted in an average profit of 6s. 6d. (about \$1.58) per acre, while also adding 2 cwt. of sulphate of ammonia resulted in an average annual profit of 3s. 6d., and either 2 cwt. or 4 cwt. of kainit in annual profits of 16s. 6d.

Plant breeding in Sweden, H. H. NILSSON (*Jour. Heredity*, 5 (1914), No. 7, pp. 281-296, figs. 7).—This article describes the old method of "selection in mass" and the modern one of "pedigreed culture", and relates the achievement obtained at the Svalöf Institute in the production and introduction of improved strains of cereals, legumes, and forage plants and the influence of this work on plant breeding in general.

A study of root systems of plants in pure and in mixed seedings, C. KRAUS (*Führung's Landw. Ztg.*, 63 (1914), Nos. 10, pp. 337-362, pls. 5; 11, pp. 369-383; 12, pp. 401-412).—The author gives results of his study at Munich in regard to the length, size, volume, and spread of root systems of cereals and legumes planted in both field and pot cultures, in mixtures, and in single varieties.

It seems from these results that an intimate knowledge of the habits of growth of root systems of agricultural plants will greatly enable the grower to space plants to better advantage, and to sow such mixtures that the soil volume will have a better distribution of roots and thus allow of a more intensive method of cultivation.

Inoculation of legumes with special reference to high moorland, A. DENSCH (*Mitt. Ver. Förd. Moorkultur Deut. Reiche*, 32 (1914), Nos. 10, pp. 237-245; 11, pp. 253-261).—This reviews recent German literature on the subject.

Proceedings of the seventy-second meeting of the Central Moor Commission (*Protokoll Cent. Moor Com.*, 72 (1913), pp. IV+350, pls. 2, figs. 25).—This gives the reports and discussions at the December, 1913, meeting of the commission covering the several moorland experiment stations throughout East Friesland.

Cultivation and management of moorland pastures and meadows, M. FLEISCHER (*Die Anlage und die Bewirtschaftung von Moorwiesen und Moorweiden*. Berlin, 1913, 2. rev. ed., pp. VIII+132, figs. 41).—A treatise covering 37 questions arising in connection with the cultivation of moorland pastures and meadows.

The seeding of meadows and pastures, C. B. HUTCHISON (*Missouri Sta. Circ.* 68 (1914), pp. 259-265).—This circular discusses the value and uses of nurse crops, timothy, red and alsike clovers, and orchard grass, and fertilizing meadows and pastures, and suggests several grass seed mixtures.

The favorable depth for grass seed, G. RICHTER (*Mitt. Ver. Förd. Moorkultur Deut. Reiche*, 32 (1914), No. 12, pp. 270-276).—Results here reported show much better yields after harrowing and rolling than after rolling only.

Study on the ancient classification of cereals, J. and C. COTTE (*Etude sur les Blés de l'Antiquité Classique*. Paris, 1912, pp. 99).—This is a discussion of the ancient classification of cereals.

The application of a new method in variety tests of cereals, K. VON RÜMKE, R. LEIDNER, and J. ALEXANDROWITSCH (*Ztschr. Pflanzenzücht.*, 2

(1914), No. 2, pp. 189-232, figs. 5).—This discusses a method previously applied to tests with stock beets (E. S. R., 31, p. 736), and now used in computing comparative values in cereal tests.

This method advocates the use of at least five check plats, and bases selection upon accurate numerical measurements of characters combined with careful biological observations. Its application is demonstrated in the results obtained in practical breeding experiments with several pure lines of wheat. The field experimental work and the mathematical calculations of these experiments are fully described.

Alfalfa (*Agr. Gaz. Canada*, 1 (1914), No. 4, pp. 285-302, figs. 6).—Cultural methods and tests of varieties of alfalfa grown are reported by J. B. Daggett for New Brunswick, L. S. Klinck and H. Nagant for Quebec, H. J. Moorhouse for Manitoba, S. E. Greenway and J. Bracksen for Saskatchewan, H. A. Craig for Alberta, and W. T. McDonald for British Columbia.

Strains of the Grimm variety are noted as being especially successful.

Alfalfa hybridization, W. SOUTHWORTH (*Jour. Heredity*, 5 (1914), No. 10, pp. 448-457, figs. 3).—The results of several years of study and hybridization to improve alfalfa are summed up as follows:

“Alfalfa apparently does not seed freely in absence of suitable insects to insure fertilization of the the flowers. Wild bees of the *Megachile* species seem to be most effective in insuring fertilization. Alfalfa flowers are not self-sterile and may be artificially self-fertilized with good results. Black medick is capable of self-fertilization and produces seed freely even when insects are prevented gaining access to the flowers.

“In the practice of hybridization of alfalfa better results are obtained by working on mature flowers than by operating on flower buds. The cross between alfalfa and black medick is effected only with considerable difficulty and prolonged effort is essential to warrant success. In the F_1 generation hybrids the plants were variable and usually greatly different from either of the parental forms. A study of the progeny of F_2 generation revealed a tendency to mendelian segregation both in height of plant and habit of growth, but further study is necessary to confirm these points.”

The farmers' alfalfa guide, J. R. M. BOYD (*Columbus, Ohio*, 1914, pp. 47, figs. 7).—A booklet of questions and answers covering alfalfa culture and based upon the author's experience.

Buckwheat, H. G. MUNDY (*Rhodesia Agr. Jour.*, 11 (1914), No. 5, pp. 739-744, pl. 1).—This article gives results of variety tests, including six selections of buckwheat in which the yield ranged from 664 to 2,048 lbs. per acre.

The effect of soil conditions on the tassels of maize, F. S. HARRIS (*Science*, n. ser., 40 (1914), No. 1023, pp. 215, 216).—From work carried on at the Utah Experiment Station to study the effect of soil factors on plants the author presents data on the corn plant to show that the number of branches per tassel is affected by the conditions of the soil and that there is a close relationship between the tassel branches and number of ears produced.

Tests made with nitrate fertilizers on maize, G. C. DUDGEON (*Agr. Jour. Egypt*, 4 (1914), No. 1, pp. 55-60).—This paper records results showing the general superiority of nitrate of soda over cyanamid or nitrate of lime in the production of maize in four different localities in Egypt.

Maize culture, A. H. E. McDONALD (*Dept. Agr. N. S. Wales, Farmers' Bul.* 78 (1914), pp. 3-88, figs. 38).—Methods of production employed in New South Wales with the corn crop are reported.

Mechanical cotton plants, W. L. BALLS (*Cairo Sci. Jour.*, 8 (1914), No. 93, pp. 135-137).—This article discusses the value of curves derived from daily

records of growth and flowering of the cotton plant in forecasting the ripening of the cotton.

"Bolly cotton" (*Bur. of the Census [U. S.] Bul. 125 (1913), p. 10*).—This article notes the increased quantity on the market of "bollies" (cotton from partly opened bolls damaged by frost) due to devised machinery for handling this product, which was formerly considered a loss by the growers.

The work of the British Cotton Growing Association, J. A. HUTTON (*Brit. Cotton Growing Assoc. [Pub.], 57 (1914), pp. 72, pl. 1*).—This is a paper read at the Third International Congress of Tropical Agriculture, held in London in June, 1914.

Cowpeas and soy beans, W. L. NELSON, A. T. WIANCKO, M. L. FISHER, C. O. CROMER, and J. K. WRIGHT (*Missouri Bd. Agr. Mo. Bul., 12 (1914), No. 5, pp. 3-48, figs. 10*).—This bulletin contains articles upon the production and uses of cowpeas and soy beans by several authors, including the text of Indiana Station Bulletin 172 (E. S. R., 31, p. 37).

Esparto industry in Almeria Province, B. F. YOST (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 165, pp. 306-308*).—This article describes esparto (*Stipa tenacissima*), its habitat, and the method of gathering and preparation, baling, etc., for shipment to Great Britain for the manufacture of paper pulp.

Guinea grass, H. O. JACOBSON (*Philippine Agr. Rev. [English Ed.], 7 (1914), No. 5, pp. 211-215*).—This article describes this grass (*Panicum maximum*) and gives its chemical composition and cultural methods. It is noted that yields at the Singalong Experiment Station in 1908 gave in four cuttings a total of 21,543 kg. from 0.3 hectare (about 32 tons per acre), the total growing period being 183 days.

Sexual studies of the hop plant, J. TOURNOIS (*Ann. Sci. Nat. Bot., 9. ser., 19 (1914), No. 2-3, pp. 49-191, pls. 5, figs. 23*).—A paper on the study of the flower and the differentiation of the sexual elements, the fertilization and formation of the embryo, and the formation and constitution of the fruit.

A bibliography of 80 titles is appended.

Kafir score card, A. H. WRIGHT (*Oklahoma Sta. Circ. 35 (1914), pp. 4*).—Score card with explanations of points for both head and grain exhibits is given.

Studies on oat breeding.—I, Variety tests, 1910-1913, F. M. SURFACE and C. W. BARBER (*Maine Sta. Bul. 229 (1914), pp. 137-192, figs. 8*).—This bulletin describes methods employed in the field work and in the keeping of records in variety tests with 34 varieties of oats covering the years 1910-1913 inclusive.

"Of the 11 varieties which have been tested for all four years the Irish Victor gave the best average yield (63.7 bu. per acre). The Imported Scotch, Lincoln, and Prosperity averaged to yield at nearly the same rate. The Senator, a horse-mane oat, with very coarse straw and large plump grains, gave the lowest average yield (49.3 bu.). A study of the variation constants (standard deviation and coefficient of variation) for the four-year period shows that the Victor (a black oat) and the Imported Scotch were by far the least variable of any of the varieties tested.

"It is pointed out in this paper that the variation constants measure a very important character of a variety. A variety which will yield very highly under favorable conditions but very poorly under unfavorable ones is not so desirable in the long run as a variety which will yield moderately well under any of the conditions that are likely to be met in any season. Further, the variation constants and the probable errors calculated with their aid give a very desirable measure of a series of tests. . . .

"The Regenerated Swedish Select and the Victor gave the highest average weight, about 41 lbs. per bushel. The Kherson and the Imported Scotch gave

the lowest weight per bushel. These were still well above the legal weight of 32 lbs. It is of interest to note that the Kherson shows a progressive increase in its weight per bushel for the four years that it has been grown in this State. . . .

"Of the varieties which have been tested for four years the Irish Victor, Imported Scotch, Lincoln, and Prosperity have made the best showing. With the exception of the Imported Scotch there appears to be but little choice between these varieties. The Imported Scotch has shown much less variability in respect to all its characters (with the exception of straw weight) than any of the other varieties. This is true both of inter- and intraseasonal variation. Under the conditions of seeding and growth at Highmoor this variety can be expected to produce a little over 60 bu. per acre every year. The chief objections to this variety are its relatively small weight per bushel and the yellow color of its grain. This latter objection is not very serious although yellow oats do not meet with so much favor on the market as the white varieties."

In discussing the results of the experiments the means, standard deviations, and coefficient of variation are used in estimating the values of the different varieties as affected by inter- and intraseasonal environmental conditions.

Peanuts (*Arachis hypogea*), C. D. GIROLA (*Rev. Facult. Agron. y Vet. La Plata, 2. ser., 10 (1914), No. 3, pp. 9-23, fig. 1*).—This article gives the history, geographical distribution, cultural methods, cost of production, and chemical analyses of the nuts and of the oil cake.

Some ecological evidence of the original habitat of the Irish potato (*Solanum tuberosum*), C. L. FITCH (*Proc. Soc. Hort. Sci., 10 (1913), pp. 99, 100*).—As evidence that the potato plant is a native of sandy open soils and a maritime atmosphere, or misty well-drained mountain slopes free from prolonged and heavy rains, the author notes his observations of the open structure of the stoma of the potato leaf, permitting rapid evaporation, and the loose incoherent structure of the root cap which is adapted only to penetration in open soils.

Observations on a bastard type of the Pearl potato, C. L. FITCH (*Proc. Soc. Hort. Sci., 10 (1913), pp. 100-104*).—In this article the typical Pearl potatoes, the "running out" type, and the bastard type are described and the results of cultural tests noted.

"The general summary of these results is that the normal Pearl tuber produces plants that are fairly productive and healthy, both in the district where it is most grown and in Minnesota, Wisconsin, and New York; that Pearl plants grown from tubers of the common run out type are most subject to disease, produce a poorer crop, and are more apt to bloom; while tubers of the bastard type produce plants that are very weak and lacking in resistance, that bear a much smaller crop, and that bloom profusely and produce abundant virile pollen and large fruits with many seeds.

"These facts are evidence that degeneracy of the potato tuber in the case of the Pearl in Colorado is accompanied in like degree by weakness and lack of resistance to disease."

Results of change of seed potatoes on moorlands (*Ztschr. Moorkultur u. Torfverwert., 12 (1914), No. 3, pp. 107, 108*).—The data show increased yields of potatoes from seed obtained from similar soil elsewhere over home grown seed of the same variety. Seed from sandy soil proved inferior to home grown seed.

The effect of sodium nitrate and ammonium sulphate on potatoes and sugar beets, A. MAUSBERG (*Landw. Jahrb., 46 (1914), No. 2, pp. 339-342*).—The results here recorded show a slightly heavier yield in a 5-year average of

potatoes when nitrate of soda was used in place of sulphate of ammonia, but the reverse was true with sugar beets.

— Influence of transplanting in the cultivation of rice (*Glor. Risicolt.*, 4 (1914), No. 9, pp. 129-136).—This article gives methods of cultivation, including transplanting. The itemized cost of production proved the method to be highly profitable.

The culture and preparation of rice in Italy (*Inst. Colon. Marseille Notice 12* (1914), pp. 95, figs. 36).—This publication gives the proceedings of the congress and exposition of rice culture at Vercelli, and the following papers: The Culture and Preparation of Rice in Vercelli, by H. Jumelle (pp. 15-21); The Problem of Importations, Acclimatizations, and Seed Selections of Rice, by N. Novelli (pp. 22-28); The Best System of Combating Weeds in Rice Fields, by E. Ferrari (pp. 29-38); Fertilizers in the Culture of Rice, by A. Menozzi (pp. 39-41); The Application of Modern Machinery in Rice Culture, by G. Allorio (pp. 42-66); The Application of Modern Machinery in the Rice Industry, by A. Tarchetti (pp. 67-80); The By-products of Rice Culture, by L. Tognato (pp. 81-87); and Rice Culture in Sicily, by A. Lo-Jacono (pp. 88-95).

— Rice, L. GRANATO (*O Arroz. Sao Paulo, Brazil, 1914*, pp. 525, pl. 1, figs. 348).—A treatise on the production of rice and its manufactured products, including some statistics from 26 rice-producing countries and a description of the culture in Brazil in particular.

Disintegration of rice grains by means of alkali, F. J. WARTH and D. B. DARABSETT (*Agr. Research Inst. Pusa Bul. 38* (1914), pp. 9, pls. 7).—This paper notes and describes a method of using caustic potash as a means of detecting varieties of rice. The action of the potash in disintegrating the starch granules of polished rice in 24 hours shows characteristic differences for the different varieties.

Sorghums, sure money crops, T. A. BORMAN (*Topeka, Kans., 1914*, pp. 310, pl. 1, figs. 71).—The eight chapters of this book treat of the following subjects: The land of grain sorghums, development of the sorghum belt, grain sorghums in general, grain sorghum yields and values, sorghum areas defined, grain sorghum farming, better grain sorghum crops, and feeding grain sorghums.

The relation of leaves to the production of sugar in beets, H. PLAHN-APPIANI (*Bl. Zuckerrübenbau*, 21 (1914), No. 11, pp. 165-168).—From a study of this subject the author determined that not only the shape and setting of the leaves, but also the structure of the root, was important in the formation of sugar.

The vascular bundle system of the sugar cane, C. E. B. BREMEKAMP (*Meded. Proefstat. Java-Suikerindus.*, 4 (1914), No. 22-23, pp. 469-478, figs. 3; *Arch. Suikerindus. Nederland. Indië*, 22 (1914), No. 14, pp. 499-508, figs. 3).—This article describes the anatomy of this system as determined in various parts of the sugar cane.

The anatomical structure of the rind of the sugar cane, C. E. B. BREMEKAMP (*Meded. Proefstat. Java-Suikerindus.*, 4 (1914), No. 22-23, pp. 478-484, figs. 4; *Arch. Suikerindus. Nederland. Indië*, 22 (1914), No. 14, pp. 508-514, figs. 4).—This article describes the different cell layers of the rind of the sugar cane as revealed by the microscope.

Sunflower cultivation, H. G. MUNDY (*Rhodesia Agr. Jour.*, 11 (1914), No. 5, pp. 730-734, pl. 1).—The history and methods of cultivation and analyses of locally grown sunflower seed are given. The yields are reported to have reached from 1,500 to 2,000 lbs. of seed per acre in Mazoe and 3,000 lbs in the Cape Province.

On the inheritance of rapidity of germination, germinative ability, and sensitiveness to light of seeds of *Poa pratensis*, H. PIEPER (*Fühling's Landw.*

Ztg., 63 (1914), No. 10, pp. 362-368).—Although there was some similarity obtained between the results of the original seeds and those of the next generation, the uniformity was not close enough for the author to determine a factor of inheritance.

The tillering of wheat, L. J. WILD (*Jour. Agr. [New Zeal.]*, 9 (1914), No. 1, pp. 31, 32).—This article gives results of an experiment that show a slight increase in the tillering of wheat by a treatment of the seed with a 3 per cent solution of sulphate or nitrate of ammonia.

Impurities of agricultural seed, with a description of commonly occurring weed seeds and a guide to their identification, S. T. PARKINSON and G. SMITH (*Ashford, England, and Bishopsgate, Canada, 1914*, pp. 105, pls. 38).—This book discusses the topics of the harm done by weeds, introduction of new kinds of weeds to the country, seeds from foreign countries, weeds common in samples, and methods of testing, with a key for the identification of the seed described in this book, and descriptions and photographs of 150 common weed seeds.

Seed testing, A. ATKINSON and B. W. WHITLOCK (*Montana Sta. Circ.* 38 (1914), pp. 11, figs. 4).—This circular describes methods of testing seeds and gives descriptions of seeds of six common weeds.

Seed control stations on the Continent (*Jour. Bd. Agr. [London]*, 1914, Aug., Sup. 13, pp. 88, figs. 4, pls. 11).—This describes the methods and work of the seed control stations at Copenhagen, Hamburg, Wageningen, Zürich, Budapest, Vienna, Munich, Breslau, and Berlin, and gives in an appendix results of some of the tests made at these stations.

Control of *Cuscuta* by devitalization of the seed, M. BRESAOLA (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 2, pp. 89-136, pls. 3).—Data are given showing the effect of subjecting several species of seeds used as host to high temperatures for varying periods of time and to a sulphuric acid bath.

Experiments in spraying to destroy dandelions, J. E. HOWITT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm*, 39 (1913), pp. 43, 44).—This notes the successful spraying of dandelions on lawns with a 20 per cent solution of iron sulphate. Six applications seemed necessary. Ninety per cent of the dandelions are said to have been killed the first season with a general improvement in the thriftiness of the grass.

HORTICULTURE.

[Horticultural investigations at the Truckee-Carson Experiment Farm], F. B. HEADLEY (*U. S. Dept. Agr., Bur. Plant Indus., Work Truckee-Carson Expt. Farm, 1913*, pp. 8-10, fig. 1).—Tabular data are given on variety tests of tomatoes and onions conducted at the farm in 1913, together with a list of the trees and shrubs which have thus far been found to be well-adapted to the Truckee-Carson reclamation project.

[Horticultural investigations at the Wisconsin Station] (*Wisconsin Sta. Bul.* 240 (1914), pp. 53, 54).—A brief statement of progress in the station's cranberry investigations, together with a note on the experimental forcing of rhubarb.

Severe winter weather and severe June frosts did considerable damage to the cranberry bog. The observations made at the station indicate that sanding the bog will have little value as a means of frost-protection when the temperature falls below 26 or 28° F. The application of rock phosphate on bare peat bog produced marked improvement in vine growth and crop yield, but also greatly stimulated the growth of grass. Nitrates and potash caused a material increase in the size of the fruit, together with improved color. In accordance with previous

results (E. S. R., 28, p. 838) the yield on plats sanded to a depth of 1 in. was much larger than that on those with no sand or on those sanded to only a depth of 0.5 in.

Cooperative tests with growers on the use of weed killers confirm the previous results of the station. A 10 per cent iron sulphate solution thoroughly applied with a good spray pump was very effective in killing wood moss.

Report on the statistics of vineyards, orchards and gardens, and root crops for the season 1913-14, L. H. SHOLL (*So. Aust. Statis. Dept. Bul. 3* (1914), pp. 6).—Statistics on the area, production, and value are given for the year 1913-14, together with comparative data for the four previous seasons.

Heredity of xenia among certain races of kidney beans, J. DANIEL (*Rev. Hort. [Paris]*, 86 (1914), No. 11, pp. 253-257, pl. 1, figs. 7).—In the study here reported crosses were made between the Spanish kidney bean and the black Belgian kidney bean during a period of three years.

The author's results show the existence of xenia in the seed resulting from these crosses. In some cases the seed coat was black like the paternal parent and in others there was a combination in various degrees of the colors of both parents. The studies thus far made with the descendants from these crosses indicate that xenia is transmitted to the progeny and that for the beans used in the experiment at least Mendel's law of inheritance does not apply.

The onion in Colorado, E. R. BENNETT (*Colorado Sta. Bul. 198* (1914), pp. 3-8).—A brief popular treatise on onion culture with special reference to conditions in Colorado.

Onion culture, J. W. LLOYD (*Illinois Sta. Circ. 173* (1914), pp. 3-16).—A short practical treatise discussing growing ripe onions from seed and sets, types of onions, the transplanting method, growing onion sets, and green bunch onions.

The California fruits and how to grow them, E. J. WICKSON (*San Francisco, 1914, 7. ed., rev., pp. 513, pls. 24, figs. 77*).—In the present edition of this work (E. S. R., 27, p. 439) the subject matter has been brought up to date.

Present state of fruit growing in Spain.—The principal fruit trees of the Rosaceæ, J. M. PRIEGO (*Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 7, pp. 836-842).—A brief statistical review of deciduous fruit culture in Spain.

A study of variation in the apple, W. J. YOUNG (*Amer. Nat.*, 48 (1914), No. 574, pp. 595-634).—The author made a study of some 24 varieties of apples obtained mostly from 14 localities in the State of Washington, although certain varieties were obtained from one locality in New Hampshire, Indiana, Missouri, New York, and West Virginia. In the present paper some brief comparative notes regarding the more conspicuous variations in each variety are given and the effect of environment upon various apple characters is discussed.

In connection with the investigation the author advances a fundamental principle upon which variation resulting from external factors depends. This principle, the Law of the Optimum, states that for any given variety there is for each character a certain intensity of each essential factor of the environment at which, other conditions remaining the same, that character reaches its highest development. In the application of this law to varietal adaptations the essential point is that all environmental factors should be of such intensity as to permit a good all-round development of the fruit.

On the chemical composition of the buds of some fruit trees, A. MANABESI and M. TONEGUTTI (*Staz. Sper. Agr. Ital.*, 44 (1911), No. 11-12, pp. 960-964; 47 (1914), No. 2, pp. 158-160).—In continuation of the work previously noted (E. S. R., 26, p. 407), analyses are reported in the first paper of fruit and leaf buds of the apple and pear, the buds being taken from the tree near the close of

the dormant season, and in the second of the leaf and flower buds of some peaches and apricots.

Summer pruning the peach, C. A. KEFFER (*Tennessee Sta. Bul.* 108 (1914), pp. 205-212, figs. 9).—This comprises a discussion of summer pruning the peach as a means of developing fruiting wood on the lower part of the main or skeleton branches which are usually bare. The subject matter is based upon the results of pruning tests conducted at the station and herein noted.

Some fertilizer tests in vineyards, F. H. HALL (*New York State Sta. Bul.* 381 (1914), popular ed., pp. 3-8).—A popular edition of the bulletin previously noted (E. S. R., 31, p. 339).

Layering as a means for increasing the yield from old vines, A. VERNEUL (*Rev. Vit.*, 42 (1914), No. 1074, pp. 57-60, figs. 3).—The author reports the successful renovation of old grapevines by means of layering.

Strawberry culture, A. K. GARDNER and H. P. SWEETSER (*Bul.* [Maine] Dept. Agr., 13 (1914), No. 3, pp. 28, pl. 1, figs. 13).—A popular treatise.

Summary of preliminary Feijoa pollinating experiments, K. A. RYERSON (*Univ. Cal. Jour. Agr.*, 2 (1914), No. 2, pp. 51-53).—Preliminary experiments conducted by the author in 1913 and 1914 relative to the nonsetting of fruit with the feijoas (*Feijoa sellowiana*) indicate that the blossoms are largely sterile to their own pollen and that the trouble may be overcome by mixed plantings of different varieties.

The Siamese pomelo, H. H. BOYLE (*Jour. Heredity*, 5 (1914), No. 10, pp. 440-444, fig. 1).—The author describes four types of seedless pomelos obtained from Siam for the Philippine Bureau of Agriculture. Two of these types are considered to be both excellent in quality and desirable for market purposes.

Tea: Green manuring at the experiment station, Peradeniya, M. K. BAMBER (*Dept. Agr. Ceylon Bul.* 9 (1914), pp. 119-134, pls. 3).—A progress report on the pruning, cultivation, and manuring experiments with tea at the Peradeniya station (E. S. R., 25, p. 139). Summarized data are given showing the yields of tea on the various plats for 1906 to 1913, inclusive.

With the flowers and trees in California, C. F. SAUNDERS (*New York, 1914*, pp. XIV+286, pls. 28).—In this work the author describes in a popular way certain characteristic features of the indigenous and exotic trees and flowers in California.

Classification of daffodils for use at all exhibitions of The Royal Horticultural Society (*London: Roy. Hort. Soc.*, 1914, pp. 73).—In the present classification, which is designed for exhibition purposes, the daffodils are divided into eleven divisions. A general list is then given of all known varieties, and each variety is referred to its proper class or division in so far as the varieties are sufficiently well-known to be classified.

Preserving cut flowers, L. KNUDSON (*Amer. Florist*, 43 (1914), No. 1376, pp. 649, 650).—Some experiments were conducted by B. M. Duggar and the author in 1908 and by the author and Lua A. Minns in 1913 to determine whether or not the keeping quality of flowers can be prolonged by special methods of treatment. In the experiments here described a large number of chemical solutions of different concentrations were tested with reference to their value for prolonging the life of flowers of relatively short duration of life.

Over 10,000 cut flowers were used in the experiments, including the following kinds: Cosmos, petunia, aster, verbena, violet, coreopsis, dahlias, *Tagetes erecta* (African marigold), *T. patula*, geranium, zinnias, sweet peas, and pansies. The results did not at all substantiate the favorable work secured by Fourton and Ducomet (E. S. R., 18, p. 44) and in no case were any striking results secured. An increase of a day or so in the keeping qualities was frequently obtained but it is believed that this might have been due to other causes. With certain

flowers which tend to foul badly when placed in water some benefit was derived by the use of such chemicals as zinc sulphate, copper sulphate, manganese sulphate, and admixtures of strontium and barium chlorid with calcium chlorid in killing micro-organisms. The author points out that the possibilities of prolonging the keeping qualities of flowers are much greater with flowers which have a long period of life. The desirability of experiments with flowers of this kind is suggested.

FORESTRY.

Studies in tolerance of New England forest trees.—II, Relation of shade to evaporation and transpiration in nursery beds, G. P. BURNS and FRANCES P. HOOPER (*Vermont Sta. Bul. 181 (1914), pp. 235-262, pls. 8, figs. 2*).—In continuation of previous work with forest seedlings (E. S. R., 31, p. 640) the authors are conducting a study of the effect of shade upon the physical conditions for the germination and development of seedlings. The experiments here reported were carried on with white pine seedlings during the summer of 1913. The work deals particularly with the effect of lath screens on evaporation from the seed bed and on transpiration from the seedlings. An attempt was also made to determine the relation between the water loss from the seedlings and evaporation as measured by both black and white porous atmometer cups. Three seed beds were used in the experiment, the conditions being the same for all, except that the first was given no shade on the top; the second was covered with a lath screen in which the laths were spaced one lath's width apart; and the third was covered with a solid lath screen. All determinations of water losses were made by weight. The plants used for weighing were grown in pots plunged in the seed beds, the tops of the pots being covered with rubber dams to prevent evaporation. The series of observations reported extended over the first two weeks of August. The data are presented in a series of curves and tables and discussed.

The responses of the atmometers and plants were not identical, the quantitative responses differing more than the qualitative responses. In the half shade bed the differences observed in responses of instruments and plants were less than those observed in the no shade bed, the effect of half shade upon the plants being more marked than on the instruments. Both plants and atmometers lost but little water in the full shade bed. The evaporation-transpiration coefficients based on the unit of dry weight of the plants for no shade, half shade, and full shade beds show that the response of the plant agrees more closely with the black atmometer than with the white atmometer. A comparison of the losses from seedlings from the no shade bed with the losses from 2- and 3-year-old potted plants in the open shows that the seedlings give off water much more rapidly than the older plants, thus indicating the need of some protection for young plants. The daily averages of the losses from instruments and plants were found to smooth out extremes and conceal quantitative differences, thus minimizing the value of conclusions based on general averages.

The authors conclude that in order to determine a definite relation between atmometer and plant measurements "we need to know the effect of variation in each of the following factors: Light, wind velocity, humidity, and temperature on instruments and plants."

A brief bibliography of consulted literature is appended.

Tree growth and seed, J. B. BERRY (*Jour. Heredity, 5 (1914), No. 10, pp. 431-434, figs. 2*).—A brief review of Engler's investigations relative to the influence of environment on tree growth (E. S. R., 30, p. 239).

Osier culture, F. KNOTEK (*Arb. Deut. Sek. Landeskult. Rat. Königr. Böhmen, No. 18 (1914), pp. 21, figs. 10*).—Practical instructions are given for the culture of basket willows.

The coniferous forests of eastern North America, R. M. HARPER (*Pop. Sci. Mo., 85 (1914), No. 4, pp. 338-361, figs. 16*).—This comprises a descriptive account of the important coniferous forest types of eastern North America. Each type is considered with reference to its geographical distribution, correlations with soil, water, climate, fire, etc. Notes are also given on the economic aspects of the trees and the regions in which they grow.

The rôle of aspen in the reforestation of mountain burns in Arizona and New Mexico, G. A. PEARSON (*Plant World, 17 (1914), No. 9, pp. 249-260, figs. 2*).—Experiments conducted for several years under the direction of the Fort Valley Station, Flagstaff, Ariz., in planting Douglas fir in aspen thickets and adjoining openings have demonstrated that aspens are of considerable value in reforestation. The superiority of the aspen-covered areas over the openings is attributed mainly to a reduction in transpiration. The value of aspens in regulating transpiration from fir seedlings appears to more than compensate for the loss in soil moisture taken up by the aspen trees.

Tree distribution in central California, W. A. CANNON (*Pop. Sci. Mo., 85 (1914), No. 5, pp. 417-424, figs. 4*).—The author here briefly outlines the root characters of the three most prominent species of oak of central California with special reference to their ability to reach ground water at different depths, and points out the intimate relationship between root character and the characteristic local distribution of the species.

Timber conditions in Little Smoky River Valley, Alberta, and adjacent territory, J. A. DOUCET (*Dept. Int. Canada, Forestry Branch Bul. 41 (1914), pp. 52, figs. 16*).—In continuation of a previous report (*E. S. R., 27, p. 646*) a report is given on the work done during the summer of 1912, completing the reconnaissance and delimitation survey of the proposed Lesser Slave Lake Forest Reserve. In addition to a description of timber conditions suggestions are given relative to the protection of these forests from fire. A map accompanies the report.

Timber and soil conditions of southeastern Manitoba, L. C. TILT (*Dept. Int. Canada, Forestry Branch Bul. 45 (1914), pp. 36, pl. 1, figs. 13*).—This embraces the results of a survey conducted under the direction of the Forestry Branch of the Canadian Government in 1912. A considerable proportion of the country was found suitable for a forest reserve and a map is included in the bulletin showing this tract.

The forests of Madagascar: Their characters, resources, and conservation, R. BADIN (*Bul. Écon. Gouvern. Madagascar, 14 (1914), I, No. 1, pp. 33-58*).—A descriptive account of the forests of Madagascar, including information relative to their exploitation and steps which have thus far been taken for their conservation.

The tannin-yielding acacias of Senegal, Y. HENRY and P. AMMANN (*Acacias à Tanin du Sénégal. Paris, 1913, pp. 53, figs. 8*).—Descriptions are given of a number of tannin-yielding acacias, including some other tannin-yielding species, together with analyses of various parts of the tree with special reference to their tannin content.

The tapping of pines and resin exploitation in Tonkin, CARRIÈRE (*Bul. Écon. Indochine, n. ser., 17 (1914), No. 108, pp. 329-335, figs. 3*).—A short descriptive account of turpentine and resin exploitation in Tonkin.

Measurement of woods for statistical purposes, D. W. YOUNG (*Quart. Jour. Forestry, 8 (1914), No. 4, pp. 253-275*).—In this paper the author discusses the

nature of the information required in making tree measurements and describes the methods adopted by the British Board of Agriculture in making tree measurements.

Lumber and its uses, R. S. KELLOGG (*Chicago, 1914, pp. 352, pls. 39, figs. 12; rev. in Engin. Rec., 70 (1914), No. 1, p. 26*).—This is a compilation of general information on the subject. Beginning with the structure and physical properties of the wood, the author proceeds to lumber grades, standard sizes of lumber, and shipping weights. A discussion of structural timbers includes standard definitions and Forest Service rules. Chapters follow on seasoning of timber, wood preservation, paints and stains, wood paving blocks, hardwood flooring and fire resistance, and lumber prices. Under the two headings "the uses of lumber" and "commercial woods" is given a somewhat long and detailed discussion of the uses to which each kind of lumber is put and the kinds of wood which supply the material for a large number of wooden commodities. Statistics as to forest products and the timber supply, and a section giving sources of information about lumber, are also included.

Vocabulary of forest terms, compiled by W. A. A. REINHARDT (*Harrisburg, Pa., 1909, pp. 24*).—This comprises a vocabulary of terms in silviculture, forest protection, and forest utilization found in Schwappach's Forestry (*Forstwissenschaft*) (E. S. R., 16, p. 1083).

DISEASES OF PLANTS.

[Investigations in plant diseases] (*Wisconsin Sta. Bul. 240 (1914), pp. 47-53, 54, 55, figs. 8*).—A summary is given of recent investigations on plant diseases carried on under the direction of L. R. Jones, R. E. Vaughan, and others, the principal investigations being on onion smut, pea blight, disease-resisting cabbage, barley seed disinfecton, root rot of tobacco, black rot of tobacco, and false blossom of cranberries.

The experiments for the control of onion smut demonstrated that formalin solution applied to the seed disinfected both seed and surrounding soil, and not only greatly reduced the amount of smut, but nearly doubled the yield.

In the pea blight investigations, which have been carried on for several years, the methods of control previously reported (E. S. R., 28, p. 844) have been tried under field conditions. Definite benefits were obtained by plowing and harrowing immediately after the removal of the crop, repeating these operations three times before freezing. The use of clean seed and a strict rotation of crops, together with plowing immediately after crop removal will greatly reduce loss from this disease. It has been previously shown that the spores of the fungus are carried over by the straw or stubble, and in connection with some of the new canning plants in the State, silos have been constructed by which the pea vines are utilized, the process of fermentation destroying the fungus.

Continued success is being met with in the experiments for the breeding of cabbage resistant to yellows, and sufficient seed of the second generation was obtained in 1913 for distribution and demonstration trials during 1914.

In experiments with the modified hot-water treatment of grain, A. G. Johnson found that soaking the grain for six hours in cold water, then for fifteen minutes in water heated to 126° F., completely eliminated the smut and reduced the barley stripe disease from 20 per cent to less than 1 per cent in treated plats.

In reporting upon the root rot and the black rot of tobacco, J. Johnson points out that serious loss in Wisconsin and Ontario, as well as elsewhere, is due to the presence of the root rot fungus (*Thielavia basicola*). This may be largely controlled by proper sterilization of the seed bed, as much of the disease origi-

nates in that way. The black rot is said to be due to *Sterigmatocystis nigra*, which affects the tobacco after it is harvested. A high moisture content and high temperature in the curing house favor the development of this disease. Practical methods for its control have been worked out which are based on the regulation of the percentage of moisture in the leaf and control of temperature during fermentation.

In cooperation with C. L. Shear, of this Department, L. R. Jones has carried on some investigations on the false blossom of cranberries, which is found to be a physiological trouble due to unfavorable cultural conditions. The most important factor for the elimination of this trouble is said to be proper drainage. Surveys made of cranberry diseases indicate that while other diseases are present, none are serious that can not be controlled by spraying or other well-recognized methods.

Fungus diseases of plants, S. L. AJREKAR (*Poona Agr. Col. Mag.*, 5 (1914), No. 3, pp. 184-192).—As a preliminary account of plant diseases, brief descriptions are given of millet smut, grapevine mildew, red rot in sugar cane, and Koleroga disease of palms, together with suggestions for their control.

Phytopathological report for 1913, E. FOEX (*Rev. Phytopath. Appl.*, 1 (1914), Nos. 18-19, pp. 13-15; 20-21, pp. 17-23; 22-23, pp. 25-29).—Condensed accounts are given of observations on diseases of cereals, tubers, forage plants, vines, fruits, berries, pines, and oaks, with some remedies tested or proposed.

Diseases of plants.—I, Herbaceous plants, B. TOMEI (*Malattie delle Piante. Piante Erbacee. Urbino, Italy, 1913, pt. 1, pp. 111*).—This contains very brief discussions of several diseases, with proposed remedies, of wheat, corn, vetch, potato, tobacco, alfalfa, clover, sulla, and sainfoin.

The introduction of model treatments of plant diseases in Posen and West Prussia, R. SCHANDER (*Mitt. Deut. Landw. Gesell.*, 29 (1914), No. 21, 294-298).—This is a brief outline of the proposed general plan and scope of operations for the protection of economic plants from various diseases in this section.

Some practical means of combating plant diseases as employed in Russia, A. DE JACZEWSKI (*1. Cong. Internat. Pathol. Comparée [Paris], 1912, vol. 2, Comp. Rend.*, pp. 948-955).—Among the results reported, it is claimed to have been shown that the general requirements for a practical fungicide are best fulfilled by a mixture of copper sulphate and alkaline polysulphids, this proving safe, cheap, and efficacious, as instanced by tests on *Phyllosticta briardi* on apple trees, the proportion formerly used (0.5 per cent of each component) being found to be reducible to 0.2 per cent of the former and 0.3 per cent of the latter.

The immense damage formerly done by *Sphærotheca mors-uvæ* to gooseberry has been greatly reduced by use of alkaline polysulphids. The hot water treatment for *Ustilago hordei* and *U. tritici* is thought to be limited in its beneficial effect only by the present difficulty in securing the best conditions for its employment.

Heredity of disease in plants and Mendelism, L. BLARINGHEM (*1. Cong. Internat. Pathol. Comparée [Paris], 1912, vol. 1, Raps.*, pp. 250-312, figs. 12).—This is a somewhat comprehensive discussion, dealing with different phases and probable origins or causes of anomaly or disease in plants, including the influence of heredity and environment, as well as of parasitism. A bibliography is appended.

Tumors of roots and rootlets, O. LARCHEM (*1. Cong. Internat. Pathol. Comparée [Paris], 1912, vol. 1, Raps.*, pp. 312-328).—This is a brief general treatment as to tumors of underground portions of plants, as regards their external characters, pathological anatomy, effects, etc., with a somewhat extensive bibliography of the subject.

The root parasites of the Bombay Deccan, H. VAN BUUBEN (*Poona Agr. Col. Mag.*, 5 (1914), No. 3, pp. 193-196, pl. 1).—The author describes the attack of *Striga lutea* on durra, pearl millet, maize, and other grasses in India.

Propagation of rust of cereals, J. BEAUVERIE (*I. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 960-965).—In this brief preliminary note the author claims to have demonstrated the frequent presence of uredospores, teleutospores, and mycelium of grain rusts in the pericarp of wild and cultivated grains. It is thought that the young plants are often thus contaminated as soon as they begin to develop in spring.

Powdery scab, a new potato disease, E. S. BRIGHAM (*Bul. Vt. Dept. Agr.*, No. 18 (1914), pp. 1-7, fig. 1).—A popular report is given of the powdery scab, due to *Spongospora subterranea*, in order that potato growers may be informed regarding the avoidance of its possible introduction.

Wart disease of potatoes, J. ERIKSSON (*Jour. Bd. Agr. [London]*, 21 (1914), No. 2, pp. 135, 136).—The author reports the results of an experiment bearing upon the possibility of eradicating the wart disease of the potato.

Diseased tubers were planted in plats surrounded to a depth of 1 meter by a zinc casing, the ground being treated some weeks later with a 1 per cent solution of commercial formalin at the rate of 10 liters per square meter (about 1 qt. per square foot). All the plats so treated were entirely free from the disease, while the control plats showed about 66 per cent of the plants infected to some extent. It is thought possible to eradicate potato wart disease from any field by employing stronger solutions where necessary.

Bacterial diseases of the roots of sugar beets, G. TRZHEBINSKIÏ (*Viestnik Sakhar. Promysh.*, No. 36-39 (1911); *abs. in Zhur. Opytn. Agron. (Russ. Jour. Expt. Landw.)*, 13 (1912), No. 4, pp. 621-625).—The author gives an account of studies of a dry and a slimy rot of beet roots noted on plantations in the Government of Kiev.

In connection with the former disease, which is described in three forms according to the portion of the plant attacked, he found two bacteria. This form of rot, which is widely distributed in southwestern Russia, differs from the dry rot as known in Germany accompanied by heart rot, in that the latter appears in the first year of the growth and not during the wintering of the roots or in transplanting. The slimy rot shows the presence of both these bacterial forms and also of a third, which is described, as are also the symptoms characteristic of this form of rot. Both transfer and contact inoculations from roots affected with slimy rot produce dry rot in healthy beets. The author is inclined to consider dry rot of the roots as dry bacteriosis.

Puccinia subnitens on the sugar beet, VENUS W. POOL and M. B. MCKAY (*Phytopathology*, 4 (1914), No. 3, pp. 204-206, pl. 1).—Attention is called to the occurrence of the æcial form of *P. subnitens* on sugar beets, the telial host of which is said to be *Distichlis stricta*.

For the control of this disease, which is said to be of increasing economic importance, the destruction of salt grass, which is quite common along the roadsides and ditches, is recommended.

[Lime treatments of soil for *Plasmodiophora brassicæ*], D. A. GILCHRIST (*County Northumb. Ed. Com. Bul.* 21 (1914), pp. 84-88).—Giving in connection with figures previously reported (*E. S. R.*, 29, p. 752) the results obtained from the use of various treatments in 1913 for finger-and-toe disease of swedes, the author states that a decrease was noted in the beneficial influence of lime mud after its employment for nine successive years on the same ground.

Diseases and deformities of mushrooms, F. GUÉGUEN (*I. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 956-960).—Giving results of some observations made on cultivated mushrooms showing abnor-

malities, the author states that along with the well known "mole" characteristic of their invasion by *Hypomyces perniciosus* there exist also in both these and wild mushrooms other characteristic deformities or ruptures. Some of these are due to parasitism, as evidenced by a characteristic odor and other indications of the organic nature of the trouble, which has been noted in connection with the presence of certain plant mites.

Plus and minus strains in the genus *Glomerella*, C. W. EDGERTON (*Amer. Jour. Bot.*, 1 (1914), No. 5, pp. 244-254, pls. 2, fig. 1).—The substance of this contribution has already been noted from another source (E. S. R., 30, p. 745).

A study of the physiological relations of *Sclerotinia cinerea*, J. S. COOLEY (*Ann. Missouri Bot. Gard.*, 1 (1914), No. 3, pp. 291-326).—A report is given of an experimental study on the physiological activities of the brown rot fungus of stone fruits, in which the conditions influencing the penetration and infection of green and ripe fruits by the fungus were studied as well as the action of the parasite on the host cells and the secretion of enzymes which act upon the cellulose and pectic substances of the host.

It was found that the brown rot organism infects immature fruit provided the skin is punctured, while on the other hand ripe or nearly ripe fruits may be readily inoculated through the unpunctured surface. The fungus was found to penetrate with equal ease any part of the host tissue, showing no preference for the middle lamella. No evidence was found that the fungus secreted a toxic substance in advance of penetration. An aqueous solution of pectin isolated from plums was coagulated by the fungus, indicating the secretion of pectinase. The changing acidity of the host as the fruit reaches maturity was not considered sufficient to explain the fact that ripe fruit is more susceptible to the disease than green fruit.

A bibliography is appended.

Protection against *Sphærotheca mors-uvæ*, D. HEGYI (*Rev. Phytopath. Appl.*, 1 (1914), No. 22-23, pp. 30, 31).—The author reports that in experiments since 1909 looking toward control of gooseberry mildew it was found that treatment with liver of sulphur caused fall of both fruit and leaves, also that iron sulphate had little effect on the disease. Bordeaux mixture, however, applied once or twice during the winter at 5 per cent and in early spring at 1 per cent strength, or lime sulphur employed according to plans outlined, is an efficient means of defense against this fungus.

The status of investigational work on pear and apple blight, D. B. SWINGLE (*Montana Sta. Circ.* 39 (1914), pp. 13-16).—The author gives a summary of work that has been carried on by this Department and various experiment stations on the cause and methods of control of pear and apple blight due to *Bacillus amylovorus*.

Black spot of the mandarin (*Agr. Gaz. N. S. Wales*, 25 (1914), No. 8, p. 684).—The prevalence of black spot in mandarin orchards in New South Wales is reported. Pending experiments for combating the disease, it is recommended that infected trees be severely pruned, and after pruning the trees and ground beneath should be sprayed with Bordeaux mixture or lime sulphur, three applications during the season being considered sufficient.

Spraying experiments with the peach and grape in 1912, E. PANTANELLI (*Staz. Sper. Agr. Ital.*, 46 (1913), No. 5, pp. 329-346).—Reporting on later experiments (E. S. R., 27, p. 855), the author states that polysulphids of calcium and barium, kept in sealed receptacles and diluted at the time of application, were found to be efficacious in controlling *Exoascus deformans* on the peach, but not *Plasmopara viticola* on the grape. Bordeaux mixture gave good results against *P. viticola*. Self-boiled lime sulphur proved helpful against *E. deformans* on peach, also against *Monilia cinerea*.

Dry leaf of the grape, M. TURCONI (*Riv. Patol. Veg.*, 6 (1913), No. 9, pp. 260, 261).—A leaf disease of the grape near Pavia, characterized by premature drying, and noted in some American varieties, is ascribed to *Pestalozzia uvicola*.

Base rot of pineapples (*Agr. News [Barbados]*, 13 (1914), No. 316, p. 190).—In a locality not known to have produced pineapples previously, cuttings carefully disinfected with Bordeaux mixture before planting developed a diseased condition, apparently due to *Thielaviopsis paradoxa*. It is thought that the presence of the fungus may be due to a previous cultivation of sugar cane in these places or perhaps to the use of organic manure. There is said to be some evidence that plants sometimes throw off the disease. Development of resistant strains is suggested.

Decay of pineapples (*Agr. News [Barbados]*, 13 (1914), No. 318, p. 222).—In continuation of the above discussion another pineapple disease is discussed, ascribed to the same causal organism, which frequently enters through the cut end of the stem and passes with great rapidity up through the core, spreading through the softer tissues and producing a water-soaked appearance; also entering readily through wounds and bruises and even through the uninjured fruit surface.

Care in handling includes cutting off and searing or waxing the stems. The fruit should cool and dry for 24 hours before packing, and should be protected from bruising or rubbing without greatly interfering with the circulation of air. Fumigation with formaldehyde gas has been found helpful, and directions for this are given.

Cladosporium disease of *Ampelopsis tricuspidatum*, M. T. COOK and G. W. WILSON (*Phytopathology*, 4 (1914), No. 3, pp. 189, 190, fig. 1).—In continuation of a previous note (*E. S. R.*, 31, p. 347), the authors report having had their attention called to the dying of Japanese ivy on buildings of Rutgers College and other buildings in the vicinity.

The disease first appeared as a wilting of the leaves, which might be confined to a small branch or might extend to a main trunk and all its branches. Within a few days all the diseased parts were dead and dry. A fungus was isolated from diseased material, and it was found to agree rather closely with the description of what is usually given as *C. herbarum*.

Spontaneous decapitation of chrysanthemums, R. FARNETI (*Riv. Patol. Veg.*, 6 (1913), No. 10, pp. 289-292).—Fall of the floral heads of chrysanthemums at flowering, due to rupture of the peduncles, led to a study of the phenomenon. It is thought that an irritative and toxic influence is exerted by a *Cladosporium* found in connection with the trouble, also that a part is played by turgescence at such times.

Black rot of roses, J. BEAUVERIE (*1. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 965-967, fig. 1).—Reporting on an examination of diseased roses sent in for this purpose, the author states that the flowers showing the peduncle disease formerly attributed to *Botrytis cinerea* (*E. S. R.*, 24, p. 351) now showed no mycelium in the diseased peduncles, and that these portions, when kept in a confined atmosphere, either dry or moist, produced no *Botrytis*, but that this fungus was noted in adjacent green portions. Further investigation, as regards the immediate nature or cause of the disease and its remedies, is considered necessary.

A study of a rose disease, J. BEAUVERIE (*1. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 968-971, figs. 2).—A brief account is given of a disease of roses attributed to *Coryneum microstictum*.

A Glæosporium disease of the spice bush, J. J. TAUBENHAUS (*Amer. Jour. Bot.*, 1 (1914), No. 7, pp. 340-342).—The author reports on a study of diseased spots

on the fruit, leaves, and tender twigs of the spice bush. This is claimed to be due to an active parasite identical with *G. officinale* from the sassafras, and also with *G. fructigenum*, which causes bitter rot of the apple.

A disease of *Gerbera*, L. MAFFEI (*Riv. Patol. Veg.*, 6 (1913), No. 9, pp. 257-259).—A brief account with description is given of a fungus, *Ascochyta gerberae* n. sp., attacking leaves of *G. jamesoni*, recently introduced into Italy from South Africa.

A disease of *Washingtonia*, G. POIRAULT and A. SARTORY (*1. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 971, 972).—Two species of *Washingtonia*, *W. filifera* and *W. robusta*, are said to show progressive attack from a disease decolorizing the leaves and suspected to be due to a *Penicillium*.

Notes on some diseases of trees in our National Forests, IV, G. G. HEDGCOCK (*Phytopathology*, 4 (1914), No. 3, pp. 181-188).—In continuation of a previous report (E. S. R., 29, p. 851), the author gives an account of the infection of various forest trees by *Herpotrichia nigra*, *Neopeckia coulteri*, *Fomes pinicola*, *F. fomentarius*, *F. applanatus*, *Polyporus schweinitzii*, and *F. roseus*. Most of these fungi are found parasitic on various species of coniferous trees.

Bark disease of the chestnut in British Columbia, J. H. FAULL and G. H. GRAHAM (*Forestry Quart.*, 12 (1914), No. 2, pp. 201-203).—Specimens of bark taken from diseased chestnut trees at Agassiz, British Columbia, have been examined, and all tests so far made indicate that the fungus is identical with *Endothia parasitica*, the cause of the chestnut bark disease. The trees growing at Agassiz are of Oriental, European, and American origin. Inoculations constituting the final tests are to be reported on later.

Pathological histology of the *Endothia* canker of chestnut, W. E. KEEFER (*Phytopathology*, 4 (1914), No. 3, pp. 191-200, figs. 3).—The author describes the different anatomical conditions shown in the bark and sapwood of chestnut when attacked by *E. parasitica*.

In an experiment conducted to determine the depth to which the fungus penetrates into the wood, it was found that the average depth of penetration for about 20 logs was approximately $\frac{1}{2}$ in., the greatest penetration being about $\frac{1}{2}$ in. The deepest penetration was found in the smaller limbs.

Damage due to oak mildew in Hungary, F. KÖVESSI (*1. Cong. Internat. Pathol. Comparée [Paris]*, 1912, vol. 2, *Comp. Rend.*, pp. 924-936).—Giving a brief account of the spread in Europe of oak mildew after its appearance about 1907, with comments on its possible relations to altitude, weather, caterpillars, etc., the author states that among the more susceptible of European oaks are *Quercus tozza*, *Q. pedunculata*, *Q. sessiliflora*, *Q. pubescens*, *Q. contorta*, *Q. cerris*, *Q. ilex*, *Q. suber*, and *Q. coccifera*. The American oaks are said to be more resistant than natives. *Fagus sylvatica* and *Castanea vulgaris* appear to be rarely attacked.

Of the various remedies mentioned, flowers of sulphur is said to be the cheapest and most efficacious in this connection.

An extensive bibliography is given.

Notes on economic fungi, M. T. COOK (*Phytopathology*, 4 (1914), No. 3, pp. 201-203, figs. 2).—A brief account is given of the crown gall due to *Pseudomonas tumefaciens* on Bolleana poplars, and of the occurrence of a sclerotium which contained a mass of well developed asci containing spores in potatoes infected by *Rhizoctonia*.

North American species of *Peridermium* on pine, J. C. ARTHUR and F. D. KERN (*Mycologia*, 6 (1914), No. 3, pp. 109-138).—Sixteen species are described, of which *P. californicum* and *P. guatemalense* are considered to be new species. A host index is given of species of *Peridermium* on species of pines.

Purchase and use of liver of sulphur (*Jour. Bd. Agr. [London]*, 21 (1914), No. 3, pp. 236-241; noted in *Agr. News [Barbados]*, 13 (1914), No. 320, pp. 254, 255).—The results are given of tests made to determine the effects of exposure by loose corking, etc., on stored potassium sulphid.

The solution, when kept in vessels covered but not corked for 18 days, deposited sulphur, and ultimately lost much or all of its value as a fungicide. It is therefore held that solutions of liver of sulphur should be prepared just before they are to be used, or the solutions, if made beforehand, should be kept in full, tightly corked bottles. Liver of sulphur in solid form should be kept in bottles or lever-topped tins of small capacity, say from 0.5 to 1 lb. capacity, to be opened just before use.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Animal geography: The faunas of the natural regions of the globe, MARION I. NEWBIGIN (*Oxford, England, 1913*, pp. 238, pls. 31, figs. 13).—In this book the author attempts to put the main facts connected with the distribution of animals in a form acceptable to the geographical student. It deals with the subject under the following chapter headings: The tundra and its fauna; the taiga, or coniferous forest, and its fauna; steppe faunas and the Temperate steppes of Asia and North America; mountain faunas; the fauna of the tropical forest; tropical savannas and deserts; special features of island faunas; the distribution of animal life in the sea; the animals of lakes and rivers and cave faunas; and zoogeographical regions.

[Game in California] (*Cal. Fish and Game Comrs. Game Bul. 1 (1913)*, pp. 67, figs. 14).—The several papers here presented are as follows: Investigation of the Large Game Situation in California with Special Reference to Deer, by F. C. Clarke (pp. 6-20); The Present and Future Status of the California Valley Quail, by H. C. Bryant (pp. 21-34); Introduction of Foreign Game Birds into the Southern San Joaquin and Tributary Sections, by A. D. Ferguson (pp. 36-40); Educating the Young People as to the Need and Value of Wild Life Conservation, by Gretchen L. Libby (pp. 41-46); and Investigation of the Economic Status of Nongame Birds, by H. C. Bryant (pp. 47-67).

The food of the common mole, P. B. WHITE (*Jour. Bd. Agr. [London]*, 21 (1914), No. 5, pp. 401-407).—The results of studies of the food of 100 individuals of the common mole (*Talpa europea*) collected in two localities are presented in tabular form. "It is clear that earthworms and, in the moles examined, leather jackets are to be looked upon as the staple articles of diet, these appearing in 92 per cent and 87 per cent of the stomachs, respectively. Centipedes came next in 50 per cent and wireworms in 41 per cent of the stomachs."

The control of rodents in field seeding, C. P. WILLIS (*Proc. Soc. Amer. Foresters*, 9 (1914), No. 3, pp. 365-379).—"Rodents and white-footed mice in particular destroy a large percentage of our field-sown seeds. The rodent loss is so high that it guarantees failure of seeding. Either the rodent must be controlled or seeding must be given up.

"Rodents have such keen noses that it is impracticable to hide seed from them by burying it deeply or by disguising its odor. It is possible that a substance poisonous or distasteful to rodents may yet be found effective for coating seeds. Up to the present no satisfactory coating has been discovered. Sowing seed incased in screen wire has little to commend it. Wholesale poisoning of rodents is ineffective. Many, but too few, animals can be poisoned. Mulching the seed-spot has a slightly beneficial effect. Covering the seedspot with tar roofing paper has given excellent protection to the seed. This method has disadvantages, however, which need further study. Complete protection is given by

covering the seedspots with a wire cone 8 in. high and 8 in. in diameter, sunk 2 in. deep in the ground, but this is too costly for general use.

"It is significant that attempts to render the seed repulsive or poisonous to the rodent have failed; that wholesale poisoning of an area has failed; but that efforts to guard the seedspot have been more successful. It is at this point that the study should be taken up, if it is hereafter continued."

Necessity for and constitutionality of the act of Congress protecting migratory birds, G. SHIRAS, 3RD (*New York, 1914 pp. 99*).—Part one of this pamphlet deals with the necessity for the migratory bird law and part two with the constitutionality of the federal law. The regulations for the protection of migratory birds (E. S. R., 29, p. 554), the text of the original Shiras bill and of the Weeks-McLean bill (E. S. R., 28, p. 302), the report of the advisory committee of fifteen on the preparation of regulations by the Department of Agriculture for the protection of migratory birds, etc., are appended.

The relation between lizards and *Phlebotomus verrucarum* as indicating the reservoir of verruga, C. H. T. TOWNSEND (*Science, n. ser., 40 (1914), No. 1023, pp. 212-214*).—It is stated that numerous blood smears made during the previous two or three months from small rock lizards of several species collected in four localities in Peru, three of which are within the verruga zone and the fourth just outside of that zone, all show small rod and granule bodies which exhibit the identical morphology of the bodies which have been named *Bartonella bacilliformis*.

"In Verrugas Canyon there are, close to the house, many large walls built of loose rock wherein the *Phlebotomus* hide in swarms during the day, issuing in the evening to enter the house and bite the inmates. These rock walls are also inhabited by the small lizards in question."

Subcutaneous injection of a young guinea pig with a large quantity of citrated lizard blood proved fatal within ten hours, liver smears showing the rods and granules, but blood, marrow, and spleen smears proving practically negative.

The author points out that on a priori grounds the inference is logical that the lizards constitute a verruga reservoir.

The relation of temperature to insect life.—I, The variation in velocity of development at different constant temperatures, E. D. SANDERSON and L. M. PEAIRS (*New Hampshire Sta. Tech. Bul. 7 (1913), pp. 125, figs. 46*).—This bulletin presents details of studies, accounts based upon which have been previously noted (E. S. R., 20, p. 851; 23, p. 358). Part 1 (pp. 3-9) gives a history and descriptions of the work; part 2 (pp. 10-41) a summary of the conclusions and of illustrations; part 3 (pp. 42-93) a summary of all the data obtained at the New Hampshire Station, upon which the studies are based; and part 4 (pp. 94-125) temperature records.

The following conclusions have been drawn: "The velocity of development, within what may be termed the normal limits, depends, other factors being equal, upon the temperature. It increases directly with the temperature, the curve for the increase within normal limits being a true mathematical hyperbole. The factor or index of development for any point on this curve is the reciprocal for that point. Thus, the reciprocal curve includes all the indexes for the curve. This reciprocal, assuming that we are correct in our first conclusion, that the curve is always a true hyperbole, takes, by definition, the form of a straight line; the inclination of this line to the axes of the curve being governed by the rapidity of development of the insect and stage. The developmental zero for the insect and stage approximates the point where the reciprocal curve (calculated from the time factor) intersects the temperature axis. The thermal constant is the constant for the curve, that is, the product of the time and temperature factors. That is, for a hyperbole, always constant.

The curve for any stage of any insect at constant temperatures can be platted by the establishment experimentally of any two points, or, if the developmental zero be known, by the establishment of any one point.

"The foregoing conclusions are primarily for constant temperature conditions. While we have less proof, the data seem to show that for temperatures showing a daily variation the effective temperature is somewhat higher than the daily mean. On the other hand, when the change is not in the nature of a daily variation, but rather a change of constant temperatures for longer periods of time we find that the results work out properly for the original hyperbolic curve. . . .

"Finally, it must be borne in mind that all temperature factors and calculations involving them must be based on degrees above the developmental zero. This may be seen in the calculation of the thermal constant."

Utilization of certain phytophagous insects in combating the enemies of cultivated plants, A. VUILLET (*Rev. Sci. [Paris]*, 52 (1914), I, No. 17, pp. 526-530; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, p. 345).—A general discussion.

Some attempts to control injurious insects by means of their natural enemies, T. A. C. SCHOEVERS (*Tijdschr. Plantenziekten*, 19 (1913), Nos. 3, pp. 91-96; 4, pp. 109-130; *abs. in Rev. Appl. Ent.*, 1 (1913), Ser. A, No. 10, p. 376).—A discussion of the subject with a summary of experimental work.

Proceedings of the Entomological Society of British Columbia (*Proc. Ent. Soc. Brit. Columbia*, n. ser., No. 3 (1913), pp. 46).—Among the more important papers here presented are Combination Sprays and Recent Insecticide Investigations, by H. F. Wilson (pp. 9-17); Methods of Taking Insect Records in the Field, by R. C. Treherne (pp. 21-24); Some Problems in Aphis Control, by L. L. Palmer (pp. 31-34); Two Injurious Insects of Economic Importance Attacking Peach, Apricot, and Plum Trees, namely, the peach twig moth and the peach borer, by W. H. Lyne (pp. 34-36); Cutworms and Their Control, by M. S. Middleton (pp. 36, 37); and The Economic Importance of Canadian Ipidae, by J. M. Swaine (pp. 41-43).

Phytopathological report for the year 1913, P. MARCHAL (*Rev. Phytopath. Appl.*, 1 (1914), No 18-19, pp. 9-13; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 7, pp. 420-422).—This annual report (*E. S. R.*, 30, p. 154) deals with the more important insects of the year.

Recent work of the Royal Entomological Station of Hungary, J. JABLONOWSKY (*Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 3, pp. 316-320).—This is a discussion of work with control measures for insect pests and rodents, which was carried on during 1913.

[Observations on the insect enemies of field crops and orchards during 1913], V. V. DOBROVLIANSKY (*Khovtáistvo*, 1914, No. 10, pp. 332-338; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, pp. 341-343).—This is a report of work conducted at the Kief Station during 1913.

The insect enemies and diseases of plants in the Government of Taurida during 1913, I. M. SHTCHEGOLEV (*Otchet Diētáeln. Pomoshch. Gubern. Ent. [Taurida] Zemstva*, 1913, pp. 24; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 5, pp. 329-331).—Among the pests mentioned as causing damage to plants during the year are the gypsy moth, *Hoplocampa brevis*, *Anthonomus pomorum*, the codling moth, *Eriocampa adumbrata*, *Luperus rufipes*, *Choreutis parialis*, etc.

Preliminary studies of the enemies of clover, G. DEL GUERCIO (*Atti R. Accad. Econ. Agr. Georg. Firenze*, 5. ser., 11 (1914), No. 2, pp. 133-183, figs. 39).—The more important insect enemies of *Trifolium* here discussed are the aphidids *Rizoberlestia trifolii* and *Aphis scallæ* n. sp., *Apion* spp., and the clover root borer, *Hylastes trifolii*.

Some experiments with maize stored in bins, A. J. GROVE (*Agr. Jour. India*, 9 (1914), No. 1, pp. 92-98).—The author states that in tests made at the Pusa farm of the efficiency of naphthalin and carbon bisulphid in destroying insects in stored maize it was found that 1 lb. of flake naphthalin distributed in corn in cylindrical bins 6 ft. high by 3 ft. in diameter was practically as effective and more satisfactory to handle than fumigation with carbon bisulphid at the rate of 5 lbs. per 1,000 cu. ft.

Enemies of mustard and means of combating them, N. SACHAROV (*Abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, pp. 355-358).—A preliminary report based on investigations at the Astrakhan Entomological Station.

Onion pests (*Wisconsin Sta. Bul.* 240 (1914), pp. 44-46, figs. 2).—In attempts to control the onion maggot (*Pegomya cepetorum*) which, together with the onion thrips, threatens the destruction of the onion crop in Wisconsin, experiments were made with sweetened arsenicals. For this purpose $\frac{1}{4}$ pint of blackstrap molasses was added to 1 gal. of water and to this arsenical poisons were added, 1 gm. of sodium arsenite proving to be the most effective. It is stated that both sexes are very greedy for the sweets, and gorging themselves until their abdomens are greatly extended, are killed within three to ten hours after the ingestion of the poison.

Two insect pests of sugar beets from Turkestan new to Russia, E. M. VASSILIEV (*Věstník Sakhar. Promysh.*, No. 3 (1914), pp. 68-75; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 248, 249).—This article relates to the injury caused by *Laphygma exigua* and *Phlyctenodes nudalis*.

Manual of fruit insects, M. V. SLINGERLAND and C. R. CROSBY (*New York*, 1914, pp. XVI+503, figs. 396).—This work, prepared in part by the senior author just prior to his death and completed by the junior author, treats of the more important insects injurious to deciduous fruits. In the preparation of this work the aim has been to give in as concise form as possible the main facts relating to the distribution, life history, and habits of the insect, the nature and extent of its injury, and means of control from the standpoint of the commercial fruit grower.

The first five chapters deal with apple insects and are followed by chapters on pear and quince, plum, peach, cherry, raspberry, blackberry, dewberry, currant, gooseberry, strawberry, grape, and cranberry insects, and insecticides.

The xylophagous insect enemies of the vine, J. FEYTAUD (*Rev. Vit.*, 41 (1914), Nos. 1046, pp. 5-7, pl. 1, figs. 2; 1047, pp. 41-45, figs. 7; 1049, pp. 94-99, figs. 3).—This is a general account of the more important wood-attacking enemies of the grapevine in France.

Insects injurious to camphor (*Cinnamomum camphora*), A. RUTHERFORD (*Trop. Agr. [Ceylon]*, 42 (1914), No. 6, pp. 463-468).—The enemies of the camphor tree in Ceylon include a thrips, probably *Cryptothrips floridensis*; a leaf miner (*Acrocercops* sp.); the large bagworm (*Clania variegata*); a bagworm, probably *Amatissa consorta*; and *Xyleborus compactus*.

The most common insects pests of pine and fir cones, I. TRÄGÅRDH (*Skogen*, 1 (1914), No. 2, pp. 42-50, figs. 5; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 4, pp. 242, 243).—The author discusses the injury caused in Sweden by *Pissodes validirostris*, *Grapholitha (Laspeyresia) strobilella*, *Phycis (Dioroctria) abletella*, an undetermined chalcidid of the genus *Megastigmus*, etc.

Ants and bees as carriers of pathogenic micro-organisms, W. M. WHEELER (*Amer. Jour. Trop. Diseases and Prev. Med.*, 2 (1914), No. 3, pp. 160-168).—A paper read before the American Society of Tropical Medicine, at Boston in May, 1914, in which the author presents a general discussion of the subject.

Destruction of locusts in Turkestan, J. P. BARSACQ (*Internat. Inst. Agr. [Rome]*, *Mo. Bul. Agr. Intel. and Plant Diseases*, 5 (1914), No. 4, pp. 558-564).—

An account of the campaign against locusts in Turkestan, including mechanical and chemical means, and a discussion of natural enemies.

The Morocco locust (*Stauronotus maroccanus*) is the most important species. The migratory locust (*Pachytylus migratorius*) possesses several permanent areas of distribution in Central Asia but this species rarely damages crops, preferring the shoots of reeds which occur in abundance near the egg-laying areas. The Italian locust (*Caloptenus italicus*) is a common species in Turkestan but until recently has only caused a small amount of injury. A number of other species are injurious though not to the same extent as the three above mentioned.

A note on the relation between the tea mosquito (*Helopeltis theivora*) and the soil, E. A. ANDREWS (*Indian Tea Assoc., Sci. Dept. Quart. Jour., No. 1 (1914), pp. 31-35*).—Investigations of the factors controlling the activities of the tea mosquito in causing blight indicate that tea planted in soil in which the ratio of available potash to available phosphoric acid is low will be more likely to be attacked by mosquito blight than tea planted in soil in which this ratio is high. It is suggested that this condition may be remedied by the application of potash manures.

Aleurodes vaporarium, an enemy of *Azales indica*, VAN HOVE (*Rev. Hort. Belge, 39 (1913), No. 24, pp. 392, 393; abs. in Internat. Inst. Agr. [Rome], Mo. Bul. Agr. Intel. and Plant Diseases, 5 (1914), No. 3, p. 417*).—This white fly, which is well known to Belgian azalea growers, is said to have been very abundant in the autumn of 1913.

A new sugar cane aphid, H. F. WILSON (*Ent. News, 25 (1914), No. 7, pp. 298, 299, pl. 1*).—An aphidid collected on sugar cane at New Orleans, La., is described as *Aphis bituberculata* n. sp.

European caterpillars and their food plants, P. BLASCHKE (*Die Raupen Europas mit ihren Futterpflanzen. Annaberg, Germany, 1914, pp. [14]+XXIX+264+75, pls. 34*).—The first part of this work (pp. 1-264) consists of a caterpillar calendar in which are given brief descriptions of the European forms, notes on their occurrence and food plants from month to month, etc. The second part (pp. 1-75) lists alphabetically and describes the food plants with the caterpillars occurring on each. Indexes to the German and technical names of the lepidopterans and the German names of the food plants are appended to the two parts.

Six colored plates of caterpillars representing 156 species and 28 colored plates of food plants in bloom, with indexes to both, are included.

Instructions for rearing mulberry silkworms, M. N. DE (*Agr. Research Inst. Pusa Bul. 39 (1914), pp. 25, pls. 4, figs. 3*).—A work prepared for use by those engaged in silk culture.

Grapholitha leplastriana, an enemy of cauliflower, G. CECCONI (*Bol. Lab. Zool. Gen. e Agr. R. Scuola Sup. Agr. Portici, 7 (1913), pp. 125-148, pl. 1; abs. in Rev. Appl. Ent., 2 (1914), Ser. A, No. 6 pp. 347, 348*).—The caterpillar of this moth, supposed to live on wild cabbage (*Brassica oleracea silvestris*) exclusively, has been found by the author to attack cauliflower at Fano in the Province of Marches.

Borer in san, M. M. DESAI (*Poona Agr. Col. Mag., 6 (1914), No. 1, pp. 39, 40*).—During the course of a rotation experiment with san as a green manure crop it was seriously injured by the attack of an undetermined lepidopterous larva which bores into the buds and shoots. Caterpillars of *Argyna cribrata* were also a source of injury.

Miscible oil spray for fruit tree leaf roller (*Archips argyrospila*), G. P. WELDON (*Mo. Bul. Com. Hort. Cal., 3 (1914), No. 7, pp. 285, 286, fig. 1*).—

Larvæ failed to hatch out from egg masses of *A. argyrosipila* treated with miscible oil applied at the rate of 1:20.

Borer in jowar, M. M. DESAI (*Poona Agr. Col. Mag.*, 6 (1914), No. 1, pp. 41-43).—The sugar borer *Chilo simplex* is reported to have injured the jowar or Indian millet crop which is a staple human food and also a great source of fodder for cattle in the Surat District.

A light trap for catching cutworm moths, G. P. WELDON (*Mo. Bul. Com. Hort. Cal.*, 3 (1914), No. 7, pp. 284, 285, fig. 1).—An illustration is given of a trap used in sugar beet fields at Oxnard, Cal. This consists of a shallow galvanized iron pan about 4 ft. in diameter set on a platform a few feet above the ground, over which is hung a gas burner inclosed in a globe and connected with a tank within the frame, in which acetylene gas is generated.

It is stated that on the morning of May 18 from 1,200 to 1,500 moths were found to have been trapped during the night. A trap placed on a beet dump with an electric light to attract the moths is said to have caught as high as 7,000 moths during a single night. Most of the moths are said to represent the cutworm species *Peridroma saucia*.

The Hessian fly in Missouri, L. HASEMAN (*Missouri Sta. Circ.* 70 (1914), pp. 21-24, fig. 1).—A brief popular account of the Hessian fly, the most destructive enemy of wheat in Missouri.

Natural enemies of Simulium.—Notes, F. M. WEBSTER (*Psyche*, 21 (1914), No. 3, pp. 95-99).—The author here brings together miscellaneous notes on personal observations of the natural enemies of Simulium.

A new schizogregarine (Caulleryella aphiochætæ n. g. and n. sp.), an intestinal parasite of the larva of a cyclorrhaphous dipteran (Aphiochæta rufipes), D. KEILIN (*Compt. Rend. Soc. Biol. [Paris]*, 76 (1914), No. 16, pp. 768-771, figs. 12).—A report of studies of a gregarine found in the intestines of a phorid (*A. rufipes*).

Leprosy: Flies in relation to the transmission of the disease, J. A. HONEIJ and R. R. PARKER (*Jour. Med. Research*, 30 (1914), No. 2, pp. 127-130).—This is a preliminary report of studies conducted at the Penikese Hospital Laboratory.

Of 95 flies used in the work, 59 were *Musca domestica*, 3 *Muscina stabulans*, 30 *Stomoxys calcitrans*, 2 *Lucilia* sp., and one an undetermined sciomyzid. The study shows that a fly will feed continuously for from 3 to 31 minutes; that the digestive tract was completely emptied in from 52 to 72 hours; that the average number of excreta deposits was for the *M. domestica* male during 46 hours 25+ and for the female 35+ (during the first 24 hours the greatest number of ejections occurred and after the first 8 hours), and for the *S. calcitrans* male during 61 hours 40+ and for the female 86+ (during the first 24 hours the greatest number of ejections occurred and after the first 3 hours); and that the average time after feeding before the first ejection varies considerably between 5 and 45 minutes, but the average is about 13 minutes. "It was found that of 12 flies of different species caught in the rooms of patients only 2 (*M. domestica*) showed the acid-fast bacilli in the excreta deposits, and that of 6 flies (also *M. domestica*) allowed to feed on the lesions of patients the excreta gave negative results. . . . From the 41 flies fed on the contents of pustules the best results were obtained. Of 21 flies (*M. domestica*) 15 were negative and 6 positive. Of *S. calcitrans* 20 were used which gave 4 negative and 16 positive results. Of another series of six flies (three of each species), two gave positive findings, two questionable acid-fast bacilli, and two were negative. . . . In no other species of flies other than *M. domestica* and *S. calcitrans* were the acid-fast bacilli found in the excreta."

Adia genitalis and *Leptohylemyia coarctata*, N. V. KURDŪMOV (*Trudy Poltav. Selsk. Khoz. Opytn. Stantsii*, No. 21 (1914), pp. 43, figs. 27; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, pp. 350-353).—A report of studies from the Poltava Station of two dipterous enemies of wheat.

An investigation into the relationship of the house fly to disease—the special importance of the fly in infant welfare, D. B. ARMSTRONG (*Amer. Jour. Pub. Health*, 4 (1914), No. 3, pp. 185-196).—The author presents the results of preliminary investigations carried on in New York City by the Bureau of Public Health and Hygiene, and in conclusion states that the Bureau is convinced of the necessity of continuing the studies on a larger, more comprehensive, and complete scale for at least one other fly season before definite positive conclusions can be reached.

Combating elaterid larvæ, D. BORODIN (*Khutorianin*, No. 12 (1914), p. 332; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, p. 344).—The author states that elaterid larvæ may best be combated by poisoned or other baits, consisting of slices of potatoes, carrots, beets, oil cakes, cabbage stalks, etc., buried in various parts of the field to a depth of 3 or 4 in. "These baits are poisoned by adding to them either Paris green or arsenic, in which case they need no further attention. In case of unpoisoned baits they must be inspected practically every week and the larvæ found on them destroyed with boiling water. [The author] also recommends maize baits, prepared as follows: About 0.25 lb. of white arsenic and 2.5 lbs. of maize well boiled in about 2.5 gals. of water, care being taken not to inhale the vapor. The baits can be best used in autumn and spring, before sowing or even afterwards, so long as the seedlings are not too high."

Orchard bark beetles and pin hole borers, H. A. GOSSARD (*Ohio Sta. Bul.* 264 (1913), pp. 68, figs. 22).—This bulletin reports studies carried on in cooperation with the Bureau of Entomology of this Department, represented by H. F. Wilson, who was stationed in the infested region during the spring, summer, and fall of 1908, a report by whom on the peach bark beetle has been previously noted (*E. S. R.*, 20, p. 955). The investigation was continued by L. L. Scott in the summer of 1909, by R. D. Whitmarsh during the seasons of 1910 and 1911, and by J. L. King during the seasons of 1912 and 1913.

The fruit bark beetle (*Eccoptogaster rugulosus*) is first dealt with (pp. 6-30). This pest, often called the shot hole borer, is the most common and attacks nearly all species and varieties of orchard fruits. The peach bark beetle, which ranks second in importance in Ohio, is next taken up at length (pp. 31-59). A few other nearly related species, known as pin hole borers, have somewhat similar habits but are of minor importance. These considered, briefly, are the banded pin hole borer (*Monarthrum fasciatum*), the apple pin hole borer, or apple strainer (*M. mali*), and the pear blight beetles *Xyleborus dispar* and *X. pyri*. These pin hole borers made their burrows in the heartwood, but the external openings through the bark resemble the exit holes of the shot hole beetles, except that they are smaller. The twig borers, namely, the apple twig borer (*Amphicerus bicaudatus*) and the red shouldered sinoxylon (*Sinoxylon basilare*) are also briefly noted.

The biologies of the fruit and peach bark beetles are summarized by the author as follows: "There are two broods per season of the fruit bark beetle (*E. rugulosus*), the adults of the first brood appearing during the latter half of May, and in maximum numbers during the first half of June, the brood being practically over by that time, though a few females linger for a month longer. Eggs are laid in a few days after the appearance of the females and hatch in three or four days. Each female deposits from 30 to over 100 eggs, with an average of about 75 to 90. The larvæ mature in 30 to 36 days after

hatching and pupate in the burrows. The pupal period lasts from seven to ten days, and the beetles of the second brood commence to appear about the middle of July and continue to issue until late August or early September. Some of the beetles of this brood may linger until late October. The progeny of this brood hibernate as larvæ in the bark and develop into the early brood of beetles the next May and June.

"The peach bark beetle hibernates in the beetle form in special cells in the bark, becoming active in late March and early April. The beetles at once commence excavating burrows in dead or living wood, but use only dead or dying wood for incubation burrows. They commence laying eggs about the twentieth of April and each female will, under normal conditions, deposit from 80 to 160 eggs. These eggs hatch in a few days and the larvæ require 25 to 30 days to become grown. The pupal period extends over four to ten days, and the beetles of the summer brood appear about the middle of July, maximum emergence occurring during the latter part of August. Beetles continue to appear irregularly until October. The progeny of this brood of beetles are larvæ during the fall months and mature as beetles upon the approach of cold weather, but do not leave their hibernation cells until the following spring."

The remedial measures are summarized as follows: "Probably the most important measure to prevent multiplication of all these beetles is to burn promptly all prunings, dead wood, and dying trees. Attacked orchards can be successfully reclaimed from attack by cultivation, by liberal fertilization with barnyard manure and commercial fertilizer, and by whitewashing or spraying with carbolized soapy mixtures. Treatment should commence in the spring. Prune severely, spray before the leaves appear, and apply a heavy coat of whitewash to the trunks and larger branches in early April. Cultivate and fertilize as soon as the ground is in suitable condition; apply a second coat of whitewash or other repellent in early July and a third about September 1. Apply thick whitewash with a broom; thin mixture may be applied with a spray pump, but should be repeated until a good coating is secured."

Orchard bark beetles and pin hole borers, H. A. GOSSARD (*Ohio Sta. Circ.* 140 (1913), pp. 16, figs. 10).—This is an abridgment of the bulletin noted above.

[Studies of *Sciaphobus squalidus* at the Poltava Agricultural Experiment Station], A. V. ZNAMENSKIÏ (*Trudy Poltav. Selsk. Khoz. Opytn. Stantsii*, No. 20 (1914), pp. VI+32, pls. 2, figs. 5; *abs. in Rev. Appl. Ent.*, 2 (1914), Ser. A, No. 6, pp. 337-339).—This paper presents the results of three years' work on this weevil enemy of fruits, its bionomics, enemies, etc.

Note on a chalcidid parasite of the pea thrips [*Frankliniella robusta*], A. VUILLET (*Compt. Rend. Soc. Biol. [Paris]*, 76 (1914), No. 13, pp. 552-554, figs. 3).—A new parasite reared from *F. robusta* in France during the season of 1913 is described as *Thripoctenus brui*. Reference is made by the author to the work by Russell, previously noted (*E. S. R.*, 27, p. 262).

The acrobat ant (*Agr. News [Barbados]*, 13 (1914), No. 323, p. 298).—An undetermined species of the genus *Cremastogaster* is said to be injurious to trees in the Lesser Antilles, chiefly by preventing cuts in the bark from healing over. In addition to the injury to trees, they seem to hasten the decay of timber in buildings.

The sheep tick (*Jour. Dept. Agr. So. Aust.*, 17 (1914), No. 9, pp. 904-909, figs. 4).—This article consists of accounts of (1) the life history of the sheep tick (*Malophagus ovinus*) by F. E. Place, (2) its effect on sheep by H. Jackson, and (3) the occurrence of the tick in South Australia by T. H. Williams.

Eriophyes ribis on *Ribes nigrum*, MISS A. M. TAYLOR (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 121-128).—A report of studies of the life history and habits of the black currant mite and the injury which it causes.

Eriophyes ribis on *Ribes grossularia*, MISS A. M. TAYLOR (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 129-135, fig. 1).—The author reports that during 1912 gooseberries were seriously deformed by an attack of *Eriophyes*. When attacked by this mite the leaves and shoots of the gooseberry (*R. grossularia*) are severely blistered and deformed, whereas the black currant (*R. nigrum*) shows no sign of injury. No phenomenal growth of the buds of the gooseberry takes place when attacked, whereas the black currant develops abnormal buds, known as "big buds."

"Migration by the agency of the wind is the general method of distribution employed by the mite on *R. nigrum*. The same habit is observed to a limited extent on *R. grossularia*, the general method being that of crawling from the scale leaves of the attacked bud to the shoot developing from it."

FOODS—HUMAN NUTRITION.

Bacteriological methods for meat analysis, J. WEINZIRL and E. B. NEWTON (*Amer. Jour. Pub. Health*, 4 (1914), No. 5, pp. 408-412).—The results are reported of the development of a method for determining the bacterial content of meat, in which the meat was ground in a mortar with sterile sand and normal salt solution to obtain an emulsion for inoculation into the culture media.

Bacteriological analyses of hamburger steak with reference to sanitary conditions, J. WEINZIRL and E. B. NEWTON (*Amer. Jour. Pub. Health*, 4 (1914), No. 5, pp. 413-417).—Employing the method described above, the authors determined the bacterial content of 44 samples of market hamburger steak. Comparisons were also made of the value of the organoleptic test, the ammonia test, and the bacterial content in determining the degree of decomposition of the meat.

The conclusions drawn are in part as follows:

The standard of 1,000,000 bacteria per gram, advocated by some as a limit, is apparently too low, since it would condemn nearly all samples of hamburger, when showing no taint or other evidence of putrefaction. Samples of other market meats, all of which would otherwise pass inspection, often exceed this limit.

The organoleptic and the ammonia tests agree fairly well, but as meat may be actually putrid and may contain millions of bacteria per gram before responding to them, they appear to be too liberal, and a stricter standard would be desirable.

A bacterial standard of 10,000,000 per gram as the limit is proposed, on the basis of which 50 per cent of the market samples of hamburger would still be condemned. This is justified on the following grounds: (a) Much of it is actually spoiled when it reaches the consumer or is to be cooked; (b) meat teeming with 10,000,000 bacteria per gram is potentially rotten and soon will be actually spoiled under ordinary methods of handling; (c) the fact that markets are prone to add sodium sulphite to hamburger, even though the dealer knows it to be contrary to law, indicates that something is wrong with the hamburger; and (d) finally, if hamburger were made from wholesome meat in the first place, then kept properly iced, it is believed that the bacterial content could readily be held within the 10,000,000 limit.

Studies of bouillon cubes, P. SACCARDI (*Arch. Farmacol. Sper. e Sci. Aff.*, 17 (1914), No. 5, pp. 229-240).—Analytical data are given concerning several commercial brands of bouillon cubes. Determinations were made of potassium, chlorine, phosphoric acid, and iron as well as of water, total organic matter, nitrogen fat, and ash.

The decline in the gluten content of flour, BALLAND (*Jour. Pharm. et Chim.*, 7. ser., 9 (1914), No. 10, pp. 510-514).—Statistical data are summarized and briefly discussed.

The bacterial content of flour, L. DIETZEL (*Ueber den Bakteriengehalt des Mehles. Inaug. Diss., Univ. Würzburg, 1912, pp. 26; abs. in Hyg. Rundschau, 24 (1914), No. 9, p. 535*).—Experimental methods are described. The author did not determine the nature of the micro-organisms isolated.

Cause of the poor baking quality of flour from wheat and rye of the 1913 harvest, H. KÜHL (*Ztschr. Öffentl. Chem.*, 20 (1914), No. 9, pp. 162-167).—Bacterial contamination of the samples was very noticeable, and the author studied the possible relation of this factor to the quality of the bread.

Municipal bread making in Catania, G. DE F. GIUFFRIDA (*Municipalizzazione del Pane a Catania. Milan, 1913, pp. 244*).—This book treats extensively of the various aspects of municipal bread making in general, and in detail discusses the practice as carried out in the Province of Catania, Italy.

Among the subjects herein treated are a historical review of the development of municipal bread baking and its economical and social aspects, including its influence upon labor conditions, social hygiene, and price of bread.

Cotton-seed flour as a possible food for man, C. A. WELLS (*Jour. Indus. and Engin. Chem.*, 6 (1914), No. 4, pp. 338, 339).—Although cotton-seed flour is high in protein, the fact is pointed out that it has no gluten-like substance and that therefore it must be mixed with wheat flour in bread making. The author regards cotton-seed flour as an economical source of protein. Though in his experience the use of limited amounts has proved wholesome, he notes that, reasoning from what has been observed in experiments with animals, large amounts might have deleterious effects, and states that the question of the toxicity of cotton-seed meal is under investigation.

Rice and rice cookery, MIRIAM BIRDSEYE (*Cornell Reading Courses, 3 (1914), No. 55, pp. 85-103, figs. 10*).—General information is given regarding the growing of rice, the rice industry, and the nutritive value and preparation of rice for the table, together with a number of recipes.

Food poisonings due to creamed cabbage, E. DESEQUELLE (*Bul. Sci. Pharmacol.*, 21 (1914), No. 4, pp. 199-204).—The author gives a digest of data regarding cases of food poisonings due to eating various creamed preparations. From the investigations carried out by a number of authors, the following recommendations for making various cream preparations or custards have been formulated:

Only boiled milk and strictly fresh eggs without the least suggestion of bad odor should be used. The yolks should be mixed with milk at the highest possible temperature which will not injure the preparation. The utensils used in the preparation of these foods should be thoroughly washed in boiling water before using. All added substances, for example gelatin, should be dissolved, if possible, in boiling water. The hands of the worker should be previously washed and covered with clean gloves during the preparation of the food.

Tropical vegetable foods, H. H. RUSBY (*Jour. N. Y. Bot. Gard.*, 15 (1914), No. 173, pp. 107-112).—This is an abstract of a lecture delivered at the New York Botanical Gardens, which summarizes information regarding the consumption of different vegetable foods in the countries of the world having a tropical climate.

The cooking of vegetables, C. H. SENN (*Jour. Roy. Hort. Soc.*, 39 (1914), No. 3, pp. 523-529).—In this paper the author discusses particularly the characteristics and preparation for the table of "stem vegetables," such as asparagus,

celery, leek, and sea kale, and gives a number of recipes. See also a previous note (E. S. R., 29, p. 566).

Hardened oils, G. MEYERHEIM (*Fortschr. Chem., Phys. u. Physikal. Chem.*, 8 (1913), No. 6, pp. 293-307).—A digest of data, including the literature of patents, regarding the formation of solid, saturated fats from unsaturated, liquid fats, hydrogen being added by means of a catalyzer. Though written from the standpoint of the soap making industry, this article is also of interest to students of nutrition since similar hardened fats are manufactured for culinary purposes.

Preserved foods and candies, A. HAUSNER (*Die Fabrikation der Konserven und Kanditen. Vienna and Leipsic, 1912, 4. ed., rev. and enl., pp. VIII+332, figs. 47*).—The author states that this edition of his handbook has been revised and enlarged.

A contribution to the knowledge of coffees, I. RÖZSÉNYI (*Chem. Ztg.*, 37 (1913), No. 145, pp. 1482-1484).—Data are here given regarding several varieties of coffees including among others Porto Rico, Mocha, Ceylon, Santos, and Domingo coffees. Potassium, sodium, calcium, magnesium, and iron were determined as well as water and total mineral matter.

The volatile constituents of coffee, J. ABELIN and M. PERELSTEIN (*München. Med. Wchnschr.*, 61 (1914), No. 16, pp. 867, 868).—The nature of and the physiological effects produced by the volatile constituents of coffee, as shown by other workers, are discussed, and the authors present the results of a quantitative study of the volatile matter obtained by steam distillation from several samples of ordinary coffee and a so-called "treated" coffee from which a part of these constituents had been removed by a patented process.

Electric cooking (*Austral. Mining Standard*, 50 (1913), No. 1291, p. 116).—A description is given of an electric stove in which the heat is obtained and distributed by numerous rods of a cheap and durable metal which is unaffected by heat, instead of by means of the series of wires ordinarily employed. The rods may be easily replaced and only as many as are required need be in operation, since each rod is an independent unit.

Electric cooking on the battleship "Texas" (*Elect. World*, 63 (1914), No. 20, pp. 1099, 1100, figs. 3).—A description is given of the electric cooking apparatus which is used for the preparation of all the food for the officers and men except for boiling meats and vegetables and preparing tea and coffee, which processes are carried out in steam jacketed caldrons. Menus are given showing the food prepared for one week.

Electric cooking, W. H. ALABASTER (*Elect. Rev.*, 73 (1913), No. 1869, pp. 451-454, figs. 5; *abs. in Sci. Abs., Sect. B—Elect. Engin.*, 16 (1913), No. 192, p. 590).—The author discusses and summarizes in tabular form data regarding the amount of energy required with electrical ovens of different makes to secure a temperature of 400° F. and maintain it for 1½ hours, and regarding the comparative efficiency of different sorts of hot plates when used to raise the temperatures of 3 pts. of water to boiling, as well as the weekly cost of cooking for a family of 2 adults and 2 children when different cooking devices are used.

Gas cooker efficiencies (*Jour. Gas Lighting*, 126 (1914), No. 2662, p. 493).—The results are reported of comparative efficiency tests of ordinary gas ovens and hot plates and of improved types. The details of the improvements embodied in the types of cookers described are not given but apparently consist chiefly of a better regulation of the volume and direction of the air supply.

A story of certain table furnishings, CLARA W. BROWNING and EDITH J. MUNSELL (*Cornell Reading Courses*, 3 (1913), No. 51, pp. 49-72, figs. 28).—Historical data are summarized regarding the origin and development of table equipment.

A proper newe booke of cokerye, edited by CATHERINE F. FRERE (*Cambridge, 1913, pp. CLXIV+124, pls. 2*).—The reprint of this sixteenth century cookbook, which gives some information regarding dietetics as well as data concerning the preparation of food at this time in England, is preceded by an introduction by the editor, and also contains a glossary-index and a bibliography of culinary literature, particularly earlier publications.

Regulation of hotel and restaurant kitchens [in Germany], R. P. SKINNER (*Daily Cons. and Trade Rpts. [U. S.], 17 (1914), No. 123, p. 1117*).—According to this report, while regulations exist for governing the sanitary condition of restaurant and hotel kitchens, there is no regular system of police inspection except when licenses are granted or complaints are entered. The condition of such places is attributed to the care of the proprietors.

[The presence of tobacco in foods] (*Weekly Rpt. Bd. Health Cincinnati, 5 (1914), No. 19, pp. [1, 2], fig. 1*).—A statement is made regarding the finding of tobacco in bread and the desirability is pointed out of more strictly enforcing the regulation which prevents the use of tobacco in bake shops.

Work in the hygiene of food and nutrition of the Prussian Board of Health in 1911 (In *Das Gesundheitswesen des Preussischen Staates im Jahre 1911. Berlin, 1912, pp. 364-399; summarized in Ztschr. Öffentl. Chem., 20 (1914), Nos. 1, pp. 6-13; 2, pp. 21-23*).—An account of the work carried on, particularly with reference to general nutrition, animal foods, vegetable foods, and condiments.

Cases of food poisoning noted in the German Army during the last two years, W. SEELE (*Ueber die in der Deutschen Armee in den letzten zwölf Jahren vorgekommenen Nahrungsmittelvergiftungen. Inaug. Diss., Univ. Berlin, 1913, pp. 29; abs. in Hyg. Rundschau, 24 (1914), No. 9, pp. 531, 532*).—The data summarized shows that meat and sausage were the most common sources of food poisoning as is natural enough when one recalls that such food is taken daily. Potatoes, and particularly potato salad, are next in order. Other materials, particularly cooked foods containing flour, also cause poisoning.

The inciting of the trouble was not always the same, but the following microorganisms were identified: *Bacillus coli communis*, *B. proteus*, *B. enteritidis*, and *B. paratyphosus*. In the case of potatoes the poisoning was attributed in some instances to a high solanin content and in others to *B. proteus*. The majority of the poisonings occurred in the months of April and May.

The etiology of beri-beri, R. P. STRONG and B. C. CROWELL (*Trans. 15. Internat. Cong. Hyg. and Demogr. Washington, 5 (1912), Sect. 2, pp. 679-696*).—The authors give some data regarding the work of other investigators and summarize the results of their own experimental studies of the subject with prisoners in Bilibid prison, in Manila.

Some groups were fed, as the principal article of diet, white rice for varying lengths of time, and other groups, white rice plus an alcoholic extract of rice polishings, the period the experiment covered being from 97 to 117 days. It was planned to supply one group with white rice and rice polishings cooked together, but it was found that the subjects would not eat this food.

Quotations from the authors' findings and conclusions follow:

"It is evident that among the individuals comprising our experiment beri-beri was produced only by means of the diet, and that the disease has therefore a true dietetic causation. It is further evident from our experiments that beri-beri develops owing to the absence of some substance or substances in the diet necessary for the normal physiological processes of the body. Without the supply of such substances in the food, beri-beri results. Such a substance or such substances are evidently present in red rice and in rice polishings, and also in small amount in the alcoholic extract of rice polishings, and when

these articles are added to what would appear to be an otherwise physiologically proper diet they usually prevent the development of the symptoms of the disease. In some instances, however, even when these substances are constituents of the diet, when the diet is without variation and composed of very few articles, and the individual suffers from loss of appetite and the assimilative functions appear to be poor and he loses markedly in weight, symptoms of beri-beri may develop. However, such symptoms may be dispersed by causing a variation in the diet by the addition of other nutritious substances."

"None of the individuals in our experiments developed symptoms suggesting scurvy. . . .

"From our experiments there is no evidence of any nature which suggests that beri-beri is an infectious disease, and on the contrary the evidence is definite that beri-beri [in the Philippine Islands] is due to the prolonged consumption of a diet which lacks certain substances necessary for the normal physiological needs of the human body."

The authors also discuss the possible relation of the phosphoric acid content of rice to the incidence of beri-beri.

The prevention of beri-beri, E. B. VEDDER (*Trans. 15. Internat. Cong. Hyg. and Demogr. Washington, 5 (1912), Sect. 2, pp. 671-678*).—The author discusses the relation of beri-beri to polished rice, and gives his reasons for believing that the solution of the difficulty does not lie in placing a tax on highly milled rice.

The protective power of normal human milk against polyneuritis gallinarum (beri-beri), R. B. GIBSON (*Philippine Jour. Sci., Sect. B, 8 (1913), No. 6, pp. 469-471*).—In view of the fact that infantile beri-beri has been attributed to a deficiency of "vitamins" in the milk of the mother resulting from the too exclusive consumption of milled rice, the author carried out a series of experiments to study the protective power of normal human milk against beri-beri. Four groups of fowls were fed 50 gm. of polished rice per day, in addition to which some of the fowls received human milk in quantities varying from 5 to 20 cc. The results of these experiments indicate that the addition of human milk to the polished rice, even in as large amounts as 20 cc. per day, was not sufficient to prevent polyneuritis.

It would appear from the work of other investigators here reviewed that fresh cow's milk had about four times the protective power of normal human milk.

A consideration of certain foods and of proximity to a previous case as factors in the etiology of pellagra, J. F. SILER, P. E. GARRISON, and W. J. MACNEAL (*Proc. Soc. Expt. Biol. and Med., 11 (1914), No. 3, p. 94*).—A statistical study was made of the foods used and the occurrence of pellagra in mill villages including about 5,000 persons.

According to the authors, the results obtained "failed to reveal any consistent relationship between the use of any particular food and the occurrence of pellagra. A somewhat similar statistical study of the location of domicile of old cases of pellagra in relation to domicile of the remaining population in these same mill villages has shown that new cases of pellagra developed almost exclusively in persons living in the same house with such antecedent cases or in houses next door to them, . . . a phenomenon which can be satisfactorily explained, in our opinion, only by assuming that pellagra is an infectious disease. Apparently it is not readily transmitted to any considerable distance."

Anaphylactic reaction in pellagra patients, by the inoculation of watery extract of spoiled maize, G. VOLPINO ET AL. (*Trans. 15. Internat. Cong. Hyg. and Demogr. Washington, 2 (1912), Sect. 1, pp. 344-346*).—A brief summary of the results of the authors' observations on inoculating pellagra patients with an

aqueous extract of spoiled maize. The authors state that the reaction was marked and found to be different from that observed when sound persons were similarly inoculated.

They state, further, that "the hypersensibility which manifests itself in pellagra patients owing to the inoculation of this watery extract of spoiled maize has particular characters which can not be found in any proportion through the injection of extract of sound maize."

The paper is followed by a discussion.

Concerning factors of toxicity and an excessive corn diet, E. CENTANNI and C. GALASSI (*Sperimentale*, 67 (1913), No. 4, Sup., pp. 142-150; *abs. in Zentbl. Expt. Med.*, 5 (1914), No. 7, p. 296).—In this contribution to pellagra, the conclusion is reached, from extended experiments with laboratory animals (guinea pigs and mice), that an excessive maize diet is responsible for illness, and not the photodynamic properties of corn.

Pellagra in the Province of Rome, G. ALESSANDRINI, A. GIANNELLI, and E. FILENI (*Policlin.*, Sez. Prat., 20 (1913), No. 34, pp. 1213-1221, figs. 2; *abs. in Hyg. Rundschau*, 24 (1914), No. 9, p. 534).—The conclusion was reached that in this Province there was no connection between corn diet and the occurrence of pellagra. On the other hand, there was apparently a relation between this disease and the water used.

Food requirements, appetite, and hunger—a dietary study, W. STERNBERG (*Das Nahrungs Bedürfnis der Appetit und der Hunger—Eine diätetische Studie. Leipzig, 1913, pp. XII+179*).—In this volume the author discusses food requirements, appetite, and hunger, under physiological and pathological conditions. A large amount of data is summarized and discussed exhaustively.

Changes in food supply and diet of the proletariat, M. RUBNER (*Wandlungen in der Volksernährung. Leipzig, 1913, pp. 4+135*).—In this volume the author discusses the effect of changing conditions on diet, especially with reference to the man of small means.

The questions considered in the various chapters are the following: The need for state supervision of the general question of diet; insufficient food; the increased cost of foodstuffs in its relation to food deficiency, to living conditions, and to social relations; the question of dietary standards; the determination of dietary conditions; changes in labor production; changes in food consumption; the protein and meat question from a physiological standpoint; the value of vegetable foods as a source of protein; the effect on dietetics of social influences; lowering the protein in the diet; sandwiches as a principal article of diet; the extent of meat consumption; and suggestions as to improving the diet of the proletariat.

The author brings together a large amount of important data in this volume, including the results of his experience and experiments. The volume as a whole constitutes an important contribution to the literature of dietetics which no student of the subject should overlook.

Experimental variations in the function of diet, A. MAGNAN (*Variations expérimentales en fonction du régime alimentaire. Thesis, Paris, 1913, No. 7; abs. in Presse Méd. [Paris], 1914, No. 19, p. 18; Zentbl. Expt. Med.*, 5 (1914), No. 9, pp. 409, 410).—Some of the conclusions follow which the author reached with different kinds of animals:

Vegetable diet increases the surface of the digestive tract, while meat diet reduces it. A similar effect is noted in the small and large intestine. The weight of the intestine is greatest in animals which take solid food, and is ascribable to a thickening of the muscle walls. In birds, the weight and surface area of the stomach are proportional to the volume of the diet. As regards

chemical action, the liver and kidneys are relatively twice as large in fish-eating and insect-eating as in carnivorous and herbivorous animals.

The minimum requirement of protein supplied by a bread diet, M. HINDEHEDE (*Skand. Arch. Physiol.*, 31 (1914), No. 4-6, pp. 259-320).—The author reports the results of a series of digestion experiments from which he draws the following conclusions:

The minimum protein requirement is about the same for bread and potatoes and is in the neighborhood of 20 gm. of digestible protein for 3,000 calories. Potato and bread protein appear to have about the same value as meat protein and can replace the body tissue gram for gram. See also a previous note (E. S. R., 31, p. 263).

Protein requirement and the food value of meat, KISSKALT (*München. Med. Wchnschr.*, 61 (1914), No. 20, pp. 1121, 1122).—The author believes in a generous protein ration as opposed to the paper noted above.

Calcium deficiency in the diet, R. EMMERICH and O. LOEW (*Ztschr. Hyg. u. Infektionskrank.*, 77 (1914), No. 2, pp. 311-328).—Data from their own investigations and those of others are summarized, which led the authors to conclude that the calcium content of the daily food may vary within wide limits on a mixed diet and that there is a possibility of calcium deficiency. In some localities there is a marked decrease in the use of milk and vegetables, the foods which are richest in calcium, while there is a corresponding increase in meat, potatoes, and bread, and other foods made from flour, which are poorest in this constituent. Such conclusions have led the authors to recommend the addition of calcium chlorid to flour in bread making. See also a previous note (E. S. R., 29, p. 565).

Concerning calcium bread advocated by Emmerich and Loew, KUNERT (*Ztschr. Gesam. Getreidew.*, 6 (1914), No. 4, pp. 73-80).—A critical discussion of the work noted above.

On age and metabolism and the significance of the excretion of creatin, R. A. KRAUSE (*Quart. Jour. Expt. Physiol.*, 7 (1913), No. 1, pp. 87-101; *abs. in Zentbl. Expt. Med.*, 5 (1914), No. 8, p. 350).—According to the author's observation, the urine of children on a creatin-free diet contained creatin. This condition ceases with boys in the fifth and sixth year, but continues longer with girls. The amount of creatin nitrogen in millimeters per kilogram of body weight is much smaller with children than with adults, increasing rapidly through the earlier years and then more slowly. When given to children per os in even small quantities part was excreted.

The conclusion was reached that children have less ability to break down creatin than adults, and that creatin is to be regarded as an intermediary product of metabolism which can be further utilized under normal conditions. The appearance of creatin in urine is dependent upon whether the process of creatin formation or creatin destruction dominates, a condition similar to that found with uric acid.

On the influence of preliminary heating upon peptic and tryptic proteolysis, A. H. BIZARRO (*Jour. Physiol.*, 46 (1913), No. 3, pp. 267-284, *figs. 6*; *abs. in Zentbl. Physiol.*, 28 (1914), No. 2, pp. 101, 102).—Artificial digestion experiments were made with egg white, fibrin, gelatin, beef, and casein. No definite conclusions could be drawn as to the digestive power of trypsin, but the experiments afforded additional evidence that this ferment induces cleavage of the amino groups very slowly. A preliminary heating of egg white to from 120 to 140° C. increases the proteolytic action of the trypsin. Similar results were obtained when fibrin, casein, and beef were heated, and contrary results with gelatin. An increase in amino cleavage products was noted after 15 hours' tryptic digestion.

The comparative chemistry of muscle—the partition of nonprotein water-soluble nitrogen, D. W. WILSON (*Jour. Biol. Chem.*, 17 (1914), No. 3, pp. 385–400).—The author reports the results of studies of the distribution of nitrogen in the muscles of invertebrates, namely, lamprey, limulus, squid, clam, scallop, and periwinkle.

“The lamprey muscle contained a minimum of total extractive nitrogen, most of which was nonamino nitrogen. The values for the total amino nitrogen rose from a minimum in the lamprey which was only 4 per cent of the total extractive nitrogen, to a maximum in the clam and scallop which was over 50 per cent of the total extractive nitrogen. . . .

“The nonamino nitrogen is high in all the extracts examined. The major portion is in the diamino-acid fraction in which it greatly exceeds the amino nitrogen. Of the compounds isolated from these and similar extracts, betain, urea, prolin, arginin, histidin, and creatin contribute all or part of their nitrogen to the nonamino nitrogen fraction. The various qualitative and quantitative relations indicate that betain is probably an important constituent of extracts of muscles from these types of animals.”

The total sulphur was also determined in the total extracts.

“The great qualitative and quantitative variations between the extracts of muscles from different vertebrates and invertebrates suggest fundamental differences in the tissue metabolism of these animals. . . . Comparative studies on the extractives of these simpler forms of life may throw some light on their rôle in the animal economy and aid in solving some of the problems of intermediary metabolism. Experiments like the above, besides furnishing interesting data, suggest points of attack where the variations are sufficiently large to furnish fruitful investigations.”

The necessity relation of lipoids to life. The behavior of such essential substances to reagents which will extract lipoids, W. STEPP (*Ztschr. Biol.*, 62 (1913), No. 9–10, pp. 405–417).—According to the author's conclusions, these important lipid substances can not be extracted from a feeding stuff by ether but are readily extracted by alcohol.

Meeting the body food requirements during a 24-hour cycle, J. BERGONIE (*Compt. Rend. Acad. Sci. [Paris]*, 158 (1914), No. 15, pp. 1079–1082, figs. 3).—From observations of the daily distribution of the energy requirement of the body and the fact that the period of maximum availability of the energy in the meals occurs about three hours after eating, the author recommends that the ordinary diet furnishing 1 part of fat, 1 part of protein, and from 4 to 5 parts of carbohydrate should be taken in 3 meals as follows: A heavy meal supplying from 1,400 to 1,500 calories at about 7.30 a. m.; a light meal supplying 300 to 400 calories at 4.30 p. m.; and a dinner supplying 700 to 800 calories at 8.00 p. m.

Rational utilization of human energy—scientific study of manual labor, J. AMAR (*Génie Civil*, 64 (1914), No. 19, pp. 373–377, figs. 10).—The author emphasizes the fact that to secure the greatest efficiency from the human motor its normal limit of fatigue must not be exceeded so that overfatigue results. Continuous action is contrary to the laws governing the human motor and rest periods of proper length must be provided to secure the maximum efficiency. In most systems for studying the efficiency of the human motor the physiological element is disregarded.

To determine the proper length and distribution of rest periods, as well as the most efficient way in which the human motor can be utilized, an experimental study was made of the energy expended in performing a number of different tasks.

The energy expended was measured by means of the oxygen consumption, this factor being determined by a respiration apparatus provided with a double

valve which permitted the subject to inhale and exhale by the mouth, the nose being closed. The work done in performing each task and the corresponding expenditure of energy by the body were measured by an especially designed ergograph. The curves obtained in this way were calibrated in kilograms and showed the various components of the forces applied by the body. At the same time the heart beat, pulse rate, and blood pressure were determined. Respiratory curves were obtained under conditions of normal fatigue and overfatigue, which, together with the arterial pressure, made it possible to follow the course of the functions essential to life during the performance of the task and to avoid excessive efforts on the part of the worker which might injure the organism.

In applying the results of these experiments to practical work in filing metal, the effect upon the respiratory exchange of varying the pressure, the contraction, the rhythm and length of the movements of the file, the position of the worker, and the intervals of rest were studied. The work of an experienced workman was also compared with that of an apprentice. Employing this same means, the laws which determine the most economical expenditure of energy in the performance of several tasks were also studied.

The fundamental factors studied in the case of the various tasks investigated were the amount of the contraction of muscle, the time during which it was sustained, the speed of the body movements, and the relation of the work periods to rest periods. The following conclusions are drawn from these studies:

The expenditure of energy is proportional to the length of the effort and degree of muscular contraction.

The expenditure of energy to produce a given task diminishes in proportion to the speed of contractions. This is true only within certain limits which produce serious physiological disturbances, such as alteration of muscular and nervous tissues when exceeded.

There is an optimum speed at which the maximum work may be obtained with the least fatigue, and this should be the true object of scientific management of industrial labor.

The rapidity of recovery of the muscle during rest is proportional to the rate at which it works. The oxygen consumption which indicates this rate may thus indicate the need of rest periods.

The price of labor expressed in terms of food fuel (*Jour. Amer. Med. Assoc.*, 62 (1914), No. 24, pp. 1895-1897).—This article deals briefly with the question of the relation of the kind of work performed to the daily requirement of energy in the food.

ANIMAL PRODUCTION.

Digestion experiments with Texas feeding stuffs, G. S. FRAPS (*Texas Sta. Bul.* 166 (1914), pp. 5-26).—This bulletin reports the results of digestion trials made with six sheep on various feeding stuffs. The experiments with the concentrates were carried out in several periods of 12 days each. In the first and last periods, alfalfa hay was fed, and in the other periods the concentrates to be tested were added, using 300 gm. of hay to 300 gm. of concentrates per day. The ration to be tested was fed 12 days, and the excrement collected during the last 6 days.

The average coefficients of digestibility of feeding stuffs, as reported by various experiment stations and including those found in these trials, together with the productive values of these feeds (pounds of fat produced by 100 lbs. of the feed, when fed in addition to a maintenance ration) are given in the table following.

Average coefficients of digestibility of feeding stuffs and productive values.

Feeding stuff.	Protein.	Ether extract.	Crude fiber.	Nitrogen-free extract.	Ash.	Productive value.
	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.	Lbs.
Alfalfa hay, average.....	75.29	38.40	46.17	68.83	49.87	8.18
Bermuda hay, average.....	53.10	41.60	53.17	50.63	33.73	7.32
Corn bran, average.....	58.20	76.63	59.56	77.21	8.48	13.33
Cold-pressed cotton seed, average.....	74.28	85.98	39.55	63.23	54.22	12.02
Cotton-seed meal, rich in hulls.....	72.90	90.90	37.30	61.80	-----	-----
Cotton-seed meal and hulls.....	77.69	97.29	51.04	67.91	26.22	14.49
Cotton-seed hulls, average.....	14.10	68.40	49.00	47.70	25.20	4.08
Cotton-seed meal, average.....	85.93	94.84	15.22	71.88	18.69	18.31
Kafir corn chop, average.....	56.20	47.20	27.40	68.80	43.40	14.63
Prairie hay, cut before frost.....	8.60	39.10	53.50	46.90	4.90	6.10
Prairie hay, cut after frost.....	9.00	57.30	66.70	57.10	28.00	8.11
Rice bran, average.....	64.35	80.85	19.05	81.92	15.98	17.15
Rice polish, average.....	67.30	82.10	25.70	91.10	30.00	20.67
Sorghum silage, average.....	9.00	56.00	58.00	64.00	-----	2.69
Silage (sorghum and cowpea).....	23.77	57.93	49.24	63.67	19.82	3.55
Sorghum fodder, average.....	35.50	62.20	60.60	61.50	-----	9.19
Sorghum hay.....	13.90	54.00	55.60	55.90	23.40	7.59
Tabosa grass hay No. 1.....	17.00	27.20	52.50	41.80	18.40	4.77
Tabosa grass hay No. 2.....	22.90	46.70	56.50	53.10	21.40	6.57

The average composition and digestible nutrients of these feeds are also given.

Composition of feeds and a method of calculating rations, N. ATHANASSOF (*Noções Sobre a Composição das Forragens e o Modo de Calcular as Rações. Sao Paulo, Brazil, 1912, pp. 56, figs. 18*).—This includes tables of composition and digestibility of grasses indigenous to São Paulo and of the more common feeding stuffs, together with a discussion of methods of calculating rations adapted from Kellner, Henry, et al.

Analyses of forage crops (*Bol. Agr. [Sao Paulo], 15. ser., No. 3 (1914), pp. 207-213*).—The composition and digestibility of the following forage crops are reported: *Panicum spectabile*, *P. altissimum*, *P. maximum*, *P. oryzoides*, *P. echinolæna*, *P. melinis*, *P. numidianum*, *Paspalum griseum*, *P. virgatum*, *P. stoloniferum*, *P. intermedium*, *P. pusillum*, *Polygonum sachalinense*, *Phaseolus compressus*, *P. sp.*, *Andropogon rufus*, *A. sp.*, *A. condensatus*, *Arracacia esculenta*, *Bromus unioloides*, *Cynodon dactylon*, *Crotalaria vitellina*, *Cajanus indicus*, *Desmodium leiocarpum*, *Galega officinalis*, *Gossypium barbadense*, *Ipomœa batatas*, *Mucuna utilis*, *Medicago falcata*, *Sechium edule*, *Spergula arvensis*, *Sporobolus argutus*, *Tricholæna rosea*, *Trifolium incarnatum*, *Triticum sativum*, *Zea mays*, *Z. caragua*, and *Oryza sativa*.

Composition and nutritive value of some feed plants, S. ULMANSKY (*Mitt. Landw. Lehrkanz. K. K. Hochsch. Bodenkul. Wien, 2 (1914), No. 3, pp. 467-486*).—Analyses and data as to nutritive value are given of *Meum mutellina*, *Plantago alpina*, *Poa alpina*, and *Festuca rubra*, var. *fallax*, pasture and hay plants indigenous to the Alps

Commercial feeding stuffs, 1913.—Feed law, B. YOUNGBLOOD (*Texas Sta. Bul. 164 (1914), pp. 5-67*).—This reports analyses of the following commercial feeding stuffs: Alfalfa meal, barley chop, corn chop, corn bran, corn feed meal, corn germ meal, corn and cob meal, cold-pressed cotton-seed cake, cold-pressed cotton-seed meal, cotton-seed cake, cotton-seed meal, dried brewers' grains, ear-corn chop, ground oats, hog flour, hominy feed, Kafir corn, Kafir head chop, Kafir meal, maize chop, maize-head chop, maize meal, mill-run bran, rice bran, rice polish, wheat bran, wheat chop, and wheat shorts. There is included general information on the feed-control service and compliance with provisions of the feedstuffs law.

Feeding stuffs (*Ber. Agr. Chem. Kontroll u. Vers. Stat. Pflanzenkrank. Prov. Sachsen, 1913, pp. 23-40*).—Analyses are reported of peanut meal, coconut cake and meal, linseed cake and meal, palm kernel cake and meal, rape-seed meal, sesame-cake meal, sesame seed, soy-bean chop, sunflower-seed meal, molasses feed, crude molasses, fresh and dried beet tops, turf molasses feed, sugar beets, potatoes, potato silage, blood meal, fish meal, calcium feed, and potato flakes, together with corn, wheat, oats, rice, barley, rye, and their various products.

Cotton-seed products and their competitors in northern Europe, E. W. THOMPSON (*U. S. Dept. Com., Bur. Foreign and Dom. Com., Spec. Agents Ser., No. 84 (1914), pp. 93*).—This bulletin reports an investigation made of the commercial feeding stuffs of Germany, the United Kingdom, the Netherlands, Denmark, Sweden, and Norway, with special reference to their competition with American products. Methods of feeding in vogue in these countries and the importance of the various cakes and meals used are discussed. The theoretical valuation of feeding stuffs as determined by the Kellner, Hansson, and other methods is treated. There are included lists of feeding stuffs dealers in the several countries.

Fish feed meal, M. KLING (*Deut. Landw. Presse, 41 (1914), No. 37, pp. 457, 458*).—In commenting on the variability of composition of the different brands of fish meal the author recommends a uniform grade, having a guaranteed analysis of 50 per cent protein, 5 per cent fat, 5 per cent salt, and from 20 to 25 per cent calcium phosphate.

Bengal beans, a new fodder, H. S. SHREWSBURY (*Bul. Dept. Agr. Trinidad and Tobago, 13 (1914), No. 81, pp. 194, 195*).—Experiments with Bengal beans, presumably *Macuna utilis*, indicate that very little, if any, hydrocyanic acid or other toxic materials are present. The taste and odor of the whole meal from the beans are pleasant and closely resemble those of pea meal. It is shown that these beans are somewhat superior in feeding value to French, Lima, or Java beans and that like these beans their nutritive properties are principally due to the high content of carbohydrates and proteins. Owing chiefly to their low percentages of fat, their value is considerably less than that of soy beans. Caution is recommended in the use of these beans as fodder.

The phosphoric substance of prairie grass, C. DUSSEY (*Bul. Soc. Vaud. Sci. Nat., 5. ser., 49 (1913), No. 181, pp. XL-XLII*).—It is shown that the principal phosphorus compounds found in prairie grass which are of nutritive value to animals are the lecithins, the phytins, and the nucleins. Of these the phytins are in greatest amount, 54 to 62 per cent; the nucleins, 30 to 40 per cent; and the lecithins, about 10 per cent.

It was found that the application of superphosphate materially increased the phosphorus content of the plant and that this in turn increased the value for feeding purposes.

Mineral requirements of farm animals (*Wisconsin Sta. Bul. 240 (1914), pp. 32, 33*).—"A dry pregnant milch goat was fed rations low in lime during the entire gestation period, at the end of which she gave birth to twin 5-lb. kids, of normal weight and vigor. During this single period of gestation, the goat lost about 20 per cent of the total amount of lime contained in her body, including the amount stored in the bodies of the offspring, although without any outward or apparent ill effects." It is estimated that for fetus building and for milk production the 1,000-lb. pregnant cow will require from 1.8 to 2.1 oz. of lime per day. Such requirements are usually met by the ordinary farm roughages such as hay and corn stover, but with straw in any large quantity as a part of the ration the lime supply would be deficient.

Value of fat from various sources (*Wisconsin Sta. Bul. 240 (1914), pp. 33, 34*).—In studies by E. V. McCollum continuing previous work (E. S. R., 28,

p. 872), in which rats fed certain mixtures composed of pure casein, carbohydrates, and salt mixtures made normal growth for periods varying from 70 to 120 days, but after that time made little or no increase in the body weight. Fat from egg yolk or butter was added to the ration. Growth was immediately resumed. When olive oil was added, however, no such effect was produced. The results suggest a difference between the physiological values of fat from different sources.

Some mechanical factors in digestion, S. SISSON (*Amer. Vet. Rev.*, 45 (1914), Nos. 4, pp. 408-422; 5, pp. 513-526).—This is a rather complete treatise on the mechanical factors involved in digestion by domestic animals, especially horses and cattle. The investigations made by Scheunert, Schattke, and others are cited.

Controlled natural selection and value marking, J. C. MOTTRAM (*London, New York, Bombay, and Calcutta, 1914*, pp. IX+130, figs. 8).—The author of this book presents a new theory with regard to the course taken by natural selection. He contends that since natural selection must appreciate differences in structure and since it must treat associations as units and bring about diversity of structure in them these structures control natural selection, so that the less valuable individuals are more liable to be destroyed than the more valuable. It is thought that the application of this theory or hypothesis may explain the origin and use of some polymorphisms.

Coat color in pointer dogs, C. C. LITTLE (*Jour. Heredity*, 5 (1914), No. 6, pp. 244-248).—From a study made of the studbook of the American Kennel Club with reference to coat color in pointer dogs it is concluded that there is a recessive type of yellow dog, analogous to the recessive yellow of guinea pigs, and that the relation of brown to black is the same in dogs as in other small mammals in which the matter has been experimentally investigated.

Nondisjunction of the sex chromosomes of *Drosophila*, C. B. BRIDGES (*Jour. Expt. Zool.*, 15 (1913), No. 4, pp. 587-606; *abs. in Science*, n. ser., 40 (1914), No. 1020, pp. 107-109).—The author of this article presents evidence tending to prove that the parallelism between the behavior of the chromosomes and the behavior of sex-linked genes and sex in the case of *Drosophila* means that the sex-linked genes are located in and borne by the X-chromosomes.

Animal industry in the Kongo, E. LEPLAE (*Min. Colon. Belg., Rap. Agr. Congo Belge, 1911-12*, pp. 210-244, figs. 29).—This report relates to the types of cattle, horses, mules, sheep, and swine indigenous to the Kongo, their improvement and utility value, and to the importation of foreign breeds into that section.

Economic factors in cattle feeding.—IV, Cattle feeding conditions in the corn belt, H. W. MUMFORD and L. D. HALL (*Illinois Sta. Circ. 175* (1914), pp. 5-19, figs. 2).—In this discussion of prevailing conditions, it is stated that about one-third of the cattle of the country other than milch cows are contained in the seven States embracing what is known as the corn belt, and that their value is equal to about two-fifths of the total value of such cattle in the United States. It is shown that the number of beef cattle bred in this section is rapidly diminishing, the supply of feeders coming largely from the West or elsewhere. At the same time there has been an enormous increase in the number of dairy cattle, the indiscriminate breeding of which to beef stock has deteriorated the quality of beef cattle. Four-fifths to nine-tenths of the beef cattle marketed from typical corn-belt localities are cattle that have been purchased as stockers or feeders, while the fattening of cattle has passed largely from the hands of general farmers to those of professional cattle feeders.

Causes attributed for these conditions are the relatively high prices of grain compared with those for fat cattle, increase in land values, extension of cattle-

feeding operations in the West, increase in farm tenancy, and neglect of soil fertility. It is thought that due to the increasing demand for grain-fattened beef cattle an increasing proportion of the cattle matured in the corn belt must be reared there, rather than in the West. Improved and intensified farming methods, the introduction of corn silage, alfalfa, and other forage crops, the more complete utilization of waste roughage, and increased attention to manure as a means of maintaining fertility will tend to render cattle production more practicable. However, there must be an increase in prices paid for cattle corresponding to the increased cost of production.

Feeding baby beef, W. P. SNYDER (*Nebraska Sta. Bul. 143 (1914), pp. 5-39, figs. 5*).—In a preliminary feeding experiment 30 450-lb. beef calves were fed for 7½ months on alfalfa and prairie hays, corn, and oats, during which time they ate 46.1 bu. of corn, 3.63 bu. of oats, and 1.32 tons of forage per head. The average total gain per head was 482.7 lbs., or an average daily gain of 2.11 lbs., while the cost per pound of gain was 6.89 cts. A net profit of \$2.70 was realized, or when profits on hogs were taken into consideration an estimated net profit per calf of \$7.96.

The experiment proper included two years' work, the first year of 223 days, the second of 233 days. In these duplicate tests five lots of from 13 to 15 head of 440-lb. grade beef calves were fed as follows: Lot 1, prairie hay, and corn and cotton-seed cake 9:1; lot 2, alfalfa hay and prairie hay 72:28, and corn; lot 3, alfalfa and silage 1:1, and corn; lot 4, prairie hay and silage 47:53, and corn; and lot 5, prairie hay and silage 9:11, with corn and cotton-seed cake 9:1. The grain ration was increased as the feeding period progressed.

The average daily gain per calf was for the two yearly tests 1.8, 1.96, 2.07, 1.63, and 1.8 lbs., the grain required per pound of gain 5.76, 5.05, 4.91, 5.96, and 5.66 lbs., and the forage 5.55, 5.51, 7.79, 8.81, and 7.97 lbs. The cost of feed per pound of gain was 7.74, 6.97, 7.03, 8.24, and 7.86 cts., while the net profit realized per head was \$9.43, \$13.66, \$15.02, \$4.99, and \$7.40, or including the profit from pork \$17.05, \$20.28, \$22.21, \$11.77, and \$13.82 for the respective lots.

From these results it is seen that a ration of alfalfa hay, corn silage, and corn gave the largest gain, the cheapest gain, and the most profit of any ration used. Rations containing alfalfa hay and those containing cotton-seed cake gave larger and cheaper gains than those not containing these protein materials. The ration composed of prairie hay, cotton-seed cake, and corn gave the same average rate of gain and about the same cost of gain as the ration composed of prairie hay, cotton-seed cake, corn, and silage, indicating that silage as fed in these tests was not worth the value usually given it. When silage was fed with alfalfa the silage was worth much more than when it was fed with prairie hay and cotton-seed cake. Cotton-seed cake was not a profitable substitute for alfalfa.

Skin temperature and fattening capacity in oxen, T. B. WOOD and A. V. HILL (*Jour. Agr. Sci. [England], 6 (1914), No. 2, pp. 252-254*).—Measurements were made of the skin temperature of 18 oxen which had been for some time on a fattening ration. Measurements were taken by means of a thermopile, the tin plate being placed over the ribs behind the shoulder blade where the skin temperature was comparatively constant.

Animals classed as good "doers," which had increased in live weight more than 2 lbs. per head per day during the last three weeks, had a lower skin temperature, amounting to about 3° C., than the "poor doers," which had increased less than 1 lb. per head per day. It was noticeable that every animal in the class of "bad doers" had a higher skin temperature than the average of the 8 "good doers." These results are considered only preliminary, but are indicative of what may be expected.

The Simmental breed of cattle, C. S. PLUMB (*Breeder's Gaz.*, 66 (1914), No. 7, pp. 228, 229, figs. 3).—An account of the characteristics, distribution, and utility value of this breed of cattle. These cattle are essentially dual purpose, being adapted for both beef and dairy purposes. The breed is a prime favorite in Switzerland, and has been exported in large numbers to portions of Germany and Hungary.

Proportions of shelled corn and alfalfa hay for fattening western lambs, W. C. COFFEY (*Illinois Sta. Bul.* 167 (1914), pp. 53-82, fig. 1).—In experiments to determine the proportions in which shelled corn and alfalfa hay should be fed to western lambs four lots of 20 69-lb. wether lambs were fed during a 90-day period corn and alfalfa hay in the following average proportions: Lot one 1 : 0.99, lot two 1 : 1.36, lot three 1 : 2.42, and lot four 1 : 3.45. The proportion of corn to hay was increased as the feeding period progressed, only a small allowance of grain being given at the start. The average digestible nutrients received per lamb per day were 0.235, 0.241, 0.247, and 0.251 lbs. of protein, and 1.441, 1.37, 1.233, and 1.169 lbs. of carbohydrates and fat for the respective lots. The gain per lamb per day was 0.3, 0.269, 0.216, and 0.203 lbs., and the total feed required per pound of gain 8.2, 9.16, 11.18, and 11.84 lbs., respectively.

In a second experiment three lots of 20 65-lb. wether lambs were fed during a 98-day period corn and alfalfa in the following average proportions: Lot one 1 : 2.03, lot two 1 : 1.31, and lot three 1 : 0.86. The average digestible nutrients received per lamb per day were 0.258, 0.281, and 0.29 lbs. of protein, and 1.651, 1.641, and 1.46 lbs. of carbohydrates and fats for the respective lots. The gains per lamb per day were 0.331, 0.32, and 0.294 lbs., and the total feed required per pound of gain 7.64, 8.22, and 9.05 lbs., respectively.

The greatest proportion of corn that it was possible to get the lambs to consume at any stage of the feeding period was one part corn to 0.66 part hay. The lambs fed the greatest proportion of corn, which was also the greatest amount, were rather difficult to keep on feed.

In experiment number one the lots consuming the largest amount of grain (the smallest amount of protein), consumed the largest amount of water. In each experiment the lambs receiving the largest proportion of corn made the largest gain; with the exception of one lot the 10 heaviest lambs in each lot made greater gains than the 10 lightest lambs. It appears that the power of lambs to consume feed increases gradually with the advance of the feeding period.

With various combinations of prices for corn and hay, excepting a combination of very dear corn and very cheap hay, it was demonstrated that the lots fed the greater proportions of corn than hay produced the cheapest gains and returned the most profit. It was also demonstrated that in order to make the feeding operation profitable with feeds of high cost a margin of \$1 per hundred-weight based on home costs and weights is necessary, but that with feeds of comparatively low cost this margin is not necessary.

In experiments with ewe lambs corresponding to experiment number one with wether lambs it was demonstrated that there was very little difference in their feeding and market qualities.

Comparing early and late shorn lambs it was demonstrated that the shorn lambs ate more feed than unshorn lambs in warm weather, but there was little difference between them in gains and no difference in market quality. Lambs left in the fleece until the end of the experiment sheared from 2 to 2.75 lbs. per head more than early shorn lambs and on this account returned more profit.

On the effects of complete and incomplete castration upon horn growth in Herdwick sheep, F. H. A. MARSHALL and J. HAMMOND (*Jour. Physiol.*, 48 (1914), No. 2-3, pp. 171-176, figs. 6).—In continuing work previously noted

(E. S. R., 27, p. 70) it is concluded that "removal of the testes from Herdwick ram lambs arrests further horn growth forthwith and at any stage of development. Unilateral castration does not stop horn growth, neither does it affect the symmetry of the horns, but there is some evidence that the further development of the horns is slower than in normal unoperated animals. Removal of the testes without the epididymes (these being retained) inhibits horn growth in precisely the same way as ordinary castration in which both organs are removed."

The wool conference in Washington (*Bul. Nat. Assoc. Wool Manfrs.*, 44 (1914), No. 3, pp. 227-271).—This reports the proceedings of the conference of wool manufacturers, wool merchants, and wool growers held in Washington, June 2, 3, and 4, 1914, for the purpose of considering the subject of improved methods of handling wool and raising sheep in the range and farm States. The subjects discussed included the manufacturing value of American wool, present methods of handling American wools on the farm and ranch, foreign methods of handling wool, methods of effecting improvement in the handling of American wool, control of predatory animals in range States, the dog problem in farm States, means of increasing the number of farm sheep, improvement in range breeding methods, and statistics on sheep and wool.

Substitutes for corn in rations for fattening swine, G. R. EASTWOOD (*Ohio Sta. Bul.* 268 (1914), pp. 147-164, figs. 3).—In experiments comparing the feeding value of corn and oats, two lots of five 265-lb. pigs each were fed during a 126-day feeding period, lot 1 receiving corn and tankage 9:1 and lot 2 oats and tankage 9:1. These lots made 1.52 and 1.9 lbs. average daily gain per pig, respectively, requiring 4.18 and 4.957 lbs. of feed per pound of gain and dressing 81 and 76 per cent, respectively. Four lots of five 150-lb. pigs were fed during an 84-day period, lot 1 receiving corn and tankage 9:1, lot 2 corn, oats, and tankage 6:3:1, lot 3 corn, oats, and tankage 3:6:1, and lot 4 oats and tankage 9:1, and made 1.75, 1.57, 1.49, and 0.99 lbs. average daily gains per head for the respective lots, requiring 4.3, 4.58, 4.73, and 5.71 lbs. of feed per pound of gain, and lots 1 and 4 dressing 80.3 and 76.1 per cent, respectively.

It is concluded that oats are less valuable per unit of weight than shelled corn, and that the larger the proportion of corn in the corn, oats, and tankage combination, the greater is the efficiency. The price of feeds will naturally influence the economy of the different feed combinations. Whenever prices will permit, oats may be used as a part of the ration during the early part of the fattening period, being gradually reduced until the last four or five weeks of feeding.

Comparing corn and hominy feed, four lots of four 90-lb. pigs fed during a 105-day period, lots 1 and 3 receiving corn and tankage 9:1, lots 2 and 4 hominy feed and tankage 9:1, and the rations being reversed at the end of 63 days, made 0.89, 1.52, 1.17, and 1.38 lbs. average daily gains per head for the respective lots during the first 63 days and consuming 4.53, 3.87, 4.1, and 3.85 lbs. of feed per pound of gain, and during the last 42 days 1.31, 1.92, 1.38, and 1.76 lbs. average daily gain per head, and consuming 3.86, 4.62, 3.95, and 4.79 lbs. of feed per pound of gain. Two lots of four 67-lb. and two lots of four 55-lb. pigs were fed during a 126-day period, lots 1 and 3 receiving ground corn and tankage 9:1, lots 2 and 4 hominy feed and tankage 9:1, and the ration being reversed at the end of 70 days. These made 1.09, 0.98, 0.75, and 0.85 lbs. average daily gains per head, respectively, for the first 70 days, consuming 4.11, 3.86, 4.52, and 4.02 lbs. of feed per pound of gain, while they made 1.64, 1.79, 1.31, and 1.41 lbs. average daily gain per head and consumed 4.05, 4.04, 4.03, and 4.27 lbs. feed per pound of gain during the last 56 days.

These results indicate that hominy feed has a feeding value for swine about 10 to 15 per cent greater than that of an equal weight of ground corn.

In experiments comparing corn, wheat, and middlings four lots of five 110-lb. pigs were fed during a 91-day period, lot 1 receiving ground corn and tankage 9:1, lot 2 ground wheat and tankage 9:1, lot 3 middlings and tankage 9:1, and lot 4 middlings alone, and made 1.57, 1.59, 1.52, and 1.44 lbs. average daily gain per head for the respective lots, requiring 3.66, 3.83, 3.72, and 3.65 lbs. of feed per pound of gain.

Comparing corn and rye, two lots of four and six 44-lb. pigs were fed during a 49-day period, lot 1 receiving corn and tankage 9:1 and lot 2 hogged-down rye and tankage, and made 0.46 and 0.51 lbs. average daily gain per head, requiring 448 and 372 lbs. of feed per 100 lbs. gain. These same pigs were put in a dry lot, lot 1 on corn and tankage as before, and lot 2 on rye and tankage, and fed during a 112-day period, making 1.09 and 1 lbs. average daily gain per head, and requiring 3.99 and 4.41 lbs. of feed per pound of gain.

In an experiment comparing light and heavy grain rations on rape pasture with a heavy grain ration in dry lot, five lots of 16-week-old pigs were fed during a 77-day period, lot 1 receiving corn and tankage 9:1, full feed in dry lot; lot 2 corn, full feed on rape pasture; lot 3 corn, $\frac{3}{4}$ full feed, on rape pasture; lot 4 corn and tankage 9:1, full feed, on rape pasture; and lot 5 corn and tankage 9:1, $\frac{3}{4}$ full feed, on rape pasture. The lots made 0.9, 1.21, 1.06, 1.47, and 1.2 lbs. average daily gain per pig for the respective lots, and consumed 3.847, 3.254, 2.781, 3.166, and 2.94 lbs. concentrates per pound of gain.

The results of this experiment, as well as those of experiments previously reported (E. S. R., 28, p. 468) indicate that "by feeding a light grain ration on pasture, gains may be produced at a much smaller expenditure for grain, though less rapidly, than by feeding a heavy grain ration on pasture, and also that the use of green feeds in connection with corn greatly diminishes the need for nitrogenous concentrates that exists in dry lot feeding."

Ground wheat versus whole wheat for fattening pigs, R. K. BLISS and C. B. LEE (*Nebraska Sta. Bul. 144 (1914), pp. 3-13, figs. 3*).—Four lots of 10 pigs each weighing approximately 138 lbs. made average daily gains per pig during an 84-day feeding period of 0.84, 1.09, 1.19, and 1.32 lbs., respectively, at a cost per pound of gain of 7.39, 6.67, 5.38, and 6.07 cts., respectively. Lot 3, fed soaked ground wheat, consumed 4.43 lbs. of wheat per pound of gain, while lot 1, fed soaked whole wheat, consumed 5.91 lbs. Grinding the wheat resulted in a net saving of 21 cts. per bushel. Lot 4, fed ground wheat and tankage, consumed 4.215 lbs. of grain and 2.07 lbs. of tankage per pound of gain, while lot 2, fed a similar mixture of whole wheat and tankage, consumed 4.858 lbs. of wheat and 2.39 lbs. of tankage, so that grinding the wheat resulted in a net saving of 7 cts. per bushel. The addition of 5 per cent of tankage proved much more efficient in reducing the amount of wheat required to produce a pound of gain when fed with whole wheat than it did when fed with ground wheat. Considerable whole wheat passed through the pigs of lot 1 and 2, and it was apparently better digested when fed with tankage. At the end of the eighth week of feeding the lots had made 42, 56.7, 56.5, and 67.5 lbs. total gain per pig, respectively; at the end of the tenth week. 57, 73, 76, and 90 lbs., and at the end of the twelfth week 70.5, 91.6, 100, and 110.8 lbs., respectively.

Five lots of nine pigs each weighing approximately 108 lbs., were fed during a 98-day period as follows: Lot 1 shelled corn dry; lot 2 whole wheat dry; lot 3 whole wheat soaked; lot 4 ground wheat moistened; and lot 5 ground wheat soaked. The test was duplicated and the results of the two tests averaged. The average daily gains per head for each lot were 1.11, 1.02, 1.05, 1.36, and 1.41 lbs., respectively, the cost per pound of gain being 5.48, 6.42, 6.35, 5.64,

and 5.46 cts., respectively, and the grain required per pound of gain 4.68, 5.11, 5.04, 4.26, and 4.13 lbs.

On ovariectomy in sows, with observations on the mammary glands and the internal genital organs, III, K. J. J. MACKENZIE, F. H. A. MARSHALL, and J. HAMMOND (*Jour. Agr. Sci. [England]*, 6 (1914), No. 2, pp. 182-186).—This continues work previously noted (E. S. R., 30, p. 673).

From examinations made of 297 pigs, including hogs, spayed sows, and sows in different stages of pregnancy "it was evident that the occurrence of pro-œstrum or œstrus was in no way correlated with the presence or absence of pigment in the mammary area. Neither could it be said that pigment was present in greater quantity during the heat period." Pigment was present in many of the spayed sows, although there are some indications that the amount present was liable to be less in the operated pigs. The pigment does not occur in white pigs. It is commonest in the black sows, but occasionally is found also in black hogs. There was considerable variation in the quantity and distribution of the mammary pigment in the colored breeds.

A case of incomplete ovariectomy was discovered in which one ovary has been retained and distinct signs of œstrus were shown by the animal, thus proving that "heat only occurs in sows when functional ovarian tissue is present, and that removal of the uterus without the complete removal of both ovaries is totally ineffective in preventing the recurrence of the œstrous cycle."

The Sapphire hog, J. A. McLEAN (*Jour. Heredity*, 5 (1914), No. 7, pp. 301-304, fig. 1).—This reports the formation of a so-called new breed of swine having as its principal characteristics blue color with variations, erect ears, trim bellies, strength of bone, and fat hog conformation with length of body. This breed is being evolved from the Yorkshire, Hampshire, Berkshire, Essex, and Chester White breeds. A large percentage of the pigs are breeding true.

Feeding draft foals (*Wisconsin Sta. Bul.* 240 (1914), pp. 31, 32, figs. 1).—Eleven pure-bred draft foals were fed by J. G. Fuller an average of 16.5 lbs. each of a mixture of ground oats, corn meal, bran, and cut alfalfa hay 6:1.5:1:1.5, on which they averaged gains of 2.1 lbs. per day at an average daily feed cost of 18 cts. They weighed at the end of the year from 1,000 to 1,200 lbs., the average cost of feed being \$51.66.

Cost of keeping work horses, W. E. FOARD (*Breeder's Gaz.*, 66 (1914), No. 7, p. 236, fig. 1).—Data secured from the records of 10 Missouri farms having from 4 to 10 horses each show the average total annual cost of keeping a horse to be \$81.91, of which feed cost amounts to \$62.29, labor \$9.84, and miscellaneous \$9.78. The total hours worked was 1,002, making the average cost 8.2 cts. per hour. There was a large variation in the cost among the several horses, also in the labor performed. As a rule the horse that worked more cost more to keep.

The inheritance of coat colors in horses, W. S. ANDERSON (*Kentucky Sta. Bul.* 180 (1914), pp. 121-145, figs. 6).—In this study the colors of 42,165 horses, representing 14,055 matings, were used.

In explanation of his findings the author concludes that from all the evidence chestnut is recessive to all colors; black dominant to chestnut and recessive to all others; bay dominant to chestnut, and black, and recessive to the three coordinate colors, gray, roan, and dun. The colors can be arranged in three series as follows: Gray, bay, black, and chestnut; roan, bay, black, and chestnut; and dun, bay, black, and chestnut; the first color of each series being dominant to all members of the series. Chestnut comes last and is recessive to all before. It is stated that there is no question that bay is recessive to gray, roan, and dun, and dominant to chestnut and black.

The author discredits the theory that strength or endurance goes with the colors. The factors, or determiners, which control the transmission of color are independent of all other qualities. The colors are unit characters and they behave as simple Mendelian colors.

It is stated that a fundamental characteristic of the chemical precursors of the melanins, the chemical compounds causing the coloring of the hair-coat, is their power to take up under different conditions different amounts of oxygen; small amounts of oxygen producing the lighter shades of pigmentation, while larger amounts cause the darker shades until the black is reached. The factor which determines the extent of oxygen resides in the germ cell.

The possibility of so breeding horses as to secure strains of chestnut, bay, black, and gray is discussed.

The origin of domestic fowl, C. B. DAVENPORT (*Jour. Heredity*, 5 (1914), No. 7, pp. 313-315, figs. 4).—In this paper the author attributes the origin of the domestic fowl to two distinct species, one the Jungle fowl, which is still found wild, and the other the unknown ancestor of the Aseel or Malay fowl. These two species are described and their introduction in the evolution of the domestic breeds of fowl explained.

Egg-laying competitions, 1913-14, D. F. LAURIE (*Dept. Agr. So. Aust., Egg-Laying Competitions 1913-14*, pp. 32).—In connection with these egg-laying competitions it was noted that of 125 pens of White Leghorns observed, eggs with tinted shell were collected from 71. It is believed that this is a character common to all birds, but subject to the phenomenon of dilution or marking. The largest number of pens showed tinted eggs during the months of June, July, August, and September.

With regard to the relationship between the characters which stand for "broodiness" and those for "color of shell," it was noted that of the 125 pens of White Leghorns, 51 pens were recorded for both "tinted eggs" and "broody birds," while 74 pens were recorded as showing only one character.

DAIRY FARMING—DAIRYING.

Comparison of one- and two-day test (*Guernsey Breeders' Jour.*, n. ser., 4 (1913), No. 3, pp. 13, 14).—Results obtained by the American Guernsey Cattle Club in a study of the advanced registry work the basis of a monthly one-day or two-day test are summarized as follows:

Of 41 cows selected at random from 38 herds, 16 gave during the year an average of 3.23 lbs. more milk fat on the one-day test (using first day) than on the two-day test, while the remaining 25 cows, gave an average of 5.1 lbs. less on the one-day than on the two-day test. Seven cows varied less than 1 lb. of milk fat in a year, five less than two, seven less than three, four less than four, five less than five, eleven less than between five and ten, and two less than 10 lbs. The least amount of variation in the 41 cows was 0.12 lbs., and the two largest were 13.63 and 16.35 lbs. milk fat.

The records of 250 cows were then worked out, and of these, 114 cows gave 527.02 lbs. more milk fat on a one- than a two-day test, while 136 cows gave 581.01 lbs. less.

Comparison of one- and two-day tests.—The trustworthiness of estimates of the richness in butter fat of a cow's production for a year, made by the method of the Guernsey Cattle Club from one one-day test per month, E. L. THORNDIKE (*Guernsey Breeders' Jour.*, n. ser., 4 (1913), No. 3, pp. 29-32).—From a study of the above records and the probable "error of the neglect of the relation of the daily percentages of butter fat to the daily amounts

of milk," and of assuming 30 daily percentages of butter from only two, it is concluded that "the trustworthiness of the advanced register records is very slightly impaired by the use of only a two-successive-days' test to sample the entire 30 of a month. It may be assumed with practical certainty that such sampling will never cause an error of over 23 lbs. in the total result for a year, that in 99 cows out of a 100 the error will be under 15 lbs., and that the average error will be $4\frac{1}{2}$ lbs. under. The divergence of a cow's record, 12 one-day tests being used, from her true record, will be under $6\frac{1}{2}$ lbs. on the average, under 21 lbs. in 99 cows out of a 100, and under 32 lbs. always."

From a study made of the records of 50 of the cows with respect to the possible divergence during a term of years, "it appears that a year's record as now taken by 12 two-day tests would never diverge from the average of 15 years' records similarly taken for that cow (were such obtainable) by more than 35 lbs., would diverge therefrom by more than 22 lbs. or more only once in a hundred times, and would diverge therefrom on the average by a little under 7 lbs." This 35 lbs. may then be taken as the upper limit of possible error since it also includes the divergence that might occur during the single year. "It seems safe to credit at least 7 of the 35 lbs. to these sources of variation which are added to those which make a record as now determined vary from the cow's true record for the year. If this is done we have then an upper limit of error for the record from 12 two-day tests of 28 lbs. butter fat by this method. . . . To say that in 99 cases out of 100 it will be true within 18 lbs., and that on the average it will be true within $5\frac{1}{2}$ lbs., is to make a thoroughly guarded statement."

Comparative value of one- and two-day tests as viewed by the experiment station (*Guernsey Breeders' Jour.*, n. ser., 4 (1913), No. 3, pp. 16, 17).—In connection with the endeavor of the Jersey and Guernsey Associations to get a uniform basis of advanced register testing, inquiries were sent to 24 experiment stations asking the comparative cost and relative accuracy of one- and two-day tests. The answers indicated that the difference in cost is slight and the accuracy of the two-day test greater.

The nature and causes of the variations in the richness in butter fat of milk from the same cow, E. L. THORNDIKE (*Guernsey Breeders' Jour.*, n. ser., 4 (1913), No. 5, pp. 35-39, figs. 6).—In connection with the milk fat tests made by the American Guernsey Cattle Club, reported above, a study was made of the causes of the variations in richness of the milk fat. It was found that a cow has a general average richness of milk which distinguishes her from other cows. If this general average of richness is taken as 100, the climatic, feeding, and other conditions related to season of the year, make her tend in any month to vary from this general average richness as follows: January 104.9, February 103.1, March 100, April 99.4, May 98.6, June 95.5, July 95.7, August 97.4, September 98.8, October 101.2, November 101.3, and December 104.5. These figures relate to the northern states from which tests were taken. The stage in the lactation period makes her tend to vary from this general average richness as follows: First month of lactation 89.6, second month 90.3, third 92.4, fourth 96.5, fifth 97.9, sixth 101.2, seventh 103.2, eighth 103, ninth 104.3, tenth 104.9, eleventh 105.3, and twelfth 109.4. However, this general tendency which the cow has as a member of the breed and species seems to be much complicated by individual peculiarities.

Of the cow and her treatment, "some cows seem to give almost as rich milk at the start as at the end; some to change gradually all along the year; some to change very rapidly in the early months and then hardly any; some to change hardly any till the later months and then very rapidly. There are in addition to these long swings and changes, irregular temporary ups and downs due to

minor causes. These fluctuations range up toward a fifth of the cow's general average richness, so that it is possible for a cow testing 5 per cent butterfat in general to go down to 4 per cent and up to 6 per cent independently of time of year, lactation period, and her own general course of change in richness. Such extreme fluctuations are however very rare, half of these irregular ups and downs being between -0.2 per cent butter fat and $+0.2$ per cent butter fat, four-fifths of them being between -0.4 per cent and $+0.4$ per cent, and nearly 96 per cent of them between -0.6 per cent and $+0.6$ per cent. The fluctuations up do not differ notably from the fluctuations down, but almost balance them in every way. The nature of these temporary fluctuations in the butter fat percentage is such as to make it probable that they are due to the combined action of many causes, each of which by itself alone would raise or lower the richness only slightly. When it happens that a large number of the 'reducing' causes act at once and few of the 'increasing' causes, there is a large fluctuation downward. Conversely, for the large fluctuations upward. Since such happenings are necessarily rare, the large fluctuations are rare."

The yield and composition of the milk of the Montgomery herd at Pusa and errors in milk tests, J. W. LEATHER and A. C. DOBBS (*Mem. Dept. Agr. India, Chem. Ser.*, 3 (1914), No. 6, pp. 147-175).—In these tests, certain of the cows appeared to yield more milk from one side of the udder than from the other, although in general similar in both quantity and quality. There was a difference found in both quantity and quality of the milk from the fore and hindquarters which appears to be characteristic of the individual cow. One cow yielded milk from the forequarter which was consistently richer than that from the hindquarter, while another yielded richer milk from the hind than from the forequarter, and a third showed no characteristic difference. It is thought that the quality of the milk is a function of the tissue of that region of the cow's udder in which it is produced and that though the opposite sides are symmetrical in this respect, the udder is in other directions no more uniform in function than it is in shape.

Fat content of milk and rate of coagulation with rennet, A. KREIDL and E. LENK (*Biochem. Ztschr.*, 63 (1914), No. 2-3, pp. 151-155, figs. 3).—The authors found that the time required for the coagulation of a milk with rennet is not constant even under similar experimental conditions. The rate of coagulation varies with the fat content, and is smaller the richer the milk is in fat.

Testing for fat in milk by the Babcock test (*Illinois Sta. Circ.* 174 (1914), pp. 11, figs. 13).—Instructions are given for the use of the Babcock test.

Bacteriological examination of market milk, P. G. HEINEMANN (*Trans. 15. Internat. Cong. Hyg. and Demogr. Washington*, 2 (1912), Sect. 1-2, pp. 133-135).—This gives the text of the article previously noted (E. S. R., 28, p. 275).

Studies in bacterial metabolism, A. I. KENDALL, A. A. DAY, and A. W. WALKER (*Jour. Amer. Chem. Soc.*, 36 (1914), No. 9, pp. 1937-1966).—This consists of a series of eight papers treating of the metabolism of various types of bacteria in milk. The observations recorded were made for the purpose of determining the nature and extent of the changes brought about by the growth of various important types of bacteria in sterile certified milk. "These determinations include the changes in reaction, as shown by alizarin, neutral red, and phenolphthalein, which indicate somewhat roughly the differential accumulation of alkaline or acid products, and the action on protein as represented by the accumulation of ammonia, ammonia being the only available index of protein breakdown applicable to this problem."

Among the bacteria studied are those of the typhoid-dysentery-alcaligenes group, intermediate or paratyphoid group, coli-proteus-cloacæ group, subtilis-mesentericus group, *Bacillus pyocyaneus*, *B. diphtheriæ*, *B. suispestifer*, *Vibrio*

cholera, *B. tuberculosis*, and coccal groups. Observations were also made on fat splitting in milk by bacterial lipase.

Preparation of buttermilk which can be preserved for a long time, R. SUWELACK (*German Patent 273,628, Jan. 30, 1913; abs. in Jour. Soc. Chem. Indus., 33 (1914), No. 14, p. 763*).—"Fresh buttermilk is heated for some time at not below 85° C., with vigorous agitation, then rendered homogeneous by forcing it, under a pressure of about 250 atmospheres, through narrow tubes against a hard surface, and after being cooled and freed from air is inclosed in air-tight vessels."

An investigation into the composition of cheese made from whole milk, G. BROWNLEE (*Dept. Agr. and Tech. Instr. Ireland Jour., 14 (1914), No. 3, pp. 499-506*).—From tests for fat made of a large number of samples of green and cured cheese it was found that on a dry matter basis "in the Cheddar cheeses the highest and lowest percentages were 53.54 and 48.72, respectively, in the green, and 52.96 and 48.6 in the cured, while for the Caerphilly cheeses the corresponding figures are 56.79 and 47.75 for the green, and 57.15 and 47.11 for the cured. The average percentage of fat in the dry matter of all the green cheese samples is 51.49 and of the cured 51.19, while that for all (327) samples is 51.33. . . . Taking the figures here found as a basis, one might safely recommend that a percentage of 45 should be taken as the limit below which the fat in the dry matter of a genuine cheese should not fall."

It is calculated that "1 gal. of milk gives 1.3 lbs. green Caerphilly cheese, 1.239 lbs. cured Caerphilly cheese, 1.056 lbs. green Cheddar cheese, and 1 lb. cured Cheddar cheese."

Pasteurized milk cheese (*Wisconsin Sta. Bul. 240 (1914), pp. 39, 40*).—Continuing work previously noted (*E. S. R., 28, p. 581*), tests conducted at various commercial factories in making pasteurized Cheddar cheese were satisfactory, an increase in yield of from 3 to 5 per cent being obtained. In some cases the texture was slightly inferior because of small holes. The extra cost of making pasteurized cheese was about \$2.25 per 1,000 lbs. Likewise satisfactory results have been obtained in making pasteurized brick cheese.

Three creamery methods for making buttermilk cheese, J. L. SAMMIS (*Wisconsin Sta. Bul. 239 (1914), pp. 3-24, figs. 7*).—Complete information is given on three methods of making buttermilk cheese, one of these previously referred to (*E. S. R., 23, p. 181; 25, p. 583*), which has been used for several years at creameries and in dairies in making cheese from ordinary buttermilk. The other two deal with the use of buttermilk obtained from cream pasteurized while sour.

Ice cream investigations (*Wisconsin Sta. Bul. 240 (1914), pp. 40, 41, fig. 1*).—In studying the factors which govern the overrun or "swell," the body texture, and the flavor of ice cream, A. C. Baer found that "the longer a cream is held cold the more viscous or the thicker it becomes, and the greater is the tendency to produce a high overrun during the freezing process. If the mixture is frozen too quickly, especially at the critical temperature between 30-28° F., not enough time is given to whip up the mixture properly and a low overrun will result. For this reason the temperature of the freezing mixture should not be too low.

"For proper whipping of the mixture to produce a good swell, a speed of at least 100 to 150 revolutions per minute is necessary in a freezer of the ordinary batch type, and from 200 to 250 revolutions in a continuous machine. Too rapid freezing produces a soggy and coarse grained ice cream. On the other hand, freezing too slowly may allow too much whipping and thus produce an undesirable open and foamy texture. Aging cream makes it more viscous, thus producing a firmer and smoother ice cream. A raw cream produces a

little better body and a smoother texture than pasteurized cream, but proper aging of the pasteurized cream will overcome this defect. Homogenizing the cream tends to produce a firm and smooth cream. Ordinarily ice cream does not usually contain enough solids in the form of milk fat and other milk solids to retain a firm body and smooth texture unless some filler is used. Cheap, inferior flavoring materials or poor grades of fillers will always show their effect on the flavor of the ice cream. A badly tainted or slightly sour cream can not be made into a well flavored ice cream."

Some improved dairy tests and methods, G. H. BENKENDORF, A. T. BRUHN, A. C. BAER, and J. L. SAMMIS (*Wisconsin Sta. Bul. 241 (1914), pp. 3-19, figs. 10*).—A method for determining the overrun in ice cream is described, which consists of melting 50 cc. of ice cream with 200 cc. of hot water into a 250-cc. flask, the use of 1 cc. of ether to reduce foam, and the filling of the flask to the 250-cc. mark with a known amount of water, this last portion of water and the 1 cc. of ether constituting the reduction in the volume of ice cream, or when compared with the volume of mix before freezing, the percentage of overrun.

A burette for calibrating Babcock test bottles is described. By means of this burette the fat percentage rather than the number of cubic centimeters can be read directly on the neck of the test bottle. A description is also given of a wire cheese curd knife having the advantage of being rigid of form and of cutting even cubes.

It is suggested that attaching a sediment tester to the wall by means of a telephone bracket and within easy reach of the man weighing the milk is a decided advantage.

In cheese-making tests with homogenized milk it was found that the homogenized milk curds were very fragile and easily broken by the curd knives and in stirring. During the salting and curing, the brick cheese formed rinds, which cracked, split open, and peeled off in layers about one-fourth of an inch thick, which would admit flies and dirt. After curing about four weeks, the cheese was poor in flavor and when cut was found to contain large internal cracks and a few mechanical holes, but none of the small round holes always present in good brick cheese. It scored considerably lower than that from ordinary milk. Unsatisfactory results were also obtained with American, Swiss, and limburger cheeses. Further study as to why homogenized milk should give cheese showing these defects is in progress.

VETERINARY MEDICINE.

Clinical bacteriology and vaccine therapy for veterinary surgeons, W. SCOTT (*London, 1913, pp. XIV+222, pls. 12, figs. 37*).—This work deals with the laboratory equipment; preparation of culture media; cultivation of bacteria; staining methods and stains; identification of bacteria—general principles; glass work requisites and how to make them; the elements of the blood which protect the animal body from pathogenic bacteria; vaccines and their mode of preparation; the syringe; phenomena following active immunization by vaccines; sera and their mode of preparation; special diseases, caused by specific bacteria, which are suitable for treatment by serovaccine therapy—bacterial diseases affecting the cutaneous system; bacterial diseases affecting synovial joints, the abdominal organs, the circulatory system, and the nervous system; diseases of the respiratory organs; swine fever; serovaccine therapy in Holland and other countries; weights and measures, etc.

Acid-fast bacilli occurring in the feces of some vertebrates, M. BERTANI (*Centbl. Bakt. [etc.], 1. Abt., Orig., 72 (1913), No. 4-5, pp. 270-273*).—In

investigations including cattle, swine, horses, rodents, birds, and other vertebrates, three nonpathogenic acid-fast species were isolated. Their cultural characteristics and mode of isolation are described.

Some structural transformations of the blood cells of vertebrates, G. L. KITE (*Jour. Infect. Diseases*, 15 (1914), No. 2, pp. 319-330, pl. 1, figs. 2).—Through the employment of a special mounting or culture medium the author has been enabled to determine that both white cells and erythrocytes of all classes of vertebrates may undergo many marked structural transformations of a reversible nature. In this paper the more important of these transformations so far observed are described.

Effect of poisons on the germ cells of the male (*Wisconsin Sta. Bul.* 240 (1914), pp. 34, 35).—In studies by L. J. Cole, alcoholic and lead poisoning of rabbits resulted in lessened vitality in the males and in their offspring.

The behavior of body temperature before, during, and after parturition with the bovine, sheep, and goat, M. LIMMER (*Ueber das Verhalten der Körpertemperatur vor, während und nach der Geburt bei Rind, Schaf und Ziege. Inaug. Diss., Univ. Leipsic, 1912, pp. 124, pls. 5*).—The results are reported of an investigation of taking numerous temperatures before and during pregnancy of bovines, sheep, and goats for the purpose of determining the value of the procedure for diagnosing the time of parturition.

An anteparturient rise takes place most markedly in bovines, and very often the temperature rises above what is usually assumed to be a physiological limit. In the goat and sheep the temperature rise is not so regular and rarely reaches a physiological hyperthermia, although in the goat, the second phase of the temperature rise is more definite and resembles that of the bovine. After a rise in temperature takes place in either of the animals, a fall in temperature is noted which in the bovine takes about two days. In the sheep it is very slow.

The temperature as an indicator for time of birth seems to be of practical and scientific value for the bovine but not for the sheep, and for economic reasons need not be considered for goats.

The significance and the origin of the so-called defensive ferments, E. ABDERHALDEN (*Deut. Med. Wchnschr.*, 40 (1914), No. 6, pp. 268-270).—The organs are deemed responsible for the enzym action and not the leucocytes. Castrated animals do not yield ferments for testicle substance when injected with the inactivated press juice of the testicle. Neither pancreas nor intestinal substance can be considered a single protein and when injected they will yield several enzymes.

This method may be of special value for determining the defensive powers of the body toward invading organisms.

The article constitutes a reply to various authors as to the objections which have been raised against the method.

Animal experimental investigations in regard to the specificity of defensive ferments, P. HIRSCH (*Deut. Med. Wchnschr.*, 40 (1914), No. 6, pp. 270, 271).—The results show that after the parenteral introduction of placenta and carcinoma tissues from the uterus, defensive ferments are produced which cleave placenta tissue but not uterine carcinoma tissue. On the other hand, the sera from carcinomatous animals cleave only carcinoma tissue.

Further experiments are in progress in regard to carcinoma and sarcoma.

Experimental investigation about autoserotherapy, G. EISNER (*Ztschr. Klin. Med.*, 76 (1912), No. 1-2, pp. 34-44, pl. 1; *abs. in Zentbl. Biochem. u. Biophys.*, 14 (1912), No. 1-2, pp. 74, 75).—In none of the 19 cases was a rise in temperature noted. The leucocyte curve, however, was positive and in almost all cases when sterile exudates were used the curve rose. The fastigium was reached four days after the injection. Pus from tuberculosis subjects induces

a rapid rise of the leucocytes which falls back rapidly. This increase in leucocytes is independent of the rise in temperature. Apparently the sera act specifically upon the leucocyte-producing organs.

Serodiagnosis according to Abderhalden, ALLMANN (*Deut. Med. Wchnschr.*, 40 (1914), No. 6, pp. 271-274).—With pregnant subjects the results were uniformly positive and in myoma negative. With carcinoma of the genitals and other inflammations the results were questionable.

Adsorption phenomena in the Abderhalden dialysis method, F. PLAUT (*München. Med. Wchnschr.*, 61 (1914), No. 5, pp. 238-241).—The presence of inorganic substances incapable of cleaving proteins by themselves, such as talc, barium sulphate, and infusorial earth, was found to produce an increase of substances in the dialyzate which gave the ninhydrin reaction.

The cases which were in man were mostly nervous disorders.

About the specificity of Abderhalden's dialysis method, H. SINGER (*München. Med. Wchnschr.*, 61 (1914), No. 7, pp. 350-352).—The results show that if the blood of healthy male rabbits is injected intravenously or subcutaneously into the same or another kind of animal, ferments are elaborated which shortly after will cleave rabbit placenta, liver, and muscle tissue. The same results were obtained with a man who received his own serum intravenously from one to two hours after drawing.

The ferments present in the body are said to be "groupe specific."

Notes about the utility of the dialyzing method in clinical and biological questions, E. ABDERHALDEN (*München. Med. Wchnschr.*, 61 (1914), No. 5, pp. 233-238, fig. 1).—In this article the author points out some of the reasons for the inconcordant results obtained by the Abderhalden method.

It often happens that about 50 per cent of the dialyzing thimbles (diffusion shells) sold are faulty inasmuch as they allow the passage of undenatured protein. Some of the shells are especially sensitive toward boiling water. The biuret test is preferred for the natural protein while the ninhydrin test is recommended for the cleavage products. The test may also be conducted by removing the undigested protein with precipitating reagents or with the ultrafilter of Bechhold.

A second source of error in the method is the use of an unsatisfactory substratum. The substratum must above all things be free from blood and diffusible products. The results obtained from organs other than placenta and tissues from pathological cases are discussed. When the method is used for diagnosing tumors or cancers, only the specific substratum should be used. Organs from another species of animals may eventually be used, but as our state of knowledge in this direction is not complete, it is advisable to use only species specific organs.

The work of other authors is critically discussed, and it is emphasized that when the results with the method are reported they should be accompanied by the other clinical findings.

The serodiagnosis of infectious diseases with the aid of Abderhalden's dialyzing method, E. VOELKEL (*München. Med. Wchnschr.*, 61 (1914), No. 7, pp. 349, 350).—This describes tests made with diphtheria, anthrax, and typhoid bacteria, nagana trypanosomes, and *Spirochæta pallida* as substrata for diagnosing the respective diseases caused by the organisms named.

Satisfactory results were obtained with typhoid bacilli and *S. pallida*, and in some cases with the serum protein of luetic subjects. The complement fixation (Wassermann's reaction) showed positive in almost every case in which the dialysis method showed the same condition. All luetic sera protein can not be used for the dialysis test.

About the hemolytic powers of the anthrax bacillus and the saprophytes similar to the anthrax bacillus, K. JÁRMAI (*Centbl. Bakt. [etc.], 1. Abt., Orig., 70 (1913), No. 1-2, pp. 72-80, pl. 1*).—Several investigators have noted that *Bacillus anthracis* has weak hemolyzing properties, and according to Burow, rabbits and guinea pigs affected with anthrax give evidences of a destruction of their erythrocytes in the course of the disease. Hutyra noted that *B. pseudoanthracis* and *B. anthracoides* hemolyze red blood cells in bouillon cultures. As these two micro-organisms are apathogenic, there apparently seems to be a contradiction as to the relation of hemolysis to pathogenicity. The micro-organisms studied in this investigation were *B. anthracis*, *B. pseudoanthracis*, *B. anthracoides*, and *B. anthracis similis*.

The slight hemolysin production of the anthrax bacillus is said to be due to its capsule, which possibly may hinder the secretion of the hemolysin into the culture fluid. The saprophytic organisms can best be differentiated from the anthrax bacillus by noting their hemolytic properties, and this can be done by observing the colonies on the blood agar plates; these, in contradistinction to the anthrax bacillus, show zones of hemolysis surrounding the colonies.

The blood of animals affected with anthrax gives a positive Ascoli reaction six hours after death. The red blood cells of animals affected with anthrax show no change but after death, when capsule formation could not take place, they are apparently acted upon by the anthrax bacillus; consequently the hemolysis noted in cadavers is a post-mortem phenomenon.

Results and outlook of the thermoprecipitin reaction, A. ASCOLI (*Arch. Path. Anat. u. Physiol. [Virchow], 213 (1913), No. 2-3, pp. 181-233, figs. 5*).—This deals with the evolution of M. Ascoli's reaction for diagnosing anthrax, and discusses succinctly the various phases of the topic under the following headings: The precipitating serum (preparation, standardization, and conservation), specificity, the material to be examined, the extracts of organs for the precipitin reaction, conducting the reaction (in the well-appointed laboratory and by the veterinarian in everyday practice), examination of bovines, pigs, horses, etc., further uses of the reaction in examining foods, in forensic medicine, hog erysipelas, blackleg, paratyphoid and meat poisoning, tuberculosis, and Malta fever, and the possible future use of the reaction for hog cholera, typhoid fever, etc.

A large bibliography accompanies the article.

Contribution to elucidating open questions in regard to anthrax and combating this disease, W. BUROW (*Beiträge zur Klärung offener Fragen beim Milzbrand und seiner Bekämpfung. Berlin, 1912, pp. 88, figs. 3*).—This is the text of an address given before the council of the Royal Veterinary High School at Dresden as a part of the requirements to gain the right to teach at that institution. It discusses and gives the reasons for the occurrence of the disease in certain animals and under certain conditions, and deals with the methods of protective and curative vaccination, the precautions to be observed when vaccinating, and the causes for failure in some cases.

Investigations in regard to the etiology of foot-and-mouth disease.—The cause and active immunization, SIEGEL (*Berlin. Tierärztl. Wchnschr., 30 (1914), Nos. 1, pp. 1-3; 2, pp. 25-27*).—The work of the Imperial Health Department (E. S. R., 31, p. 282) is criticized inasmuch as no experiments were conducted in regard to the presence of micro-organisms in the blood, the presence of cocci in the undeveloped vesicles, or the filterability of the virus. The results obtained in the infection tests point to specific properties of the cocci although the lesions present in the mucous membrane of the mouth were only a modified form of foot-and-mouth disease. Many cases of natural foot-and-mouth disease occur in which blebs are not present.

The cocci previously reported (E. S. R., 28, p. 376) were found to be present in the blood of every fresh case of the disease, especially at the time when the fever was on the rise and before the eruption of the vesicles. In sections of vesicles not fully developed the organisms were noted but not in a fully developed state. The biologic and morphologic characteristics of these microorganisms are hard to determine, and among a group of the pathogenic cocci there are always others which are morphologically identical but can not be differentiated by the ordinary means. Certain characteristics were noted, however, and these consisted of (1) the property possessed by the organism of passing through a filter; (2) the development of first generations into definite cocci or streptococci when taken directly from the animal and inoculated into spleen bouillon; and (3) the intracellular growth which differentiates them from *Staphylococcus pyogenes*.

While we have no very definite information in regard to the best procedure for actively immunizing bovines against this disease, it would seem that it is best to select an attenuated virus which does not produce a marked form of the disease.

Remarks in regard to the article noted above by Sanitary Councilor Dr. Siegel, VON OSTERTAG (*Berlin. Tierärztl. Wchnschr.*, 30 (1914), No. 2, pp. 27, 28).—A short reply to the above.

The deliberation of the German Agricultural Council with regard to the present status of combating foot-and-mouth disease (*Molk. Ztg. Berlin*, 24 (1914), No. 7, pp. 69, 70).—Addresses and discussions by Löffler, von Nathusius, Brieger, Nevermann, and Krause are given.

Reinvestigation of mallein in the horse establishments of northern Caucasus, GORDSJALKOWSKY (*Vet. Vrach*, 1913, No. 35-36; *abs. in Berlin. Tierärztl. Wchnschr.*; 29 (1913), No. 48, pp. 860, 861).—As the result of studying the value of mallein for diagnosing occult glanders, it is concluded that healthy horses sometimes give a reaction with mallein which in some cases is hard to differentiate from the real positive reaction. Consequently glanders should be diagnosed finally on the basis of the clinical symptoms.

Some diseases of animals caused by bacilli of the hemorrhagic septicemia and colon groups, H. ZEISS (*Arch. Hyg.*, 82 (1914), No. 1, pp. 1-32; *abs. in Rev. Bact.*, 4 (1914), No. 2, p. 24).—The author describes an outbreak of a disease among canaries in which an organism was isolated that belonged to the hemorrhagic septicemia group and resembled the fowl cholera bacillus. A bacillus which appears to be the same was isolated in pure culture from a tubercular-like abscess in a rabbit. A bacillus closely resembling *Bacillus coli communis* was isolated in an outbreak of disease among chickens.

Capsule formation by the bacteria of hemorrhagic septicemia, P. B. HADLEY, RUTH BRYANT, and MARGUERITE ELKINS (*Centbl. Bakt. [etc.]*, 1. Abt., *Orig.*, 72 (1914), No. 6-7, pp. 478-480).—Among 17 cultures examined by Gozony's India ink method,^a all of which were known by cultural tests and by animal inoculations to belong to the fowl cholera group, not one was found that gave the slightest suggestion of capsule formation. At the same time capsulated ink bacteria and other capsulated organisms added to the ink for control purposes were demonstrated.

In view of the results the authors conclude that it can scarcely be doubted that the bacteria seen and described by Gozony were not bacteria of hemorrhagic septicemia.

Necrotic stomatitis, I. E. NEWSOM (*Colorado Sta. Bul.* 197 (1914), pp. 11-20, *figs.* 3).—This paper presents accounts of calf diphtheria, sore mouth disease

^a *Centbl. Bakt. [etc.]*, 1. Abt., *Orig.*, 68 (1913), No. 7, pp. 594-597.

in pigs, and lip and leg ulceration in sheep. These diseases are said to have caused widespread loss in Colorado during the past ten years.

In regard to the etiology of rabies, F. PROESCHER (*Berlin. Klin. Wchnschr.*, 50 (1913), No. 14, pp. 633-636, figs. 17; *abs. in Ztschr. Immunitätsf. u. Expt. Ther.*, II, Ref., 7 (1913), No. 5, p. 228).—With the aid of the antiformin test a microscopically visible organism was noted in the brain of rabid animals and man.

The methods for protectively vaccinating against rabies, N. POKSCHIS-CHESKY (*Ztschr. Hyg. u. Infektionskrankh.*, 76 (1914), No. 3, pp. 453-468).—After reviewing the work of others, including that of Miessner, Kliem, and Kapfberger, and Pfeiler and Kapfberger (*E. S. R.*, 30, pp. 281, 282), the results of the author's work, which was done for the purpose of determining whether it was possible by the original Pasteur method and the intraperitoneal injection of fresh brain substance from passage rabbits to immunize negatively experimental animals, chiefly dogs, are reported.

The results show that the original and the modified Pasteur methods are not efficacious for immunizing dogs against a subdural or intramuscular infection with a rabies virus.

In testing experimental animals as regards immunization it is necessary to use satisfactory methods of infection such as the subdural and intramuscular methods with street virus. The intraocular method is not reliable and uncertain results are always obtained by subcutaneous application and by the bite of a rabid animal. The intraperitoneal method with large doses of fixed virus gave a certain active immunity in dogs and rabbits. The immunity was tested with an intramuscular injection of street virus. Only one-half of the cases immunized intraperitoneally were proof against a subdural infection.

The treatment of tetanus by antitetanic serum, E. E. IRONS (*Jour. Infect. Diseases*, 15 (1914), No. 2, pp. 367-377).—An analysis of 225 cases treated during the period 1907 to 1913 shows the mortality of tetanus treated by tetanus antitoxin to be about 20 per cent lower than the average mortality of tetanus treated without serum. The mortality of the cases treated by efficient methods and adequate doses is considerably lower than that of cases receiving small doses subcutaneously.

On the American method of standardizing tetanus antitoxin, A. MACCONKEY (*Jour. Hyg. [Cambridge]*, 13 (1914), No. 4, pp. 467-492).—This is a study of the American method (*E. S. R.*, 20, p. 379) of standardizing tetanus antitoxin. In the experiments two standard toxins were examined. It was found "that, provided control experiments are carried out from time to time (as in the case of standard diphtheria toxin), this method of standardizing tetanus antitoxin is—as claimed for it—simple, accurate, and reliable."

Gosio's vital reaction for the tubercle bacillus, S. BELFANTI (*Ztschr. Chemother.*, I, *Orig.*, 1 (1912), No. 2, pp. 113-121, figs. 2; *abs. in Zentbl. Biochem. u. Biophys.*, 14 (1913), No. 22, p. 878).—Living tubercle bacilli of the human, bovine, and avian types strongly reduce potassium tellurate. The intensity of the reaction is proportional to the vitality of the organisms. In addition to the reducing properties, the tubercle bacillus possesses synthesizing powers toward tellurium salts. Compounds are produced which possess a garlic-like odor.

Precipitating action of blood serum with lipoids of the tubercle bacillus, L. PRETI (*München. Med. Wchnschr.*, 61 (1914), No. 5, p. 241).—It was observed that when an emulsion of the lipidlike substances obtained by extraction of 1 to 2 months' old tubercle bacilli with alcohol and ether was added to the blood serum of patients affected with tuberculosis, a marked precipitate was

obtained in about 6 hours. The test was tried with 100 subjects, 64 of which were positively tuberculous. Fifty-three of the 64 gave a positive reaction.

The bovine tubercle bacilli in tubercular pathologic changes and the relation of bovine tuberculosis to human tuberculosis, E. BERTARELLI (*Centbl. Bakt. [etc.]*, 1. Abt., *Orig.*, 70 (1913), No. 1-2, pp. 10, 11).—The separation of tubercle bacilli into human and bovine types is regarded as a very indefinite classification. Many bacilli noted in man and which have the characteristics of the bovine type of bacilli are in reality the human type of organism.

Notes and observations on twenty cases of tuberculosis, W. CAUDWELL (*Vet. Rec.*, 26 (1914), No. 1334, pp. 491-496).—These notes deal with work conducted under the Tuberculosis Order of 1913 (Great Britain). The cases are divided into two categories, those confirmed by clinical and other evidences and those which were not confirmed. Some of the cows were in milk.

In 12 of the clinically certain tuberculosis cases the lungs and bronchial and mediastinal glands were diseased. In 9 cases the mediastinal glands were affected and the liver was diseased in 6. In 1 case the heart and pericardium were diseased. Tuberculosis was rarely found on the surface of the spleen, but the uterus was often diseased. Two cases had affected mammary glands.

A discussion of the paper at a meeting of the South Eastern Veterinary Association is included.

Bovine tuberculosis, S. DELEPINE (*Separate from Proc. Nat. Vet. Assoc.*, 30 (1912), pp. 11).—The investigations reported were conducted in Cheshire, Lancashire, and Aberdeenshire from 1897 to 1899. Statistics are given of 379 bovines which were treated with tuberculin and after death submitted to autopsy.

When classified according to age it was found that among animals up to 1 year of age 3.4 per cent were tuberculous; 1 to 2 years, 13.2; 2 to 3 years, 24.1; 3 to 5 years, 23.5; 5 to 9 years, 48.9; and 9 to 13 years, 76 per cent. In Great Britain during 1910 among 1,319,562 bovines of 1 to 2 years of age, 200,582 were found tuberculous, and among 4,120,813 animals over 2 years old, 1,483,492 were tuberculous.

The mode of infection in bovines is from bovine to bovine and this may be brought about directly or indirectly. The construction and ventilation of the buildings in which animals are kept are deemed of great importance in obtaining milk free from tubercle bacilli. Plans are presented for eliminating tuberculosis from herds on the basis of the tuberculin test and the removal of the animals.

Some facts about brain and retropharyngeal gland tuberculosis in the bovine, KNESE (*Berlin. Tierärztl. Wehnschr.*, 30 (1914), No. 1, pp. 3-5).—The author emphasizes the fact that tuberculosis of the brain often occurs in bovines from 3 months to 1 year in age. In animals not affected with abdominal (visceral) or pulmonary tuberculosis the brain as a focus of the disease is often overlooked. The retropharyngeal lymph glands as a focus for this pathologic condition have also been too little considered in looking for tuberculosis in young animals.

An outbreak of tuberculosis in pigeons, F. S. JONES (*Amer. Vet. Rev.*, 44 (1914), No. 4, pp. 497-500, figs. 3).—A detailed description of three cases in pigeons from which the tubercle bacillus was isolated. The organisms were alcohol acid fast, thus differing from those studied by Morse (*E. S. R.*, 25, p. 689). The lesions resembled those produced by the avian bacillus.

About the action of antiformin on the tubercle bacillus, DONGES (*Ztschr. Hyg. u. Infektionskrankh.*, 75 (1913), No. 1, pp. 185-192).—There are strains of

tubercle bacilli from both human and bovine sources which are very resistant toward antiformin. These lose some of their infecting capacity only when exposed for from 12 to 24 hours to concentrated antiformin.

Tuberculosis and Tuberculosan, W. BUROW (*Berlin. Tierärztl. Wchnschr.*, 29 (1913), No. 48, pp. 854-858).—A polemic, in which the author claims that the various methods for eradicating tuberculosis are not to be displaced by Burow's method, but are aided by it.

Tuberculosan—BUROW, RAUTMANN (*Berlin. Tierärztl. Wchnschr.*, 29 (1913), No. 41, pp. 729-732).—This is a critical analysis of a circular sent out by a firm manufacturing Tuberculosan. The preparation, according to the author, has no immunizing properties whatever.

Is the eradication of tuberculosis with Tuberculosan proven? RAUTMANN (*Berlin. Tierärztl. Wchnschr.*, 30 (1914), No. 3, pp. 43-45).—This is answered negatively and, according to the author, no specific properties can be attributed to Tuberculosan.

Investigations about complement-fixing antibodies in experimental and spontaneous tuberculosis and also in paratuberculous enteritis, O. BANG and C. W. ANDERSEN (*Centbl. Bakt. [etc.]*, 1. Abt., Orig., 69 (1913), No. 7, pp. 517-538, figs. 3).—The sera of tuberculous bovines were found to contain complement-fixing antibodies, and their quantity was in proportion to the gravity of the disease. The complement fixation test is not specific and simply indicates that acid-fast bacilli are present.

The sera from cows affected with paratuberculous enteritis (Johne's disease) behave in the same manner with the complement fixation test as do those from tuberculous cows. The sera from paratuberculous cows contain many antibodies, and in advanced cases where the mammary gland is affected the milk may contain them. In the more severe forms of tuberculosis the milk undoubtedly contains many antibodies.

The sera of rabbits treated subcutaneously with killed or avirulent living tubercle bacilli were found to contain and retain many antibodies for a considerable length of time. Unlike the case of the tuberculous bovine, infection of the rabbit with virulent tubercle bacilli does not induce the formation of large quantities of complement-fixing substances. The rabbits often, when strongly tuberculous, show only a small amount of antibodies.

A good antigen may be prepared with slightly emulsified tubercle bacilli, whereas tuberculin, according to this investigation, is an inferior antigen. Horses, like rabbits, receiving subcutaneous injections of killed tubercle bacilli yield a blood containing much antigen.

Antibodies can also be detected in the blood of birds with the complement fixation test.

Report on actinomycosis (ray fungus disease) and tuberculosis in imported South American ox tongues, E. W. HOPE (*Liverpool, 1914, pp. 20*).—In his report as medical officer of health at the port of Liverpool, the author summarizes investigations based upon examinations of 147,501 South American ox tongues as follows:

"Diseased conditions are present in South American tongues to an extent of 2.5 per cent. No doubt many tongues are rejected by the inspectors in South America, especially those which show extensive lesions in the blade of the tongue. Recent importations show that the majority of these tongues are being more carefully inspected; the glands are frequently incised and properly skewered in position. Actinomycosis (ray fungus disease) is present in South American tongues, and must be fairly prevalent among the cattle. Tuberculosis is also present among these infected South American tongues; all those glands which showed caseous or calcareo-caseous nodules were submitted to

experimental examination with the result that 67.7 per cent produced generalized tuberculosis in guinea pigs. Seven cases of mixed infection (actinomycosis and tuberculosis) were found.

"From the frequent presence of actinomycosis and tuberculosis in the lymphatic glands attached to imported frozen tongues, it has become imperative that importers should see that all the glands are left attached to the tongues."

A brief report upon an examination of South American tongues, by J. M. Beattie (pp. 14-16), and a report upon 46 South American and 2 North American ox tongues and tongue glands examined for actinomycosis and tuberculosis, by D. M. Alexander (pp. 17-20) are appended.

[Work of the government bacteriologist in vaccinating against tick fever, pleuro-pneumonia, and blackleg], C. J. POUND (*Ann. Rpt. Dept. Agr. and Stock [Queensland], 1912-13, pp. 85-87*).—A short account of the results obtained during 1912-13 from immunizing 23,083 animals against tick fever. Many of the animals were inoculated by the owners, and the balance, 9,498, were treated by the officers of the department.

Where the cattle were kept from tick infestation the average mortality was only 2 per cent. "In several instances cattle from clean districts were placed immediately after inoculation in tick-infested and redwater paddocks, and although in each case the owner was advised as to the very great danger which would follow, he stated that he was prepared to take the risk, with the result that the losses were in some instances as high as 50 per cent."

Several steers free from tuberculosis and blackleg, which were immunized against tick fever and whose blood was proved to give a reaction in susceptible cattle, were sold as blood supply animals. In addition some stud animals were immunized. Altogether there were 72 valuable bulls, and one of these died, this being the first fatal case out of 200 animals inoculated at the station. The immunity conferred by injecting blood taken from an animal that has recovered from either naturally or artificially produced fever, while not absolutely perfect, is considered to be of a very high order.

The injection of normal horse serum (the horse is a nonsusceptible animal) into cattle or the administration of quinin subcutaneously or intravenously did not protect the animals against the disease. Specially prepared and tested pleuro-pneumonia virus was supplied during the year for protective vaccination, and 32,420 head of cattle were treated. Several complaints were received with reference to cattle dying after inoculation. Some of the tails of the cattle had to be amputated after inoculation.

Twelve hundred and thirty head of young stock were vaccinated against blackleg.

Effects of tick eradication on the cattle industry of the South, W. F. WARD (*U. S. Dept. Agr., Bur. Anim. Indus., Effects of Tick Eradication on the Cattle Industry of the South, 1914, pp. 26, figs. 8*).—This paper discusses the recent improvements that have taken place in the tick-free areas of the Southern States and suggests methods of improvement which should be adopted as soon as the ticks have been eradicated from any section.

Bighead in sheep, H. J. FREDERICK (*U. S. Dept. Agr., Bur. Anim. Indus., Bighead in Sheep, 1914, pp. 6*).—This is a report of investigations conducted by this Department in cooperation with the Utah Experiment Station.

Bighead is an affection that has been observed by sheepmen for upwards of 30 years. It is characterized by a sudden swelling of the head and ears and the presence in the swelled portions of the head of a straw-colored serum which often drips from the parts. The affected tissues present a gelatinous appearance, and the swelling is often so severe that the animal's vision is partially

or entirely obscured. This, with a severe irritation of the head, causes the animal to be extremely restless and to walk aimlessly about until exhausted. It occurs in Utah and surrounding States, the greatest losses occurring in southern and central Utah, southern Idaho, eastern Nevada, and western and southern Wyoming. It is a condition induced by severe exertion of sheep during very warm weather, especially after a cold storm or cold night, and is not transmissible from affected to healthy sheep. It attacks all kinds of sheep, both young and old, male and female, but is not common among lambs.

It may be prevented by handling the sheep properly, that is by not driving them too far or too fast on the trail, especially before shearing in the spring. When sheep are affected they should be dropped out of the herd, or the entire band should be held and allowed to rest, in the shade if possible, and be moved only during the cooler parts of the day. Sheep with swelled heads should have their heads anointed with olive oil or vaseline and be kept quiet for from 12 to 24 hours.

Vaccination against sheep pox with sensitized virus, C. DUBOIS (*Rev. Gén. Méd. Vét.*, 22 (1913), No. 264, pp. 649-661).—The purpose of these experiments, which were made with young or adult sheep, was to test the efficiency of the vaccine upon breeds of sheep which are very receptive to pox. The animals, 15 in all, were given one-quarter to one-half, and whole doses (0.2 cc.) of vaccine. They were found to be extremely sensitive toward the vaccine and 3 out of 5 receiving the one-quarter dose reacted distinctly. When the entire dose was given, all the animals gave a positive reaction, but although the latter findings speak in favor of giving an entire dose, the symptoms which follow are rather intense.

The lambs and sheep under treatment behaved better than did the ewes. Ewes in lactation, when vaccinated, show a diminution in their milk secretion, but those in a period of gestation rarely abort.

The method produces an immunity which protects animals against an infection such as would be produced when the sheep are kept in contact with naturally diseased animals. The vaccine is without danger and in infected localities the use of the sero-vaccine is advised.

Experimental studies on contagious agalactia (deficiency of milk) in goats and sheep, R. MARRA and N. COCCIANTE (*Gior. R. Soc. Naz. Vet.*, 61 (1912), Nos. 15, pp. 329-337; 16, pp. 353-360; *abs. in Internat. Inst. Agr. [Rome], Md. Bul. Agr. Intel. and Plant Diseases*, 4 (1913), No. 4, pp. 608, 609).—"The writers give first a short review of the various works so far published dealing with the contagious agalactia of sheep and goats and then pass on to a detailed account of the disease. The chief symptoms of the latter are fever, alteration of the lacteal glands, joints, and eyes of the animals; but, as a rule, the former are alone affected.

"The writers were able to produce the malady artificially in healthy sheep by means of subcutaneous injections of the blood or milk filtrate taken from diseased animals. Further, they were able to prepare a serum for immunization against contagious agalactia which has proved to be very efficient."

Interim report of the departmental committee appointed by the Board of Agriculture and Fisheries to inquire into swine fever, with minutes of evidence, index, and appendix (*Bd. Agr. and Fisheries [London], Interim Rpt. Dept. Com. Swine Fever, pts. 1 (1911), pp. 16; 2 (1911), pp. IV+398, figs. 4; 3 (1914), pp. 4+38*).—These reports include the deliberations of the committee appointed to study the following points: "(a) To what extent is it possible for contagion to spread by infective excretions being carried mechanically by attendants and animals other than swine. (b) Whether external parasites, such as certain lice, carry the disease from sick to healthy swine. (c) Whether

pigs which have, to all appearance, recovered from swine fever remain long infective to other swine. (d) Whether apparently healthy pigs which have been exposed to infection are capable of transmitting the disease as carriers. (e) For what period it would be safe to consider swine which have recovered from swine fever to be immune against a further attack. (f) What use, if any, could be made of artificial methods of immunization to expedite the eradication of swine fever? (g) Whether any of the methods which have lately come into use in connection with other diseases could be employed in the diagnosis of nontypical cases of swine fever."

No experimental data are reported, but certain tentative recommendations are made and the opinions of experts and others interviewed by the committee are included.

Hog cholera control, G. H. GLOVER (*Colorado Sta. Bul.* 197 (1914), pp. 3-11).—This popular account includes a discussion of the hog cholera campaign in the San Luis Valley, with a report of work done by the Monte Vista Hog Growers' Association from February 10, 1913, to February 1, 1914.

The preparation of hog cholera immune serum, A. D. FITZGERALD (*Vet. Alumni Quart.* [*Ohio State Univ.*], 1 (1913), No. 1, pp. 5-7).—A short description of the preparation and standardization of antihog-cholera serum.

Preliminary report on the results of the treatment of 140,000 head of swine with serum-virus in Ohio, P. FISCHER (*Vet. Alumni Quart.* [*Ohio State Univ.*], 1 (1914), No. 3, pp. 64-67).—The figures given are based upon the compiled reports sent in by owners whose herds were treated during a period of two years, ended November 4, 1912. Approximately 2,000 herds of swine in all parts of the State of Ohio and comprising 140,000 animals were treated by official veterinarians, but reports were received for only 1,762 herds containing 116,714 hogs. The serum-virus treatment was used only for healthy herds.

Of the original number of swine in the herds considered (100,773), 11,056 had died before treatment was applied. There were left untreated on account of supposed infection 9,850, of which 6,321 died from cholera. Also 21,319 had temperatures ranging from 104 to 108° F., indicating the probable presence of infection at the time of treatment and 10,276 died after treatment. Of 2,816 pregnant sows treated, 1,445 were reported as farrowing healthy litters, 473 as having aborted, and 898 sows were not reported.

Compiled reports for the years 1910-11 and 1911-12 on 526 healthy herds comprising 39,958 animals show that 26,997 animals, of which 5,920 showed high temperatures indicating possible infection, received serum-virus treatment; 9 animals received serum-alone treatment; and 14,204 animals were left untreated on account of previous treatment or because they were ready for market or for experimental observation. Of the treated pigs 12 were reported by the owners as having died from what they believed might have been cholera. Six hundred and sixteen apparently healthy pregnant sows were included among the treated animals in the healthy herds, and of these 459 sows were reported as having farrowed healthy litters, 104 were not reported, and 53 sows were reported as having aborted.

These figures show that the danger from serum treatment, so far as causing abortion is concerned, is not serious.

"Since 1908 about 250,000 head of swine have been treated with protective serum (serum alone or serum and virus) under the direction of the state veterinarian with serum prepared in the laboratories of the State Serum Institute."

The results seem to indicate that where the serum-virus method was used in healthy swine, practically perfect results were obtained.

The control of hog cholera by slaughter methods, G. HILTON (*Amer. Vet. Rev.*, 44 (1914), No. 5, pp. 573-580).—In Canada the "premises on which this malady is suspected, as well as adjacent ones, are promptly quarantined and measures taken to establish a diagnosis. Directly this is accomplished, all infected and contact hogs are slaughtered. The carcasses of the hogs which have shown evidences of the disease, together with all débris, are cremated, and when this procedure is impracticable they are covered with lime and deeply buried. The apparently healthy hogs are suitably slaughtered on the owner's premises, the carcasses carefully inspected, and a license issued permitting the removal for sale purposes of any which are considered wholesome. It is, however, not customary to remove the carcasses of hogs which have been in direct contact with those showing symptoms of the disease.

"As soon as all carcasses and contact matter have been satisfactorily disposed of, the cleansing and disinfection of the premises is proceeded with; this is done under the supervision of the veterinary inspector in charge of the outbreak, and must be performed in a manner entirely satisfactory to him. Cheap, crudely constructed, insanitary hog houses are burned, while proper measures are taken to disinfect effectively the more modern structures. The yards to which hogs have had access are covered with lime and carefully plowed under, and the trees in the orchards or yards and fences are also disinfected from the ground to a suitable height. No hogs are permitted to be brought to any farm until a period of three months has elapsed from the completion of disinfection."

Compensation is paid only for animals which are slaughtered at the request of the inspector, and "a maximum valuation of \$50 is allowed for registered pure-bred hogs, and \$15 for grades, the value in each case being adjusted by the inspector whose decision is final."

The distribution of the disease in Canada is also discussed. The importation, manufacture, sale, or use of hog cholera serum is prohibited in Canada.

Suggestions relative to the prevention of hog cholera, J. H. KASTLE and R. GRAHAM (*Kentucky Sta. Bul.* 181 (1914), pp. 149-155).—This paper includes a tabular summary of results obtained from the use of antihog-cholera serum at the station during the month of June, which shows as low a mortality attending and following the inoculation as has been obtained elsewhere in the United States. Of 3,180 hogs treated in 100 herds, reports of which were received, 2,961 or 93.1 per cent survived.

About infectious abortion in pigs and hog cholera, DÖRRWÄCHTER (*Mitt. Ver. Bad. Tierärzte*, 12 (1912), No. 10, pp. 149-153).—During the last few years (1911-12) abortion has occurred in hogs without giving any clue to the causative factors. As a premonitory sign in some animals the vagina was swollen and an exudate was present. In other animals these phenomena were entirely absent, but after abortion in all animals an odorless, grayish-yellow exudate was present. Marked constitutional disarrangement was hardly ever present before abortion took place. The fetuses and the afterbirths were often eaten by the hogs. The boars used for serving the animals in no case showed signs of a diseased condition. The clinical appearances are described in detail in the article with the methods of disinfection and isolation.

A little later a very malignant form of the disease occurred and as a result many sows died. The remarkable part of this enzootic was the presence of an acute endometritis which is often noted in animals affected with hog cholera. The pathologic anatomy resembled endometritis with a subsequent septicemia. The bacteria noted in the uterine secretions at first appeared to be diplococci but closer observation showed them to be bacilli with rounded ends. Whether the organism in question was the *Bacillus abortus* (Bang), *B. suissepticus*, *B. suispestifer*, or *B. bipolaris septicus* was not established.

The *Bacillus abortivus equinus* as an etiological factor in infectious arthritis of colts, E. S. GOOD and W. V. SMITH (*Jour. Infect. Diseases*, 15 (1914), No. 2, pp. 347-349).—The authors have isolated the organism causing infectious abortion in mares from a colt affected with infectious arthritis. "At the present time it is impossible to say as to what rôle the *B. abortivus equinus* plays in the disease of infectious arthritis of colts, but that it is capable of producing this disease, as are the other germs noted by investigators, is evidenced in this instance."

The etiology of pyemic arthritis in foals, F. W. SCHOFIELD (*Jour. Infect. Diseases*, 15 (1914), No. 2, pp. 409-416).—The author's studies of the characteristics of the bacillus which causes pyemic arthritis in foals show it to belong to the colon-typhoid group and to be closely related to *Bacillus paratyphosus* B.

Attention is called to the fact that the organism isolated, and here described, has a very close relationship to the one recently isolated by Good (E. S. R., 29, p. 779) in contagious equine abortion. "In cultures the only difference observed is that the bacillus of equine abortion causes fermentation in raffinose while my organism does not attack this carbohydrate. However, difference in strains would readily account for this. The most convincing evidence that these organisms are but strains of the same species is that they can not be differentiated by means of the complement fixation test. Serums giving complete fixation with antigen prepared from my organism also give fixation in corresponding dilutions with antigen prepared from the bacillus of equine abortion. With characteristics that correspond so closely, these organisms appear to be but strains of the same species, and it is quite probable that the same organism may be responsible for both septic arthritis and abortion. These diseases commonly coexist in the same locality; furthermore, it is of frequent occurrence for a mare to abort one season and during the next to deliver a colt that develops septic arthritis. The more one studies the clinical history of these diseases the more convincing becomes the probability of their common etiology in many instances."

A text-book of horseshoeing for horseshoers and veterinarians, A. LUNGWITZ and J. W. ADAMS (*Philadelphia and London*, [1913], 11. ed., pp. 216, figs. 229).—In this eleventh edition of Lungwitz's work, J. W. Adams assumes entire responsibility owing to the author's having reached the age of retirement. In revising the tenth edition, translated in 1904, many chapters have been rewritten and illustrations withdrawn and others added in order to keep pace with the progress in farriery. The effect of weight in the shoe in altering the flight of the foot is discussed, as are rubber pads, so widely used in the United States. Attention is directed to many innovations of more or less value that have appeared during recent years.

The various chapters deal with (1) the gross anatomy of the horse, (2) the foot in its relation to the entire limb, (3) shoeing healthy hoofs, (4) shoeing horses that forge and interfere, (5) winter shoeing, (6) hoof nurture, (7) general remarks concerning the shoeing of defective hoofs and lame horses, (8) inflammations of the pododerm (pododermatitis), (9) defects of the hoof, and (10) shoeing mules, asses, and oxen.

Vaccine treatment of chicken pox in fowls (*Wisconsin Sta. Bul.* 240 (1914), pp. 36, 37, fig. 1).—In experiments with the vaccine treatment of chicken pox, first suggested by Manteufel (E. S. R., 23, p. 792), highly beneficial results were obtained by F. B. Hadley, B. A. Beach, and J. G. Halpin in ailing as well as in healthy fowls.

The vaccines were prepared by grinding diseased tissues, such as pox scabs and affected membranes, and subjecting them to a temperature of 55° C. (131° F.) for one hour. "Four hundred and forty fowls were treated five days apart

by a double vaccination. In this lot only 4 subsequently developed the disease while in 75 unvaccinated controls 26 well-marked cases of chicken pox occurred in three weeks. Although there seems to be a considerable variation in the natural susceptibility of fowls to artificial inoculation, birds treated with the vaccines and placed in infected pens escaped the disease while it was possible to infect controls." See also a previous note (E. S. R., 30, p. 785).

RURAL ENGINEERING.

Irrigation manager and his legal problems, F. H. NEWELL (*Jour. Electricity*, 33 (1914), No. 5, pp. 95-100, figs. 4).—A discussion is given of the water situation in the Western States, particular stress being laid upon the economic use of water as a determining factor in its assignment. Illustrations are given of what are pointed out to be the evils occurring under the desert land and Carey acts and of their elimination by the reclamation act.

Report on irrigation for the year 1913 (*Dept. Int. Canada Ann. Rpt.*, 1914, pt. 7, pp. 179, pls. 12, figs. 50).—This is a report on administrative work, inspections of irrigation projects, stream measurements, special hydrographic surveys, and drainage investigations for the year ended March 31, 1913. A special section by H. O. Brown deals with the rating of current meters. Maps and tabular data accompany the report.

Irrigating plant for 625 acres, E. R. FEICHT (*West. Engin.*, 5 (1914), No. 1, pp. 22-26, figs. 5).—This article describes the selection of apparatus and its erection and operation for a small irrigating plant in which first cost as well as satisfactory operating results were conditions of vital importance.

Irrigation from tube-wells, F. HUGHES (*Agr. Jour. Egypt*, 4 (1914), No. 1, pp. 66-70).—Results of examinations of well waters and the soils and crops watered by them in Upper and Lower Egypt indicate that "damage to land or crops by the use of well water is rare," but "that water having over 1,000 parts per million of dissolved matter should be avoided when possible."

A weir chart, R. J. BROWER (*Power*, 40 (1914), No. 1, p. 9, fig. 1).—The author explains his idea of a chart applicable to all weirs by which the discharge for any width is readily determined by simple multiplication.

The transportation of débris by running water, G. K. GILBERT and E. C. MURPHY (*U. S. Geol. Survey, Prof. Paper No. 86* (1914), pp. 263, pls. 3, figs. 89; *abs. in Jour. Wash. Acad. Sci.*, 4 (1914), No. 7, pp. 154-158).—Investigations made to determine the laws which control the movement of bed load of débris, and especially to determine how the quantity of load is related to the stream's slope and discharge and to the degree of comminution of the débris, are reported. In each experiment a specific load of sand and gravel sorted into grades of uniform size was fed to a stream of specific width and discharge.

A competent slope σ limiting transportation was found for each combination of discharge, width, and grade of débris. With lower slopes there was no load and increase of slope increased the débris capacity, which varied as $(S-\sigma)^n$, in which S equals the stream's slope and n ranges from 0.93 to 2.37, the values being greater as the discharges are smaller or the débris coarser. For each combination of width, slope, and grade of débris, there was a competent discharge, k . The capacity varied as $(Q-k)^o$, in which Q is the stream's discharge and o ranged from 0.81 to 1.24, the values being greater as the slopes are smaller or the débris coarser. For each combination of width, slope, and discharge, there was a limiting fineness of debris ϕ . The capacity varied with $(F-\phi)^p$, in which F is the degree of fineness and p ranged from 0.50 to 0.62, the values being greater as slopes and discharges are smaller. For any combination of slope, discharge, and fineness there was a particular ratio of depth to width corresponding to maximum capacity and ranging from

0.5 to 0.04, being greater as slope, discharge, and fineness were less. With constant slope the capacity varied with the 3.2 power of velocity, with constant discharge it varied with the 4.0 power of velocity, and with constant depth with the 3.7 power of velocity.

In general, débris composed of particles of a single size moved less freely than débris containing particles of many sizes. The load, including that carried in suspension and that dragged along the bed, increased the energy by adding its mass to that of the water, and decreased it by restricting the mobility of the water and by the work required in transportation.

Capacities were notably larger for flume transportation than for stream transportation and increased for rolling particles with coarseness and for leaping particles with fineness. Capacities also increased with slope, and usually with discharge, but were reduced by roughness of bed.

The position of the level of maximum velocity was higher in loaded streams as the load was greater, and higher in unloaded streams as the slope was steeper, the discharge greater, and the bed rougher.

The constant of the Pitot velocity gage (the ratio between the head realized and the theoretical velocity head) was found to be not the same in all parts of a conduit, being less near the water surface and greater near the bottom or side.

Subirrigation and drainage for golf greens (*Engin. News*, 72 (1914), No. 4, pp. 199, 200, figs. 3).—A system is described and illustrated.

Drainage of Shoshone irrigation project, D. W. MURPHY (*Engin. Rec.*, 69 (1914), No. 23, pp. 634-636, figs. 6).—This article describes the construction of a system of closed and open drains which was made necessary by the rising water table and the rapidly increasing area of water-logged soil. Cost data on excavation with the dragline scraper and the ditch excavator are also given.

Reclamation of alkali lands, F. B. HEADLEY (*U. S. Dept. Agr., Bur. Plant Indus., Work Truckee-Carson Expt. Farm 1913*, pp. 11-14, fig. 1).—The porosity of soils made impervious to water by an excess of alkali salts was greatly increased by treatment with either gypsum or quicklime. Gypsum is concluded to be the more desirable of the two.

For the reclamation of alkali soils a drainage system of redwood 2,620 ft. long was constructed at an average depth of 4½ to 5 ft. The drainage water is pumped from a sump by a 3-in. centrifugal pump, discharging slightly over ½ cu. ft. of water per second, and operated by an electric motor. It was found that each watt of electricity used pumped 1.195 second-feet of water.

The total alkali salts removed by the drainage system is shown in the following table:

Quantity of electricity used and of water and total salts pumped by the drainage system of the Truckee-Carson Experiment Farm in 1913.

Month.	Electricity.	Water pumped.		Average salts.	Salts pumped.
		Cubic feet.	Pounds.		
	<i>Kilowatts.</i>	<i>Cubic feet.</i>	<i>Pounds.</i>	<i>Per cent.</i>	<i>Pounds.</i>

Electricity versus steam in drainage pumping (*Elect. World*, 64 (1914), No. 6, pp. 275-277, figs. 4).—Data on first cost and operating expenses of steam and electrically driven pumping stations used for draining agricultural lands along the Illinois and Mississippi rivers are given. They show that the cost of building a modern electrical pumping station varies from 50 to 60 per cent of the cost of building a steam station to do the same work. It is claimed to have been established that the total operating expense for electrical pumping stations for drainage district service is from 10 to 35 per cent less than the total operating expense of steam stations under the same conditions.

Construction and maintenance of sand-clay roads in Georgia—methods and cost, J. C. KOCH (*Engin. and Contract.*, 42 (1914), No. 5, pp. 107-111, figs. 7).—This article gives detailed methods and costs of both construction and maintenance of sand-clay roads in Georgia, using top soil, other natural sand clays, and artificially mixed sand clay for surfacing.

Standard cross sections for Illinois roads (*Engin. and Contract.*, 42 (1914), No. 5, pp. 111-113, figs. 4).—Cross sections for macadam, brick, and concrete roads used in the construction of roads in Illinois in 1914 are given, with the reasons for their adoption.

The organization and standards of the Iowa Highway Commission (*Engin. and Contract.*, 42 (1914), No. 3, pp. 55-58, figs. 14).—This article describes the organization of the Iowa Highway Commission and gives illustrations of the road and culvert standards adopted by them.

Standard I-beam and pile highway bridges of the Iowa State Highway Commission (*Engin. and Contract.*, 42 (1914), No. 5, pp. 102-104, figs. 3).—This article gives design drawings and essential data for standard I-beam and pile highway bridges of this commission, as well as drawings of standard pile abutments for steel highway bridges.

Experiments on the effect of compression on a small gas engine, E. G. ROEHM and W. W. TANGEMANN (*Gas Engine*, 16 (1914), No. 7, pp. 413-420, figs. 10).—A series of tests on a vertical single-cylinder 4-cycle gas engine of 4½-in. bore and 8½-in. stroke, rated at 3 horsepower, hit and miss governed and with mechanically operated valves, is reported. The object was to determine and explain the effect of increasing the compression on the economy.

The degree of compression was varied by changing the clearance volume, which was effected by redesigning the cylinder head and providing for its vertical adjustment by telescoping the head into the cylinder and placing spacer rings under the shoulder, thus obtaining compression ratios ranging from 2.5:1 up to 8.5:1. A large gain in economy as regards gas consumption and thermal efficiency was obtained up to a compression ratio between 5 and 6:1. Above this at all horsepowers the economy tended to decrease. The percentage of total heat in gas absorbed by the jacket water reached a maximum at a compression ratio of 3.5 to 4.5:1, and a minimum between 5 and 6:1. The British thermal units absorbed by the jacket water per brake horsepower hour were least between compression ratios of 5 and 6 to 1, and tended to rise beyond 6:1. The British thermal units per brake horsepower hour appearing as sensible heat in exhaust decreased up to a compression ratio of 6:1 and then increased above 6.5:1. The minimum was reached at lower compression ratios with the higher loads. The maximum horsepower obtained with various compression ratios increased steadily by use of higher compression.

It is concluded that for a gas similar to a natural gas having a high heating value (950 to 1,100 B. T. U. per cubic foot) the most economical operation is obtained by using compression ratios between 5.5 and 6.5:1.

Fuel consumption of gasoline engines (*Wisconsin Sta. Bul.* 240 (1914), p. 41).—A series of tests conducted by F. White with farm engines of from 3 to 6

horsepower to determine the relative economy under different loads indicated that the larger engines are as economical in the use of fuel on a small load as are the smaller engines when carrying the same load.

Gasoline engine troubles and the care and operation of gasoline engines, G. E. P. SMITH (*Arizona Sta. Bul. 71 (1913), pp. 797-814, pl. 1, figs. 5*).—This bulletin is intended primarily for the popular discussion of gasoline engine troubles, but deals in addition with several other important features concerning the care and operation of engines. It deals particularly with 4-cycle engines, which are said to constitute at least 95 per cent of the gasoline engines in use in Arizona. A trouble-hunting chart for gasoline engines is included which takes up in detail troubles in starting and troubles after starting.

In a discussion of fuel consumption it is pointed out that for fuel economy an engine should work close up to its rated load, and that it is not advisable, therefore, to purchase an engine with much excess of power above the required amount. It is further stated that the fuel consumption for a 10-horsepower engine, or larger, with good compression should not exceed 1 pint per brake horsepower hour on full rated load, or $1\frac{1}{2}$ pints per brake horsepower hour at one-half load.

Information obtained from investigations of Strong and Stone previously noted (E. S. R., 28, p. 384) regarding the economical adjustment of the needle valve is also given.

Tests of feed mills, H. WIRTH (*Arb. Deut. Sek. Landeskult. Rat. Königr. Böhmen, No. 19 (1914), pp. 52, figs. 13*).—Seven feed mills, including three stone mills, two roller mills, and two toothed disk mills, are described and illustrated and comparative tests, using different grains, are reported. The tests were divided into (1) a comparative accomplishment test of the unused mills, (2) a duration test, and (3) a second accomplishment test of the used mills after being subjected to the first two tests.

The amounts of coarse meal ground exceeded the amounts generally claimed for the machine by the manufacturers, but the amounts of fine meal were generally less than claimed. The power utilization was greater than claimed, and when the mills were running empty varied between 0.22 and 0.53 horsepower.

Only three of the mills were able to grind oats to a fine meal. Generally a better degree of fineness of the ground product was obtained with the stone mills than with the other two types. Any desired degree of fineness of meal was, however, more readily and cheaply obtained with the roller mill, and the toothed disk and roller mills were the more suitable for the production of coarse and medium meal.

The hourly capacity of the roller and toothed disk mills exceeded that of the stone mills, while the stone mills were more easily cleaned and less noisy.

A magnet was satisfactorily used in six of the mills for excluding foreign metal bodies, but the success of this method is found to depend not only on the strength of the magnet but on its arrangement, location, and inclination.

Handling silage, L. W. CHASE and I. D. WOOD (*Nebraska Sta. Bul. 145 (1914), pp. 5-25, figs. 19*).—This bulletin gives general information regarding cutting and loading corn for silage, silage cutters and cutting, filling and sealing silos, and removing silage from pit and above-ground silos by means of hand, horse, and mechanical power, and general cost data on silo filling.

For cutting corn the use of corn knives is considered advisable only on very small jobs and then only when sled harvesters or corn binders are not available. The sled harvester is said to be probably the cheapest of the three methods, but the corn binder is considered to be the most satisfactory.

The cost of cutting and loading by means of the sled harvester was found to be \$1.28 per acre in one case and \$1.98 per acre, or \$0.259 per ton in another. The cost of cutting corn with a corn binder on 16 Nebraska farms and of delivering it bound was about \$1.77 per acre or \$0.236 per ton. Power cutters with fan blowers are considered to be always advisable where many large silos are to be filled. The drag carrier may be used successfully in filling pit and semipit silos but is not successful where a long carrier is required or in windy countries unless the carrier is covered.

A description and illustration of a simple homemade hand hoist for pit and semipit silos is appended.

Concrete silos (*Chicago, Pittsburgh, and Minneapolis, 1914, pp. 104, figs. 76*).—This is a pamphlet of practical information for the use of farmers and rural contractors regarding the construction of monolithic concrete and concrete block silos and concrete silo water tanks. A large amount of specific data is given accompanied by diagrammatic illustrations.

The construction and equipment of dairy barns, W. D. NICHOLLS (*Kentucky Sta. Bul. 179 (1914), pp. 37-112, figs. 46*).—This bulletin gives information to dairymen on the construction and equipment of dairy buildings. In dealing with the subject the author has kept in mind the average farmer of limited capital. A number of detailed plans of dairy buildings are included in which it has been the intention to keep economy and efficiency paramount. Elaborate and costly barns are considered to be unnecessary for permanence, sanitation, comfort of cows, or convenience in the production of clean milk.

It is stated that money invested in a dairy barn should be required to pay at least 10 per cent a year to cover interest, depreciation, taxes, insurance, etc. It is also stated that a good business farmer seldom puts more than \$50 per cow in a dairy barn. Labor saving arrangements are emphasized and it is stated that in nearly all cases abundant hay storage should be provided by the construction of a roomy hay loft over the first story. This is considered to be by far the cheapest hay storage.

The barn should be large enough to meet the present needs of the farm and to allow for a reasonable growth in crop and stock production, but ordinarily when home grown silage and roughage feeds are produced no more than 60 to 80 cows should be placed in one stable.

The importance is emphasized of so locating the dairy barn as to avoid odors and contamination from hog pens, chicken houses, and other places which are liable to be unclean. It is stated that, if possible, the barn should run north and south so that the sunlight may enter from both sides during the day.

From the standpoint of economy it is considered desirable to have the barn as narrow as possible, consistent with efficiency and sanitation. The advantages and disadvantages of timber and plank framing for the dairy barn are discussed and the latter arrangement is seemingly favored.

It is considered usually desirable to place the cows in two rows. The plan of facing the cows inward may be used to advantage when the greatest economy of floor space is desired since it permits the use of a narrow barn. With the cows facing outward a wide barn is necessary, but this width permits a driveway wide enough for a team to be driven through from end to end, thus loading the manure directly from gutter to wagon or spreader. The standard width of a cow stall is $3\frac{1}{2}$ ft., and for small cows like the Jersey the length of the stall from gutter to manger should be $4\frac{1}{2}$ ft., for long cows like the Holstein or Shorthorn, 5 ft., and for very long cows, $5\frac{1}{2}$ ft.

Other desirable features are described and illustrated, and the importance of a plentiful supply of water for the cows is especially emphasized.

An extensive section gives costs and bills of material for a number of the barns described.

The dairy barn at the Kentucky Agricultural Experiment Station, J. J. HOOPER (*Kentucky Sta. Bul.* 179 (1914), pp. 113-117, figs. 4).—This barn is described and illustrated.

Making a poultry house, M. R. CONOVER (*New York, 1912, pp. 54, pls. 8, figs. 4*).—This book treats in a popular manner with the planning and construction of poultry houses, dealing specifically with such features as floors, foundations, walks, windows, ventilation, doors, nests, roosts, and runs.

Figuring radiation for kitchens using gas fuel, J. A. DONNELLY (*Dom. Engin.*, 68 (1914), No. 5, pp. 127, 128).—A formula is suggested for calculating the necessary amount of radiation for heating rooms by hot water which is particularly applicable to kitchens.

[Sanitation] (*Bien. Rpt. Bd. Health Minn., 1911-12, pp. 439-450, figs. 10*).—This section treats briefly with the disposal of dairy, residential, and school sewage, and gives plans for sewage-disposal apparatus. Suggestions are also presented for constructing an Imhoff tank and for converting a septic tank into an Imhoff tank.

Local venting of plumbing v. safety first, I. A. MANN (*Dom. Engin.*, 68 (1914), No. 6, pp. 152-155, figs. 5).—The author discusses the subject from the bacteriological standpoint and concludes that local vents in sanitary plumbing systems are wasteful, expensive, unnecessary, and dangerous.

The relation of methods of disposal of sewage to the spread of pellagra, J. F. SILER, P. E. GARRISON, and W. J. MACNEAL (*Proc. Soc. Expt. Biol. and Med.*, 11 (1914), No. 3, pp. 94, 95).—In this summary of their work, the authors state that, judging from their field studies, "pellagra has spread most readily in communities in which unscreened surface privies were in use. . . . In two mill villages completely equipped with a water carriage sewer system, it was impossible to find cases of pellagra which had certainly originated there. Individuals suffering from pellagra contracted elsewhere were not lacking in these communities."

RURAL ECONOMICS.

[Economic studies] (*Wisconsin Sta. Bul.* 240 (1914), pp. 4-18, figs. 7).—A chart showing the distribution of the price paid by the consumer for Cheddar cheese among producer and middleman (E. S. R., 29, p. 675) is presented and discussed, together with data in regard to the marketing of potatoes. The two main services which must be rendered in marketing potatoes are the storing of the supply harvested in one month in order that there may be potatoes for the remainder of the year, and distributing the surplus potatoes of the principal potato districts to regions where fewer potatoes are produced than consumed. The storing of potatoes is a function mainly performed by the producer. The work of the local dealers is largely that of sorting and loading into cars. It was found that generally there were too many warehouses at each shipping station for their economic handling. However, many local dealers handle lumber, feed, and machinery in addition to potatoes.

The station is also making a detailed study of rural credit in Dane and Rusk counties as illustrating the diversity of conditions existing in the State. It is also investigating the methods employed by the local banks in meeting the requirements of local rural credit.

Among the conclusions drawn from other studies were that on two farms the value of manure did not pay for the labor of feeding, milking, and caring for the dairy herd, and that those farmers who had increased their investment in

operating capital are realizing greater profits than those operating their farms less intensively. From rural social surveys made in different parts of the State it is concluded that the village or small city of the agricultural type in Wisconsin is the center of a real rural community, that a certain area of land surrounding this village or small city is as necessary to it as is the land under its dwellings, shops, and stores, and that the major interests of the farm family on this adjacent area of land are identical with those of the dwellers in the village or small city trading center.

An investigation of piece wage in agriculture, VON ESDEN-TEMPSKI (*Landw. Jahrb.*, 46 (1914), No. 3, pp. 455-498).—The author describes the influence of payment by the piece upon agricultural laborers hired by the year, the seasonal or migratory laborers and free laborers, and methods of determining the payment. He apparently believes it puts a premium upon skill, but requires a very careful arrangement and analysis of the farm operations to be administered successfully.

The movement of wheat prices and its causes, L. PERIMANN (*Schr. Ver. Sozialpolit.*, 139 (1914), pt. 3, pp. 73, figs. 10).—The author discusses the relative changes in the prices of wheat in Prussia, France, England, and the United States over a long series of years, the various factors influencing the daily, monthly, and yearly fluctuations, and the relation of the price of wheat to the general price movement.

Markets and rural economics, T. J. BROOKS (*New York*, 1914, pp. 397).—The author discusses the agencies controlling prices, methods of marketing, cooperation, rural credit, cost of living, and their relationship to farming and the farmers. A brief bibliography is included.

Farmers' market bulletin (*Farmers' Market Bul.* [N. C.], 1914, Nos. 1, pp. 16; 2, pp. 19; 3, pp. 79).—According to Bulletin 1, if the farmer is to take any part in the business of marketing his own produce, there must be (1) an organization to grow a uniform product within each community, (2) an organization to gather information from the farmers who have products for sale and to distribute this to possible buyers, (3) an organization for obtaining information of prices of different markets and for distributing this information to all producers, and (4) an organization to distribute to a central agency for redistribution all orders and inquiries which the individual farmer or farmers' organizations can not fill. The North Carolina Experiment Station in cooperation with the State Department of Agriculture is attempting to perform the function of the central agency. The bulletin also contains regulations for answering all inquiries concerning sale of agricultural products and for listing products in the bulletin, and a list of farmers who have specified products for sale.

Bulletin 2 contains a partial list of fruit and vegetable growers in North Carolina, with acreage and probable shipping dates. Bulletin 3 outlines the organization necessary for the marketing of truck and fruit and gives a list of buyers and the character of business done and products handled by those purchasing such products, not only in North Carolina but in other States.

Proceedings of the seventy-fourth annual meeting of the New York State Agricultural Society (*N. Y. Dept. Agr. Bul.* 60 (1914), pp. 1441-1715, pls. 27, fig. 1).—A number of the discussions at this annual meeting related to the marketing of agricultural products, cooperation, rural credit, drainage, work of farm bureaus, and agricultural education.

Proceedings of the Agricultural Conference and Corn Shown (*Proc. Agr. Conf. and Corn Show*, 1913, pp. 269).—Among the principal topics discussed were the relationships between the farmers and city consumers, methods of

marketing, and improving agricultural production. Several of the speakers gave descriptions of the various agencies working to solve these problems.

Report of the Missouri Country Life Conference, 1914 (*Missouri Bd. Agr. Mo. Bul. 12 (1914), No. 4, pp. 138, figs. 29*).—At this conference were discussed means of improving rural conditions as they have been actually worked out through the school, church, public organizations, and better credit facilities.

Facts and fiction about crops, C. G. HOPKINS (*Science, n. ser. 37 (1913), No. 952, pp. 470-476*).—The author in this article alleges that there are serious discrepancies between the estimates of the U. S. Department of Agriculture and the returns obtained by the Census, and that crop yields have been decreasing.

Statistics of crops, G. F. WARREN (*Science, n. ser., 40 (1914), No. 1021, pp. 121-126, fig. 1*).—The author maintains that there are errors in reasoning in the above article, and gives an explanation for the apparent differences between the estimates of the Department of Agriculture and the Census returns. He calls attention to the fact that by the bringing into cultivation of large areas of land with low yields the average yield for the United States has decreased, but that in the region east of the Mississippi there has been very little change in the farm acreage. Considering the five eastern geographic divisions and the six important crops, corn, wheat, oats, hay and forage, cotton, and potatoes, it is found that in 19 instances the highest rank occurred in 1909 as against 5 instances in 1899, 3 in 1889, and none in 1879.

Agricultural statistics of Ireland, 1913 (*Dept. Agr. and Tech. Instr. Ireland, Agr. Statis. 1913, pp. XXXV+2-145*).—This annual statement contains statistical tables showing the acreage and production of crops, the number of occupiers and holdings, and the number of live stock. Between 1851 and 1913 the acreage in cereal crops decreased from 3,099,401 to 1,263,963 acres, and green crops and flax from 1,513,142 to 1,063,786 acres, while hay increased from 1,246,408 to 2,481,822 acres. The number of holdings under one acre increased from 37,728 to 88,133 and those above one acre decreased from 570,388 to 519,941.

Agriculture under the influence of mining and manufacturing in the Ruhr coal region of the Rhine, W. AVERECK (*Volksw. u. Wirtschaftsgesch. Abhandl., 3. ser., No. 1 (1913), pp. VI+87*).—Between 1882-1907 the number of agricultural establishments increased from 34,163 to 44,221. Those under 2 hectares (5 acres) comprising 91.24 and 94.81 per cent, respectively, of the total number. The land used for agricultural purposes decreased from 37,877 to 28,845 hectares. In 1878 agricultural land comprised 68.6 per cent of the total land surface, whereas in 1907 it comprised only 43.1 per cent. The most marked decrease took place in the pasture and grazing land. The number of horses and swine increased while the number of cattle, sheep, and goats decreased. The increase of the value of land, foodstuffs, and farm animals had a tendency to decrease the profits.

Statistics of agriculture in Switzerland (*Statis. Jahrb. Schweiz, 21 (1912), pp. 58-75*).—Contained in this annual report are statistical data showing for cantons the area, production, and value of the principal agricultural products, the production of butter and cheese, and the number of live stock.

In foreign fields, J. E. WING (*Chicago, 1913, pp. 549, pl. 1, figs. 41*).—This book contains a description of agriculture as noted by the author in his travels through South America and Western Europe. The facts observed relate principally to the sheep industry.

AGRICULTURAL EDUCATION.

The relation of the agricultural college to the state normal school, A. V. STORM (*Addresses and Proc. Nat. Ed. Assoc.*, 51 (1913), pp. 516-521).—This paper deals with the relation between the agricultural college and the state normal school in the preparation of teachers mainly as an administrative and only incidentally as a pedagogical subject. The conclusion is reached that rural and elementary grade teachers should receive their preparation in agriculture in the state normal school, while all other teachers giving instruction in agriculture should be prepared in the college of agriculture. The reasons given for this conclusion are based on the fundamental conditions inherent in the two classes of institutions in most of the States.

How the adoption of a course of study in agriculture and related subjects would help the public schools, J. MAIN (*Addresses and Proc. Nat. Ed. Assoc.*, 51 (1913), pp. 808-812).—In this discussion the author shows how the adoption of a uniform high school course in agriculture would make possible the training of teachers in secondary agricultural pedagogy; would enhance the utilitarian value of high school agriculture by the elimination of "freak courses" and valueless exercises and the inclusion of essentials duly proportioned; would make possible the accrediting of schools and the evaluation of agriculture as a preparatory training, and permit the student of agriculture to carry to distant schools an intelligible report of work completed just as he now may in Latin or algebra; and would save the sciences and the scientific methods to the high school from which they are in danger of being lost.

Report of the committee on courses of study in agriculture, E. C. BISHOP (*Addresses and Proc. Nat. Ed. Assoc.*, 51 (1913), pp. 804-807).—Among the topics reported on are a unified course of study, development of project work, home and school gardening, farm management, farm mechanics, agricultural booklet, community survey, and boys' and girls' club work, preparation of teachers, use of text-books, made-up-text and theme-book, credit for home work, and personal, home, and community hygiene.

Agriculture and gardening in the public schools, C. F. PALMER (*Addresses and Proc. Nat. Ed. Assoc.*, 51 (1913), pp. 812-818).—In this discussion the author contends that agriculture is as important a subject in the city schools as in the country schools, the differences lying more in the opportunities for carrying on the work and the outside experience that the pupils bring to it than in any innate differences between country and city youths. The work in school gardening in Los Angeles, one of the few large cities of this country conducting the work as a definite part of their educational system, is described in detail from the author's personal experience as supervisor of agriculture in the public schools. Gardening has been in operation in a number of schools with varying degrees of success for several years but has demonstrated its value, and over a year ago led to the establishment of a department of agriculture consisting of a supervisor, assistant supervisor, and three special teachers. Each of the four assistants was assigned a definite section of the city to develop. Headquarters for conferences with teachers and the distribution of seeds, plants, cuttings, etc., have been provided. Weekly classes in agriculture for teachers have been conducted under the auspices of the state university which through this department established its first extension course in agricultural teaching.

In what way can the nature-study movement be of assistance to agricultural teaching and social center work for rural communities, J. H. PAUL (*Addresses and Proc. Nat. Ed. Assoc.*, 51 (1913), pp. 803, 804).—The author

outlines briefly three courses in nature study offered by the School of Education of the University of Utah, one of which is required of all regular normal students. Primary and kindergarten students take the course that deals primarily with trees, the forest, and forest life, intermediate grade teachers the course that deals with the local weeds, minerals, and the native bird life of the Rocky Mountains, and those aiming to teach in higher grades study insect life in the fall, rocks and soils in the winter, and plant life in the spring. Each course bears three hours of college credit, or four hours if the laboratory work is taken.

[Reports of the general committee and subcommittees on horticultural courses] (*Proc. Soc. Hort. Sci.*, 10 (1913), pp. 47-63).—In these reports three fundamental principles underlying the permanent improvement of horticultural teaching and a course in pomology are outlined by C. G. Woodbury, chairman of the general committee on horticulture and of the subcommittee on pomology.

J. W. Lloyd, chairman of the subcommittee on olericulture, reports that if anything like uniformity in instruction in vegetable growing is to be established in the agricultural colleges of this country, the first step must be an attempt to unify the scope, method, and thoroughness of instruction given in the courses already offered in common by a number of institutions rather than to bring about a similarity in the number of courses. It is recommended that not more than two courses in vegetable gardening be adopted by all the colleges at the present time, viz, a general elementary course at present offered in some form by 35 different institutions, and a more advanced course dealing specially with the commercial phases of vegetable production and distribution. Courses in vegetable growing are outlined.

A. C. Beal, chairman of the subcommittee on floriculture, gives a brief statement of the present status of instruction in floriculture in this country and recommends that the professional courses be preceded and founded upon thorough courses in the histology and morphology of plants, plant physiology, chemistry, soils, and fertilizers (plant pathology and economic entomology also being important subjects); that a range of glass of the commercial type is necessary as well as a man having good practical experience with the ability to teach; and that in the absence of suitable text-books the lecture method of presentation of the various subjects in commercial floriculture, with extensive reference reading and thoroughly practical and definitely planned laboratory work to supplement the lectures, be utilized.

The problem of coordinating secondary school and college courses in horticulture, W. J. WRIGHT (*Proc. Soc. Hort. Sci.*, 10 (1913), pp. 9-13).—The author points out some of the reasons for the difficulty experienced in coordinating secondary school and college courses in horticulture.

The relation of horticultural practices to the horticultural curriculum, C. I. LEWIS (*Proc. Soc. Hort. Sci.*, 10 (1913), pp. 14-18).—After briefly outlining the field of the college horticultural graduate the author discusses the feasibility of various means of increasing the practical training of such graduates, viz, by following the European system of establishing trade schools, the requirement of more secondary training in horticulture, the establishment of secondary or trade schools within the colleges, the requirement of horticultural experience for admission to college courses, increasing the number of credits for the 4-year course by teaching horticulture during the entire year, requiring the horticultural graduate to spend a certain time in practical work after graduating, and the adoption of the apprenticeship system. He also discusses the amount of laboratory and field work that can be done consistently in horticultural courses with the number of credits at present required in the average

college, the equipment necessary to give the proper training, the relation of training given for professional lines to that given for practical lines, and the introduction of a new college course requiring each senior to take a half-year course in which the principles and practice will be combined.

College courses in the harvesting and marketing of fruits and vegetables, W. G. BRIERLY (*Proc. Soc. Hort. Sci.*, 10 (1913), pp. 25-30).—A course in harvesting and marketing fruits and vegetables is outlined. The work can be given in one continuous course or may be divided into two separate courses. Allowance must be made for approximately 40 lectures with the necessary time for reviews and quizzes and at least 16 laboratory periods and time for a considerable amount of assigned reading.

Growing prize corn, P. G. HOLDEN (*Philadelphia*, 1914, pp. 48, figs. 69).—This booklet has been prepared for the particular use of boys, and the text and illustrations have been taken from the author's *Corn Secrets* (E. S. R., 25, p. 34).

Progress of agricultural education in 1912-13, F. B. JENKS and C. H. LANE (*Rpt. Comr. Education [U. S.]*, 1913, I, pp. 211-233).—This is a review for 1913 of the leading features of progress in agricultural education in this country and abroad, including the agricultural education work of this Department, the Graduate School of Agriculture, and educational and other conventions.

Agricultural education [in Latin America], E. E. BRANDON (*U. S. Bur. Ed. Bul.*, No. 30 (1912), pp. 104-114, pls. 4).—This chapter gives an account of the beginnings and present organization of agricultural instruction in Latin-American countries, expenditures for and dissimilarities in organization of their agricultural colleges, their admission requirements and curriculum, grades, and agricultural careers of students, number, physical equipment, courses of study, and types of elementary agricultural schools, and an agricultural normal school in Argentina.

Agricultural education in the Republic of Argentina, T. AMADEO and C. VALLEJO (*La Enseñanza Agrícola en la República Argentina. Buenos Aires: Min. Agr.*, 1913, pp. 312, figs. 330).—This is an account, prepared for the International Exposition at Ghent, of the system of agricultural instruction and experimentation in Argentina, and its development beginning with the establishment of the first practical school of agriculture in 1823.

Thirteenth annual general report of the Department of Agriculture and Technical Instruction for Ireland (*Dept. Agr. and Tech. Instr. Ireland, Ann. Gen. Rpt.*, 13 (1912-13), pp. VI+363).—This is the report of the department's administration and funds and on the details of its work during 1912-13, including agricultural and technical instruction.

Christchurch Technical College agricultural department (*Jour. Canterbury Agr. and Past. Assoc.*, 3. ser., 2 (1914), pp. 37-39).—An account is given of the theoretical and practical instruction in agriculture at this college.

Agricultural pupil scheme, W. G. FREEMAN (*Bul. Dept. Agr. Trinidad and Tobago*, 13 (1914), No. 79, pp. 89-94).—This is an outline of a scheme which has been approved by the board of agriculture of Trinidad for the training of students at least 16 years of age for such positions as overseers of estates. The course of theoretical and practical instruction extends over three years, the first two on estates managed by the department of agriculture and the third on an approved private estate. The expenses are to be defrayed from the profits made on the estates. The admission requirements, curriculum, and cost of the scheme are given.

Agricultural education, R. H. RIJKENS (In *De Nederlandsche Landbouw in het Tijdvak 1813-1913. The Hague: Dept. Landb.* [1913], pp. 91-130).—The

author gives a detailed history of the development of agricultural education in the Netherlands.

The feminist movement in agriculture, ODETTE BUSSARD (*Vie Agr. et Rurale*, 3 (1914), No. 23, pp. 625-628).—The author describes the facilities for instruction in agriculture and home economics for women in France, viz, the High School of Agriculture and Home Economics at Grignon, 38 local schools of agriculture and home economics, farm women's clubs, and women's sections in large agricultural societies.

The exhibition of rural school work, ANNA B. COMSTOCK (*Nature-Study Rev.*, 10 (1914), No. 5, pp. 161-167, figs. 6).—A description is given of a nature study exhibit by the rural schools of New York State during Farmers' Week at the College of Agriculture of Cornell University.

Agricultural extension service (*Wisconsin Sta. Bul.* 240 (1914), pp. 55-87, figs. 20).—An account is given of the activities of the extension service, which embrace (1) demonstration work of the different departments, mainly carried on under field conditions; (2) the county agricultural representative system in which resident instructors are located in the several counties; and (3) the combined activities given in connection with the farmers' courses, schools, trains, etc.

MISCELLANEOUS.

Report of the director, 1913, H. L. RUSSELL (*Wisconsin Sta. Bul.* 240 (1914), pp. 98, figs. 54).—This contains the organization list, a report of the work of the station during the year, portions of which are abstracted elsewhere in this issue, brief summaries of the publications of the year, and a financial statement for the federal funds for the fiscal year ended June 30, 1913.

List of publications of the Kentucky Agricultural Experiment Station (*Kentucky Sta. Bul.* 181 (1914), pp. 156-166).—A complete list of the publications of the station since its establishment.

NOTES.

Connecticut State Station.—H. K. Hayes, in charge of plant breeding work, has accepted an appointment as associate professor of agronomy and associate agronomist at the Minnesota University and Station beginning January 1, 1915.

Idaho University and Station.—F. L. Kennard, professor of field crops and farm management and agronomist, has been appointed instructor of agronomy and agronomist at the Minnesota substation at Crookston, vice O. I. Bergh, who has been transferred as superintendent of the Grand Rapids (Minn.) substation. J. F. Nicholson, bacteriologist of the university and station, has resigned.

Illinois University.—Citizens of Spring Valley, Bureau County, have donated to the university for experimental purposes 17 acres of land near a local high school. A similar offer of 20 acres of land near Kewanee, Henry County, has been made by Thomas McNamara.

Maine University.—V. G. Aubrey, instructor in animal industry, has been appointed extension specialist in poultry in Rutgers College.

Minnesota Station.—Alex Carlyle, assistant in plant breeding, has accepted the superintendency of the experiment farm established in connection with the new provincial school of agriculture at Vermilion, Saskatchewan.

Missouri University and Station.—The biology building authorized by the last legislature is now in use by the departments of zoology and botany. It is a 2-story and basement structure 220 feet long by 60 feet wide and cost \$110,000. It has been designed specifically for biological work and contains many features of interest to experimenters along this line. It is regarded as probably the most modern laboratory building on the university campus. J. B. Rand has been appointed extension assistant in animal husbandry and veterinary science, and assigned to the hog cholera eradication work.

Nebraska University.—J. E. Miller, of Lincoln, and E. P. Brown, of Arbor, have been elected regents for a six-year term beginning January 1, 1915, succeeding George Coupland and C. E. Anderson. P. L. Hall, of Lincoln, has been appointed regent, vice C. S. Allen, resigned, this appointment holding until the next general election.

New Mexico College.—Miss Dora Edna Ross, of the extension division of the University of Missouri, has been appointed to take charge of the extension work in home economics.

North Carolina College and Station.—F. B. Sherwood has been transferred from the position of instructor in chemistry in the college to that of assistant chemist in the station.

Ohio State University.—Malon Yoder, of the department of agronomy, has been appointed assistant in grain standardization in this Department with headquarters at Portland, Oreg.

Vermont University.—E. L. Ingalls has been appointed in charge of the agricultural club work in the public schools.

Wisconsin University and Station.—Hjalmar O. Watrud has been appointed extension instructor in agricultural economics in the college of agriculture and assistant in agricultural economics in the station.

INDEX OF SUBJECTS.

NOTE.—The abbreviations "Ala. College," "Conn. State," "Mass.," etc., after entries refer to the publications of the respective experiment stations; "Alaska," "Guam," "Hawaii," and "P. R." to those of the experiment stations in Alaska, Guam, Hawaii, and Porto Rico; "Can." to those of the experiment stations in Canada; and "U.S.D.A." to those of this Department.

immunization against anthrax	82	yellow, relation between stand density and wood volume	743
immunization against cholera, Mich.	585	<i>Pinus</i> , characteristics and classification	743
in Kongo	865	<i>Pinus</i> —	
in United States	73, 167	<i>excelsa</i> as a host of white pine blister rust, U.S.D.A.	647
internal parasites, Iowa	286	<i>excelsa</i> , blister rust affecting	349
liver lipoids, chemistry of	577	<i>radiata</i> , proliferation of spur shoots in	326
metabolism experiments, Ohio	268	<i>virginiana</i> , fungus diseases of	348
nitrate of soda for	265	<i>Piophilha casei</i> . (See Cheese skipper.)	
origin and distribution	564	Pipe drains, old, renovation	685
pasture and grain crops for, U.S.D.A.	470	<i>Piper betle</i> , composition of leaves	103
pure-bred <i>v.</i> cross-bred	568	Pipes—	
Sapphire, notes	870	large, strength of	186
skim milk and potatoes for	75	reinforced, tests	784
slaughter tests at Smithfield Show	565	water, loss of head in due to bend	384
sore mouth disease in, Colo.	880	wood-stave, use	685
susceptibility to blackleg	585	Piroplasmosis—	
tests of breeds, N.Mex.	470	bovine, etiology and treatment	85
text-book	470	(See also Texas fever.)	
treatise	769	canine, in Porto Rico	781
tubercular, pathological changes in organs	777	equine, parasites of	382
Piles, preservation with creosote	241	immunization	585
<i>Pilobolus crystallinus</i> , spotting of roses by, Conn.State	641	in Brazil	85
<i>Pimpla</i> —		<i>Pissodes validirostris</i> , notes	849
<i>conquisitor</i> , notes, Mass.	752	<i>Pisum sativum</i> , relation of seed weight to mortality	35
<i>instigator</i> , parasitic on gipsy moth	652	Pituitary extract, effect on milk secretion	272
<i>maculator</i> , parasitic on alfalfa weevil	61	<i>Pityogenes bidentatus</i> , notes	61
Pimplides in British Museum, revision	656	Plant—	
Pin hole borers, studies, Ohio	852	alkaloids, synthesis	409
Pine—		anatomy, physiological, treatise	728
blister rust, control of Ribes generation	451	associations, studies	35
blister rust, notes	247, 348	bases, studies	309
blister rust, notes, U.S.D.A.	647	bases, treatise	10
blister rust, treatment	50	breeding at Svalöf, Sweden	830
cones, insects affecting	849	breeding experiments, Can.	829
diseases, notes	841	breeding, physiological correlations and climatic reactions in	629
dry rot, studies	547	breeding, treatise and bibliography	131
rust, notes, Conn.State	641	characteristics, relation to seed weight	824
rust, overwintering on currants, N.Y. State	54	chlorosis, relation to soil alkalinity	50
rust, studies	153	cultures, nutrient solutions for	425
seedlings, damping-off, treatment	647	diseases—	
seedlings, evaporation studies	824	control	541
seedlings, white, development in nursery beds, Vt.	640	control in Great Britain	243
seeds, destruction by squirrels	154	control in Japan	241
stands, stem height in	538	control in Malaya	50
Pineapple rots, notes	844	control in Posen and West Prussia	841
Pineapples—		control in various countries	145
cover crops for, P.R.	635	due to antagonistic stocks and scions	740
culture	494	heredity of	841
growth on calcareous soils, P.R.	627, 816	in Barbados	547, 746
Pines—		in Connecticut, Conn.State	641
accretion in lower part of stems	538	in Dutch East Indies	540
as affected by smoke	521, 730	in Germany	539
as affected by soot	827	in India	641
lodgepole, volume table for	743	in Maryland	745
longleaf, paper pulp from, U.S.D.A.	144	in Mecklenburg	343
natural and artificial regeneration	537	in Ohio in 1912	49
scrub, fungus diseases of	348	in Samoa	347
spur shoot of	522	in Taurida	547, 848
western, turpentine production from	744	in Union of South Africa	539
white, bark disease of	247	international control	49, 342, 699
white, damping-off of seedlings, Vt.	640
