THE SOCIETY OF CHEMICAL INDUSTRY

LIST OF PAPERS PRESENTED TO THE SOCIETY & PUBLISHED IN THE TRANSACTIONS DURING 1921

N.B.—The words within ( ) indicate the Section or Group of the Society (if any) before which the paper was read and the issue of the Journal in which it appears.

PAGE

Alleman, G. The manufacture, properties, and employment of heat-intercepting structural glass. (Annual Meeting, Oct. 31) 241T

Archbutt, L. Lubrication and lubricants. (Bristol and S. Wales, Dec. 31) 287T

Ardagh, E. G. Activated carbon. (Annual Meeting, Oct. 15) 230T

Baillie, W. L. The relation between the density and the composition of glasses. (June 30) 141T

Barnett, W. L. The action of hydrazines on cellulose acetates. (Mar. 31) 61T

Chloro-cellulose esters, and the action of chloro-acyl chlorides on cellulose. (Nov. 15) 253T
Erratum 274T

A new method for the production of cellulose acetate. (Jan. 31) 8T

Note on the action of chloroform on phenylhydrazine. (July 15) 167T

Preliminary note on syntheses with chloroacetyl chloride. (Dec. 15) 286T

Bayley, F. *See* Sinnatt, F. S. 1T

Beedle, F. C., and T. R. Bolam. The hydrolytic alkalinity of pure and commercial soaps. (Bristol and S. Wales, Feb. 28) 27T
Discussion (Apr. 15) 74T

Bolam, T. R. *See* Beedle, F. C. 27T

Bruce, A. The action of sulphur on cement in the tropics. (Oct. 15) 240T

Burnand, J. R. *See* Schidrowitz, P. 268T

Burrell, B. A., and G. W. Douglas. The presence of nitrates in the leaves of trees growing near picric acid works. (Yorkshire, Mar. 31) 60T

Butler, R. R. Solutions of acetylene in acetone at high pressures. (Feb. 15) 25T

Carter, C. L. A chemical investigation of mutton-bird oil. Part I. (Sept. 30) .. 220T

Coffey, S. The effect of heating linseed oil under pressure at constant temperature. (Nottingham, Feb. 15) 19T

PAGE

Coleman, E. G. *See* Parkes, J. W. 257T

Cooke, W. T. The influence of sodium chloride and sodium sulphate on the solubility in water of sodium β-naphthalenesulphonate. (Sydney, Mar. 15) 56T
Addendum (Oct. 15) 239T

Curtis, R. Works accounts from the chemist's point of view. (Manchester, Aug. 15). (Abstract) 175T

Dodd, A. H. Guanidine carbonate as a standard alkali. (Apr. 30) 89T

Douglas, G. W. *See* Burrell, B. A. 60T

Drakeley, T. J., and G. F. Martin. Draining crystals in a centrifugal machine. (Dec. 31) 308T

Drummond, A. A. Note on the recovery of alcohol vapour from air. Comparison of working data with theoretical conclusions. (Dec. 15) 284T

Drummond, J. C. Factors influencing the nutritive value of lard and lard substitutes. (London, Apr. 30) 81T

Evans, J. *See* Haworth, J. 91T

Ewan, T., and J. H. Young. The preparation of guanidine salts and of nitroguanidine. (Glasgow, June 15) 109T

Farmer, R. C. The stability of benzoyl peroxide. (London, Apr. 30) 84T

Findley, A. E. The corrosion of coke oven walls. (Liverpool, Jan. 31) 7T

Flürscheim, B. J. Some properties of tetranitraniline (TNA). (May 31) 97T

Fowler, R. A. A note on the calculations involved in the preparation of acid mixtures for the manufacture of nitrocotton. (July 15) 166T

Foxwell, G. E. The path of travel of the gases in the coke-oven. (Sept. 15) 193T
Errata 220T

Grounds, A. *See* Sinnatt, F. S. 1T

Haddon, C. L. The effect of some physical conditions on calcium sulphate cements. (Newcastle, June 15) 122T

Journal of the Society of Chemical Industry
Vol. XL. 1921

Name Index

N.B.—The Review, Transactions, and Abstracts Sections of the Journal are paged separately and are indicated by the letters R, T, *and* A *respectively following the number of the page.*

The letter (P) *indicates that the matter referred to is a patent.*

An asterisk appended to the number of a page indicates that the title only of an article is given, or in the case of patents, either the title only or the title and a reference to a previous patent.

The titles of new books are given within quotation marks.

Subject Index

N.B.—The Review, Transactions, and Abstracts Sections of the Journal are paged separately and are indicated by the letters R, T, *and* A *respectively following the number of the page.*

The letter (P) *indicates that the matter referred to is a patent.*

An asterisk appended to the number of a page indicates that the title only of an article is given, or in the case of patents, either the title only or the title and a reference to a previous patent.

List of Journals Abstracted, with Abbreviations Used, and Addresses of Publishers and Prices.

JOURNAL.	ABBREVIATION.	ADDRESS OF PUBLISHER AND PRICE.*
Agricultural Bulletin of the Federated Malay States	Agric. Bull. F.M.S.	Dept. of Agriculture, Kuala Lumpur, F.M.S. $1.5.
Agricultural Journal of India	Agric. J. India	W. Thacker and Co., 2, Creed Lane, London. 3s.
Agricultural Research Institute, Pusa, Reports and Bulletins	Rep. (Bull.) Agric. Res. Inst., Pusa.	Supt. Govt. Printing, Calcutta. Price varies.
Allgemeine Zeitschrift für Bierbrauerei und Malzfabrikation	Allgem. Z. Bierbrau.	Michaelerstrasse 25, Vienna XVIII/1. 75 fr. (Fr.) per annum.
American Journal of Pharmacy.	Amer. J. Pharm.	145, North Tenth Street, Philadelphia, Pa., U.S.A. 30 cents.
American Journal of Science	Amer. J. Sci.	New Haven, Conn., U.S.A. 50 cents.
Anales de la Asociacion Quimica Argentina	Anal. Asoc. Quim. Argentina	1790, Lavalle, Buenos Aires. 60 c.
Anales de la Sociedad Española de Fisica y Quimica	Anal. Soc. Espan. Fis. Quim.	D. M. T. Gil, Corredera Baja de San Pablo, num. 59, Madrid. 15 pesetas per annum.
Analyst	Analyst	Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 2, 4, 6, 8, Orange Street, London, S.W. 3s.
Annalen der Chemie	Annalen	C. F. Winter'sche Verlagshandlung, Leipzig, Germany. M. 100 per annum.
Annales de Chimie	Ann. Chim.	Masson et Cie., 120, Boulevard St. Germain, Paris, VIe. 40 fr. per annum.
Annales de Chimie Analytique	Ann. Chim. Analyt.	M. Crinon, 20, Boulevard Richard-Lenoir, Paris, 11e. 2 fr.
Annales des Falsifications	Ann. Falsif.	M. Filaudeau, 42 bis, Rue de Bourgogne, Paris. VIIe. 4 fr.
Annales de l'Institute Pasteur	Ann. Inst. Pasteur	Masson et Cie., 120, Boulevard St. Germain, Paris, 6e. 4 fr.
Annales de la Science Agronomique Française et Etrangère	Ann. Sci. Agron.	Librairie Berger-Levrault, 5, rue des Beaux-Arts, Paris, 6e. 15 fr. 25.
Annali della R. Stazione Chimico Agraria Sperimentale di Roma	Ann. R. Staz. Chim. Agrar. Sperim. Roma	R. Stazione Chimico-Agraria Sperimentale di Roma, Rome.
Apotheker-Zeitung	Apoth-Zeit.	Levetzowstrasse 16b, Berlin, N.W. 87. M. 1.20.
Archiv der Pharmazie	Arch. Pharm.	Selbstverlag des Deutschen Apotheker-Vereins, Berlin, Germany. £1 18s. per annum.
Archives des Sciences Physiques et Naturelles	Arch. Sci. Phys. Nat.	Rue de Vieux-Collège, 4, Geneva, Switzerland. 6 fr.
Archivio di Farmacologia Sperimentale e Scienze Affini.	Arch. Farm. Sperim.	Via Depretis, 92, Rome. Lire 2.
Atti della Reale Accademia dei Lincei, Roma	Atti R. Accad. dei Lincei, Roma	Tipografia della R. Accademia dei Lincei, Rome. Lire 10 per annum.
Australasian Pharmaceutical Notes and News	Austr. Pharm. Notes and News	Elliott Bros., Ltd., O'Connell St., Sydney, N.S.W. 3d.
Berichte der Deutschen Chemischen Gesellschaft	Ber.	Dr. F. Oppenheim, Lohmühlenstrasse, 67, Berlin, S.O. 36, Germany. £2 10s. per annum.
Berichte der Deutschen Pharmazeutischen Gesellschaft.	Ber. deuts. Pharm. Ges.	Verlag von Gebr. Bornträger, Berlin, W. 35, Schöneberger Ufer 12A, Germany. 15s. per annum.
Berichte des Ohara Instituts für landwirtschaftliche Forschungen	Ber. Ohara Inst. landw. Forsch.	Verlag der Ohara Schonokai, Kuraschiki Provinz Okayama. Price varies.
Biedermann's Zentralblatt für Agrikulturchemie	Biedermann's Zentr.	O. Leiner, Königstrasse 26B, Leipzig, Germany. M. 45 per annum.
Biochemical Journal	Biochem. J.	Cambridge University Press, Fetter Lane, London. E.C. 20s.
Biochemische Zeitschrift	Biochem. Zeits.	Verlag von J. Springer, Berlin, W. 9, Linkstrasse 23-24. M. 64 per volume.
Blast-Furnace and Steel Plant	Blast - Furnace and Steel Plant	Thaw Building, 108, Smithfield St., Pittsburgh, U.S.A. 25 cents.
Board of Trade Journal	Bd. of Trade J.	H.M. Stationery Office, Kingsway, London, W.C. 2. 6d.
Bolletino Chimico - Farmaceutico	Boll. Chim. Farm.	Via Cappuccio, 19, Milan, Italy. L. 1.80.
Brennstoff-Chemie	Brennstoff-Chem.	Verlag W. Girardet, Essen. 3s. per quarter.
Brewers' Journal	Brewers' J.	L. M. Reed, Eastcheap Buildings, Eastcheap, London, E.C. 3. 3s.

---

* The price for single copies is given where these are sold separately. In other cases it is only possible to buy the Journals in question in complete volumes. For many of the German and Austrian Journals special prices are charged to foreign purchasers; the actual cost is given where possible.

Journal.	Abbreviation.	Address of Publisher and Price.
British Journal of Photography	Brit. J. Phot.	24, Wellington Street, London, W.C. 2. 4d.
Buletinul Societătei de Chimie din România	Bul. Soc. Chim. România	Boulevard Carol, 32, Bucarest.
Bulletin de l'Association des Chimistes de Sucrerie et de Distillerie	Bull. Assoc. Chim. Sucr.	156, Boulevard Magenta, Paris, 10*e*, France. 4 fr.
Bulletin of Agricultural Intelligence and Plant Diseases	Bull. Agric. Intell. ..	International Institute of Agriculture, Rome. 5 fr.
Bulletins of the Bureau of Bio-Technology	Bull. Bureau Bio-Technol.	Murphy & Son, Ltd., Sheen Lane, Mortlake, London, S.W. 14.
Bulletin of the Forest Experiment Station, Meguro, Tokyo	Bull. Forest Exp. Stat., Meguro	Bureau of Forestry, Dept. of Agriculture and Commerce, Tokyo.
Bulletin of the Institution of Mining and Metallurgy ..	Proc. Inst. Min. and Met.	Cleveland House, 225, City Road, London, E.C. 1.
Bulletin of the Kentucky Agricultural Experiment Station	Bull. Kentucky Agric. Exp. Stat.	University of Kentucky, Lexington, Ky., U.S.A.
Bulletin of the Rubber Growers' Association (Incorporated)	Bull. Rubber Growers' Assoc.	38, Eastcheap, London, E.C. 3.
Bulletin of the School of Mines and Metallurgy, University of Missouri	Bull. School Mines and Met., Univ. Missouri	Director of Mining Experiment Station, Rolla, Mo., U.S.A.
Bulletin de la Société de Chimie Biologique	Bull. Soc. Chim. Biol.	Dunod, 47 & 49, Quai des Grands-Augustins, Paris (VIe). 3 fr.
Bulletin de la Société Chimique de Belgique	Bull. Soc. Chim. Belg.	M. J. Wauters, Palais du Midi (Galerie du Travail 7), Brussels.
Bulletin de la Société Chimique de France	Bull. Soc. Chim. ..	Masson et Cie., 120, Boulevard Saint-Germain, Paris, 6*e*. 70 fr. per annum.
Bulletin de la Société Française de Photographie	Bull. Soc. Franç. Phot.	51, Rue de Clichy, Paris, 9*e*. 2 fr.
Bulletin de la Société Industrielle du Nord de la France	Bull. Soc. Ind. Nord..	Rue de l'Hôpital Militaire 116, Lille, France.
Bulletin de la Société Industrielle de Mulhouse	Bull. Soc. Ind. Mulhouse	Berger-Levrault et Cie., 5, Rue des Beaux-Arts, Paris. 60 fr. per annum.
Bulletin de la Société d'Encouragement pour l'Industrie Nationale	Bull. Soc. d'Encour. ..	Secrétariat, Rue de Rennes 44, Paris, 6e., France. 36 fr. per annum.
Canadian Chemistry and Metallurgy	Canad. Chem. Met. ..	Westman Press, Ltd., 57, Queen Street West, Toronto. 40 cents.
Le Caoutchouc et la Gutta-Percha	Caoutchouc et Gutta-Percha	A. D. Cillard fils, 49, Rue des Vinaigriers, Paris, X. 36 fr. per annum.
Cellulose-Chemie	Cellulose-Chem. ..	Supplement to Papierfabrikant.
Centralblatt für Bakteriologie, Parasitenkunde, und Infektionskrankheiten	Centr. Bakt.	Verlag von G. Fischer, Jena, Germany.
Chamber of Commerce Journal	Ch. of Comm. J. ..	Oxford Court, Cannon Street, London, E.C. 6d.
Chemical Age	Chem. Age	Benn Bros., Ltd., 8, Bouverie Street, London, E.C. 4. 6d.
Chemical and Metallurgical Engineering	Chem. and Met. Eng.	McGraw-Hill Co., 10th Avenue at 36th Street, New York. 25 cents.
Chemical News	Chem. News	97, Shoe Lane, London, E.C. 4. 6d.
Chemical Trade Journal ..	Chem. Trade J. ..	Davis Bros., Danes Inn House, 265, Strand, London, W.C. 6d.
Chemiker-Zeitung	Chem.-Zeit.	Dr. W. Roth, Cöthen, Anhalt, Germany. £1 10s. per annum.
Chemisch Weekblad	Chem. Weekblad ..	D. B. Centen, O.Z. Voorburgwal 115, Amsterdam. 0.25 fr.
Chemische Industrie ..	Chem. Ind.	Now incorporated with Zeitschrift für angewandte Chemie.
Chemische Umschau auf dem Gebiete der Fette, Oele, Wachse, und Harze	Chem. Umschau ..	Verlag der Chemischen Umschau, Friedrichstrasse 4, Stuttgart. M. 96 per annum.
Chemisches Zentralblatt ..	Chem. Zentr.	Verlag Chemie Ges., Berlin, Germany. £2 15s. per annum.
Chemist and Druggist ..	Chem. and Drug. ..	42, Cannon Street, London, E.C. 9d.
Chimie et Industrie	Chim. et Ind.	49, Rue des Mathurins, Paris. 10 fr.
Collegium	Collegium	K. Schorlemmer, Haltingen, Baden, Germany. 30s. per ann.
Communications of the Netherlands Government Institute for advising the Rubber Trade and Rubber Industry	Comm. Netherlands Govt. Inst. for advising Rubber Trade	
Comptes-Rendus hebdomadaires des Séances de l'Académie des Sciences	Comptes rend.	Imprimerie Gauthier-Villars, Quai des Grands-Augustins, 55, Paris. 140 fr. per annum.
Comptes-Rendus des Travaux du Laboratoire Carlsberg	Comptes-rend. Trav. Lab. Carlsberg	H. Hagerup, Copenhagen. Price varies.

Journal.	Abbreviation.	Address of Publisher and Price.
Deutsche Zuckerindustrie	Deuts. Zuckerind.	Dessauerstrasse, 18, Berlin, S.W.11. M. 30 per vol.
Elektrochemische Zeitschrift	Elektrochem. Zeits.	Brandenburgische Buchdruckerei u. Verlagsanstalt Ges., Mühlenstrasse, 9, Berlin-Schöneberg, Germany. M. 4.
Engineering	Engineering	C. R. Johnson, 35 and 36, Bedford Street, Strand, London, W.C. 1s. 2d.
Farben-Zeitung	Farben-Zeit.	Krausenstrasse 35-36, Berlin, S.W. 19. 15s. per annum.
Fermentforschung	Fermentforsch.	Verlag von S. Hirzel, Leipzig, Germany. M. 60 per vol.
Feuerungstechnik	Feuerungstechn.	O. Spamer. Heinrichstrasse, 9, Leipzig-R., Germany.
Fuel Research Board Technical Papers	Fuel Res. Bd. Tech. Paper	H.M. Stationery Office, Kingsway, London, W.C. 2. Price varies.
Gas Journal	Gas J.	W. King, 11, Bolt Court, Fleet Street, London, E.C.4. 1s.

To the Members of the Society of Chemical Industry.

We have audited the above Balance Sheet, dated 31st December, 1920, with the Books and Vouchers of the Society, and have verified the investments, and we are of opinion that such Balance Sheet correctly sets forth the financial position of the Society at 31st December, 1920.

MR. JOHN ALLAN IN THE CHAIR.

THE INORGANIC CONSTITUENTS OF COAL WITH SPECIAL REFERENCE TO LANCASHIRE SEAMS.

BY F. S. SINNATT, M.B.E., M.SC.(TECH.), F.I.C., M.I.MIN.E.; A. GROUNDS, B.SC.(TECH.), A.I.C.; AND F. BAYLEY, M.SC.(TECH.), A.I.C.

This paper describes a stage in the study of the inorganic constituents of certain typical seams in the Lancashire coalfield, and records a part of an investigation of the various coals from a number of viewpoints. The work has been carried out under the auspices of the Lancashire and Cheshire Coal Research Association.

It is well known that the coals in the Lancashire coalfield contain, as a rule, a low percentage of inherent ash. Of twenty distinct seams examined recently, none contained more than 6% of ash, whilst a great number contained less than 3%. Bickershaw Yard coal contained as little as 0·8%. The coals vary in properties from those which are practically non-caking to one (Mountain Mine) which possesses probably the highest caking power of any known coal, and yields a perfect metallurgical coke.

In distinguishing the coals the names in most common use have been adopted, but it must be recognised that other terms may be applied to the same seams in different localities.

For the purposes of this paper only the natural inorganic constituents of the seams have been considered. Every care was taken in obtaining the samples on which the work was carried out. A solid pillar was cut from the whole seam the cross-section of which was from 6 to 18 ins., according to the ease with which the coal could be handled. The piece of coal was packed in a box, and carried to the laboratory for examination.

The present investigation included the following objects:—

To determine if any relationship could be established between the composition of the white partings (ankerites) and the ash produced when the coal is incinerated.

To attempt to trace the source of the carbon dioxide evolved when coal is treated with mineral acids.

To investigate the form of combination in which iron exists in the coal substance.

The last subject is of interest in view of the fact that according to the work of Powell and Parr (Bulletin 111, University of Illinois) the greater proportion of the iron present in certain American coals occurs in the form of pyrites, and with this fact is associated the assumption that the iron does not enter into the preliminary stages of the oxidation of coal.

It would appear from the experiments described in the present paper that a proportion of the iron in Lancashire coals exists in the ferrous state, either in the white partings (or ankerites) or some other form of combination.

Most coal seams contain a proportion of white inorganic partings, of which no study has appeared in the literature. It will be seen later that the material may be considered either as substituted calcium carbonate, or as dolomitised siderite. The term ankerite, which is the one generally accepted in mineralogy for compounds having a similar constitution, has been adopted to distinguish the substance of the white partings.

The ankerites occur in the form of sheets varying in thickness from ½ in. to a mere film, at right angles to the bedding plane and on the face of the coal, but also frequently on the end of the coal. The layer of material may be so thin as to be transparent, and its presence can only be detected by the fact that after being allowed to stand in the air the coal becomes covered with an opalescent film, consisting of oxidised ankerite. When ankerite occurs adjacent to a band of vitrain it is frequently perfectly white in colour, whilst portions in contact with clarain or durain are comparatively dark, and impregnated with fine coal. It has been observed that a band of ankerite frequently terminates at a point where a layer of fusain occurs. The latter material is highly porous in nature, and it would appear that the ankerites have been deposited from a liquid medium which has travelled horizontally along the layer of fusain.

The ankerites form a distinct line of weakness in the coal, and if the latter is treated with dilute mineral acids, marked disintegration of the lumps is produced, owing to the decomposition of the compounds. The whole of the specimens examined contained varying percentages of iron practically entirely in the ferrous condition, and it will be seen from the analyses that certain examples contained a distinct percentage of manganese.

Average specimens of the ankerites from a number of seams have been analysed, and the results are given in the following table:—

TABLE I.

Percentage composition of the white partings (ankerites).

	Lower Mountain Mine.	Arley.	Ravine Mine.	Sapling Mine.	Hoo Cannel.	Rushy Park.	King Mine.

Calcium carbonate	48·93	51·00	53·14	76·41	53·70	51·36	55·08
Magnesium carbonate ..	28·30	24·07	33·65	0·66	23·48	18·28	12·10
Ferrous carbonate	23·46	15·81	8·40	21·68	22·82	26·18	29·68
Manganese carbonate ..	—	1·33	1·80	—	—	0·96	0·50
Calcium sulphate	—	—	0·44	—	—	—	—
Silica	—	6·05	2·25	1·70	—	2·45	—
Ferric oxide ..	—	0·60	0·25	0·17	—	0·63	—
Pyrites ..	—	1·11	—	—	—	0·09	2·47

Specimens of ankerite obtained from the different layers in certain seams differ considerably in composition; the following analyses show the greatest variation yet encountered:—

TABLE II.

Ankerite from seam 8ft. thick.

	Top 15 in.	Bottom 7 in.
	%	%
Silica	0·91	2·25
Calcium carbonate	52·09	53·14
Magnesium carbonate ..	29·74	33·65
Ferrous carbonate	16·15	8·40
Manganese carbonate ..	1·41	1·80
Ferric oxide	0·33	0·25
Calcium sulphate	nil	0·44

The compounds undergo oxidation on exposure to air and become covered with reddish-coloured ferric compounds.

The following analyses show the change in composition which occurred when a specimen of ankerite was exposed to the air in contact with the coal. It should be pointed out that the two specimens of ankerite were of necessity obtained at a slight distance from one another and some small difference in chemical composition was detected:—

TABLE III.

	Sample freshly mined. Colour: white.	Sample after exposure to air for 12 weeks. Colour: red.
	%	%
Ferric iron	0·33	0·91
Silica	0·91	0·17
Ferrous oxide	9·29	10·58
Manganese oxide	0·87	1·08
Calcium oxide	29·17	29·31
Magnesium oxide	14·22	13·32
Carbon dioxide	44·67	44·74

The oxidation of the ankerites is influenced by tho presence of carbon dioxide and water. As would be expected, the compounds are freely soluble in water in the presence of carbon dioxide, and the solution which results rapidly undergoes oxidation in the presence of air, with the precipitation of basic ferric compounds.

No accurate method of determining the percentage of ankerites in coal has been elaborated, but an approximate value was obtained for one sample of coal by crushing about 1000 g. until it would pass through a sieve of 4's mesh, and separating all the ankerite that was visible by picking it out with forceps. The coal contained 4·2% of total ash and 3·0% of ankerite. The equivalent weight of ignited ankerite was 1·7%, *i.e.*, 40·5% of the ash was derived from the ankerite present.

Samples of the coals from which the ankerites described above were obtained were incinerated at a temperature of 900° C., and the resulting ashes were analysed with the following results:—

TABLE IV.

Composition of coal ashes.

	Lower Mountain Mine.	Arley.	Ravine Mine.	Sapling Mine.	Hoo Cannel.	Rushy Park.	King Mine.
	%	%	%	%	%	%	%
Silica	40·20	43·21	35·00	38·92	32·98	25·49	29·45
Ferric oxide ..	25·66	12·38	9·99	48·40	23·34	38·80	26·32
Alumina ..	25·41	28·47	31·58	3·68	26·86	20·61	29·53
Calcium oxide ..	3·52	7·12	11·63	5·04	6·88	7·08	5·96
Magnesium oxide	1·98	2·36	2·45	0·50	3·10	3·22	0·11
Sulphur trioxide	2·02	4·30	7·68	0·16	3·04	1·25	1·98
Alkalis and loss	1·21	2·16	1·67	3·30	3·80	3·55	6·65
Percentage of ash in the coal	3·00	3·20	5·20	4·00	24·4	2·4	4·6

A comparison of the above results shows that the proportion of the various constituents occurring in the ash is not by any means parallel with that found in the ankerites.

The percentage of carbon dioxide evolved when the coals were treated with mineral acids was determined by a method described in Bulletin No. 7 of the Lancashire and Cheshire Coal Research Association, from which the following results are extracted:—Mountain Mine, 0·57% CO_2; Arley, 0·18%; Ravine, 0·32%; abnormal sample I., 6·85%; Pemberton 2 ft., 0·72%; Garswood 9 ft., 0·14%; Hoo cannel. 1·84%; Rushy Park, 0·76%; Lower King, 0·77%; Bickershaw Yard, 0·40%.

It was thought that it might be possible to calculate approximately the proportion of the ankerite in a particular seam by the above determination, but it was found that the percentage of carbon dioxide evolved was in excess of that required to combine with the whole of the bases occurring in the coal as ankerites.

The following example shows the result obtained if the carbon dioxide evolved is assumed to be derived solely from ankerites:—

TABLE V.

1. Lower Mountain Mine.

Ash=3·03%. Carbon dioxide=0·57%.

Constituents.	Coal ash original analysis (100 g.).	Gross constituents of coal ash in 100 g. of coal.	Ankerite analysis.	Ignited ankerite eqnivalent to CO_2 in 100 g. of coal. g.
Silica	40·20	1·218	—	—
Ferrous oxide ..	nil	—	14·56	—

Sulphur trioxide ..	2·02	0·061	—	—
Pyrites	—	—	—	—
Alkalis and loss ..	1·21	0·036	—	—

From the above consideration it will be clear that the amount of carbon dioxide evolved when coal is treated with mineral acids is more than sufficient to combine with the bases found in the inorganic constituents of the coal, and must be derived from other sources than ankerites.

The source of the carbon dioxide has not been traced accurately, but it will be shown later that a portion of the iron in coal probably occurs as ferrous carbonate, as distinct from that occurring in the ankerites. The percentage of carbon dioxide is, however, of some interest from an analytical point of view. Unless the amount of carbon occurring as carbon dioxide is deducted from that found by combustion of the coal the percentage of organic carbon will be too high. The percentage of carbon dioxide should be deducted from the percentage of volatile organic matter, as presumably the whole of the carbon dioxide is evolved at a temperature of about 900° C. In the case of the abnormal sample, the volatile organic matter determined was too high by 6·8%.

Mr. N. Simpkin, in collaboration with one of us, is continuing certain phases of the work, and has treated the coals with dilute hydrochloric acid, and determined tho amount of iron which passes into solution; the total amount of iron present was also found.

It appeared desirable to ascertain what proportion of this iron occurred in the ferrous state, and specimens of the fresh coal were treated with hydrocloric acid (10%) in an atmosphere of carbon dioxide. The excess of coal was removed by filtration in an atmosphere of carbon dioxide, and the amount of iron in the filtrate determined. It was found that the liquid contained a negligible quantity of iron in the ferric condition. The iron in the ferrous condition was determined by oxidation and subsequent titration with a standardised solution of titanous chloride. As this examination had to be performed on fresh samples of coal the results are not exactly parallel with those previously quoted. The preliminary results are, however, strictly comparative, and are given in the following table:—

TABLE VI.

Coal.	Total iron. %	Iron (ferrous) extracted with hydrochloric acid. %	Iron (ferrous) extracted with hydrochloric acid. Percentage of total iron.
Rushy Park	0·494	0·176	35·6
Lower Mountain Mine ..	1·779	0·535	29·7
Arley	0·612	0·047	7·7
Ravine	1·379	0·205	14·9

The results quoted in this paper are of interest as indicating that a distinct percentage of the iron in coal, which differs widely in different seams, is present in the ferrous condition in the ankerites, and in some other form of combination; it does not necessarily follow that the iron extracted by means of hydrochloric acid is present in the coal in the ferrous condition, since it may have been produced by the action of coal upon ferric compounds. In certain cases distinct oxidation of the ankerites can be detected within a month of the seam being obtained from the mine.

From a chemical standpoint it will be of interest to obtain information as to the relative rates of oxidation of ankerites of different compositions, and the effect of this oxidation upon the oxidation of the coal substance and of pyrites. It is not obvious which type will most readily oxidise, but upon the behaviour of these compounds will depend the degree to which coals will weather, and as a corollary their properties during storage.

Oxidation obviously produces a change in volume or thickness of the sheets of ankerite, and consequently is a factor contributing towards the disintegration of masses of coal. When coal has been allowed to stand for extended periods, oxidation of sheets of ankerites has been observed at a considerable depth into the coal. Up to the present no direct evidence has been obtained as to whether the primary heating of coal can be connected with the presence of ankerites, and the effect of manganese etc. upon the general action of the ankerites. At the same time, in view of the clearly recognised action of ferrous and manganese carbonates as catalysts it appears of considerable interest to examine the subject in the light of the information described in this paper It would also appear that carbon dioxide may be an active agent in the oxidation of the compounds; we have found that ankerites are freely soluble in water containing carbon dioxide, and that the resulting solution rapidly undergoes oxidation with precipitation of the iron in the form of ferric compounds. In a mass of coal evolution of carbon dioxide is known to take place, and in the presence of any excess of moisture the conditions are such as to bring about the oxidation of the compounds, with carbon dioxide and water taking part in the reaction.

When coal containing ankerites is burned, bands of residue from the ankerite will remain separate from the inherent ash of the coal unless the temperature is sufficiently high to fuse the whole mass. The residual material from the ankerite will consist of highly infusible oxides. It would follow that coal which has been broken to a small size will contain the ankerite and silicious coal ash in more intimate contact than when larger sizes are used.

Analysts make a practice of quoting the colour of coal ashes, and it is well known that such ashes consist of a mixture of particles widely different in colour. We therefore made it a rule to pulverise coal ashes to a fine powder (1/200 mesh) in order to obtain an impression of the colour as a whole.

DISCUSSION.

The CHAIRMAN suggested that the authors might determine how it was that the ankerites themselves were provocative of the oxidation of the coal material. If a portion of the coal were mixed with definite quantities of the ankerites it might be possible to determine how far the ankerites themselves were excitants of the coal oxidation. It might also be interesting to determine whether any of the particular seams of coal mentioned as containing manganese exhibited any greater tendency towards heating in the mass than those which were free from it, in view of the well-known catalytic effect which manganese possessed as an oxidation exciter.

Mr. H. L. TERRY said that as many of the analyses showed such low amounts of iron and manganese carbonates the term "ankerite" did not seem particularly appropriate. Certainly such terms as "dolomitic siderite" or "sideritic dolomite" were cumbrous and not to be recommended. He had often found coal partings to be of a dolomitic nature, but one sample he had had from the Lower Mountain Mine coal at Rishton, near Accrington, was pure calcite. Was this consistent with the authors' investigations? He noticed a great variation in the amounts of iron carbonate in the analyses quoted, and in many cases the manganese did not rise above what was ordinarily found in some limestones. Ankerites were not uncommon in the dolomitic beds of the lower carboniferous limestone in Derbyshire, and they were probably more widely distributed than was generally supposed. A peculiar manganese ore known as wad used to be obtained to a considerable extent at one time from pockets in the limestone adjacent to some of the mineral veins in Derbyshire. He had found that the oxides of manganese and iron were always mixed with magnesia, and he thought that the obscure origin of these deposits could be attributed to the action of carbonic acid on ankerite deposits. This was a matter he intended to probe further. At the Killeen copper mine, Co. Tipperary, the ore was associated with well crystallised ankerite showing about 30% each of the carbonates of calcium, magnesium, and iron, with 6—7% of manganese carbonate.

Mr. WILLIAM THOMSON enquired what was meant by the "face" and the "end" of the coal, and also what process was adopted for estimating the carbon dioxide when the coal was treated with hydrochloric acid. Was it possible that some of the sulphides of iron in the coal would give off hydrogen sulphide which might be estimated as carbon dioxide? The authors had suggested various explanations as to why coal might become heated or take fire, but the usual explanation was that the oxidation of the pyrites produced the heat and fire.

Mr. STEVENSON asked whether the experiment had been made of grinding coal in a fairly high vacuum. Coal contained large quantities of occluded gaseous matter. Was there any possibility of carbon dioxide being occluded in the coal and set free on treatment with acid? If a sample of coal from one of the seams were treated with a ferric salt, say ferric chloride, and hydrochloric acid, a portion of the ferric chloride might possibly be reduced to the ferrous state. If so, that would lead somewhat to a modification of the view that the ferrous condition was the only one found.

Mr. MCCULLOCH said that he had been unable to find any calcium or magnesium in the clays associated with some of the Lancashire coal seams. Could any theory be put forward as to how the ankerite came to be in the coal? If the ankerite was carried by a hard water, then it would appear that the surfaces of the under and over clays should contain considerable quantities of calcium and magnesium.

Mr. Booth suggested that the ankerites were due to water infiltration from the limestone; the presence of comparatively high percentages of magnesium and manganese suggested this. The ferrous iron was no doubt derived from the chlorophyll present in the green parts of the coal measure flora. One would, of course, expect to find quite high percentages of ferrous carbonate. Coals which were liable to spontaneous ignition usually contained microscopically small yellow grains, as pointed out by Lomax. The possibility of these being chlorophyll grains should not be overlooked. The variation in the percentage of iron in the ankerities might be accounted for by the varying iron content of this coal seam, due to difference in constitution.

Mr. Grounds said that although Capt. Sinnatt has advanced no definite theory as to the connexion between ferrous carbonate, manganese carbonate, and spontaneous ignition, he had nevertheless hinted that there might be a connexion between these three factors. The South Wales bituminous coals contained 19—30% of volatile organic matter, as compared with 23—40% in the Lancashire coals. He thought it was generally agreed that spontaneous combustion was more liable to take place in coals containing a high percentage of volatile organic matter than in those containing a low percentage. Spontaneous ignition very rarely occurred with anthracites or steam coals. Ankerites were not present in the South Wales bituminous coals to anything like the same extent that they occurred in the Lancashire coals, and travelling westward from the Cardiff valleys towards the Swansea area, *i.e.*, the anthracitic centre, there was a gradual transition in the same seam from a bituminous coal which contained 23% of volatile organic matter to an anthracite containing only 9%. At the same time there was another transition in the Eastern coals containing, say, 23% of volatile organic matter. There were quantities of ankerite visible, yet not so visible as in the Lancashire coals, while among the anthracites there were scarcely any ankerites at all. It seemed rather peculiar that the coals which possessed the highest volatile organic matter should have also the highest quantity of ankerites and also were the most liable to spontaneous ignition.

Mr. Bloch asked whether Capt. Sinnatt had adopted any process to separate the alkali from the coal.

Mr. Varley referred to the figures in table III. showing that the result of exposing ankerites to air was to increase the ferric iron from 0·33% to 0·91%, whilst there was an increase in the amount of ferrous oxide from 9·29% to 10·58%; another remarkable point was the diminution of the silica from 0·91% to 0·17% after 12 weeks' exposure. Did the analyses shown give the composition of the same uniform sample before and after exposure to air, and if not could such results be relied upon for purposes of comparison?

Mr. Taylor mentioned that a piece of Mountain Mine coal weighing about 4 lb. was exposed to the air for about 13 months, at the end of which time the surface of the coal was covered with a white powder. When the coal was digested in water and the solution examined, the iron constituent was found to be in a ferrous condition. The solution also contained ammonium and sulphate in the proportions of one of ammonium to 40 of iron and 40 of sulphate. The oxidation or sulphating of coal might not be attributable to the iron in the coal.

Dr. A. C. Dunningham said that the authors' investigation into the nature of coal ash might be of great service owing to the well-recognised fact that the practical value of coal depended not only on its theoretical heating value, but on the nature of its ash. It might also be of value in yielding information which would lead to a method of purifying coke. This was probably even now the cheapest form of carbon, which for some purposes was required in a very pure form.

Captain Sinnatt, in reply to Mr. Varley, said that it was necessary to leave half of a piece of ankerite on the coal to stand for 12 weeks, whilst the other half was analysed. The same sheet of ankerite was used, but, as had been indicated in the paper, this material was not by any means constant in composition, and consequently the analytical figures for material one inch or so apart might be different. The silica in different samples might vary widely, as it was found deposited on the face of the material in local aggregations. It would be necessary, therefore, to accept these results until some better way of comparing the analyses could be adopted. The analyses only emphasised the point that considerable variations in the composition of the ankerites must be expected in a very short distance. The suggestion made by Mr. Allan was valuable, and if a method could be elaborated experiments would be carried out to test the influence of different percentages of manganese upon the oxidation of coal. In one part of the Ravine Mine the ankerite contained 4% of manganese, and although this observation was an isolated one, it was well known that the Ravine was the most liable to fire of any of the coals in the Lancashire coalfield. The remarks of Mr. Terry were of considerable interest, and it was most important that some name should be generally adopted for these white partings. The Lower Mountain Mine was, in certain parts, characterised by having a roof largely composed of marine fossils. It was quite possible, therefore, that intrusions of pure calcite would be found in it. The observations on the dolomites were especially pertinent. The terms " face " and " end " were used as applied in the coal industry, the face being the portion of the seam at which the collier worked, as the coal tended to fall in sheets towards him, owing to the line of weakness formed by the ankerites, etc. The end was at right angles to the face, and contained less of the partings. The method used for the determination of carbon dioxide was one elaborated by one of the authors (Sinnatt, Analyst, April, 1913); the contamination of the gas by hydrogen sulphide was not possible. The question of the influence of the pyrites upon the oxidation of coal was a debatable one, and had not been introduced into the paper, as Mr. Lomax of Bolton was at present engaged upon a systematic examination of the subject. Every endeavour had been made to eliminate occluded carbon dioxide. Each sample of coal was boiled with water for 20 minutes, in order to eliminate the occluded gases. The suggestion that the action of ferric chloride on coal should be examined was a valuable one; it was well known that iron pyrites had a reducing action on ferric chloride, but the exact action of the coal substance upon ferric chloride had received little attention. The authors agreed that the ankerites were distributed throughout the coal substance, and their thoughts tended to an opinion that some of the iron might be present in the coal in the form of an organic compound. The suggestion made by Mr. Booth that the iron was derived from the chlorophyll in the vegetation from which the coal was formed would account for practically all the iron found in coal seams. It was proposed, at a future date, to attempt to separate the ankerites by the froth flotation process. With reference to the remarks of Mr. Taylor, it would appear that he had been dealing with a deposit formed on the surface of the coal.

NEW PROCESS FOR THE VULCANISATION OF RUBBER.

BY S. J. PEACHEY AND A. SKIPSEY.

The importance of the vulcanising process as one of the essential operations in the manufacture of all rubber goods is perhaps not fully appreciated, except by those who are directly connected with the industry; yet it may be said without exaggeration that but for the timely discovery of the process by Goodyear in 1839 the then newly-founded industry would not only have failed to attain its present position and magnitude, but would almost certainly have retrogressed.

Although it yields a vulcanised rubber of excellent quality, the Goodyear process itself possesses certain disadvantages, the chief of which are as follows:—(1) It necessitates the continuous use of steam both as a heating agent and as a medium for exerting pressure on the goods under treatment (and thus avoiding the development of porosity). (2) It is a comparatively slow process. (3) It restricts the manufacturer in his choice of filling and colouring agents. Organic filling agents, with very few exceptions, are destroyed or seriously deteriorated by the combined action of heat and sulphur, and in many cases by heat alone. Thus cheap and useful filling materials such as wood meal, leather, cotton, and wool wastes cannot be successfully employed in the manufacture of rubber goods. The manufacturer has to fall back on inorganic compounding materials such as barytes, chalk, china clay, kieselguhr and the like. Further, the majority of coal tar dyestuffs are destroyed or modified by the action of sulphur at a temperature of 140° C., so that the manufacturer has to confine himself to the use of mineral pigments such as zinc oxide, antimony sulphide, chrome green, and so on, a fact which explains the rather drab colours common to most rubber goods. Delicate tints are practically unobtainable.

The new process which forms the subject of this paper removes these restrictions and renders possible the production in the rubber trade of wholly new technical and artistic effects. The discovery of the process resulted from an investigation on the behaviour of rubber towards different forms of sulphur. Sulphur is remarkable for the number of allotropic forms which it is capable of assuming. In all three states of aggregation—solid, liquid, and gaseous—sulphur appears to be capable of varying its molecular complexity. An attempt was made to compare the action of these different forms of sulphur on rubber, and this attempt was interrupted by the discovery that the interaction of sulphur dioxide and hydrogen sulphide produces momentarily a form of sulphur which rapidly combines with rubber at the ordinary temperature, yielding an effective vulcanisation. The reaction between the two gases must take place in contact with the rubber or no vulcanisation results. In other words, the liberated sulphur is active only at the moment of its liberation, and it is fair to assume, therefore, that the effect is produced by atomic sulphur.

In applying the new process the rubber is exposed alternately to the action of sulphur dioxide and hydrogen sulphide. The gases readily diffuse into (probably dissolve in) the rubber, and there interacting produce active sulphur, which immediately combines with the rubber at the ordinary temperature, yielding a product wholly comparable with that obtained by the Goodyear hot process. Evidence is accumulating to show that the product is actually superior in strength; this may be explained by the fact that the depolymerisation of rubber produced by heat is avoided in the new process.

The process appears to be of fundamental importance for the following reasons:—

(1) It is a true sulphur vulcanisation—as distinct from the sulphur chloride vulcanisation produced by Parkes' "cold cure."

(2) It eliminates the use of heat and to a great extent the use of mechanical pressure.

(3) It employs two gases, both of which can be produced on a large scale at a very cheap rate.

(4) It is rapid in action.

(5) It enables the manufacturer to employ organic filling agents which cannot be used in conjunction with the hot process or with the Parkes process (most organic materials are attacked and destroyed by contact with sulphur chloride).

A number of cheap and highly durable materials may be fabricated from various wastes in this manner and employed as floor and wall coverings, for boot and shoe manufacture, and for fancy leather goods and upholstery work. Further, in numerous manufacturing processes unconnected with the rubber industry the process renders possible the use of rubber as a binding agent for fibrous and granular materials as an alternative to the resins, bitumens, gums, and like substances which have hitherto been employed, with the result that the toughness and flexibility of the products are considerably increased.

(6) Coal-tar dyestuffs and even natural dyes like chlorophyll, which, with a few exceptions, are destroyed by the hot cure and also by the sulphur chloride cure, can be introduced into rubber mixings to be cured by the new process with the production of delicately-tinted materials hitherto quite unobtainable.

The process possesses the advantage of extreme simplicity, and its translation from the laboratory to the works should prove a simple matter.

The process can be extended to the vulcanisation of rubber in solution. If a solution of rubber in benzol or naphtha be saturated or partly saturated with hydrogen sulphide and mixed with a solution of sulphur dioxide in the same solvent, the liquid sets in a few moments to a stiff jelly, and on eliminating the solvent by evaporation a fully vulcanised rubber is obtained. The use of the mixed solutions for producing perfectly vulcanised seams and joints has proved highly successful, and inner tubes repaired by the new process have an excellent life.

Further, by the use of the solution process, re-formed leather soles and heels may be attached to boots without the aid of stitching or nailing, and, indeed, a whole boot may be produced from the re-formed leather without a single stitch being necessary.

During the past month or so certain modifications of the process have been devised, but these must form the subject of a later paper.

Discussion.

Mr. **Bailey** asked whether the presence of the sulphur dioxide or the hydrogen sulphide in the rubber was likely to result in deterioration of the rubber in use. Also whether the removal of the gas was complete.

Mr. **Tomkinson** asked if the water produced caused any porosity in the finished goods.

Mr. **Marcroft** pointed out that one of the best red pigments was antimony sulphide, and that it usually contained a fair percentage of free sulphur. The same remark applied to ultramarine. Was that free sulphur affected during vulcanisation, or would it "sulphur up" afterwards?

Mr. Leon said that he had made experiments with the process described and had found that quite a lot of sulphuric acid was formed. How was this got rid of? He assumed that there was a certain amount of free sulphur in excess at the end of the process; did that "bloom" up and, if so, what method could be adopted for its prevention?

Dr. Bloch asked how the new rubber compared with leather or with rubber vulcanised by the hot process in the wear of boots and shoes.

Mr. Terry said that he had examined a sample of the rubber treated according to the authors' process, and after a lapse of six months in his possession he had found it to be perfectly sound. The problem in the rubber world was to find a really satisfactory "ageing" test. In order to obtain proof that rubber was properly vulcanised and not surface-cured the de-vulcanising processes could generally be employed. Rubber "cold-cured" by the Parkes process could always be de-vulcanised quite easily, especially in hot alkali, which removed the chlorine; but if the rubber cured by the "Peachey" process was treated by a hot alkaline solution there was practically no effect; the strongly vulcanised rubber remained intact. That was evidence of complete vulcanisation and not merely "surface curing," as in the Parkes process.

Prof. Green asked whether the process could be applied to the treatment of outer covers for tyres. It would appear that if it was possible to combine the strength of a fibrous material with the resiliency of rubber a great advance might be made in the wear of outer covers.

Mr. G. H. Gray asked how it was proposed to manufacture a solid rubber tyre such as was used on a commercial vehicle.

Mr. Peachey, in reply, said that the two gases were introduced separately, both being comparatively easily soluble in the solid rubber, especially the sulphur dioxide. The amount of sulphur dioxide absorbed by rubber was surprising. Hydrogen sulphide was more than sufficiently soluble to yield a coefficient of vulcanisation up to, say, 5, which was higher than was required in practice. Adsorption was not relied upon at all, but absorption of the gas followed probably by solution. Generally speaking, excess gases, as far as could be judged by smell, were driven out of the rubber after about one hour's exposure. The practice had been followed throughout of giving the shorter sulphur dioxide treatment first and finishing up with the H_2S in excess, so that there was very little possibility of free SO_2 remaining and practically no danger of free acid forming. To get a fully vulcanised rubber it was only necessary to introduce some 2½% of sulphur; therefore the amounts of the two gases required to vulcanise a mixture containing, say, 50% of rubber were surprisingly small, and there was only a negligible amount of water produced. The water diffused out of the rubber quite rapidly; it never existed in the liquid form in the finished product, and the vulcanisation need not be followed by any drying operation; mere exposure to the air for a few hours, at any rate, caused all necessary elimination of water. As regards the free sulphur present in antimony sulphide and ultramarine, it was disadvantageous to have free sulphur present in a mixing which had to be vulcanised by the new process. He supposed it tended in some way sympathetically to convert the atomic sulphur into molecular sulphur. In all mixings which were made for the new process ordinary sulphur would not be present, and the use of antimony sulphide would be especially avoided, as that substance could be replaced by much better and brighter colours. In the "dry" treatment the rubber or rubber mixing to be vulcanised was exposed to sulphur dioxide for 10 minutes, after which a very short exposure to the air was given to remove the adsorbed gas from the surface. The material was then introduced into another chamber where it was exposed to the hydrogen sulphide for 20 to 30 mins. In the case of "solution vulcanisation," it was very easy to prepare standard solutions, and in practice a standard solution of sulphur dioxide was prepared by weight. It was convenient to use a solution containing 0·8% of this gas in benzene, and to saturate a 10% rubber solution with hydrogen sulphide, and mix four volumes of the hydrogen sulphide solution containing the rubber with one volume of the benzene solution. The actual proportion of the two gases interacting was theoretical. Small amounts of free sulphur were invariably formed in the rubber. The combination was not quite complete, as apparently a small amount of the atomic sulphur was changed into molecular sulphur, but the amount was small compared with the amount that was left in the rubber by the "hot" process. It was a matter of surprise to learn that Mr. Leon had found acid in his samples; possibly he had used the sulphur dioxide in excess, or at any rate not in sufficient deficiency. In his own experiments the hydrogen sulphide had been invariably kept in excess, and by treating the rubber first with sulphur dioxide and then with hydrogen sulphide the formation of any trace of free acid could be avoided. If, however, faulty working led to the formation of a trace of free acid the material could be treated with ammonia, just as in the sulphur chloride process. The question of the treatment of rubber of one inch thickness was rather beyond the present limits of the process. The porosity of a mixing was actually greater when it was fairly heavily loaded, and it was surprising what penetration was obtained. Although exact diffusion figures were not available, it might be assumed that both sulphur dioxide and hydrogen sulphide diffused into rubber at least as rapidly as carbon dioxide, and in the case of sulphur dioxide more rapidly. They would not attempt by the new process to deal with material one inch thick, but would avail themselves of the new method of building up which had become possible as the result of the new solution process. It was possible now to build up material of any thickness after it had been vulcanised in sheets and to get a solid mass in which the joints were of a strength equal to that of the material itself. The treatment of thick articles would, therefore, involve new methods of building up, but it was quite desirable that such new methods should be introduced. The leather compounds prepared by this process were 2½ times as durable as new leather.

Liverpool Section.

THE CORROSION OF COKE OVEN WALLS.

BY A. E. FINDLEY.

The work described in this paper was undertaken with the idea of throwing some light on the effect of certain ingredients in the coking slack on the corrosion of the oven walls. The ingredients which were suspected of producing the most harmful effect were salt, iron, and moisture.

For the purposes of this work the total amount of salt present in the coals examined was not determined, but only that amount which could be removed by washing 200 grams of each coal by percolation with cold water under exactly similar conditions. The main object of this washing was to test the retentive capacity for water of different coals (as sent to the ovens), and also to show to what extent this retentive capacity depended on the fineness of the coals after crushing. Subsequently each coal was washed until 100 c.c. of the wash water required 2 c.c. or less of $N/50$ silver nitrate solution. In each case the same amount of wash water was used on a definite weight of coal. The quantity of salt extracted was proportional to the quantity actually present in the coal within certain limits. the finest crushed slack was used, the coal in the hoppers is not saturated with water. The subjoined table indicates the first stages of the work for four different Yorkshire coking slacks.

The relative retentive capacities for water in the table are purely empirical and are based on the rate of draining under similar conditions.

The following conclusions may be drawn from the table:—

(1) As the amount of salt increases the durability of the oven walls decreases.

(2) If the amounts of both salt and iron present are high, as at Waleswood, durability seems to be still further diminished.

(3) Iron and moisture may be present in relatively large amounts, but this does not appreciably affect the durability of the oven walls if the amount of salt is very low, as at Hoyland Silkstone.

(4) The higher temperature in vertical flues of a regenerative oven system tends to shorten the life of the oven walls.

W. J. Rees has shown (*Cf.* Ceram. Soc., Spring, 1920) that iron may be carried right through and out of a fireclay brick by means of salt at 950° C. Working side by side with Rees I have endeavoured to throw some light on the mode of transference of iron from coal into the fireclay of the oven walls, because Rees has shown (Trans. Ceram. Soc., 1918) that spalling mainly takes place at a layer of hæmatite formed some distance inside the bricks; he explains the presence of hæmatite by assuming that the iron is carried into the bricks as chloride until it meets with oxidising conditions.

Tests on four coals in South Yorkshire.

Colliery.	Type of ovens.	Salt. %	Fe_2O_3. %	Water. %	Ash. %	Relative retentive capacity for water.	Relative fineness.	Life of ovens.
Waleswood ..	Simon-Carves, (*a*) regenerative (*b*) waste heat.	0·142	1·45	15·5	8·75	8	4·1% above ¼" 20·5% above ⅛" less than ¼" 21·1% above 1/16" less than ⅛" 54·3% less than 1/16"	(*a*) 18 months (*b*) 2¼ years roughly
Monckton Main..	Simon-Carves, waste heat.	0·086	0·82	11·5	9·0	3·4	16·25% above ¼" 41·5% above ⅛" less than ¼" 16·75% above 1/16" less than ⅛" 25·5% less than 1/16"	Roughly 3 years.
Wharncliffe Woodmoor	Simon-Carves, regenerative.	0·038	0·71	8·4	4·9	1	28·8% above ¼" 29·6% above ⅛" less than ¼" 14·3% above 1/16" less than ⅛" 27·3% less than 1/16"	Roughly 4 years.
Hoyland Silkstone	Semet-Solvay, waste heat.	0·028	1·09	12·4	8·05	29	1·43% above ¼" 9·34% above ⅛" less than ¼" 12·05% above 1/16" less than ⅛" 65·98% less than 1/16"	No repairs since 1917 when ovens were built.

J. W. Cobb has shown that, however finely a coal be crushed, washing with cold or boiling water does not remove all the salt, and that further prolonged boiling with water and with dilute nitric acid will yield further quantities of salt; consequently, the figures given for salt in this work are better for the purposes in view than figures taken from the average results over one year's working at the coke ovens using the coals examined, because they have been obtained under almost exactly similar conditions, whilst the conditions for the determination of salt at different coke ovens are very variable.

The amount of water in the coal going to the hoppers will be dependent initially on the size of the unwashed coking slack; the amount of water retained in the coal after crushing (*i.e.*, the amount of water which does not drain out, however long the coal remains in the hoppers) will depend entirely on the fineness of the crushing. The results obtained have proved this conclusively, and also that at the Hoyland Silkstone Colliery, where

The following experiments were carried out by heating 5 g. of thoroughly mixed coal (ground to pass a 30-mesh sieve) in silica tubes to 900° C.—950° C. under the conditions stated:—

Substance heated.	Period in hours.	Atmosphere.	Fe_2O_3 found in ash, calc. on original coal %
Coal A	4½	Air	1·56
..	4½	Steam and air	(a) 1·46 (b) 1·42
Coal + $CaCl_2$	4½	Air	1·42
..	4½	Steam & air	1·43
Coal	4½	Steam & air & HCl	1·28
*Coke	4½	Coal gas	1·53
Coal B	4½	Air	1·44
Coal, $MgCl_2$, & NaCl	4½	Air	1·32
*Coke, $CaCl_2$, & NaCl	4½	Coal gas.	1·32
Coal, $CaCl_2$, & NaCl	4½	Air & steam	1·42
*Coke	45	Coal gas	1·44

* Where coke is quoted it is the coke from 5 grams of coal.

It will be seen that the maximum loss of iron is obtained by burning the coal in an atmosphere of hydrochloric acid vapour and air. Chlorides appear to be capable of removing iron in the presence of air and steam or of coal gas, but coal gas alone is not effective in removing iron from coal or coke. Of the above results those with chlorides cannot be regarded as absolutely conclusive, as I have found that the majority, although all pointing to the fact that iron is removed, are not outside the limits of experimental error; for definite proof of the removal of iron it is necessary to depend on the result obtained with hydrochloric acid which, in my opinion, is quite beyond the limits of probable error of experiment. There is no doubt that chlorides have the same effect in the presence of gas and steam at the temperature of the ovens, as most chlorides likely to be present in coal will yield hydrochloric acid under the conditions existing in coke ovens.

A NEW METHOD FOR THE PRODUCTION OF CELLULOSE ACETATE.

BY W. LEIGH BARNETT, B.SC., A.I.C.

A variety of substances have been employed as catalysts of the acetylation of cellulose, the chief of which are strong dehydrating agents, such as sulphuric acid, phosphoric acid, zinc chloride, chlorides and oxy-chlorides of sulphur and phosphorus, dimethyl sulphate, chloroacetic acids, etc. Chlorine does not act readily unless under special conditions, and then only very slowly. Combined in the form of chloroacetic acids, large quantities are required compared with the weight of cellulose employed. Many of these catalysts possess the disadvantage that they give coloured or cloudy solutions owing to decomposition and degradation of the cellulose ester. Sulphuric acid, which is largely employed, tends to give dark-coloured solutions and also to hydrolyse the product, in addition to which the properties of the resulting esters vary considerably. Further, the films are generally brittle owing to the fact that all the sulphuric acid cannot be removed successfully. It is claimed that addition of substances which neutralise the effect of the acid, or other condensing agent, keep the syrupy solutions of cellulose acetate in good condition and prevent them from giving brittle products. A distinct improvement in the acetylation of cellulose results from the use of sulphuryl chloride as catalyst (Chem. Fabrik von Heyden, E.P. 24,382 of 1910), whereby superior cellulose acetate solutions result, and these solutions are not decomposed by the sulphuryl chloride.

For an investigation into the esters of cellulose it was necessary to make use of cellulose acetates which had been prepared in such a way as to ensure the minimum amount of change in the parent complex. All of the ordinary methods for acetylating cellulose were rejected on the grounds that either the ester solutions were coloured after acetylation had occurred, or that the solutions were not brilliantly clear, and for these reasons there was no guarantee that the esters when isolated would not contain products of degradation. By using a mixed catalyst of chlorine and sulphur dioxide I have found that satisfactory results are obtained with the minimum amount of change in the parent complex. If cellulose be treated with a suitable mixture of glacial acetic acid, acetic anhydride, and a trace of chlorine, practically no acetylation results unless the mixture be heated for some time. Similarly, if sulphur dioxide be substituted for the chlorine, no acetylation occurs, and if the mixture is heated it takes place to a smaller extent than in the case of chlorine. If, however, traces of both chlorine and sulphur dioxide be introduced, either separately or together, into the mixture, acetylation proceeds to a remarkable extent, and a perfectly clear, colourless solution, or even jelly results. By suitably choosing the conditions for the reaction it is possible to obtain a great variety of pure esters, possessing valuable properties of strength, film flexibility, transparency, and solubility. Acetylation proceeds at any temperature, and as no signs of discoloration occur, owing to the great ease of control of the reaction, no special precautions are necessary. The combined use of chlorine and sulphur dioxide is equally efficient in producing other esters, such as the butyrate, benzoate (using benzoyl chloride in acetic acid), etc.

The great reactivity of this mixed catalyst is probably due to the fact that first the cellulose itself acts as a condensing agent for the chlorine and sulphur dioxide, which produce small amounts of sulphuryl chloride in intimate contact with the cellulose, and these traces of sulphuryl chloride, being produced in *statu nascendi* under such conditions, are much more effective in promoting the subsequent acetylation.

A large number of experiments were carried out in order to ascertain the best conditions for the acetylation of various kinds of cellulose. Swedish filter paper, bleached and grey American cotton yarn, and cotton wool were employed, whilst variations in the method of adding the catalysts together with alterations in relative quantities and conditions of temperature were introduced. The best method for isolating the cellulose ester from the acetic acid solutions was found to consist in the addition of chloroform or acetone to the reaction solution, followed by mixing with an excess of water. When the volatile solvent is distilled out the cellulose acetate is gradually precipitated, due to the rising of globules of the chloroform solution through the water. The globules become covered with a fine film of precipitated cellulose acetate, and on stirring these are disintegrated. By this means the ester is obtained in the form of a fine white powder, and can easily be washed free from acid. The products can be dried at 100° C. for several days, and do not show any signs of decomposition or darkening in colour. The properties of film strength etc. are not impaired by continued heating.

The product depends on the conditions of acetylation. If the temperature be kept below 65° C., and only a trace of sulphur dioxide be employed, the product is chiefly a cellulose diacetate. If the ratio of chlorine to sulphur dioxide be nearer to unity then the product is mainly cellulose triacetate, particularly if the temperature be allowed to rise above 65° C.

The following table shows the nature of the products obtained after varying intervals:—

Time. Hrs.	Yield. %	Acetic acid. %	Cellulose. %
1	178	63·9	58·9
2	173	63·7	53·1
24	174	—	—
48	173	63·3	51·5
72	173	62·0	46·9
72	176*	61·9	48·8

* In this case there was formed in addition a small quantity (1·2%) of an acetate insoluble in acetic acid. Theoretical yield for cellulose triacetate, 178%: C 49·9%, H 5·6%. The product contained C 49·2%, H 5·3%.

In one experiment 200 g. of acetic acid, containing only sufficient chlorine to colour it, was poured on to 50 g. of filter paper, and after standing for some time 250 g. of acetic anhydride was added, followed by the passage of a few bubbles of sulphur dioxide. The temperature rose spontaneously and was kept down to a maximum of 65° C. by cooling with water. Within an hour a clear solution resulted. After standing over night it set to a firm jelly, which was diluted with acetic acid and separated by means of chloroform. The fine white powder ultimately obtained was soluble in acetone, chloroform, pyridine, hot nitrobenzene, aniline, and slightly soluble in a mixture of alcohol and benzene. Analysis showed it to be a diacetate (C, 48·17, 48·93% ; H, 5·66, 5·73% ; theory requires C, 48·76% ; H, 5·73%). Acetic acid by hydrolysis of an acetone solution (*cf. infra*, the analysis of cellulose acetates), 48·81—48·98% ; theory requires 48·8%.

In another experiment 5 g. of filter paper was immersed in 20 c.c. of glacial acetic acid, and 20 c.c. of acetic anhydride containing 0·32 g. of chlorine added, followed by 2 c.c. of acetic anhydride containing 0·26 g. of sulphur dioxide. The mixture rapidly gelatinised, and in less than five minutes solution was complete. After a further five minutes' stirring 20 c.c. of chloroform was added and the ester separated as usual. The product formed fine white flakes of cellulose triacetate (62·4% of acetic acid; theory requires 62·5%). Using the same quantity of cellulose, 20 c.c. of acetic acid, 45 c.c. of acetic anhydride containing 0·066 g. of chlorine and 1 c.c. of anhydride containing 0·069 g. of sulphur dioxide, and warming the mixture slightly, a fine pulp was produced after 10 minutes, which rapidly gelatinised and gave a clear viscid solution from which the ester (acetic acid 64·2%) was isolated.

Preliminary experiments showed that acetylation proceeded best when the weights of chlorine and sulphur dioxide were approximately in the ratio of their molecular weights. This was ascribed to the formation of sulphuryl chloride, and it was therefore considered that by working at its boiling point (69° C.) the reaction would be greatly expedited, since then the sulphuryl chloride would tend to remain gaseous and the escaping bubbles should aid in the rapid clarification of the solution. A mixture of 2 g. of filter paper with 10 c.c. of acetic acid was heated to 69° C., 6 c.c. of acetic anhydride containing 0·28 g. of chlorine added, and then 3·7 c.c. of the anhydride containing 0·25 g. of sulphur dioxide, the temperature being maintained at 69°—70° C. by means of a thermostat.

It is interesting to note that both the acetic acid figures and the values for the recovered cellulose fall off with increase of time of acetylation. The decreasing figures for the cellulose recovered may be taken to indicate some change of the cellulose complex, and although the yields of ester isolated at different stages are the same, this can be explained by the fact that esters from modified cellulose are insoluble in water. The cellulose recovered in the above cases was found to possess the characteristic properties of cellulose, being insoluble in any of the solvents for cellulose acetate and soluble in cuprammonium from which it was reprecipitated by acids.

Cotton wool and bleached and grey American cotton yarn gave similar results to those described for filter paper.

Parallel experiments were made using cotton wool and filter paper. The air-dried samples were immersed in cold diluted Fehling's solution for 30 mins. and washed free from copper solution, and the absorbed copper removed by digestion with dilute acetic acid. The cotton (7·33% moisture) was found to have absorbed 0·83% of copper and the filter paper (5·73% moisture) 0·54% on an air-dry basis (these amounts of copper are proportional to the amounts of cellulose hydrate present. The residual cellulose was boiled with dilute Fehling's solution for 15 mins., the absorbed copper removed, and the products acetylated at 69°—70° C.; the following results were obtained (on an air-dry basis):—

	Cotton.		Filter paper.
Copper. %	1·50	..	3·82
Residual cellulose. %	92·1	..	87·4
Yield of ester (total). % ..	170	..	163

The filter paper cellulose acetylated more vigorously, but the cotton gave a solution of better colour and higher viscosity than the filter paper. After standing for 24 hours a small amount of the cellulose acetate insoluble in acetic acid was precipitated, amounting to 10·6% in the case of the cotton product and 3·9% in the case of the filter paper. These results indicate that the presence of much cellulose hydrate lowers the yield of cellulose triacetate, due no doubt to the formation of soluble products of degradation of the cellulose.

The acetylation of cellulose in presence of a large quantity of water was examined with bleached and with grey American cotton yarns. The absorbed copper due to cellulose hydrate was determined by the action of Fehling's solution in the cold. The wet cellulose was pressed after treatment with the acetic acid and washing with water, and the damp cellulose then acetylated at 65° C. for an hour. Acetylation was more noticeable in the case of the grey cotton. The products were separated by means of chloroform, and the dry products, which retained the fibrous condition, were re-acetylated, giving clear viscous solutions, that from the bleached cotton being superior. The bleached cotton gave 18% of an ester insoluble in chloroform. The following figures show the experimental data:—

—	Bleached.	Grey.
Moisture. %	6·65	7·20
Copper % on dry cellulose	0·33	0·26
First acetylation, yield	103	131
Second acetylation, yield	150	142
Chloroform-soluble portion, C%	48·68	47·60
,, ,, ,, H%	5·73	5·68
Acetic acid. %	49·6	51·4
Recovered cellulose. %	65·6	51·2

These results appear to indicate that the main ester from the bleached cotton is a diacetate, whereas that from the grey is a mixture of esters approximating to the diacetate.

Note on the analysis of cellulose acetate.

Several methods of hydrolysis of the ester and estimation of the acetic acid by subsequent distillation and titration of the volatile acid, have been suggested. These all possess the disadvantage that the cellulose regenerated by the reaction itself decomposes at the same time, giving rise to volatile acids for which a correction is necessary. It was found that, in the case of acetone-soluble cellulose acetates, the estimation can be greatly simplified. Briefly the method consists in dissolving the weighed cellulose acetate in acetone, hydrolysing the ester in the cold by shaking with a known amount of standard caustic soda in a stoppered flask, allowing to stand for a day, diluting with water, and titrating the excess alkali with standard acid and phenolphthalein. A blank experiment is carried out, using a similar quantity of acetone to which a known weight of cellulose (Swedish filter paper) has been added, and also a blank on a similar volume of acetone. From the two blank estimations a correction for any acidity in the acetone, and also for any decomposition of the cellulose, is made.

The following results with cellulose diacetate give the necessary data:—

Material.	Weight. g.	Acetone. c.c.	*N*/10 NaOH. c.c.	*N*/10 H_2SO_4. c.c.	Acetic acid. %.
Ester	0·3167	30	47·0	18·85	48·98
,, ...	0·3387	30	47·0	17·05	48·81
Cellulose	0·3000	30	47·0	44·20	—
Blank	—	30	47·0	45·90	—

The loss due to the 0·3 g. of cellulose is thus 1·7 c.c. *N*/10 NaOH. Inspection of the amount of caustic soda neutralised by the ester indicates that the ester is approximately a diacetate, and therefore the regenerated cellulose initially amounted to approximately two-thirds of the weight of ester taken Hence the number of c.c. of *N*/10 NaOH equivalent to that neutralised by the regenerated cellulose from the first estimation is

$$\tfrac{2}{3}\times(0{\cdot}3167/0{\cdot}30)\times1{\cdot}7=1{\cdot}2 \text{ c.c.}$$

This gives the alkali that is equivalent to the acetic acid as being 45·9 − 18·85 − 1·2 c.c. *N*/10 NaOH = 48·98% acetic acid. Similarly the correction for the cellulose from the second case is found to be 1·3 c.c. This being allowed for gives 48·81% of acetic acid When the same ester was submitted to alkaline hydrolysis, and the acetic acid determined by distillation, the results were from 43·54 to 44·07%.

In the case of samples of the triacetate the figures will show that the approximate amount of acetic acid is 60%; hence the regenerated cellulose will be about 55%. The correction is therefore based on this and the results worked out as above.

The estimation becomes simpler if the same weight of ester be taken for all estimations, as then the correction to be applied will be uniform.

The ordinary methods of estimation of the acetic acid, which involve distillation and titration of the acid in the distillate, are not accurate enough to detect differences of the order of 1% of acetic acid which are readily indicated by this more exact method.*

My thanks are due to the Department of Scientific and Industrial Research for permission to publish these results, also to Professor Sir W. J. Pope for allowing the investigation to be conducted in the Chemical Laboratory, Cambridge.

POSSIBLE DEVELOPMENTS IN HYDROGEN MANUFACTURE.

BY ERIC K. RIDEAL, D.SC., M.A.

The processes now in operation for the manufacture of hydrogen from coal or coke as raw material have centred round the steam-iron process for small scale and the water-gas catalytic process for large manufacturing units. The electrolytic production of hydrogen using coke as the source of power is only economically possible when the hydrogen is formed as a by-product in some electrochemical industry or in special cases where its actual generation and consumption may be confined to interpeak periods on the electrical load.

The Linde-Frank-Caro process of separating hydrogen from water-gas by liquefaction possesses the advantage of delivering hydrogen free from all impurities except carbon monoxide, and conveniently under pressure. The two chief disadvantages of the system are, firstly, the cost of operation and upkeep of the relatively complicated, high-speed machinery involved in the liquefaction plant, which can be partly set off by the proceeds resulting from the installation of an oxygen recovery plant on the liquefier; and, secondly, the high carbon monoxide content (2—4%) of the hydrogen when operating under conditions which will furnish the maximum yield of hydrogen (*i.e.*, 80—85% of the total available in the water-gas). This gas can of course be utilised for many industrial purposes, *e.g.*, for filling balloons or hardening fats, but not in those catalytic processes in which low-temperature hydrogenation is desired, such as in the preparation of the finer hydrogenated oils and hexahydrobenzene, or where the carbon monoxide exhibits a marked inhibiting action, as in the synthesis of ammonia using an iron-base catalyst, or again where it acts specifically as a poison as in the synthesis of ammonia with an irreversible catalyst such as sodamide or uranium carbide. Using a water-gas of average composition (42% CO, 49% H_2, 4% CO_2, 5% N_2 and CH_4) 2·4 volumes would be required to produce one volume of hydrogen. The general utility of the method can only be extended by some effective method for the removal of the carbon monoxide, a point which will be referred to later.

In the steam-iron processes the two representative types are exemplified in the Lane or retort, and the Messerschmidt or block type generators. Under normal conditions these operate between temperatures of 650° and 850° C., and it is interesting to note how far existing practice falls short of the theoretical possibilities of the method. The utilisation of a contact material more reactive than spathose has been suggested in many patents. Such material must be superior to spathose in two respects; firstly, it must operate at a lower temperature, or more rapidly at the same temperature; and, secondly, it must present a larger active surface under operating conditions.

To produce some 2000 cb. ft. per hour of hydrogen 7000 kg. of spathose is required; if complete conversion ($Fe \rightleftarrows Fe_3O_4$) were effected only 75 kg. would be necessary. The actual yield indicates an output of only 14 cb. ft. of hydrogen per cb. ft. of retort space per make, and a 1% conversion of the spathose. Taking average spathose of 2 in. diameter and mean density 5, the calculated effective conversion depth is of the order of 0·1 mm.; microscopical examination reveals a penetration of 2—3 mm., indicating that but little of the surface is reactive and that the rate of chemical action is consequently partly limited by diffusion of the reactants into the interior. Since a 50% loss on screening after two months operation is by no means uncommon, it is evident that there is considerable room for improvement in this respect. The replacement of the spathose by various forms of activated irons, especially iron-manganese and iron-copper, certainly results in increased yields for short periods, but the enhanced activity at the high temperatures of operation is usually short-lived, owing chiefly to irreversible poisoning during the reducing phase, and loss in catalytic activity due to the thermal treatment which the material undergoes especially in its exothermic phase. At the period of the armistice experiments were being commenced by the Munitions Inventions Board and Department of Explosives Supply to ascertain how far this small surface yield could be increased by an inversion of the process; *i.e.*, instead of passing water-gas and steam over iron oxide, it was attempted to blow finely divided iron oxide through a pipe by means of hot water-gas and transfer the reduced oxide to another pipe, also maintained at suitable temperatures, for oxidation with steam. On paper this scheme presents striking possibilities not only as regards economical utilisation of the spathose—a relatively secondary matter—but also in respect of the size of plant required and the almost certain increase in the activity of the material in this form, permitting lower operation temperatures and an economy in both water-gas and steam. Several types of mechanical devices for the separation of dusts have recently been designed which should provide those interested in the development of such a process with sufficient working data for a suitable design of plant.

The economy of steam and water-gas in the steam-iron process can likewise be examined by comparison

---

* Recent determinations show that even better results are obtained by using 25 c.c. of acetone, *N*/1 alkali, and *N*/10 acid. The correction in this case for the regenerated cellulose is smaller, and for comparative purposes can be neglected.

with the theoretical consumption on a basis of unit hydrogen production.

The reactions indicated by the equations,

$$Fe+H_2O \rightleftarrows FeO+H_2;\ 3Fe+4H_2O \rightleftarrows Fe_3O_4+4H_2,$$

have been examined in detail by numerous investigators, notably by Deville (Comptes rend., 1870, **70**, 1105, 1201), Debray (*ibid.*, 1879, **88**, 1341), Preuner (Z. physik. Chem., 1904, **47**, 385), and Chaudron (Comptes rend., 1914, **159**, 237). The various data do not show complete agreement as to the heats of reaction calculated by means of the van't Hoff isochore, but both reactions are strongly exothermic (from 32·1 to 44·1 kg.-cals. per g.-mol.). The heat liberated during the steaming phase can generally be noted on the pyrometer and is entirely lost to the system. The effluent gas will of course consist of steam and hydrogen, and during the complete make the ratio of steam to hydrogen can never fall below the equilibrium values as determined by the above reversible equations; these are 0·176:1 at 440° and 1·0:1·0 at 1500° C. In actual practice, especially towards the end of the steaming phase, a great excess of steam will be present in the effluent gas. Some actual observations on a Lane setting indicated a steam:hydrogen ratio of 1·66:1·0 at the commencement and 6·5:1·0 at the end of a good make, the average being about 3·0:1·0. Thus during the major portion of the make nearly ten times the amount of steam necessary for the reaction was passing through the system, entailing loss both in material and in sensible heat. This loss could doubtless be minimised by fixing a suitable automatic valve on the steam inflow.

The reactions occurring during the reducing phase are much more complicated than those in the steaming phase. Apart from numerous secondary reactions common to both phases, the main reactions on reduction are unknown. It is, however, practically certain that the hydrogen reduces the oxide in accordance with the above equations, but it is as yet uncertain whether the carbon monoxide effects reduction in a similar manner:

$$FeO+CO \rightleftarrows Fe+CO_2;\ Fe_3O_4+4CO \rightleftarrows 3Fe+4CO_2,$$

or whether it operates in a secondary manner due to the intermediate formation of hydrogen according to the well-known water-gas reaction,

$$CO+H_2O \rightleftarrows CO_2+H_2.$$

Although carbon monoxide is a more powerful reducing agent than hydrogen below 850° C., when the equilibrium value constant of the water-gas reaction becomes unity (Henry, Phil. Mag., 1836, **39**, 324; Fay and Seeker, J. Amer. Chem. Soc., 1903, **35**, 641), yet in the absence of moisture it is extremely sluggish. Moisture acts as a catalyst, possibly because the hydrogen formed is a more rapid but less powerful reducing agent than carbon monoxide. An analysis of the spent water-gas from a Lane setting indicated, however, that the water-gas equilibrium was obtained at the operating temperature of 650° C. It is thus possible with the aid of the data on the system hydrogen, water, iron and its oxides, together with those on the water-gas reaction to calculate the theoretical consumption of water-gas during the reducing phase. It may be noted in passing that these data are at variance with those of Baur and Glaessner (Z. physik. Chem., 1903, **43**, 358), Schenck (Ber., 1905, **38**, 2132; 1907, **40**, 1704, and Falcke (Z. Elektrochem., 1906, **22**, 300) on the reactions in blast-furnaces. The cause of the differences is possibly due to the deposition of carbon or the formation of carbides in the blast furnace. The reduction of iron oxide by carbon monoxide appears to be an exothermic reaction at these relatively low temperatures.

The theoretical consumption of water-gas per volume of hydrogen produced has been calculated by Dr. Taylor and the writer, with the following results:—

Cycle $Fe \rightleftarrows Fe_3O_4$

Temperature, °C.	Water-gas consumed.		Vols. water-gas per vol. hydrogen.
	% H_2.	%CO.	
650	30	41	2·85
750	33	40	2·77
850	41	35	2·63

If, on the other hand, the ore does not operate through the cycle $Fe \rightleftarrows Fe_3O_4$ but through the cycle $FeO \rightleftarrows Fe_3O_4$, the consumption of water-gas will be lower, although a smaller yield per kg. of ore will naturally result.

Temperature. ° C.	% H_2.	% CO.	Vols. water-gas per vol. hydrogen.
650	42	64	1·8
750	56	70	1·6
850	66	80	1·4

The actual consumption varies between two and three volumes.

The utilisation of the carbon monoxide fraction of the water-gas for reduction purposes has been suggested by several investigators, notably by Jaubert. As has already been indicated, the reaction appears to be exothermic at 650° C., but on the other hand the reaction velocity may be exceedingly low. In addition, precautions have to be taken against the precipitation of carbon on the iron through the secondary reaction $2CO \rightleftarrows C+CO_2$. This latter difficulty can, of course, be readily remedied by application of one of the three general methods which have been suggested. All of these rely upon the maintenance of a suitable ratio of carbon dioxide to carbon monoxide in the reducing gas so as to prevent the precipitation of carbon. According to the data of Boudouard (Ann. Chim. et Phys., 1901, VII., **24**, 5), and Rhead and Wheeler (J. Chem. Soc., 1910, 2179, and 1911, 1141), the ratio carbon dioxide/carbon monoxide is 1·67 at 650° C., 0·72 at 700°, 0·60 at 750°, and 0·07 at 800°. These conditions can easily be produced by operating at very high temperatures, where it will be noted that the ratio sinks to such a small value that the carbon dioxide present in the water-gas or the small quantity produced as it enters the retort is sufficient for the purpose. In general, however, this is not an economical method owing to the short life of the retorts and to the increase in the radiation loss from the bench. The higher CO_2/CO ratio necessary at the lower temperatures can be obtained either by the admission of a little air, as in the block type generator, where partial internal heating obtains, or by the admission of steam during the reducing phase, when an increase in the carbon dioxide content results through the operation of the water-gas reaction. Alternatively the same result may be obtained by passing the mixture of steam and water-gas through a pre-convertor containing catalytic material maintained at a suitable temperature. If more careful investigation supports Jaubert's views as to the merits of carbon monoxide as a reducing agent it would be a comparatively simple matter, provided that due attention be paid to the CO_2/CO ratio, to produce such a gas by the passage of spent water-gas, after removal of the steam by condensation, back through the water-gas generator. Such a gas is clearly much more economically produced than "straight" blue water-gas.

It is evident that with iron oxide as contact material no great improvement over existing practice in water-gas consumption is to be expected, although a marked improvement in steam consumption is theoretically possible. Economy of steam can readily be effected by the employment of activated irons, as is exemplified by the following figures obtained with spiegeleisen (18% Mn) as contact material.

Temp., °C.	Vols. steam per vol. hydrogen in effluent gas.
600	2·0
650	1·8
660	1·5
720	1·25

To reduce the consumption of water-gas involves the utilisation of an oxide more easily reducible than iron; other considerations, such as cost and fusibility of the reduced metal, have apparently militated against the adoption of such materials.

The fuel employed for keeping the retort system hot must also be included on the debit side in hydrogen manufacture. From this point of view the block type of generator is far superior to the retort type, but the hydrogen produced by the former is usually not so pure owing to the difficulties associated with the scavenge. Experiments in Sweden on a typical retort setting of brick and magnesia showed a radiation loss of some 470,000 kg.-cals. per hour. With an average water-gas of 75 kg.-cals. net per cb. ft. a consumption of 6300 cb. ft. per hour would be necessary to make up the deficit. During this period 4000 cb. ft. of hydrogen is produced with an internal consumption of 10,500 cb. ft. of water-gas. The spent water-gas has thus just sufficient fuel value to compensate for the radiation loss, provided that it be burnt in the most economical manner. One proposal for the economical utilisation of heat from the spent water-gas is to effect its combustion by the reduction of some comparatively readily reducible oxide, such as copper oxide, the heat being recovered by re-oxidation of the hot copper with air. By a suitable arrangement of shells in a generator of the block type, it would thus be possible to reduce the iron oxide in one shell and oxidise the copper in another, burning the whole of the water-gas within the unit. The re-oxidation of the reduced copper with air would, however, probably occasion a very great local elevation of the temperature.

The purification of hydrogen from the steam-iron process.

The general methods of purification in use entail merely the removal of the carbon dioxide and hydrogen sulphide.

Sulphur is the most dangerous impurity in hydrogen employed for catalytic purposes; whilst it is customary to remove the hydrogen sulphide from the original water-gas, the organic sulphur compounds such as carbon bisulphide and thiophene remain. Owing to the high percentage of carbon monoxide in the water-gas it would not be feasible to remove this by catalytic decomposition on the surface of hot nickel according the reaction,

$$CS_2+2H_2=C+2H_2S.$$

The quantity of carbon deposited from the carbon monoxide would prove a serious factor in the operation of this (the Carpenter-Evans) process unless the operation were conducted at very high temperatures.

It is well known that in the catalytic water-gas process the sulphur compounds are converted into hydrogen sulphide by hydrolysis at the surface of the catalyst, $CS_2+2H_2O=2H_2S+CO_2$. In the presence of suitable catalytic agents this reaction proceeds much more rapidly than the hydrolysis of carbon monoxide (the water-gas reaction); thus by admitting a small quantity of steam to the water-gas and passing the mixture over a carefully prepared alumina-iron oxide catalyst, the organic sulphur compounds undergo hydrolysis and but little of the carbon monoxide is converted. Precipitated alumina containing suitable quantities of water will actually hydrolyse carbon bisulphide in the cold. The presence of sulphur compounds in the hydrogen is due chiefly to the formation of sulphides during the reduction period; this can most conveniently be obviated by working with a water-gas free from sulphur.

Hydrogen sulphide can also be removed from hydrogen by a process of selective combustion. Iron oxide admixed with certain promoters can be utilised for the oxidation of the hydrogen sulphide at a temperature of about 280° C., according to the reaction $2H_2S+O_2=2H_2O+S_2$. A small quantity of steam must be present to prevent the reduction of the iron oxide. The sulphur is carried forward in the gas stream and sublimes in the colder portions of the tube. The process is, however, complicated by a number of interesting side reactions. If the correct ratio of hydrogen to steam as calculated from the data of Preuner and Chaudron be employed, the following equilibrium is simultaneously obtained: $3S+2H_2O\rightleftharpoons 2H_2S+SO_2$. Although the equilibrium concentrations of hydrogen sulphide and sulphur dioxide at the temperature of operation are small, they are by no means negligible, and as a result an appreciable quantity of flowers of sulphur is deposited with the condensed water in the condenser. In addition, if the catalyst column be long, rehydrogenation of the sulphur vapour occurs, $S_2+2H_2=2H_2S$. This phenomenon is well marked in catalysts containing nickel. Still a third possible method for the removal of hydrogen sulphide is its selective oxidation in a liquid medium, *e.g.* colloidal iron hydroxide, the iron sulphide being regenerated by aeration. Only partial oxidation of the sulphur occurs, the greater bulk being deposited as free sulphur, $2FeS+2H_2O+O_2=2Fe(OH)_2+S_2$.

The sulphides of copper and nickel undergo a similar oxidation, a reaction possibly common to the sulphides of all heavy metals. The reaction velocity at 20° C. varies in a marked manner from metal to metal; nickel is extremely reactive, copper almost inert, and iron of medium activity. It would appear possible that by a suitable choice of metal and the addition of a catalytic oxidation accelerator, *e.g.* a vanadium salt, a reaction velocity comparable with the rate of formation of the sulphide could be obtained. Under these conditions a purely catalytic process for removing sulphide would become operative as distinct from the discontinuous process now in operation in certain coal-gas plants.

For the removal of carbon monoxide there are likewise several alternative schemes which appear capable of industrial development. Of these may be mentioned the method of selective combustion, the process utilising the water-gas reaction, and that of methanation. The methanation process of Sabatier, in which nickel is used as contact agent for the reaction $CO+3H_2=CH_4+H_2O$, proceeds rapidly and smoothly at relatively low temperatures, provided that the hydrogen is free from substances containing sulphur. The method has but small merit for hydrogenating processes in which a circulatory system is in use, for apart from the actual hydrogen consumption—a not unimportant item in a gas containing 2—4% of carbon monoxide—the methane rapidly accumulates in the system, lowering the partial pressure of the hydrogen, unless frequently removed by blowing off.

The utilisation of the water-gas reaction appears much more promising. It has already been indicated that in the steaming phase, 7—10 times the amount of steam actually necessary is passed through the retort system. Since the retort contains iron oxide, it follows that the water-gas equilibrium should be obtained in the effluent hydrogen containing but small quantities of carbon monoxide and dioxide. This was actually found to be the case; the ratio of carbon monoxide to dioxide in the hydrogen was found to conform to the ratio of steam to hydrogen as demanded by theory, the ratio being high at the commencement and very low towards the end of a make. It should thus be possible to lower the carbon monoxide content of the hydrogen, either by passing the gas as it issues from the retort through another retort in the same bank maintained at a somewhat lower temperature, *e.g.* 450° C., or by mixing the hydrogen from which the carbon dioxide has been removed (or even hydrogen which has already passed through the hydrogenation plant, and is consequently rich in carbon monoxide) with the steam entering the system one or two minutes after the commencement of a make. The following figures indicate the purification which could be effected on an average make of hydrogen containing 0·3% CO and 1·8% CO_2 with these alternative methods.

1. Passage of the make through a catalyst chamber maintained at 450° C. with a hydrogen:steam ratio of 1:3:—Entering gas, 0·3% CO, 1·8% CO_2; effluent gas, 0·07% CO, 2·03% CO_2.

(2) Passage of the hydrogen after removal of the carbon dioxide through the Lane setting two minutes after commencement of the make, when nearly 50% of the make has already been produced: Entering gas, 0·3% CO, 0·0% CO_2; effluent gas, 0·13% CO, 0·9% CO_2. The method of selective combustion involves the removal of the sulphur compounds from the hydrogen. The hydrogen is then mixed with a little more than the requisite amount of oxygen—for very small concentrations of carbon monoxide with twice the theoretical amount for complete combustion—together with a small amount of steam, and passed over suitable catalytic materials such as activated iron or copper oxides. Combustion of the carbon monoxide is complete and a little water is formed. The oxygen is most conveniently generated by electrolysis. This process works admirably on units dealing with 1000 cb. ft. per hour, but has not yet been tested on a larger scale.

The water-gas catalytic process.

It has already been indicated that the minimum water-gas consumption for the steam-iron processes lies in the neighbourhood of 2·5 volumes per volume of hydrogen, and that the steam consumption is at least 4 volumes, which could theoretically be reduced to about 1·5 volumes per volume of hydrogen. The development of the Mond and Langer catalytic process by the Badische Co. has resulted in the production of 1 vol. of hydrogen by the consumption of 1·2 vols. of water-gas and 2·5—3 vols. of steam. Apart from the problem of the removal of the carbon dioxide, accomplished automatically in the steam-iron processes, it is much more economical than these latter in operation.

The resulting gas has, however, to be freed from some 30% of carbon dioxide and 2—3% of carbon monoxide; this is generally accomplished by pressure-scrubbing with water and then with cuprous salts.

Although the process is more economical than the steam-iron processes, it has not been developed for small-scale work, being in general confined to units so large that the water-gas and steam costs are the sole determining factors. Further investigation on many points is desirable to stimulate a more rapid extension of the process.

Water-gas producers for the production of blue gas suitable for direct use in a hydrogen converter still have to be designed. Of the usual 5—6% of inert nitrogen and methane present—sufficient to condemn the hydrogen for many industrial purposes, unless the cost of production were very low—at least half and frequently much more than half is derived from the air and is not due to the presence of nitrogenous substances in the coke. The faulty scavenge after the air-blow is very clearly marked if the nitrogen content of the resulting gas be plotted against the period of the make. Again, although the water-gas reaction is exothermic ($CO+H_2O=CO_2+H_2+10,000$ cal.), the amount of heat liberated is usually insufficient in small units to maintain the system at the usual temperature of operation, 550°—600° C., even with good heat-interchangers and lagging; the loss by radiation is extremely great. This problem would be solved in the most suitable manner by the utilisation of a catalyst operative continuously at 450° C. instead of 550°—600° C. Under these conditions the reaction would be autothermal and a much purer gas would be obtained, since the value of K, the equilibrium constant of the water-gas reaction, sinks from 0·24 at 550° C. to 0·10 at 450° C. With a steam:gas ratio of 2·5:1 the carbon monoxide content would be 3·0% at the higher and 1·17% at the lower temperature. Although many of the activated catalysts will operate on purified water gas at this temperature for reasonable periods, yet up to the present time no one of them has stood the test of operation under industrial conditions.

For small plants alternative methods to pressure scrubbing for the removal of the carbon dioxide and monoxide suggest themselves. Electrolytic regeneration of caustic soda from sodium carbonate would prove a simple but slightly expensive method of operation. By the employment of a divided cell, the electrolytic hydrogen produced could be utilised to augment the main supply. The consumption of water-gas would be about 1200 cb. ft. and of power about 160 kw. per 2000 cb. ft. of hydrogen.

It would be more economical to absorb the carbon dioxide in sodium or potassium carbonate and then to regenerate the bicarbonate,

$$K_2CO_3+CO_2+H_2O\rightleftharpoons 2KHCO_3.$$

To effect complete dissociation into the normal carbonate it would be necessary to heat the salt to about 100° C. and to remove the carbon dioxide by vacuum pumping or by spraying in a current of air or steam if the carbonate be in the form of a solution. Absorption would be effected at ordinary temperatures where the partial pressure of the dioxide is very low. The approximate theoretical fuel consumption for decomposition and heating of the bicarbonate to 100° C. is 9700 B.Th.U. per 1000 cb. ft. of scrubbed hydrogen, equivalent to a fuel consumption of only 33 cb. ft. of water-gas. Even if the dissociation process operated with a thermal efficiency of only 10%, this would only entail a consumption of 0·3 vol. of water-gas per volume of hydrogen produced. Where hydrogen is being manufactured for the synthesis of ammonia absorption in ammonia could be employed. The various methods for the removal of carbon monoxide have already been discussed.

The direct production of hydrogen from coke.

The hydrocarbons readily decomposed at low temperatures, such as acetylene or ethylene, are too valuable to be used as a source of hydrogen in competition with the methods already discussed. Other hydrocarbons, such as methane and the paraffins, require such a high temperature for their dissociation as to render their technical utilisation a matter of some difficulty; thus to produce hydrogen containing less than 2·5% of methane a temperature of over 900° C. would be necessary.

The methods based upon the reactions of the water-gas producer are more promising:—

(*i.*) $C+H_2O=CO+H_2$.
(*ii.*) $CO+H_2O\rightleftharpoons CO_2+H_2$.
(*iii.*) $C+CO_2\rightleftharpoons 2CO$.

For the ultimate conversion of carbon and steam into hydrogen and carbon dioxide by means of these reactions it is necessary to operate at a low temperature. As has already been noted, it is quite possible to arrive at an equilibrium in the water-gas reaction (*ii.*) at temperatures as low as 400° C. with the aid of a catalyst. If some means were at hand for accelerating (*i.*) the most economical solution of the problem of hydrogen manufacture would be found.

The reaction is heterogeneous and catalytic stimulation is consequently difficult. Several methods for increasing the reaction velocity have, however, been suggested, and some of them have proved feasible on a semi-industrial scale. Thus Harries (J. Gasbeleucht., 1894, 81) utilising a very reactive form of carbon, viz. wood charcoal, obtained equilibrium without the addition of any catalytic material at a temperature of 700° C., but apart from the necessity of employing a special fuel the reaction velocity was found to be exceedingly slow.

Bergius (G.P., 259,030/11, 262,831/12) showed that reactions (*i.*) and (*ii.*) could be accelerated by the simultaneous employment of pressure and a catalyst. He was able to obtain a reaction velocity sufficiently high for technical utilisation at a temperature of 300° C. The pressure was maintained above the critical pressure of water (89 atm.), whilst chlorides, and especially thallium chloride, were employed as catalytic materials. The gas so obtained contained but small traces of hydrocarbons.

Attempts have likewise been made to run the water-gas producer at low temperatures, *e.g.*, 500°—800° C., and to accelerate the reactions (*i.*) and (*ii.*) by the addition of suitable catalytic materials. Haber suggested that the ash, and especially the ashes containing iron, accelerated the water-gas reaction and facilitated the interaction between the carbon and steam, but did not influence the reaction velocity of the interaction between carbon and carbon dioxide. This hypothesis was in part confirmed by Gwosdyz (Z. angew. Chem. 1918, 137), who showed that the reaction velocity of the water-gas reaction was greatly affected by the ash content of the coke. A coke containing 8·5% of ash yielded 29% of carbon dioxide, whilst pure carbon (lampblack, 0·1% ash) yielded only 8·6% of carbon dioxide at 560° C. More recent patents describe the spraying of the coke with suitable catalytic materials before feeding into the water-gas generator. The difficulty associated with the process if the ordinary type of generator be employed would largely depend on the nature of the clinker and the mechanism for its removal. For water-gas generators operating at high temperatures, *e.g.* 1300° C., any increase in constituents forming clinker or fusible slag is to be avoided, but at 600°—700° C. a small increase in clinker content could be permitted. Again the process would appear capable of inversion; powdered coke sprayed with catalytic material could be injected into a current of steam superheated at 700° C., thus obtaining a simultaneous increase in the reaction velocity due to an increase in reacting surface and the elimination of the clinker problem.

THE ABSORPTION OF ETHYLENE AND PROPYLENE BY SULPHURIC ACID.

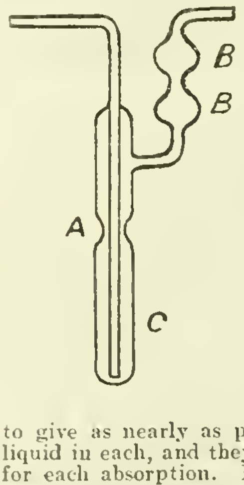
BY SYDNEY GLENN PRESTON PLANT AND NEVIL VINCENT SIDGWICK.

It has been known for a long time that ethylene can be absorbed by sulphuric acid, and this was made the basis for the commercial production of ether by Fritzsche (Chem. Ind., 1898, 21, 27; 1912, 35, 637). The dissociation and decomposition of ethylsulphuric acid at different temperatures has been investigated by Kremann (Monatsh., 1910, 31, 211). The object of the present work was to investigate the effect of varying the conditions upon the rate of absorption of ethylene by sulphuric acid, and also to study the products and the mechanism of the reaction. The ethylene used was prepared by passing the vapour of 97% alcohol over pumice soaked in phosphoric acid and maintained at a temperature of 280°—300° C. The gas was passed from a holder through two wash-bottles containing cold concentrated sulphuric acid, and then through the absorption vessels in series immersed in an oil thermostat. After leaving the last vessel, the gas was passed through another sulphuric acid wash-bottle and collected in a second holder. In this way pressure was applied at the beginning of the series and suction at the end, so that it was possible to maintain a fairly regular stream of gas through as many as five absorption vessels in addition to the wash-bottles for about three hours. The vessels were removed after definite intervals of time, washed with ether and then with water, and finally dried and weighed. The gas was repeatedly analysed by absorbing the ethylene in bromine water, and the volume sent through the vessels during each stage was read off from the graduations on the gas-holder. The gas in the second holder was transferred to the original one and the absorption continued. When not connected up in the series the vessels were kept in the desiccator, the delivery and exit tubes being closed.

The absorption vessel.

Since the experiments were carried out by having an acid of different strength in each of the vessels in the thermostat, it was necessary for the conditions in each to be comparable. By passing the gas at such a rate that the quantity absorbed is small compared with that sent through, the amount passing through each vessel will be approximately the same. Experiments have shown that above a certain minimum value the speed of the gas has only a small effect upon the absorption. The vessels were tested by filling each with sulphuric acid of the same strength and passing the gas for a definite time through all in series, and then calculating the percentage increase in weight of each acid. If the vessels are satisfactory the results would be almost identical. Several variations of the ordinary type of Liebig bulbs were tested, but these proved to be unsatisfactory owing to the difficulty of controlling the distribution of the acid in the bulbs. These difficulties were overcome by using the absorber represented in Fig. 1.

The corresponding parts of each vessel were made from tubing of the same bore, the delivery tube being sealed in a central position with its end as near the bottom as possible. The constriction, A, served to break the bubbles which rose during the passing of the gas, and thereby to check the tendency of the liquid to be carried over into the safety bulbs, BB. The liquid was carried over to a small extent in the final stages of the absorption into the lower bulb, and on a few occasions into the upper one. A small mark, C, was made on the outside of each vessel at a point so as to give as nearly as possible the same amount of liquid in each, and they were filled up to this point for each absorption. Five vessels were made and tested by the method described and found to be satisfactory.



The influence of the speed of the gas upon the absorption.

To investigate this point the gas used in each absorption was taken from a large storage gas-holder, so that the percentage of ethylene in it was constant. It was passed from a graduated bottle of five litres capacity through two wash-bottles containing cold strong sulphuric acid, and then through one absorption vessel containing in every case 99·3% acid and immersed in the thermostat at 70° C. The gas leaving the final wash-bottle was allowed to escape into the outer atmosphere, thereby avoiding changes of pressure which a receiving gas-holder introduces. The pressure driving the gas through the vessel was maintained almost constant by allowing water to siphon from an elevated reservoir into the gas-container, keeping the level of the water in the reservoir carefully regulated. Before each absorption the gas was allowed to bubble for some time through the first two sulphuric acid wash-bottles in order to remove all the air. Before introducing the absorption vessel the gas in the container was brought to atmospheric pressure and its volume read. After each absorption, which was of two hours' duration, the gas in the container was again brought to atmospheric pressure and its volume observed. The following results were obtained:—

Speed of gas in litres per hour.	Increase in weight of acid %
0·60	1·90
0·74	2·09
1·07	2·59
1·54	2·90
2·29	3·07
3·81	3·43

These figures indicate that above 1·7 litres per hour at 70° C. the effect of small variations in the speed of the gas is quite small. This result is quite empirical and will depend upon the nature of the absorption vessel used, since upon this depends the relative amount of liquid surface exposed to the gas and the extent of the stirring.

The effect of the purity of the ethylene upon the rate of absorption.

This was investigated by passing mixtures of ethylene and air of different compositions through 99·3% acid at 70° C. for 2½ hours and observing the percentage increase in weight in each case. The following are the results obtained:—

Ethylene %	Increase %	Ethylene %	Increase %
92·7	3·66	50·7	2·62
86·4	3·87	46·4	2·30
84·0	3·58	41·1	2·21
78·9	3·62	37·3	1·91
72·7	3·58	29·6	1·44
69·6	3·52	25·2	1·32
64·6	3·41	17·9	1·06
59·8	3·14	8·0	0·48
57·3	2·72		

It follows from these figures that above about 69% the percentage of ethylene in the gas has little effect upon the degree of absorption. Confirmation of these results is obtained from the absorption curves.

Analysis of the product of the absorption.

Upon pouring the product of the absorption into water an oil separated at the bottom of the vessel and proved to be diethyl sulphate. Ethylsulphuric acid, some free sulphuric acid, and water are also present in the product. To estimate the amounts of each present the acid liquid was extracted twice by shaking with light petroleum spirit (b.p. 40°—60° C.), and the ethylsulphuric acid and diethyl sulphate estimated by oxidation with a standard solution of potassium bichromate (Benedict and Norris, J. Amer. Chem. Soc., 1898, **20**, 293). The diethyl sulphate remaining with the petroleum spirit was hydrolysed by heating with water for ½ hour before estimating it. As a rule the difference between the sum of the amounts of ethylene corresponding to each product as found by analysis and the increase in weight of the acids during the absorption did not exceed 2%. The amounts of free sulphuric acid and water present in the product were calculated from a knowledge of the original quantity of acid and its strength. A trace of free alcohol is present in the product as a result of hydrolysis, but will appear as ethylsulphuric acid in the analysis. The actual quantity present is very small, and certainly less than the error (usually about 2%) appertaining to the analytical methods, so that any estimation of it would have been of little value.

The absorption at 50° C.

Three vessels were arranged in series, each containing an acid of different strength, the weakest acid being the first and the strongest the last of the series. The following figures show the percentage increase in weight of the acids based upon the actual (anhydrous) sulphuric acid present. The experiment was conducted in stages of 2–3 hours each, the vessels being weighed at the end of each interval. No appreciable decomposition took place, the acids remaining quite clear throughout, and becoming very slightly brown towards the end.

Time in hours.	Percentage increase in weight. 93·1% acid.	97·6% acid.	99·3% acid.
3	1·24	1·70	2·52
6	2·48	3·57	5·66
9	3·63	5·49	9·38
11	4·82	7·15	12·98
15	6·39	10·90	21·63
18	7·99	14·79	26·78
21	9·68	19·10	29·53
23·5	11·10	22·21	30·99
26	12·51	24·49	32·01

33	15·44	28·10	—
35	16·03	28·67	—
37	16·56	29·23	—

These results are plotted as curves in Fig. 2.

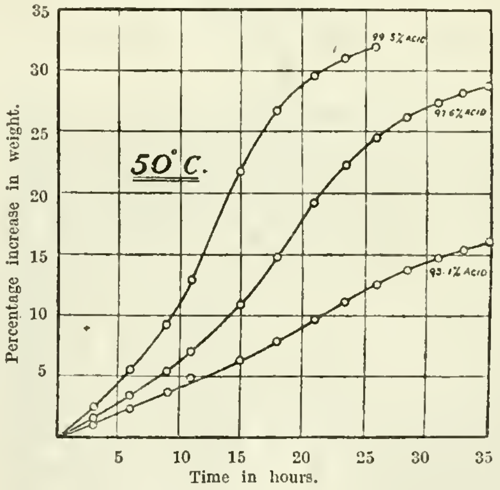

FIG. 2.

The following are the results obtained from the analysis of the products:—

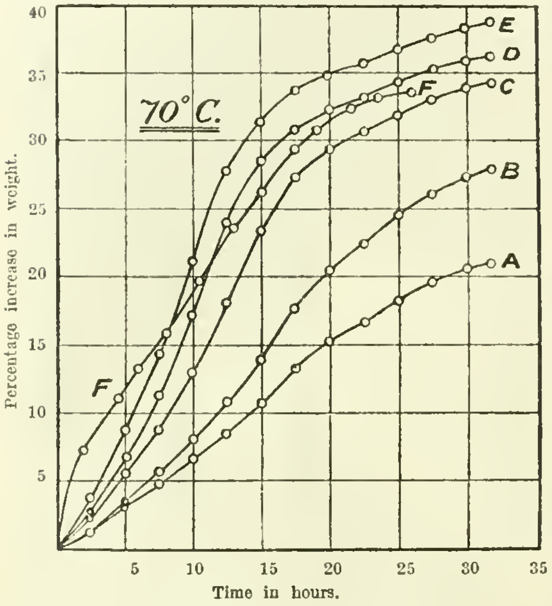
Acid strength.	Increase in weight. %	Ethylsulphuric acid. %	Diethyl sulphate. %	Sulphuric acid. %	Water. %
93·1	16·56	60·1	Nil	33·9	6·0
97·6	29·23	73·9	15·8	8·4	1·9
99·3	32·01	72·7	22·2	4·6	0·5

The absorption at 70° C.

These experiments were carried out in the same manner as those at 50° C., with the following results:—

Time in hours.	Percentage increase in weight. 93·1% acid.	95·8% acid.	98·1% acid.	98·8% acid.	100·1% acid.
2·5	1·36	1·28	2·27	2·75	3·83
5	3·16	3·52	5·59	6·82	8·89
7·5	4·78	5·67	8·84	11·32	14·29
10	6·59	8·05	13·05	17·16	21·11
12·5	8·52	10·84	18·11	23·98	27·79
15	10·59	13·95	23·32	28·50	31·46
17·5	13·29	17·78	27·31	30·97	33·64
20	15·22	20.47	29·36	32·37	34·97
22·5	16·56	22·37	30·55	33·20	35·69
25	18·19	24·48	31·95	34·39	36·75
27·5	19·52	26·01	33·04	35·23	37·58
30	20·50	27·30	33·89	35·93	38·24
31·75	20·83	27·98	34·25	36·23	38·62

These results are plotted as curves in Fig. 3.



A, 93·1% acid; B, 85·8%; C, 98·1%; D, 98·8%; E, 100·1%; F, 14% "oleum."

FIG. 3.

There are two small irregularities in each of these curves. The third point in each case, corresponding to 7½ hours, is slightly lower than would be expected from the general direction of the curves; in this case it was found that the ethylene had been passed at too slow a rate. The second and more obvious irregularity is at the ninth point after 22½ hours, which is again too low, but in this case it is due to the fact that the percentage of ethylene in the gas fell to 61·2%. Apart from these two points each curve is quite regular, showing at first a continuous acceleration in the rate of absorption followed by a retardation as the reaction proceeds. The colour of the acid gradually becomes yellow. In no case, however, was there any appreciable decomposition, even with the maximum absorption obtained, all the liquids remaining quite clear. The possibility of the decomposition of the ethylsulphuric acid was investigated by inserting after the absorption vessels a vessel containing about 2 c.c. of $N/10$ iodine solution diluted with water. In no case was there any appreciable decolorisation of the iodine. The absorption was stopped after 31¾ hours, at which point it became difficult to maintain a steady stream of gas through the vessels owing to the large bulk of liquid in them. The volume of liquid increases about 100% during the absorption.

The following table gives the composition of the products obtained:—

I. Acid strength. %	II. Increase. %	III. $C_2H_5.HSO_4$	IV. $(C_2H_5)_2SO_4$	V. H_2SO_4	VI. H_2O
93·1	20·83	69·5	2·2	22·5	5·8
95·8	27·98	79·1	9·4	8·2	3·3
98·1	34·25	74·8	20·3	3·5	1·4
98·8	36·23	68·1	29·3	1·7	0·9
100·1	38·62	70·0	30 0	nil	nil

The absorption at 100° C.

Three of the acids used at 70° (93·1%, 98·1%, and 100·1%) were placed in the same vessels and the absorption investigated in the same manner at 100° C. The following are the figures obtained:—

Time in hours.	Percentage increase in weight. 93·1% acid.	98·1% acid.	100·1% acid.
2·5	2·43	5·18	7·43
4	4·34	8·88	11·88
5·5	6·37	13·08	16·67
7·5	8·63	17·11	21·35
9	10·29	20·14	24·52
11	12·39	24·12	28·26
13	14·80	27·02	30·72
15	16·88	28·44	32·08
17	18·69	29·22	32·97
19	19·70	29·34	33·72
21	20·36	29·34	34·00

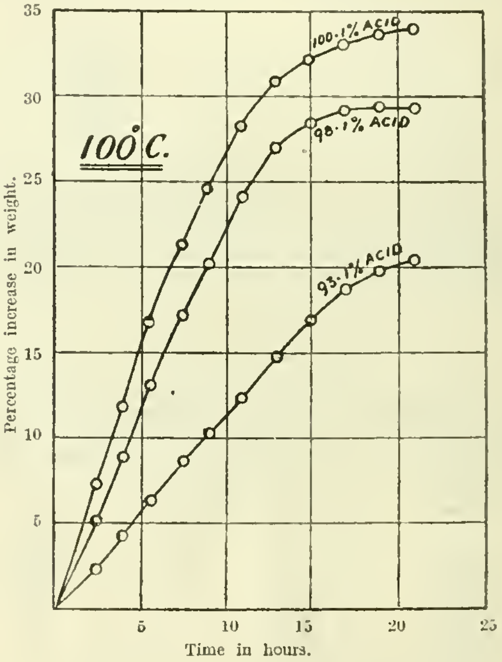


FIG. 4.

These curves (Fig. 4) show the same regularity which characterises those at 70° C. Decomposition of the ethylsulphuric acid is quite marked at 100° C. After running for 1½ hours the strongest acid showed a considerable blackening in colour, and after two hours this was very marked. At the end of 2½ hours the 98·1% acid was brownish yellow and the weakest acid slightly yellow. All the acids were quite black after 11 hours. The question of decomposition has been more fully investigated at 125° C.

The analysis of the products was difficult owing to the decomposition which had taken place interfering with the ease and rapidity of the separation with petroleum spirit. The results obtained were of little value and are omitted.

The absorption at 125° C.

This was investigated mainly for the purpose of observing the effects of the decomposition of ethylsulphuric acid. The gas was more rapidly absorbed at this temperature than at 100° C. until the decomposition of the product retarded the increase in weight and finally made it negative. Only two acids were used, viz.: 93·1% and 100·1%. Both rapidly became black and opaque, and an analysis of the products was impossible. The stronger acid became almost solid from the quantity of carbonaceous material which separated. The following figures were obtained:—

Time in hours.	Percentage increase. 93·1% acid.	Percentage increase. 100·1% acid.
1·5	2·26	5·41
2·5	3·63	6·92
4	5·53	7·81
5·5	6·46	7·12
7	7·80	6·29
8·5	8·29	4·39
10	7·71	2·65
11·5	6·19	—
13	4·33	—
14·5	2·56	—
16	—0·31	—

The absorption by oleum at 70° C.

The absorption of ethylene by fuming sulphuric acid was investigated by passing the gas through 14% oleum contained in one of the absorption vessels at 70° C. The following figures indicate that the mechanism of the reaction is essentially different from all the other cases:—

Time in hours.	Percent. inc. in weight.	Time in hours.	Percent. inc. in weight.
2	7·47	15	26·25
4·5	11·09	17·5	29·48
6	13·29	19	30·86
8	15·90	21·5	32·56
10·5	19·68	23·5	33·11
13	23·53	26	33·54

From a study of the curve given in Fig. 3 it is at once apparent that the autocatalytic character, which is so well marked with the other acids, is absent. The absorption in the earlier stages is very rapid, and this is in all probability due to the combination of the free sulphur trioxide with the gas to give carbyl sulphate, the anhydride of ethionic acid. After a few hours the absorption is proceeding at a rate which corresponds to that which would be observed with about 98% acid, which indicates that the carbyl sulphate acts merely as a diluent in the same manner as water.

The mechanism of the reaction.

Apart from decomposition there are three successive stages in the absorption, viz.: (1) The solution of ethylene in the liquid, (2) its reaction with sulphuric acid to give ethylsulphuric acid, and (3) its reaction with ethylsulphuric acid to give diethyl sulphate. It is not necessary for all the sulphuric acid to be converted into ethylsulphuric acid before reaction (3) proceeds, as the analyses prove. The theoretical increase in weight for all the acid to be converted into ethylsulphuric acid is 28·57%. At this point, however, a considerable quantity of diethyl sulphate has been formed. The quantity of ethylene actually dissolved as such in the acid being no doubt negligible, the observed increase in weight is a measure of the amounts of reaction (2) and (3) which have taken place. The rate at which the gas was passed was such that a small change in its speed had no appreciable effect upon the absorption, so that the liquid phase must be regarded as saturated with ethylene. These two reactions proceed at rates which are proportional to the products of the concentration of ethylene and the concentrations of sulphuric acid and ethylsulphuric acid respectively.

The curves indicate that the ethylsulphuric acid has a distinct autocatalytic effect, which can also be seen by subtracting each figure from the one succeeding it for any absorption with the exception of those into which decomposition enters. This can be explained by the greater solubility of ethylene in the liquid phase as ethylsulphuric acid accumulates in the system, which is what one would expect. At the end of the experiment, where the rate of absorption is very much diminished, there is still about 70% of the primary product present, so that ethylene must combine with ethylsulphuric acid more slowly than with sulphuric acid.

The amount of diethyl sulphate present at different stages in the absorption.

This question, which has been previously referred to, was more fully investigated by passing the gas through three vessels, each containing 98·1% acid, immersed in series in the thermostat at 70° C. and by taking out the vessels at convenient points in the absorption and analysing the products in the usual manner after observing the percentage increase in weight. The following are the results obtained:—

Increase in weight. %	$(C_2H_5)_2SO_4$ %
25·14	7·9
29·37	14·5
32·42	21·1

Diethyl sulphate begins to appear after about a 20% absorption. The effect of varying the different conditions upon the production of diethyl sulphate can be investigated by a study of the absorption curves together with the corresponding analyses, and a comparison of the results so obtained with this standard curve for 98·1% acid at 70° C. The influence of the water present with the sulphuric acid is found to be small apart from its retarding action upon the absorption in general. The amount of diethyl sulphate present at any given degree of absorption is practically independent of the strength of the acid used.

The absorption of propylene by sulphuric acid.

Experiments have been carried out with propylene on lines similar to those with ethylene. It has been recognised for some considerable time that the former gas was far more readily absorbed by sulphuric acid than the latter. This has been confirmed. It was found that when the gas was passed through 97% sulphuric acid at 25° C. a 50·06% increase in weight occurred after two hours. Absorptions were conducted using acids of strengths between 80% and 90% at 25° C., and the velocities measured were of the same order as those obtained with ethylene and 100% acid at 70° C. The chemical reactions which take place in the case of propylene are far more complex than those between ethylene and sulphuric acid. Apart from the production of propylsulphuric acid and dipropyl sulphate, a colourless oil separated out on the surface of the acid during the course of the absorption. This was separated, washed with an aqueous solution of sodium carbonate, and dried over calcium chloride. The liquid proved to be a mixture, and on distillation under a pressure of 30 mm. the boiling point gradually rose from 55° to 155° C. An investigation showed that this product contained no sulphur, and, furthermore, appeared to consist of saturated compounds. Three fractions were collected on distillation, analyses were made, and various physical constants determined. It was found that some oxygen was present and that the liquid reacted with metallic sodium. It seems probable that the colourless liquid which separates out during the absorption of propylene by sulphuric acid is a mixture of open-chain secondary alcohols. These have probably been produced by propylene polymerising to give a higher olefine with the double bond in the 1.2-position, having a formula $CH_3.(CH_2)_{3n}CH:CH_2$. Sulphuric acid then adds on to the double bond and the compound so produced is hydrolysed to give the corresponding secondary alcohol. The physical constants indicated that the complexity of the molecule was of the order of C_{12}.

Organic Chemistry Laboratory, Oxford.

PRELIMINARY NOTE ON THE ABSORPTION OF LIGHT BY CAOUTCHOUC.

S. JUDD LEWIS, D.SC., F.I.C., AND B. D. PORRITT, M.SC., F.I.C.

In view of the changes which are produced in rubber when exposed to light and air, it is somewhat surprising that no record appears to exist of any effort having been made to study the action of light on caoutchouc in a quantitative manner. It was therefore decided to carry out some preliminary experiments to determine the character of the absorption of light of short-wave length by caoutchouc, to which experience has shown that the successive physical and chemical changes which occur during "perishing" must be attributed.

With this object a specially good sample of "fine hard Para" rubber was selected in the crude condition before subjection to any manufacturing operation. This was cut into fine strips and submitted to repeated extraction with cold distilled water for a period of over a week, followed by extraction with cold acetone until the washings were no longer coloured. A final prolonged digestion with several changes of absolute alcohol was employed to ensure the complete removal of resins and soluble colouring matters, and the extracted rubber was thereafter dried at ordinary temperature in a current of hydrogen to prevent oxidation. The dry material was then transferred to a stoppered separating funnel in which it was allowed to swell and slowly dissolve in anhydrous ethyl ether (purified by treatment with sodium and fractional distillation) without agitation. The clear caoutchouc solution was withdrawn at intervals before it became unduly viscous, from the bottom tap, the passage of proteid and insoluble matter being prevented by the insertion of a small plug of asbestos fibre, and the volume removed was replaced by the addition of fresh solvent.

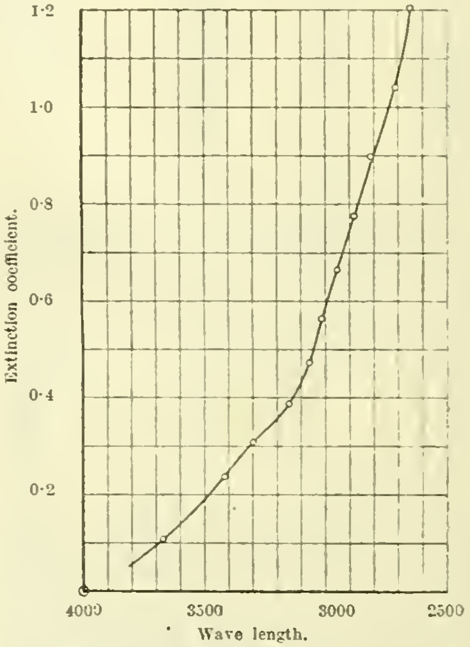
In this way a sufficient quantity of a perfectly transparent, colourless solution of caoutchouc was obtained containing approximately 0·94% of solute by weight. As it was found that this solution gave only very feeble absorption, it was reduced by spontaneous evaporation to about two-thirds of its original volume, thus increasing its strength to approximately 1·5 per cent.

The method of procedure followed was similar to that described elsewhere (Proc. Roy. Soc. B., **89**, 329), with the exception of the photometer employed, which was of the new sector type, the details of which have lately been published (Chem. Soc. Trans., 1919, **115**, 312).

The 2 cm. cell containing the solution was placed in the one path of light, and a duplicate cell filled with the purified ether, similar to that used for the preparation of the solution, was placed in the other beam for the purpose of providing a control. The absorption effect was therefore confined to the solute alone, that of the solvent being eliminated. The ether employed was found to give no absorption at wave lengths above 2170 sufficient to interfere with the experiment.

The results obtained are exhibited in the accompanying curve, in which are plotted the values of the extinction coefficient, that is of log I/I′, relative to a 3% solution in a cell of unit thickness as ordinates against wave lengths as abscissæ (I is the intensity of the incidental light, and I′ is that of the light transmitted). The curve has not been smoothed out, as the slight irregularities may prove to be significant.

In considering these preliminary results it is in the first place remarkable that caoutchouc should be so transparent to light as to call for the use of so concentrated a solution as 1·5% in a 2 cm. observation tube.



Ultra-violet absorption spectrum curve of ethereal solution of caoutchouc calculated on a 3% solution in a 1 cm. cell.

The curve exhibits only a general absorption which is fairly strong for wave-lengths below 2700, but rapidly diminishes with increase in wave-length.

Neither with the strong solution nor with weaker ones has there been any decisive evidence of absorption bands, but the investigation has not gone far enough to say whether caoutchouc is capable of exhibiting these or not.

Further work is in progress on different types of rubber and allied compounds with a view to confirming these preliminary observations, and if possible securing some evidence regarding the constitution of caoutchouc.

The authors desire to thank the North British Rubber Co., Ltd., for their permission to publish this work, some of which was carried out in their research laboratory.

THE EFFECT OF HEATING LINSEED OIL UNDER PRESSURE AT CONSTANT TEMPERATURE.

BY SAMUEL COFFEY, B.SC. (LOND.).

A considerable amount of work has been published on the properties of linseed oil and the effect of heat, oxidation, etc. The fact that linseed oil lost much of its power of absorbing iodine after heating led Fahrion (Z. angew. Chem., 1892, 5, 171) to suggest that polymerisation had taken place; and this was confirmed by Fokin (Ref. Augsb. Seifens.-Zeit., 34, 821). Later Ingle (J., 1911, 344) found that by heating the oil in a large dish at 195°—200° C. for 43 hours the sp. gr. rose from 0·9315 to 0·9800, while the yield of hexabromides fell from 35% to 0·9%, and the iodine value from 180 to 121. Similar results were obtained by R. S. Morrell (J., 1915, 105), who found that linseed oil thickened at 260°—280° contained two modifications, both of which were soluble in light petroleum, but only one in acetone, and approximately equal quantities of the two components were present in the thickened oil. The part insoluble in acetone exhibited every evidence of polymerisation, and all traces of linolic and linolenic acids in the oil had disappeared. The soluble component closely resembled thickened poppy-seed oil, which consists largely of linolic glycerides; the inference as to this is clear. Closely similar results were obtained by Krumbhaar (Chem- Zeit., 1916, 40, 937), who heated the oil for shorter periods at higher temperatures. In this case the sp. gr., viscosity, and acid value increased while the saponification value remained constant.

In all these cases, as far as can be ascertained, the oil was heated in a more or less non-oxidising atmosphere at atmospheric pressure. Under these conditions a certain amount of volatile products is evolved, and even after seven hours' heating the oil darkens considerably in colour. It has been found, however, that by heating the oil in sealed glass tubes the colour was very much less intense, and the odour of the oil, instead of being somewhat obnoxious, as is the case when linseed oil is heated under ordinary pressure, was pungent but rather pleasant and different from that of the original oil. The author therefore thought it of interest to study the results obtained by heating linseed oil under pressure.

Linseed oil was heated at 250° in sealed tubes which contained very little air, so that oxidation effects and loss of volatile matter were eliminated.

The same sample of "pure" raw oil, direct from the presses, was used throughout the experiments, and as it was obtained from a reputable firm specially for the work, it was assumed to be unadulterated, and purification was deemed unnecessary. Its constants were: Sp. gr. at 20° C., 0·9310; saponification value, 189·0; acid value, 6·4; iodine value, 189·1; hexabromide value, 43·0; glycerol, 10·0%. At the commencement of the experiment seven similar tubes containing approximately equal quantities of oil were sealed and heated in a sand bath in an air oven to 250°—260° C.; a similar tube, but longer, containing the same amount of oil, open to the atmosphere, and in which a thermometer was placed, was also inserted in the sand. In no case was the temperature allowed to rise above 260°. The temperature was kept constant for 42 hours, and a tube was removed every seven hours. All the samples of oil were examined together along with the original oil in order to ensure that the conditions for the experiments were identical. All determinations were made at least twice. The oil heated under atmospheric pressure gradually darkened in colour and gave off volatile matter having the characteristic odour of burnt fat, presumably due to acrolein.

The original oil was of a clear golden brown colour, which after seven hours' heating in the sealed tube had changed to a very pale yellow with a slight green fluorescence, which, according to Lewkowitsch, is characteristic of "litho oils" (linseed and tung oils, which have been heated without appreciable oxidation). Further heating appeared to have only a slight effect on colour; even after 42 hours' heating the colour and the fluorescence were not very much more intense than those of the oil heated for seven hours, and in each case the product was paler in colour than the original oil. The specific gravity at 20° C. (determined by the density bottle method) and the relative viscosity at the same temperature (determined by Poiseuille's capillary tube method; original oil=1) are given in Table I.

TABLE I.

Time of heating. hrs.	Sp. gr. at 20° C.	Relative viscosity at 20° C.
0	0·9310	1·00
7	0·9480	2·26
13·5	0·9634	3·52
21	0·9714	4·07
28	0·9723	17·50
35	0·9810	34·40
42	0·9875	49·90

It will be seen that the rise of sp. gr. is practically a linear function of the time during the first 21 hours' heating; it then increases but slightly during the next seven hours, and finally again increases more rapidly, but not so rapidly as at first.

The viscosity rises slowly during the first 21 hours' heating, and then suddenly rises extremely rapidly and practically linearly with time, until after 42 hours' heating it reaches a value 50 times its original value. This most marked break in the continuity of the viscosity curve at 21 hrs. coincides with similar though less distinct breaks in the sp. gr. and acid value curves. It is therefore probable that this stage represents the end or the commencement of some fundamental change in the composition of the oil.

Further qualitative evidence is obtained from a study of the relative solubilities of these oils. In ether and light petroleum, in each case solution was complete, but more solvent was required as the heating continued. In acetone, however, a marked difference was observed. The original oil and the samples which had been heated for 7 and 14 hrs. were miscible with the solvent, but of the oil which had been heated for 21 hrs. a small quantity (about 5%) remained undissolved even after repeated extraction. As the heating continued this insoluble portion became larger; after 28 hrs. it was about 25%, while after 42 hrs. it constituted the larger part of the product. This insoluble product was a thick heavy oil. It is remarkable that the insoluble product should appear after 21 hrs.' heating, at the same time as discontinuities in the viscosity, sp. gr., and acid value curves (*cf. infra*) show themselves, and it seems safe to presume that these marked changes are caused by the production of this thick insoluble product which in all probability is identical with that obtained by R. S. Morrell by thickening the oil at 260°—280° C. (J., 1915, 105, *loc. cit.*)

Chemical properties.—The acid value and saponification values were determined by titration with alcoholic potash,[*] the hexabromide value by the Hehner-Mitchell method as used by Ingle (*loc. cit.*), and the iodine value by Wijs' method (Lewkowitsch, "Analysis and Technology of Oils, Fats, and Waxes," p. 240 *et. seq.*). It was found by Morrell (*loc. cit.*) that the iodine values of thickened linseed oil determined by this method increased with the time the thickened oil was in contact with the iodine solution. To eliminate this effect as much as possible the oil was left in contact with the solution for exactly 3 hrs. before titration with standard thiosulphate solution. The results of these determinations aro given in Table II. :—

TABLE II.

Time of heating. hrs.	Acid value.	Saponif. value.	Iodine value.	Hexabromide value.
0	6·4	189·0	189·1	43·0
7	10·4	188·2	176·7	mere trace
13·5	11·4	188·3	152·1	—
21	12·6	188·7	142·0	—
28	14·6	189·0	125·2	—
35	15·0	189·0	110·4	—
42	15·0	188·8	107·0	—

These figures show that the saponification value, as in Krumbhaar's experiments (*loc. cit.*), remains unaltered. The iodine values decrease fairly regularly as the heating is continued, the decrease being most rapid at first, but there are no breaks on the curve.

The hexabromide value of 43% in the original oil had become almost zero after 7 hrs.' heating, showing that all traces of the most highly unsaturated glycerides had disappeared, probably owing to polymerisation into glycerides of more saturated di-acids, *e.g.*, $COOH\cdot C_{17}H_{29}\cdot C_{17}H_{24}$ COOH etc. (*Cf.* Morrell, *loc. cit.*)

The acid values are particularly interesting. The original oil had an acid value of 6·4.[†] On heating, however, the value gradually rose in a continuous manner until after 21 hours' heating. The continuity of the curve is then broken, and the acid value rises abruptly to a constant value from 28 hrs. onwards, equal to about 2·4 times its original value.

It is noteworthy that in these experiments the increase in acid value is not nearly so large as when the oil is heated under atmospheric pressure and volatile matter allowed to escape. In Krumbhaar's experiments, for example, after heating for 20 hrs. at 300° the acid value was 40 times the original, and showed no indication of becoming constant.

No explanation of this pronounced increase in acid value appears to have been put forward. While appreciating the fact that considerably more experimental evidence is required before the point can be settled, the author would suggest that this is due to the direct hydrolysis of the glycerides by water. Raw linseed oil always contains small amounts of water, hence some hydrolysis will take place, and an equilibrium will be set up according to the mass action law as $\{C_{(\text{glyceride})} \times C_{(H_2O)}\} \div \{C_{(\text{glycerol})} \times C_{(\text{acid})}\} = K$(constant,) and the final acid value for a given oil at constant temperature will be constant as found experimentally. Assuming that K also is small, then for the present case 0·4% of water would be quite sufficient to account for the increase in acid value.

In the case of previous experiments, done under ordinary pressures at temperatures about 300°, the glycerol produced by hydrolysis would be volatilised, and so the hydrolysis would go to completion. Also at these temperatures the glycerol would probably be converted into acrolein and water, and so the latter would be continuously formed, and this would account for the high acid values observed.

In conclusion, the author desires to express his thanks to Prof. F. S. Kipping, D.Sc.,F.R.S., for his kind interest and encouragement during this work.

Chemical Dept., University College,
Nottingham.

---

[*] Some workers consider alcoholic potash to be unsuitable for determining acid values, but the author has found that with neutral alcohol and well kept solutions identical results are obtained with baryta and with potash. It has also been found that acid and saponification values determined by alcoholic potash gave glycerol values identical with those found by the acetin method, although the acid value was as high as 5·3.

[†] The allowable acid value for linseed oil seems to be somewhat vague; some authorities give it as up to 6 or 7, whilst some say it should not exceed 1 or 2. It should be remembered, however, that in this case a raw oil was used which had undergone no purifying treatment. For four such oils of widely different origin the author has found values of 5·3, 6·4, 5·2, and 3·0—all above 2 but below 7.

Communications.

THE DETERMINATION OF AROMATIC HYDROCARBONS IN MIXTURES OF HYDROCARBONS.

BY H. T. TIZARD AND A. O. MARSHALL.

In the course of a general research on the behaviour of fuels in internal combustion engines, it became necessary to devise a simple and accurate method for determining the proportion of aromatic hydrocarbons in petrol. The method outlined in this paper is a development of that described by F. B. Thole (J., 1919, 39 T), according to which the mixture is sulphonated with 98% sulphuric acid and the densities before and after sulphonation determined. Thole claims that by the use of 98% acid aromatic compounds are completely removed, while other saturated hydrocarbons are only attacked to a limited extent. He estimates the separate hydrocarbons benzene, toluene, xylene, by fractionating the sample of petrol and dividing the product into three portions: (*a*) b.p. 40°—95°, (*b*) 95°—122°, (*c*) 122°—150° C. It is assumed that (*a*) contains all the benzene and (*b*) all the toluene. The three fractions are then sulphonated separately, and the densities before and after sulphonation determined. The aromatic content is calculated from the difference in densities, making an allowance for the expansion known to occur when aromatic and non-aromatic hydrocarbons are mixed.

Our experiments support Thole's conclusion as to the efficacy of 98% sulphuric acid, and in general confirm the accuracy of his "cutting points," with certain exceptions that will be mentioned later. But the procedure of determining densities before and after sulphonation is open to the great objection that the time involved and care necessary for really accurate density determinations are considerable, and further that the correction to be applied for the divergence of densities of petrols containing aromatic compounds from a simple mixture law is uncertain. Thole's method, too, is only applicable to a very limited extent to the determination of xylene content, since the densities of the three xylenes are different, and it also does not lend itself to a quick and accurate determination of total aromatic content for a similar reason.

The measurement of the critical solution temperature of hydrocarbons in aniline can be used instead of the measurement of density, to determine aromatic content, with greater ease and greater accuracy. Chavanne and Simon, who have worked on similar lines, have recently pointed out (Comptes rend., 1919, 168, 1111, 1324; 169, 185, 285) that paraffin, naphthene, and aromatic hydrocarbons are very distinctly differentiated by the temperatures above which they are completely miscible with aniline. This temperature for paraffins is high (about 70° C.), for naphthenes about 30°—50° C., while aromatic hydrocarbons are miscible down to very low temperatures. The addition of aromatic compounds to paraffin and naphthene hydrocarbons lowers this critical solution temperature by an amount very nearly proportional to the concentration of aromatic hydrocarbon present. The curves in Fig. 1 show results of experiments made in this laboratory on the solubility in aniline of a "petrol" freed from aromatic hydrocarbons, and the same mixed with different amounts of benzene, up to 39% by weight. The curves show the temperatures above which mixtures of aniline and the "petrol," represented in composition by the abscissæ, become homogeneous. When cooled to temperatures represented by points below the curves separation into two layers occurs. The critical solution temperature in each case is represented by the maximum point; above this point mixtures in all proportions of the respective petrol and aniline are homogeneous.

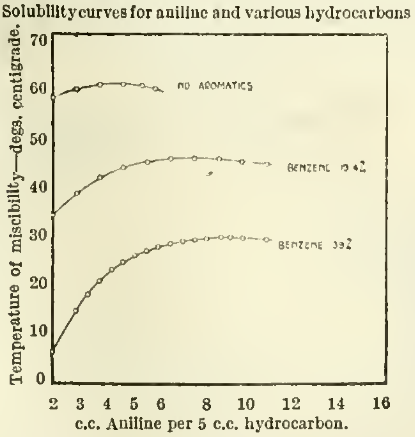

Fig 1.

The most important feature of these curves is that the proportion of aniline and hydrocarbon at the critical point varies from approximately equal volumes when no aromatic hydrocarbons are present to about 9 volumes of aniline to 5 of "petrol" when the latter contains about 40% of aromatics.

Now, Chavanne and Simon always determine the critical solution temperature, *i.e.*, the temperature represented by the maximum points of the curves in Fig. 1. When this method is used to determine aromatic hydrocarbons it involves following out two such curves, one before and one after sulphonation in every case. This is obviously unpractical, and tends to make the method as laborious as that of the accurate determination of densities. This was recognised at an early stage of the present investigation, and it was decided to measure in every case not the true critical solution temperature, but the temperature of solution of equal volumes of aniline and the hydrocarbon. In practice this comes to the determination of the point of separation into two layers of the "equal" mixture, when it is gradually cooled down from a temperature at which it is homogeneous. This temperature is called by us the "aniline point"; it can be determined with considerable accuracy—certainly to within 0·1° C. with a little practice. In the case of mixtures containing a very small percentage of aromatic hydrocarbons the aniline point corresponds to the true critical solution temperature within 0·1° C., but when a high percentage of aromatic hydrocarbons is present it may be quite considerably different. In the first case it is obvious from the curves that any possible error in the volumes of aniline and petrol taken causes only a negligible error in the temperature observed; in the second case it can also be shown that the error is inconsiderable. When the aromatic content is as high as 39%, a 2% error in volume measurement only makes a difference of 0·3° in the "aniline point," which corresponds in this case to 0·3% of aromatic hydrocarbons, *i.e.*, the error in such an event would be less than 1% of the total aromatic hydrocarbons present. This is an outside estimate of the possible error due to this cause; by always using the same pipettes in measuring out the aniline and the hydrocarbon respectively the volume error is very unlikely to be as much as 2%.

The actual critical solution temperature of aniline and the 39% benzene mixture was found to be rather ill-defined, and it was difficult to get consistent readings to 0·1°, while the "aniline point," *i.e.*, the temperature of separation of equal volumes, was very sharply defined, and could be very accurately determined.

The actual determination of the aniline point is made most conveniently by measuring out from pipettes, 10 c.c. each of aniline and the hydrocarbon into a large test-tube, fitted with a stirrer and a delicate thermometer (reading in 0·2° to 0·1° C.), heating until a clear solution is obtained, then cooling slowly and noting the temperature at which turbidity appears. The mixture is then warmed again very slightly until it is just clear, and the point of turbidity redetermined on cooling. It is necessary to repeat this once or twice in accurate determinations in order to eliminate any error due to possible lag of the thermometer. It is found that a very slight turbidity first appears, and then the mixture suddenly becomes completely cloudy, the thermometer bulb being obscured over a range of about 0·1°. The temperature at which this complete turbidity occurs is taken as the aniline point.

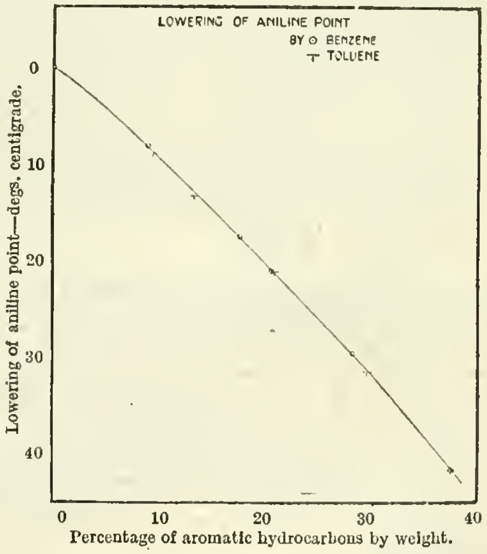

Fig 2.

The means of heating is a naked flame. When the aniline point is more than 10° above room temperature, the experimental tube is surrounded by a larger tube, so as to leave an air space between the tubes, which ensures that warming and cooling take place gradually. When the aniline point is below room temperature, the tube can be cooled in ice and water, or a freezing mixture. More conveniently the cooling can be accomplished by placing ether in the larger external tube, through which air can be drawn. The apparatus is thus of the greatest simplicity, and from this point of view alone the method has great advantages over those depending on the measurement of other physical properties such as refractive index or density.

There is further the very considerable advantage, shown during the course of this investigation, that benzene, toluene, and xylene appear to have practically the same effect in lowering the aniline point when added to any mixture of hydrocarbons in the same proportion by weight. Figs. 2 and 3 show the results of special experiments made to find out the effects of the different aromatic hydrocarbons. For these experiments, benzene, toluene, and *o*-, *m*-, and *p*-xylene, were obtained in as pure a state as possible, and the aniline points were determined of special mixtures made up by weight of

(*a*) Benzene and toluene with a mixture from which all aromatic hydrocarbons had previously been removed by sulphonation (Fig. 2).

(*b*) The different xylenes with a similar mixture of higher boiling point. In this case also two check mixtures were made up containing benzene and toluene respectively (Fig. 3).

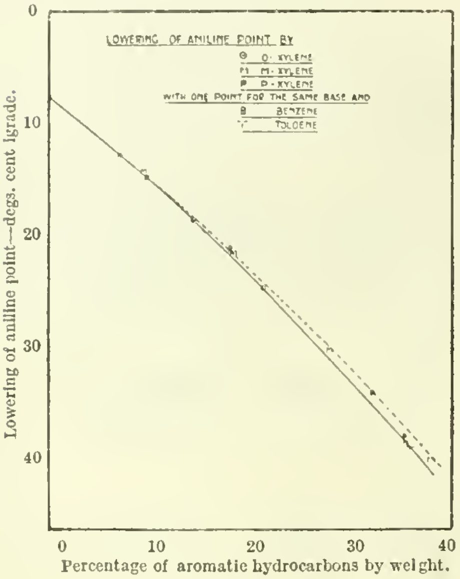

FIG. 3.

Benzene, toluene, and o-xylene were found to have identical effects within the errors of experiment, while *m*- and *p*-xylenes lowered the aniline point rather less than the same weight of benzene or toluene. But for all practical purposes it is safe to assume that the same proportions of these hydrocarbons by weight have the same effect in lowering the aniline point, and the following table, from the figures of which Fig. 2 has been constructed, gives the relation between the lowering of the aniline point of a mixture containing no aromatic hydrocarbons and the amount of aromatic hydrocarbon added:—

Percentage of aromatic hydrocarbon in mixture.	Lowering of aniline point.
5% by weight.	4·2° C.
10	8·6
15	13·2
20	18·1
25	23·2
30	28·5
35	34·0
40	39·8

The total aromatic content of any petrol can therefore be determined by this method with considerable accuracy.

The procedure is to determine the aniline point of the petrol, then to shake for ½ hr. 30—50 c.c. of the petrol with three times its volume of 98% sulphuric acid, allow to stand, separate the acid, wash the residue with sodium hydroxide solution and water, and dry over calcium chloride. The aniline point of the residue is then determined. The difference between this and the aniline point before sulphonation gives directly the percentage of aromatic hydrocarbons in the mixture. The accuracy has been tested in two cases by making up artificial mixtures by adding known weights of benzene, toluene, and xylenes to a sample from which all aromatic hydrocarbons had previously been removed. The results were:—

	Case I.	Case II.
Percentage by weight of benzene added	12·4	2·3
" " " toluene "	14·5	16·5
" " " xylenes "	11·3	3·0
Total	38·2	21·8
Total found by aniline point method	38·6	21·8

If the whole of the added aromatic portion had been *m*-xylene, the error caused by assuming that this hydrocarbon had the same effect as benzene and toluene would be not more than 3% of the total weight added, but naturally this is a circumstance not likely to occur in practice.

FIG. 4.

The curve is the same as Fig. 2, but the bases used vary widely.

It has been found that when extreme accuracy is not desired the processes of washing and drying the mixture after sulphonation can be omitted. The estimation is then extremely simple, for it is only necessary to pipette off 10 c.c. from the supernatant liquid after sulphonation, and to determine its aniline point immediately. The temperature of turbidity does not differ by more than 0·2° from that of the washed and dried mixture, and the time saved is very considerable.

The above example incidentally gives a proof of the completeness of the removal of aromatic hydrocarbons by shaking with excess of 98% sulphuric acid for ½ hr. In general our experiments have confirmed Thole's conclusion that the use of acid of this strength prevents action on other hydrocarbons. Very little sulphur dioxide is evolved, and the mixture only gets warm on shaking when there is a large proportion, say 40%, of aromatic hydrocarbons. It is possible that the use of even more dilute acid would be advantageous for analytical purposes, but it has not been thought worth while to examine this question at present. A special experiment during the sulphonation of a mixture containing 10% of aromatic hydrocarbons showed that nearly all the latter were removed in the first 2½ minutes of shaking.

In another case, when it appeared likely that the non-aromatic portion was attacked by the acid, the residue after the first sulphonation was again shaken with fresh acid. There were undoubtedly signs of a further reaction, but the aniline point after this treatment was found to be unchanged, showing that such action as occurred did not affect the accuracy of the method for determining aromatic hydrocarbons.

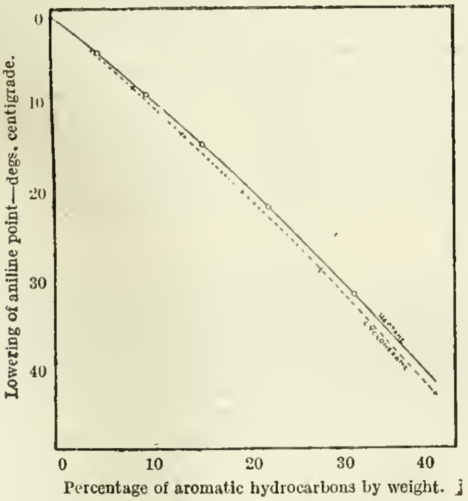

FIG. 5.

Lowering of aniline point of $\left\{\begin{array}{l}\text{heptane}\\ \text{cyclohexane}\end{array}\right\}$ by benzene.

The next question of practical importance that arises is to what extent the lowering caused by a given weight of aromatic hydrocarbon depends on the nature of the non-aromatic base. Is the lowering, for example, the same when the base is cyclohexane, which has an aniline point of about 30° C., as it is with a pure paraffin such as heptane, which has an aniline point above 70° C.? This would certainly not be expected, and special experiments, made with mixtures of pure specimens of these hydrocarbons with benzene, have shown that it is not the case. The results of these experiments are shown in Fig. 5, the lowering in the case of heptane being less than it is when the non-aromatic base is cyclohexane. The standard curve lies between these two, and the difference between the two curves corresponds to a difference of about 3% of the weight of aromatic hydrocarbons added. But although the nature of the non-aromatic base does affect the degree of lowering, the effect is generally too small to be of practical importance. This is shown more clearly in Fig. 4. In this figure the standard curve of Fig. 2 is reproduced, and the experimental points shown represent results obtained with all the different "natural" petrols so far examined. These petrols range from a Borneo product which has the highest proportion of naphthenes, to American petrol which has the lowest. The aniline points of these fuels after removal of aromatic hydrocarbons vary from 54° C. in the case of former to 64° C. in the case of latter. All the points lie on the same curve within the experimental errors, except those taken with *m*-xylene, to which reference has already been made. It appears, therefore, that in practice the nature of the non-aromatic base has a negligible effect, and the figures given in Table I. may be taken as standard figures for all natural "petrols."

At the same time, if any doubt exists as to this a check on the accuracy of the determination can easily be obtained in the following way. After the aniline point of the sulphonated residue has been measured, the percentage of aromatic hydrocarbons is calculated approximately from the data given in Table I. (or Curve 2). A solution containing approximately the same weight of benzene, or, better still, two solutions, one containing slightly less, and one slightly more than the calculated result, are made up by adding known weights of benzene to the sulphonated base. The aniline points of these artificial mixtures are determined, and the true aromatic content of the original petrol can be obtained by a very slight interpolation. This procedure is often of value when the non-aromatic base contains a large proportion of low-boiling fractions and has a high aniline point. An actual example will make the method clear. The aniline point of mixture before sulphonation was 36·8° C., and after sulphonation 62·7°. During the latter determination some boiling was observed. A difference of 25·9° C. corresponds to 27·6% of aromatic hydrocarbons from the standard curve. A mixture of the sulphonated product and benzene was then weighed out, containing 28·09% of benzene. The aniline point of this solution was 36·6° C. From the standard curve it is found that when the aromatic content is 28% a difference of 0·2 in the aniline point corresponds to a difference of 0·19 in the aromatic content. Hence this is the correction to be made to ascertain the true percentage of aromatic in the original petrol, which is

$$28{\cdot}09 - 0{\cdot}19 = 27{\cdot}9\%.$$

In all the above experiments freshly distilled aniline was used. Commercially "pure" aniline contains small quantities of aminothiophene, the presence of which accelerates oxidation when the aniline is exposed to air and light. In order to ascertain the effect of impure aniline on the aniline point method, moist air was bubbled through aniline for six hours. Experiments made with this product showed a rise of no less than 10° C. in the true "aniline point" of a hydrocarbon base containing no aromatic hydrocarbons. So far as the accuracy of the method for determining aromatic hydrocarbons goes this would be of no consequence if the "lowering" due to addition of aromatic hydrocarbons were the same, but this is not the case.

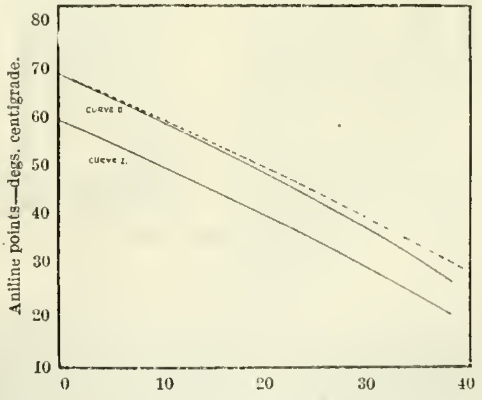

FIG 6.

Lowering of aniline points by benzene.
Curve I. Using freshly-distilled aniline.
Curve II. Using impure aniline.

The lower curve in Fig. 6 represents aniline points taken with freshly distilled aniline; the upper curve shows aniline points of the same mixtures with impure aniline. The dotted line has been drawn parallel to the lower curve, and is seen to be of a different slope to the upper continuous curve. Care should therefore be taken to use fairly freshly distilled aniline, but it may be pointed out that all disturbing factors of this kind are eliminated by using the more accurate method outlined above. It would probably be advantageous to use aniline, freed from aminothiophene, or, alternatively, prepared from benzene free from thiophene.

It is important to notice that the purity of the aniline employed seriously affects any analytical methods which depend on the knowledge of absolute aniline points. Chavanne and Simon use the critical solution temperature in aniline to differentiate between naphthene and paraffins etc., and to determine the proportions of such hydrocarbons in petrol. But, owing to the above and other difficulties, an estimation made in this way is only very approximate, although it is often of value to use the method in combination with the density method.

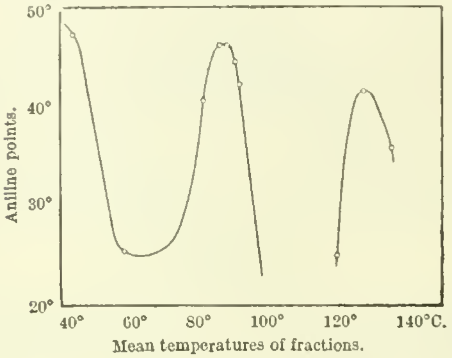

Fig. 7.

Cutting point curve.

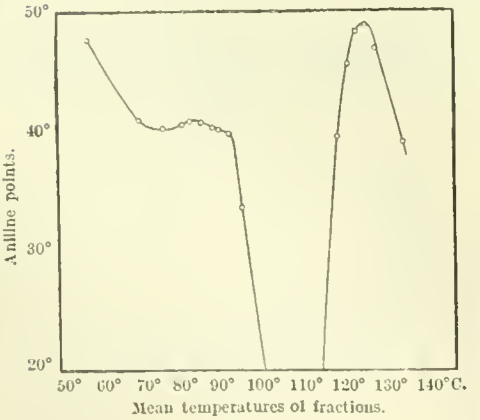

Fig. 8.

Cutting point curve.

The extension of the aniline point method to the determination of the individual aromatic hydrocarbons involves a separation of the sample by fractionation into fractions containing the benzene, toluene, and xylenes, etc., and separate sulphonation of each of the fractions. In spite of the considerable differences in the boiling points of these aromatic hydrocarbons (benzene 80·4°, toluene 110·3°, xylenes about 139°), it is well known that even when a very efficient fractionating column is used, they distil over wide ranges of temperature. Thole recommends "cutting points" about half way between the boiling points. He assumes that the fraction distilling over up to 95° contains all the benzene, that between 95° and 122° all the toluene, and that from 122° to 150° all the xylenes. Probably this is not true, but it is reasonable to assume that any benzene distilling over above 95° is balanced by an approximately equal amount of toluene distilling over below 95°. If the densities of the successive fractions are determined it is found that maximum densities occur at about 80°, 110°, and 140°, and minima at about 95° and 122° C. If the aniline points of the successive fractions are determined it is found that maximum points occur near the latter temperatures, indicating that the percentage of aromatic hydrocarbons in the distillates coming over at these temperatures passes through a minimum. It is naturally much quicker to determine aniline points, and if it is considered desirable to ascertain the "cutting points" for any particular fuel as accurately as possible, the petrol is fractionated, and the aniline points of small fractions coming over within small ranges of temperature near 95° etc. are determined. The temperatures at which the aniline points pass through maximum values are taken as the correct cutting points, and a separate fractionation then made.

The following were the results obtained with the two "artificial" petrols referred to above (Case I. and Case II.). In Case I., in which the proportions of benzene, toluene, and xylene were approximately equal, the cutting points found were 95° and 124° C. (see Fig. 7). Sulphonation of the separate fractions and determination of aniline points as described above gave the following results:—

	Found. %	Correct value. %
Benzene	12·5 ..	12·4
Toluene	14·4 ..	14·5
Xylene	10·6 ..	11·3

In Case II. the proportion of toluene was purposely made high compared with that of benzene and xylene. The aniline points of the successive fractions are shown in Fig. 8, from which it is seen that the maxima occur at 90° and 125° C. Analysis of the fractions obtained by cutting at these temperatures gave:—

	Found. %	Correct value. %
Benzene	2·4 ..	2·3
Toluene	16·7 ..	16·5
Xylene	2·3 ..	3·0

The agreement for benzene and toluene is very good in both cases. The xylene found is a little too low. This may be partly attributed to some uncertainty in the purity of the xylene taken to make up the mixtures, but probably mainly to the fact that the xylene fraction was only one-fifth of the whole in the first case, and one-seventh in the last. It partly consists of the liquid obtained by draining the fractionating column and condenser, and any loss due to incomplete drainage tends to make the xylene value rather too low.

The errors that would have been caused by taking the normal cutting points of 95° and 122°, instead of 90° and 125° may be estimated in the following way.

Between 90° and 95°, 40 c.c. distilled over, containing about 10% of aromatic hydrocarbons. The total amount of the product distilled was 500 c.c., so that this represented

$$\frac{1}{10} \times \frac{40}{500} = 0{\cdot}8\ \%$$

of aromatics in the total. If this had been included in the benzene fraction it would have raised the benzene value to 2·4+0·8=3·2%, whereas the actual benzene content was 2·3%.

On the other hand only 8 c.c. distilled between 122° and 125°, and the distillate contained 8%

aromatics. Had this been included in the xylene fraction, it would have raised the percentage of xylene by 8×8÷500=0·13, and the final values would have been benzene 3·2%, toluene 15·8%, xylene 2·4%. Hence in extreme cases, when the aromatic content consists mainly of one hydrocarbon, the error due to assuming the correct cutting points to be 95° and 122°, without making a special determination, may be fairly considerable, but for all ordinary cases these cutting points are sufficiently accurate.

In conclusion, to show the degree of agreement found in actual analyses between the total aromatic content, and the sum of the individual hydrocarbons, the experimental figures for a number of products examined in this laboratory are quoted:—

Fuel.	Benzene. %	Toluene. %	Xylene and higher aromatics. %	Total. %	Total found independently. %
(1)	6·1	16·3	16·7	39·1	38·0
(2)	7·2	17·5	10·3	35·0	35·2
(3)	5·6	8·0	1·3	14·9	14·6
(4)	4·9	4·1	0·9	9·9	10·0
(5)	0·7	3·8	3·8	8·3	8·6
(6)	2·7	4·4	1·8	8·9	8·4
(7)	2·7	4·9	2·2	9·8	10·1
(8)	1·0	1·8	1·4	4·2	4·4

It should be remembered that as outlined above this method is only applicable to the estimation of aromatic hydrocarbons in mixtures which contain negligible quantities of unsaturated hydrocarbons. The presence of the latter introduces a serious complication, which will be dealt with in a later paper. The method has now been in use for some time with satisfactory results in the laboratories of the Asiatic Petroleum Company, to the directors of which we are indebted for permission to publish the above results.

Organic Chemical Laboratory, Oxford.

SOLUTIONS OF ACETYLENE IN ACETONE AT HIGH PRESSURES.

BY RAYMOND R. BUTLER, B.SC., A.I.C.

In the course of experiments in connexion with the solution of acetylene in acetone at high pressures, it became necessary to obtain a knowledge of the rate of expansion of a given volume of acetone when saturated with acetylene at pressures in the neighbourhood of 10 atmospheres.

An examination of the literature on the subject revealed a remarkable dearth of information.

Claude and Hess (Comptes rend., 124, 626) showed that the increase of solubility of the gas in acetone is nearly proportional to the pressure. This is the basis upon which the dissolved acetylene industry was founded. They also showed that when saturated at a pressure of 1 atm. the acetone increased in volume by about 4%.

Siller ("Versuche über gelöstes Acetylen," 1913) found that the expansion factor was 4·7% up to a pressure of 75 lb. per sq. in.; no investigation was made at higher pressures.

It was therefore decided to investigate the nature of the solution at higher pressures, and in view of the danger attending the compression of the acetylene at pressures greater than 2 atm. specially designed apparatus was necessary.

Method of storage of gas.

Since gas containing acetone vapour, as delivered from cylinders of dissolved acetylene, was useless for our purpose, the gas was stored in a cylinder of 2 cub. ft. capacity filled with beech charcoal, of Belgian manufacture, of absolute sp. gr. 1·41.

It was desired to obtain a porosity of about 80% in the gas storage cylinder, the water capacity of which was 124 lb. 10 oz. weight of water. It was therefore necessary to fill the cylinder with 35 lb. 3 oz. of charcoal. The cylinder so prepared was completely exhausted of air and occluded gases by subjecting it to a hot vacuum process at 100° C. for 24 hours. It was then cooled, and when cool filled with acetylene by means of a compressor.

The acetylene used was obtained from calcium carbide in a carbide-to-water generator, from which it passed through a hydraulic main, purifiers containing chromic acid mixture, and dust traps, previous to entering the compressor.

The gas was allowed to enter the cylinder from the compressor slowly in order to avoid local overheating, with consequent danger of explosion. Acetylene compressed at a pressure greater than 2 atm. is liable to decompose with violence unless absorbed in a porous mass the interstices of which have an average diameter of less than 0·5 mm. (Le Chatelier).

On disconnecting from the compressor, and cooling, the cylinder was found to contain gas at a pressure of 175 lb. per sq. in.

Absorption apparatus.

The apparatus used for the absorption experiments is illustrated in Fig. 1. It consists of a constant temperature bath, F, through which a steady stream of water flowed from a thermally-regulated constant-temperature cistern; an inner glass pressure tube, B (34 in. in length, approx. diam. ⅜ in.), held by means of tie-rods, H, between metal plates, G, G, and making a gas-tight joint with each plate by means of a fibre seating (see Fig. 2); an outer steel safety tube, C, surrounding B, and having a narrow slit running from end to end, through which the level of the acetone could be observed, and its height obtained accurately on a metal scale (not shown).

Since it is impossible to obtain acetylene of 100% purity by any ordinary method, the gases other than acetylene (which are but slightly soluble in acetone) were allowed to escape by means of the gas outlet valve, E, which served as the fine-adjustment valve for each high pressure reading.

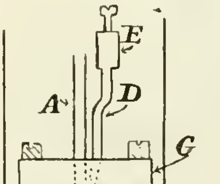

Fig. 1.

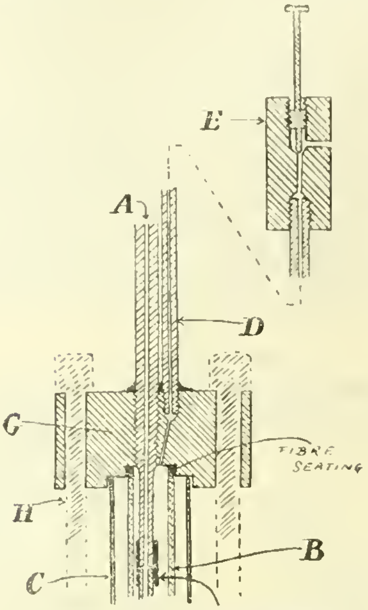
The compressed gas from the storage cylinder was admitted by way of a standard pressure gauge into A, whence it bubbled up through 20 c.c. of acetone in B, collecting in the space above the acetone and establishing the necessary pressure on the surface. When the gas passed through without dissolving (this was readily indicated by the bubbles) the excess of gas was allowed to escape slowly through E.

The pressures were then finally adjusted by means of E so that the state of balanced pressures was obtained, and the acetone rose inside A. Each reading was taken under the same conditions, the height being read when the level of the acetone inside A was identical with that of the main bulk of acetone surrounding A. Great care was necessary in the final adjustments made by the valve, E, as it was found that any slight irregularity in the glass below the surface of the acetone had a tendency to form a centre from which bubbles of dissolved gas attempted to escape from solution.



Rubber connexion between metal and glass.

FIG. 2.

The acetone used had b.p. 56·5° C.; sp. gr. 0·794 at 15° C., coefficient of acetylene absorption, 23·8 volumes at 15° C.

The readings were taken at 15·8° C. It was found by experiment that 1 cm. height of acetone in inner tube B=0·472 c.c. The following results were obtained:—

Absolute pressure, lb. per sq. in.	Scale reading, in cm.	Increase in length, in cm.	Expansion in c.c.	Increase in volume. %
0	40·8	—	—	—
15	42·5	1·7	0·80	4·0
30	44·6	3·8	1·80	9·0
45	46·4	5·6	2·64	13·2
60	48·4	7·6	3·60	18·0
75	50·0	9·2	4·34	21·7
99	52·7	11·9	5·62	28·1
125	56·4	15·6	7·36	36·8
145	58·8	18·0	8·50	42·5

The above results when plotted on a curve, with pressures as abscissæ, and expansions as ordinates, show that up to a pressure of 10 atm. (absolute) the expansion follows a straight-line law, the percentage expansion per atmosphere increase in pressure being 4·4%.

This figure is important, in view of the Home Office order permitting the filling of dissolved acetylene cylinders to a pressure of 15 atm. It is obvious that under these conditions the acetone in the cylinder may expand by as much as 64% of its original volume.

In a cylinder containing 40% of its volume of acetone, the final volume of the acetone, calculated from this factor, is 65·6% of the volume of the cylinder. In addition, an ordinary dissolved acetylene cylinder, filled with porous material having a porosity of 80%, has a total volume of solid matter within it of 20% of its volume. The total free space actually existing in the charged cylinder is thus only 14·4%.

This figure must be still further reduced should the acetone expand, due to any pronounced increase of temperature of the cylinder and contents.

There is no evidence that any compound is formed between the solvent and the solute. Up to a pressure of 10 atm. absolute the phenomenon appears to be entirely physical in nature.

These results were obtained in the course of a series of experiments carried out in the laboratories of the Dissolved Acetylene Company, London, S.W. 8.

NOTE ON THE RATE OF REACTION OF PICRIC ACID WITH NITRATING ACID.

BY D. L. HAMMICK.

During the course of some experiments on the yields of picric acid obtainable by carrying out the nitration of phenol at higher temperatures than are usual, it became necessary to ascertain the rate of reaction between picric acid and the nitrating acid. The following experiments were therefore carried out.

A nitrating acid was made up of equal parts by weight of water, nitric acid (68%), and sulphuric acid (sp. gr. 1·345). Pure, recrystallised picric acid was dissolved in excess of this mixture and heated in a 250-c.c. Kjeldahl flask in a constant temperature oil bath. Loss of water and nitric acid by evaporation was prevented by the insertion of a close-fitting glass condenser into the neck of the flask. Portions of the picric acid solution were removed from time to time, diluted, extracted with ether, and the extract evaporated and dried at 100° C. The residual picric acid was then estimated with titanous chloride by Knecht and Hibbert's method.

The results obtained are given below. The initial concentration, a, of the picric acid is in grams per 100 c.c. of solution; $a—x$ is grams picric acid in 100 c.c. of solution after time T (in days). K is the unimolecular velocity constant in the equation.

$$K = \frac{2 \cdot 3}{T} \cdot \log \frac{a}{a-x}$$

Temperature.	115°±1°C.		106°±1° C.		96°±1° C.	
a, g. per 100 c.c.	0·809		1·198		1·813	
T	$a-x$	K	$a-x$	K	$a-x$	K
2	0·490	0·25	0·920	[0·130]	1·657	[0·045]
3	0·368	0·26	—	—	1·644	0·033
4	0·291	0·26	0·838	0·089	1·600	0·031
5	0·248	0·24	—	—	1·542	0·032
6	0·202	0·24	0·628	[0·110]	—	—
7	0·164	0·23	—	—	1·469	0·030
8	0·120	0·23	0·608	0·085	—	—
9	—	—	0·570	0·083	1·381	0·030
10	—	—	0·504	0·086	—	—
11	—	—	—	—	1·299	0·030
12	—	—	0·417	0·088	—	—
13	0·032	0·25	—	—	—	—
Mean		0·245		0·086		0·031
Period of half-change ..	2·76 days		8·1 days		22·3 days	

It is apparent from the above results that even at comparatively high temperatures the rate of destruction of picric acid by nitrating acids is too slow to affect the yields obtained by the nitration of phenol.

Oriel College, Oxford.

ERRATUM.

In the discussion on the paper by S. J. Peachey and A. Skipsey (J., Jan. 15, 1921, p. 5 T) for "Mr. Bailey" (col. 2, line 9 from bottom) read "Mr. F. Bayley."

MR. E. WALLS IN THE CHAIR.

THE HYDROLYTIC ALKALINITY OF PURE AND COMMERCIAL SOAPS.

BY F. C. BEEDLE AND T. R. BOLAM.

In two earlier communications from the Bristol laboratory,[*] which constitute the only quantitative measurements of hydrolysis in soap solutions, it was shown that the hydrolysis of soaps was unexpectedly slight.[†] The two independent methods involving E.M.F. measurements and catalysis prove that the hydrolytic alkalinity of soap solutions is negligible for most purposes since the concentration of hydroxyl ion is only about $N/1000$.

The object of the present paper was to obtain further data for pure salts of the fatty acids and to investigate soaps made with single typical oils as well as commercial soaps.

Experimental method.

Of the two available methods for the determination of hydroxyl ions in such solutions, the E.M.F. method suffers in the investigation of commercial soap from the serious drawback that the potential of the hydrogen electrode will probably be affected by the presence of unsaturated compounds. The method of the catalysis of nitrosotriacetone-amine[‡] to give phorone was therefore adopted. The reaction is unimolecular, and the velocity is proportional to the concentration of hydroxyl ion. The volume method had been found to be accurate to within about 2 or 3% at the ordinary temperature.

The results are calculated according to the system proposed by McBain (Trans. Faraday Soc., 1917, 13, 1), which consists in always setting the rate-constant equal to unity and in choosing the unit of time accordingly.

The formula used here is consequently

$$T = 2{\cdot}303 \text{ log. } A/(A - x)$$

instead of the hitherto customary

$$k = 2{\cdot}303/t. \text{ log. } A/(A - x)$$

where k is the rate-constant. The disadvantages of the system hitherto employed, as compared with that proposed, are illustrated by the rate of reaction in the presence of $0{\cdot}000656N$ OH' at 90·0° C. The statement that "the rate-constant is 0·112" is meaningless until the further information is given that "time has been measured in minutes." Under the new system this becomes—"the time unit is 8·9 minutes"—a statement which is much more readily visualised, is self-contained, and does away with small decimals. It further means, in the case of unimolecular reactions such as the present, that the reaction requires 8·9 minutes to proceed to the extent of 63·2% or nearly two-thirds of completion.

The chief difficulty to be avoided in this method is the sorption of the amine by the soap in concentrated solution; so that dilute solutions containing not more than 1 g. in 100 c.c. of water had to be employed. It was soon found too that this influence persisted much more strongly at lower temperatures, and hence the temperature of 90° C. was adopted for the present experiments.

The values of the time units for definite concentrations of hydroxyl ion were measured by observing the rate in solutions of sodium hydroxide. These solutions were made up from sodium and boiled-out conductivity water. The reaction was carried out in a silver flask containing a small glass tube, which could be dropped into the solution in the flask when it was desired that the reaction should commence. In some cases this tube contained the soap solution, in others the solution of nitrosotriacetone-amine; 0·1300 g. of that substance was employed in each case.

The concentrations of the soap solutions are expressed in weight normality; that is, gram-equivalents of the soap per 1000 g. of water in the case of the pure soaps such as the oleate. The commercial soaps are expressed in "percentages"; that is, the number of grams of commercial soap contained in 100 c.c. of solution at room temperature. The values given in this column refer in the cases of sodium oleate and abietate to grams of anhydrous fatty acid in 100 c.c. of solution. The concentration of hydroxyl ion, on the other hand, is invariably expressed in volume normality at 90° C.

It is essential to flush out the vessels used with air free from carbon dioxide. Although with the soaps of the pure saturated fatty acids constant results were obtained for the time units and reaction constant throughout the whole course of any one reaction, nevertheless in most of the present cases which involve unsaturated fatty acids it was found that there is a tendency of the velocity of the reaction to fall below the value required for the unimolecular formula after the reaction has proceeded part way. This is possibly due to slight oxidation, and hence in all such cases the constant initial part of the reaction was taken as the basis of calculation of the hydrolysis-alkalinity given in the tables. A blank test showed that a solution of sodium oleate did not absorb a volume of air sufficient to affect the volume measurements.

In the first series of experiments carried out by one of us (T. R. B.), the value for the product C.T—that is, concentration of OH'×value of time units at 90°—was found to be 0·00561, and this value was used for calculating with olive oil, coconut, toilet and cold process soap. In the remaining experiments (by F. C. B.) the value C.T=0·00583 was used.

In all cases here recorded experiments were carried out at least in duplicate, and about ten readings were made in each experiment. The experimental results are summarised in Tables I. and II. The many interesting points arising are discussed under the separate headings below.

Pure sodium oleate.

Since all the data for pure soaps so far published refer to solutions prepared from pure saturated fatty acids, it is desirable to supplement them with data for an unsaturated fatty acid for comparison, particularly as this is an important constituent of some of the soaps studied here.

Oleic acid "Kahlbaum" was employed, and the solutions were prepared by Miss Laing, as in previous communications, using a quantity of alkali equivalent to the titration value in aqueous alcohol determined experimentally.

Examining the results of the tables, it is seen that the hydroxyl concentration (hydrolysis-alkali) passes through an absolute maximum in $N/20$ sodium oleate solution. The actual percentage hydrolysis is negligible at high concentration, but increases rapidly in very dilute solution.

Comparison with the previously communicated results of McBain, Bolam, and Martin shows that the hydrolysis-alkalinity of the oleate amounts to almost exactly as much as in the sodium and potassium palmitate.

Sodium palmitate	0·00091	—	—
do. (E.M.F. method)	0·00100	0·00066	—

In the case of all these soap solutions, it is probable that the maximum concentration of hydroxyl ions observed in about $N/20$ solution is quite real. Whilst in more dilute solution the percentage hydrolysis rapidly rises, this is counterbalanced by the diminishing concentration of the soap itself. With increasing concentration, on the other hand, the concentration of hydroxyl ion drops off owing to the gradual disappearance of the simple fatty ion and its replacement by colloidal ionic micelle, for it is the simple fatty ion only that is hydrolysed and the low values for the hydrolysis-alkalinity found with the catalytic method at high concentrations of soaps are only partially ascribable to the sorption of amine by soap. The attainment of the maximum hydroxyl ion concentration in the comparatively dilute ($N/20$) solution of sodium oleate is characteristic of the very colloidal nature of the oleates, since the oleate is more colloidal than the palmitate (maximum $N/10$), and very much more so than the abietate ($>N/10$).

Sodium abietate (rosinate).

For this constituent of washer and household soaps there were likewise no available data. The material employed was a specimen prepared by Miss K. M. Gibbons from best W.W. rosin. The rosin was boiled in anhydrous alcoholic solution of sodium ethoxide (free from carbon dioxide) for many hours in order to ensure complete saponification, and very carefully adjusted to give an exactly neutral solution when samples were tested with phenolphthalein in aqueous alcohol free from carbon dioxide. Thereupon the sodium salt was completely dried and analysed by Miss Laing.

The data in the tables show that the "abietic" acid is about as strong as palmitic and oleic acids, but that its salts being less colloidal, are more hydrolysed in stronger solutions. This agrees with other evidence which would place sodium rosinate amongst the lowest soaps.

Coconut oil and olive oil soaps.

Coconut oil is known to be a constituent of certain free-lathering soaps, some of which are said to have an action upon the skin, and olive oil soap is especially recommended for sensitive skins.

Thus Simmons* states: "The soap made from coconut oil has a rather irritating effect on sensitive skins, consequently the proportion of coconut oil in fats to be saponified for toilet soap should never exceed 25%," and again, "olive oil forms a very mild neutral soap especially adapted for sensitive skins . . . not a very good detergent."

It appeared of interest to inquire whether the irritant action of coconut oil soap was due to great hydrolytic-alkalinity or to some other cause, such as the presence of an active constituent or perhaps a specific action of the laurates themselves, which form the chief constituent of the oil.

Two special soaps were prepared from coconut oil and sulphur olive oil, respectively, through the kindness of Messrs. Christopher Thomas and Bros., Ltd., in lots of about ½ ton apiece. These were boiled in the ordinary way and "fitted" with the utmost care to produce a neutral settled soap. This was important, as the papers referred to have shown that any free alkali will partly remain present as such in the solution, and the hydrolytic-alkalinity would therefore be increased to that extent. Analysis of the olive oil soap showed only 0·008% of free alkali. These soaps were diluted with boiled-out conductivity water to form the solutions studied.

The tables show at a glance that, contrary to expectation, the coconut oil soap solution contained even less OH′ than the olive oil soap. Free alkali could only account for 3·5% of the total hydrolytic alkalinity.

These data dispose of the presumption that soap solution with coconut oil as a constituent are more alkaline than those containing olive oil. Hence

---

* "Soap," W. H. Simmons, pp. 9, 10. (Pitman's "Common Commodities of Commerce" Series.)

irritation of the skin generally stated to be produced by a commercial free-lathering soap in dilute solution must be ascribed to something other than the actual alkalinity of the solution.

Evidence confirmatory of these views is to be found in the results for a soluble washer household soap as compared with a mere old-fashioned type of tallow-rosin household soap. The hydrolytic-alkalinity in both of these is identical (0·00077*N* and 0·00079*N*), and is nearly four times greater than that of a soap made from coconut oil alone.

Indeed, it would appear that the hydrolytic-alkalinity of soap solutions is essentially that produced by the most hydrolysable constituent, the others having but little effect.

Toilet soaps.

The tables include measurements carried out on a milling base for toilet soap containing 0·078% of free alkali by analysis. It will be noticed that the alkalinity of this soap is very slightly more than that of the pure olive oil soap.

McBain and Martin have shown that the degree of alkalinity of soap solutions rises rapidly as the homologous series of fatty acids is ascended, and, of course, as indicated above, the most highly hydrolysed constituent of the solution will be the chief controlling factor in the determination of the hydroxyl ion. This would ascribe the high degree of hydrolysis to the important amounts of higher saturated fatty acid present, although the alkalinity falls appreciably short of that of a pure sodium palmitate solution, being in this case about 75% of the value obtained for the latter. This bears out the results obtained by McBain and Martin with toilet soaps in much more concentrated solution. Household soaps, on the other hand, they found to be less alkaline than the toilet soaps, but the values obtained in this case were open to serious doubt on account of the effect of unsaturated constituents on the hydrogen electrode.

In dilute solutions the household soaps are not very much more alkaline than the best toilet soap, and, if anything, rather less so than the coal tar soap, which is sometimes recommended by the medical profession for sensitive skins. The most alkaline soap examined is an imported shaving soap, probably because it contains so much stearate.

Cold process toilet soap.

Simmons also states (*loc. cit.*, page 37) that "since fats and oils can never be completely saponified without an excess of alkali, and it is obviously impossible to add such an excess to a cold process soap without getting a strongly alkaline soap . . . cold process soaps always contain small amounts of free acid and uncombined alkali . . . and uncombined alkali has, of course, an irritating action on the skin."

Consideration of the low temperature-coefficient of heterogeneous reactions would make this statement appear very doubtful, and the evidence of the measurements in the tables show that saponification is complete. The specimens used were samples of commercial soap of English manufacture, and the measurements were made as soon as possible after making up the solutions. The alkalinity of the solutions is so like that of the other soaps that it is probably all due to hydrolysis.

Sodium carbonate.

Simmons (*loc. cit.*, p. 25) states that "sodium carbonate has an irritating effect on sensitive skins, and consequently must only be present to a very small extent in a toilet soap, usually not exceeding 0·15%. The experiment gave a concentration of hydroxyl ion in 0·15% sodium carbonate solution at 25°, amounting to 0·0010 N. This is very interesting, for although alkalinity rises rapidly with rise of temperature, very hot water cannot be employed in washing. Thus a maximum alkalinity recognised as permissible is about 0·001—0·002*N* OH′, which is exactly equal to the maximum alkalinity hitherto recorded for a commercial soap, namely in a well-known imported shaving soap measured at 90° in rather high concentration by McBain and Martin (*loc. cit.*; see also Tables I. and II. for the dilute solution), and which is at least twice as much as obtains for any of the concentrations of soap solutions included in Tables I. and II.

Summary.

1. The free alkali contained in any well-made soap, intended to be neutral, accounts for only a fraction of the alkalinity (OH′) which is observed in dilute solutions of soap and which is due to hydrolysis.

2. The hydrolysis-alkalinity of dilute soap solutions rarely amounts to *N*/1000; that of concentrated solutions not more than *N*/500. The latter alkalinity is that which corresponds to about 0·15% of sodium carbonate, larger quantities of which should not be found in toilet soaps.

3. Sodium oleate and the sodium salt of rosin are about as much hydrolysed as the palmitate, but in stronger solutions the oleate is less and the resinate more hydrolysed in correspondence with their respective degrees of colloidal properties.

4. Soap prepared from pure coconut oil has an exceptionally low hydrolytic-alkalinity. Neutral soap from pure olive oil exhibits a hydrolytic-alkalinity similar to good toilet soap and slightly exceeded by household soaps and some other toilet soaps.

5. The hydrolytic-alkalinity of a soap solution appears to be chiefly conditioned by the most hydrolysable constituent present. Thus shaving soap exhibits a high degree of hydrolytic-alkalinity. Similarly, the hydrolytic alkalinity arising from coconut oil soaps does not account for any irritating action on the skin. Such action must be ascribed to some other constituent present, such as, possibly, a specific action of the laurates contained in it. Soaps consisting largely of the more readily sorbed soaps of the higher fatty acids should not exhibit irritating action upon sensitive skin, as in these mixtures sorption of such constituents as the laurates by the skin will be largely obviated.

6. A free-lathering soluble washer household soap exhibits about the same hydrolytic alkalinity as a tallow rosin (0·0008*N* OH′).

7. A well-made cold-process soap does not exhibit hydrolytic-alkalinity appreciably greater than could be expected from any toilet soap made from the same materials. In other words, the OH′ concentration is too small to have an effect even upon sensitive skin.

In conclusion, we desire to thank Prof. McBain for the interest he has shown in our work, which was undertaken at his suggestion, and the Colston Society of the University of Bristol and the Chemical Society of London for grants in aid of the investigation.

London Section.

MR. JULIAN L. BAKER IN THE CHAIR.

THE ANALYSIS OF LIQUID AND GASEOUS MIXTURES OF ETHER, ALCOHOL, AND WATER.

BY IRVINE MASSON AND T. LAWSON MCEWAN.

Despite the widespread applications of ether-alcohol as a solvent on the large scale, especially in the nitrocellulose industries, the published methods of analysis of these mixtures are either tedious or unreliable, and in any case approximate only; and for the analysis of mixtures of the vapours diluted with air, which should serve to control processes for the recovery of evaporated solvent, satisfactory methods appear to have been entirely lacking (*cf.* Mallinckrodt and Alt, J. Ind. Eng. Chem., 1916, 8, 807; Wolff, Chem.-Zeit., 1910, 34, 1193; Kochmann and Strecker, Biochem. Zeits., 1912, 43, 410). The methods now described were therefore devised and tested, and were adopted at Gretna and other cordite factories during the war.

Fleischer and Frank (Chem.-Zeit., 1907, 31, 665) described an approximate method in which the aqueous ether-alcohol sample was shaken with water and paraffin (" Benzin "), the increase in volume of the oil being taken as the volume of ether present. From this and from the density of the sample the apparent density of the alcohol-water portion was algebraically calculated, and the strength of this found from ordinary alcohol tables. It was thus assumed that all the ether was extracted by the oil, and, further, that no change in volume takes place on mixing ether with aqueous alcohol. As the sequel shows, neither assumption is correct, and the results deviate from the truth by about 10% for the ether and by much more for the alcohol.

By using extraction with paraffin and water, however, if due allowance be made for the partition of ether and alcohol between the two layers, the ether content of a sample can be found within less than 1% of the truth; and if this result and the density of the sample are compared with actual experimental data for the densities of synthetic ternary mixtures, the alcohol content may be found with an accuracy of 1%.

In the case of vapours similar principles apply to the ether estimation, the vapours being first absorbed in sulphuric acid.

A.—Liquid mixtures.

Paraffin, water, ether, and alcohol together form two layers, of which the upper contains all the paraffin, most of the ether, and a part of the alcohol. If sufficient water be present to reduce the concentration of alcohol in the aqueous layer below about 25%, little alcohol can pass into the upper layer with the ether; similarly, excess of paraffin improves the extraction of ether into the upper layer. These conditions are met if 1 vol. of the sample is shaken with 2 vols. of paraffin and 2 of water. In these circumstances the volume of the paraffin increases by an amount which may be between 80% and 105% of the volume of ether actually present, according to the kind of oil used and, to a slight extent, on the ether content of the sample tested.

The light paraffins give the highest apparent efficiency of extraction; heavier varieties, such as centrifugal oils and paraffin " B.P." give emulsions or are too viscous. Two qualities are here specified. For ordinary purposes by much the best is petroleum ether, of sp. gr. 0·68 at 20°/4°, b.p. 40°—75° C. For special cases, to be referred to later, a mobile paraffin of sp. gr. 0·75 at 20°/4°, b.p. 120°—140° C., is used; lamp oil, even after purification, is an unsatisfactory substitute. A convenient source of the oil is the xylene fraction of Borneo oil, as obtained from the Asiatic Petroleum Company; this oil is treated at 100° with oleum to remove aromatic and unsaturated hydrocarbons, and is shaken successively with alkali, water, anhydrous calcium chloride, and mercury, being finally filtered. Other sources are doubtless available.

Emulsification is avoided by the use of water containing a little acid (2% H_2SO_4) for the extraction.

Finally, owing to the high coefficients of expansion of ether and of petroleum ether, due care must be taken in analysis to counteract the rise of temperature which occurs on mixing alcohol with water. The actual distribution of the components seems to be little affected by this temperature-change, so that where weighing is adopted no such precaution is necessary.

(*a*) *Estimation of ether.*

(i.) *Large samples.*—A separating-funnel containing 200 c.c. ± 1 of petroleum ether as already specified is weighed to 0·1 gram. 100 c.c. ± 0·5 of the sample is added and the weight again taken. 200 c.c. ± 1 of water containing 2% H_2SO_4 is added, without weighing, and the corked vessel is vigorously shaken, after which it is allowed to stand for a few minutes with occasional rotation. The aqueous layer is now run off so that a few c.c. remains, and the corked vessel allowed to stand for ten minutes, adherent drops of moisture being released by intermittent swirling. The aqueous layer is now finally run off and the vessel and contents weighed. The total time required for the analysis is 20 minutes.

The gain in weight of the oil is about 90% of the true weight of ether present; the true value is found from a curve which should be drawn from the determinations with synthetic mixtures recorded in Table I. The accuracy of the result is within 1%, excepting where much water is present in the sample, when the value read from the curve is low by 1% (see Table I.).

TABLE I.

Ether extraction by petroleum ether.—Weight method.

(Ether-alcohol-water, 100 c.c.: p.e., 200 c.c.; 2% H_2SO_4, 200 c.c.)

Mixtures with 94% spirit.			Mixtures with 75% spirit.

71·2	65·1	0·92	17·8	15·6	0·88
			33·9	30·7	0·92

(ii.) *Small samples.*—Where only 20—30 c.c. of liquid is available the following method is accurate. A burette of 100 c.c., graduated in tenths, has bound to it a thermometer, with its bulb kept closely in contact with the burette at about the 30 c.c. mark by means of rubber rings. A jacket of cotton wool is wrapped around the bulb and burette at this point. Mercury is put in up to the lowest mark; 40 c.c. ± 0·1 of water containing 2% H_2SO_4 is added, and 40 c.c. ± 0·1 of petroleum ether. The burette is corked, and after 5 minutes' settling the exact volume of the upper layer is read and the temperature noted. From another burette 20 c.c. ± 0·1 of the ether-alcohol-water sample is measured into the analytical burette. This is then tightly corked and is inverted 15 times, with vigorous shaking, after which it is allowed to stand upright for at least 10 minutes, with occasional twirling between the hands, the temperature being finally reduced to the initial value. The volume of the upper layer is now read and the increase noted. A difference in temperature of 1° C. between the readings affects the result by 0·3%. The increase in volume is about 90% of the true volume of ether. The experimental data, from which the conversion curve is to be drawn, are given in Table II.

(*b*) *Complete analysis.*—This entails a determination of ether content as described, together with a measurement of sp. gr. at 20° C. The densities of forty synthetic mixtures were determined, and are given for reference in Table III; from these the figures of Table IV were obtained by graphic methods. The curves of the diagram corresponding with Table IV (which does not lend itself to accurate reproduction on a small scale) give by inspection, from the ascertained ether content and sp. gr., the required alcohol content of the sample; the percentage of water follows by difference.

The accuracy of the method is within 1% for ether and alcohol.

B. Vapour mixtures.—The vapours can be completely absorbed in strong sulphuric acid, and nearly all the ether can be extracted with paraffin if the acid be then suitably diluted. If alcohol and water are to be jointly determined, the gain in weight of the acid is measured before extracting the ether; the results give the alcohol+water by difference. Where, however, it is desired to estimate each constituent, the air-stream bearing the vapours is drawn first through ignited alumina, which extracts the moisture and leaves only the alcohol and ether to be absorbed by the acid. Thus two pairs of weighings and one paraffin-extraction, made with a single sample of the vapour-laden air, give a complete analysis.

The alumina is prepared by precipitation with ammonia from aluminium nitrate; after thorough washing it is ignited at a dull red heat. The white crumbly product is very hygroscopic, and is the only material found to absorb moisture sufficiently rapidly without retaining notable quantities of alcohol and ether.

Whatever type of acid-bubbler is used should be chosen with a view to ease in pouring out as well as to efficiency and lightness; it need not have a capacity greater than about 30 c.c. One bubbler next to the alumina tube is filled with 10 c.c. of pure sulphuric acid (sp. gr. 1·84), and a second with 5 c.c. The two are weighed (unless ether alone is to be determined, when neither weighings nor alumina-tubes are required) and are connected in series with the alumina-tube on one side, and with a graduated aspirator on the other through a guard-

tube containing sulphuric acid. The air-sample should contain less than 5 g. of ether, and the rate of aspiration may be as rapid as the efficiency of the absorbers will allow. It is advisable to stand the acid-bubblers in cold water. At the end of the absorption any alcohol which is present in the alumina is removed by means of a stream of dried air; the absorption tubes are then weighed (for water and for alcohol+ether), and the ether-determination is made.

For this purpose a burette of the Mohr type is used, having a stem of 50 c.c. graduated in tenths and terminating below in a bulb of capacity not less than 80 c.c. A thermometer with cotton wool wrapping is attached, as described above. Before the analysis, mercury is put into the burette up to the lowest mark.

The principal bubbler is now emptied into the burette, and is washed in with the contents of the second. Enough sulphuric acid (sp. gr. 1·84) is added to bring the volume of the acid layer to 20 c.c. ± 0·1. Mercury is then run out to make room for the addition of 40 c.c. ± 0·2 of the mobile paraffin already specified, the volume of which is exactly read *in situ* after draining. More mercury is run out, and 50 c.c. ± 0·2 of water is carefully added, the burette being tilted; a cork is at once inserted and is held firmly while the acid and water are gently but thoroughly mixed, the burette being cooled by means of water. The burette is now inverted 12 to 15 times, and is read in the same manner as described above. The gain in volume of the oil is from 70 to 84% of the volume of ether actually absorbed; the conversion is given in Table V, from which a curve should be drawn. Excess of alcohol vapour does not affect the ether-determination.

THE RECOVERY OF SOLVENT-VAPOURS FROM AIR. THE USE OF CRESOL AND OF SULPHURIC ACID FOR ETHER AND ALCOHOL.

BY IRVINE MASSON AND T. LAWSON McEWAN.

The recovery of solvent-vapour from air into which it has been evaporated has for many years been in operation in the case of cordite factories using acetone, the absorbing agent used for this solvent being an aqueous solution of sodium bisulphite (the Robertson-Rintoul process, E.P. 25,994 of 1901). With the development of cordite R.D.B., there arose the need for recovering ether-alcohol, another absorbent being required; and the economic value of the recoverable ether, alcohol, benzene, etc., used in other nitrocellulose and in rubber industries is great. Several methods suggested for such purpose, which have been tried on the full scale, have failed owing to fundamental unsoundness which preliminary physico-chemical work in the laboratory would have discovered.

The present paper gives a short account of two laboratory investigations dealing with the use of cresol[*] and of sulphuric acid respectively, for the recovery of ether-alcohol vapours highly diluted with air; and they include a contribution to the calculation of scrubbing-efficiencies in general. The investigations relate, first, to the efficiency with which the scrubbing liquid can absorb the vapours, and, secondly, to the conditions for separating the absorbed material from the liquid.

Cresol.

A.—Absorption.

The efficiency of absorption of a vapour by a non-volatile liquid depends in the first instance on the vapour pressures of liquid mixtures of the two. Measurements were therefore made of the vapour pressures at various temperatures of solutions in different concentrations of ether and of alcohol in cresol, pure and crude. Two experimental methods were used: in one a jacketed nitrometer (with mercury-sealed tap) and its reservoir served as a barometer into which the liquid mixture could be introduced; in the other, known volumes of air were drawn through the liquid in appropriate saturators, the quantity and composition of the vapour so evaporated being determined. In both methods there are inherent possibilities of error, but these can be avoided; and the results obtained were in sufficiently close agreement with each other and with the standard data by which they were tested, for all practical purposes. The effects of moisture (present in the air to be scrubbed) were also tested; the ranges of temperatures and of vapour-concentrations were restricted to those to be expected in practice.

The latent heats of solution of liquid ether and of alcohol in cresol at ordinary temperature were also measured, in order to calculate thermal effects in the scrubbers, and were found to be respectively 60 Cals. and <2 Cals. per kg. of liquid dissolving in 4 kg. of cresol.

Some of the vapour pressure data are given in Table I., corrected for the slight partial pressures of cresol, and expressed in grams of vapour per cubic metre. It will be found that, for the concentrations concerned, the curves are practically rectilinear and Henry's law holds. At higher concentrations (not recorded here) the curves first steepen and finally flatten again, as is usual with such mixtures.

It was proved that when alcohol and ether are present together in cresol, each has little or no

---

[*] The use of cresol was the subject of a patent by Brégeat; E.P. 128,640.

significant effect on the partial pressures of the other; nor, except at the higher temperatures, does the presence of dissolved water materially affect the partial pressure of ether in cresol.

TABLE I.

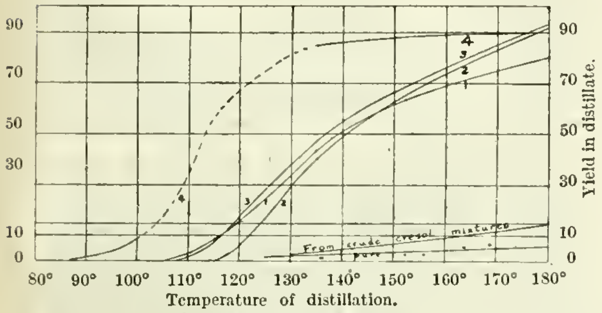
B.—Regeneration.

The recovery of the absorbed vapours was obviously to be accomplished by distillation; hence measurements were made of the yields got at different temperatures by distilling ½-kg. samples of 20% solutions of solvent in cresol—a strength which the vapour pressure measurements had indicated would be the maximum to be dealt with in practice. A method for analysing the distillates (described in another paper) was worked out and used.



Distillation from cresol.

FIG. 1.

The tenacity with which cresol retains ether and alcohol, even at high temperatures, as shown by curves 1—3 of Fig. 1, pointed to the need for steam-distillation; experiments with this, recorded in curve 4, confirm the necessity and define the temperatures to be used. Finally, since cresol is itself slightly volatile, the distillates were analysed for this component; the results are shown in the lowest curves of Fig. 1.

C.—Application of data.

The plant initially available on the full scale consisted essentially of scrubbing towers built up of tray-segments, the vapour-laden air bubbling up through the trays in series in counter-current to the liquor, which thence passed to stills; the absorbent, now freed from solvent, was cooled and returned to the beginning of the cycle.

(a) *Absorption.*—The efficiency of absorption is throughout expressed as the percentage of the entering weight of vapour which is removed from the air by the scrubbing-liquid. Provided that equilibrium is established at each contact of vapour-laden air with absorbent, the efficiency would be affected only by (1) the temperature, (2) the flow ratio, *i.e.*, weight of absorbent used per cb. m. of air, (3) the concentration of solvent which may be already present in the absorbent, and (4) the number of "effects." Under equilibrium conditions, in a case like the present one, to which Henry's law applies, the concentration of vapour in the entering air has in itself no influence on the efficiency as defined, except through the thermal effects referred to below.

In practice, true equilibrium is not achieved in each "effect"; but no data as yet available for a tower-design suffice for the quantitative application of a theory of counter-current scrubbing (*cf.* Donnan and Masson, J., 1920, 236—240 T). If, however, we calculate the relationships between flow-ratio, number of effects, and efficiency, on the assumption that equilibrium is attained at each effect, we can at least establish the minimum requirements which must be met to achieve specified efficiencies; this will now be exemplified.

Thermal effects.—The temperature of the air-stream varies with different local conditions; that of the towers varies from top to bottom owing to the heats of absorption. The latent heat of condensation of alcohol is 250 Cals. per kg.; that of ether is 90 Cals. per kg., to which must be added about 60 Cals. for the heat of solution in cresol; and the specific heat of cresol is about 0·55. Thus if the air reaching the scrubbers contain, for example, 40 g. of alcohol and 20 g. of ether per cb. m. the heat liberated by the absorption of this could heat 1 kg. of cresol through about 23° C., or 1 kg. of cresol + 1 cb. m. of air through about 15°. This figure would be increased, and the efficiency in consequence lowered, if the incoming air were richer in vapour or if the flow-rate of cresol were to be reduced. From the data about to be discussed, it appears that a rise of mean temperature of 10° would reduce the efficiency by roughly 5—10%; but the question is one of temperature-gradient and heat interchange, and is not at present amenable to more exact calculation. We may nevertheless reckon isothermally with a mean *effective* temperature, bearing in mind the fact that the efficiencies so deduced will approximate most nearly to the truth when the vapours are dilute and the liquor-feed is high; and by adopting here an effective temperature of 30°, we provide a margin and in a simple way obtain (as will be seen) results well borne out in practice and therefore useful as a forecast of the working conditions to be adopted.

Efficiency of absorption.—We may define Henry's coefficient (k) as the equilibrium-ratio between the weight of substance dissolved per kg. of cresol and the weight remaining as vapour per cb. m. of air. For ether at 30°, $k = 1{\cdot}06$; hence if 1 cb. m. of ether-laden air be brought to equilibrium with 1 kg. of fresh cresol, $1{\cdot}06 \div 2{\cdot}06 = 51{\cdot}5\%$ is the efficiency of absorption. For alcohol at 30°, k is 4·32, and the efficiency is $4{\cdot}32 \div 5{\cdot}32 = 81\%$. The absorption of ether is thus the dominant problem.

In general, if q kg. of absorbent be brought into equilibrium with 1 cb. m. of air, then whether the absorbable constituent were initially all in the air, all in the absorbent, or divided between them, the final result would be that, of the *total* weight of it present, a fraction $qk/(qk+1)$ must remain in the liquid. (Where Henry's law is not applicable and k is not a constant, the values of this fraction for the concentrations dealt with are found from the experimental curves.)

The values of $qk/(qk+1)$ for ether at 30° and for flows of 0·4, 0·6, 0·8, 1, and 2 kg. of cresol per cb. m. of air are 30, 39, 46, 51·5, 68% respectively; with a single "effect," these numbers are the efficiencies of absorption.

Now consider a two-effect counter-current scrubber, with a specified feed of 1 kg. of cresol per cb. m. of air, containing, say, 100 g. of ether vapour per cb. m. The first cubic metre admitted meets the layer A in the bottom effect, and 51·5% is absorbed as explained above; 48·5 g. of vapour passes on to layer B in the upper effect, which absorbs 0·515×48·5=25 g.; the remaining 23·5 g. of vapour is lost. The layer A now flows out of the tower and a second cubic metre of air with 100 g. of ether meets first the layer B, now occupying the lower effect, and already charged with 25 g.; hence of the *total* 125 g. 51·5%, or 64·5 g., is absorbed, the remaining 60·5 g. passing up to the fresh top layer, C. Proceeding in this way for each successive admission of air and its accompanying flow of liquid, we obtain the results shown in Table II.

Table II.

Fig. 2.

Thus after 4 cb. m. of air has passed, a steady state is reached, the recovery being henceforth 68·5%.

We may similarly calculate the efficiencies for other flow-rates, using the appropriate values for $qk/(qk+1)$, and for any specified number of effects. (General algebraic formulæ, which might replace this arithmetical method, grow too cumbersome with many effects). A separate calculation is made for each type of system and for each different flow-rate. The results of these calculations for ether at 30° C. are shown in Fig. 2, which includes also a curve for 20° and two curves for alcohol at 30°. From this can be judged the maximum efficiency of counter-current absorption which can be reached with cresol, working either with a single effect or with multiple effects up to six, and feeds of cresol up to 1 kg. per cb. m. of air-stream.

It is clear that increasing the number of effects much beyond six is necessary only to make up for the non-attainment of equilibrium in each effect, which is in turn due to the finite velocity of dissolution of a gas, to excessive thermal effects caused by "waves" of vapour, and to imperfections in the design of the scrubber. A feed of 1 kg. of cresol per cb. m. of air should give a recovery of over 90% with six to eight effects at an effective temperature of 30°. Experience on the large scale has justified this conclusion.

(b) *Regeneration.*—Fig. 1 is self-explanatory. It is evident that steam-distillation is called for, and that unless local rectification is provided, 3—5% of the primary distillate will be cresol, which will have to be returned to the system. One kg. of cresol containing 40 g. of alcohol and 20 g. of ether would require, for heating it from 30° to 130° with separation and distillation of the vapours, roughly 70 Cals. (specific heats of ether and of alcohol vapours=0·44 approx.); while the remaining cresol will require to be cooled to, say, 15° before re-use, therein parting with about 65 Cals.

It is not proposed to deal with certain other factors affecting the use of cresol, such as the presence of naphthalene and of pyridine homologues in the crude material; the slight loss of cresol in the air issuing from the scrubbers, corresponding with its measurable vapour-pressure at low temperatures; its increase in viscosity after long use; and its attack on metals other than iron and steel. These were well investigated by the Research Laboratories of H.M. Factory, Gretna, where the installation of the cresol process on a large scale led to most satisfactory results.

Sulphuric Acid.

The general procedure in this case was the same as with cresol, with additional work called for by two variants not paralleled in the case of cresol, namely, the strength of the sulphuric acid and the chemical action of the more concentrated acids upon alcohol.

A.—Absorption.

The vapour-pressure results, recorded in Table III., showed that while Henry's law is approximately valid for each strength of acid within the range of the experiments, the solubility of ether vapour in particular varies from small to great according to the concentration of the acid dealt with. The solubility-coefficients (k) for ether range from 0·02 with 50% sulphuric acid at 30° C. to 4·2 for 82% acid at 20°.

We may thus consider the general relations between solubility-coefficients, k, as determined in the laboratory, and the efficiencies of absorption obtainable in scrubbers.

To decide the merits of an absorbent for a given vapour, we must first ascertain from the vapour pressures whether the value of k is such as will

10·0	0·50	0·75	0·88	0·91	0·94	0·95	0·97	0·98	0·99

bring $qk/(qk+1)$ above the critical value when the flow-rate (q) is kept within reasonable limits. This can conveniently be ascertained from Table IV., which applies to any vapour and absorbent of the general type dealt with.

Thus, once the solubility-coefficient of the vapour in the proposed liquid has been determined, reference to Table IV. enables us to see what flow of the liquid is needed to give values of $qk/(qk+1)$ sufficient to correspond with high efficiencies, as set forth in Table V., where the number of effects which will be required is stated. Each figure in this table is the result of a separate calculation such as that exemplified on p. 34 T.

It is seen that no really useful absorption can be expected when $qk/(qk+1)$ is less than about 0·5, as shown to the left of the zigzag line in Table IV.

Table V.

Absorption-efficiencies for specified values of $qk/(qk+1)$ and multiple effects.

Solubility of vapours in sulphuric acid.

Fig. 3.

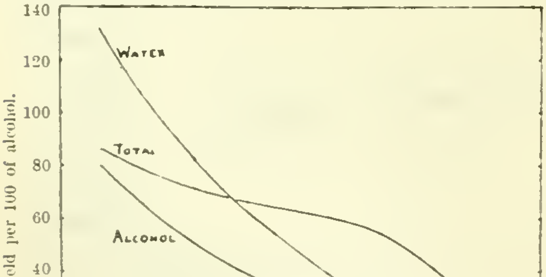
Turning now to the particular case before us, the values of k, the solubility-coefficients, are given for ether and for alcohol in Fig. 3. Reference from this to Tables IV. and V. at once shows that alcohol is very easily absorbed even in acid as weak as 50% H_2SO_4; the coefficients are so high that difficulty would be anticipated—and is in fact met with, as will be seen—in expelling the dissolved alcohol from acid by distillation. The trend of the curves indicates that a sufficiently high value for k (alcohol) would be given by 0% H_2SO_4; direct determinations of the partial pressure of alcohol in pure water support this, and the use of pure water-scrubbing for recovery of alcohol alone is a proved success on the large scale, being advantageous alike for efficiency and for freedom from plant troubles due to acid.

For ether, on the other hand, it is clear that without excessive feeds of liquor, no acid weaker than 70—75% H_2SO_4 will result in satisfactory absorption. At an effective temperature of 30° C., the curve and tables show that a flow of 74% H_2SO_4 of 1 kg. per cb. m. of air treated would give 86% efficiency of absorption, six effects being required; 1·5 kg. would give nearly complete absorption. For 66% H_2SO_4, no flow less than 5 kg. per cb. m. would give good absorption even with a large number of effects.

The remarks made in the first part of this paper concerning thermal effects are applicable here, especially in connexion with the use of the highest strengths of acid; but no measurements were made of heats of solution when the present work was done.

B.—Regeneration.

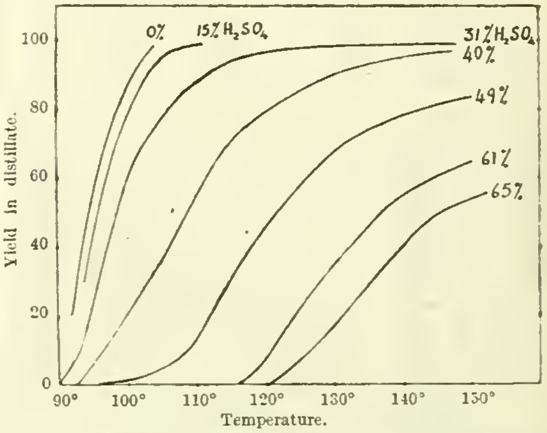
In absorption, ether presents the greater difficulty; in distillation, whereas ether is easily separated, alcohol remains, and if the temperature and concentration of the acid be too high, ethylsulphuric acid and ether can be formed, of which only the latter distils over. Experiments were therefore first made in which alcohol and sulphuric acid of various strengths were mixed in the ratio of 1:5 and were distilled evenly up to a temperature of 150° C., the distillates being measured and analysed by the method described on p. 29 T. Fig. 4 shows the results obtained with acids which contained over 50% H_2SO_4 before being mixed with alcohol. The various curves show the total recovery (up to 150°) per 100 g. of alcohol originally present, the separate amounts recovered as alcohol and as ether respectively, and the associated water which distils over. The ether-yield is expressed in terms of the weight of alcohol from which it was formed during the distillation.



Yields on distillation to 150° C. of 100 grams alcohol + 500 grams sulphuric acid.
(Ether is expressed in terms of alcohol).

FIG. 4.

Considering the total recovery, it is seen that with 82% H_2SO_4 practically no liquid distils over up to 150° (SO_2 being evolved in considerable quantity); with 70% acid a 55% recovery is reached, of which about three-fifths appears as ether and two-fifths as alcohol; 60% acid gives 66% recovery, the proportions of alcohol and ether recovered being reversed; 50% acid gives 83% recovery, only one-twelfth now being ether. It was found that increasing the rate of heating made very little difference in the yield or composition of the distillates, nor did the presence of added ether materially aid the recovery. It is evident that to achieve proper recovery in one distillation the acid must be diluted to be at most 50% H_2SO_4 (not counting the alcohol present).



Yields on distillation of 100 grams alcohol + 500 grams sulphuric acid of specific strengths (any ether formed is included in terms of alcohol).

FIG. 5.

A second series of distillations was therefore made with acids weaker than 50% H_2SO_4, the results of which, shown in Fig. 5, enable the yield on distillation to any desired temperature with specified strengths of acid, to be gauged.

The distillates obtained naturally become more aqueous the higher the yield extracted. At yields of 80%, the spirit obtained from 51% H_2SO_4 is 28% alcohol; from 49% H_2SO_4 it is 44%; and from 31% H_2SO_4, 55%.

Finally, there is the question of the strength of the acid after it has been subjected to distillation. With acids stronger than approximately 65% H_2SO_4 heated to 150° with alcohol, the chemical formation of ether sets free more water than is removed by distillation, so that the final acid is of about 65% strength. With weaker acids, ether-formation takes place either to a less extent or not at all, and distillation results in concentration. The net result is to give acid of 60—65% H_2SO_4 at temperatures of 140°—150°, and of 50—55% at 130°.

C.—Conclusions as to the use of sulphuric acid.

(1) On account of the difficulty of absorbing ether, 74% H_2SO_4 will require to be supplied to the scrubbers, with a flow-rate not less than 1½ kg. per cb. m. of air treated, and with at least six effects in the scrubber. Alcohol will be very thoroughly absorbed. With more concentrated acid the feed can be less, according to the tables; but it is probable that thermal effects would then outweigh the advantage gained.

(2) In the absence of alcohol, distillation of the effluent liquor at low-pressure steam temperatures will readily yield up practically all the ether; but

when alcohol is present, it is essential that the effluent be diluted to be below 50% H_2SO_4 and preferably to 40% H_2SO_4 (not counting the absorbed solvent present) before it is distilled. The distillation must then be carried up to 150° for acid diluted to 50%, or to 130° with 40%, in order to regain nine-tenths of the absorbed alcohol.

(3) The acid resulting from the distillation at 150° will be about 60% H_2SO_4, or 50% H_2SO_4 from that at 130°, besides containing some remaining unexpelled alcohol in the form of ethylsulphuric acid. In a cyclic recovery process, this would require to be separately concentrated up to 74% and cooled, before being returned to the top of the scrubbers.

(4) Thus it will be seen that, while sulphuric acid of about 75% strength would be of the same degree of utility as cresol if ether were the only substance to be recovered, where both ether and alcohol together are concerned, it cannot compete with cresol on account of the heavy costs attaching to the re-concentration which is required. Where alcohol alone is in question, the simplest efficient absorbent is water.

(5) In the course of the paper two tables, based on vapour pressures, are given which specify, for any simple scrubbing liquid and any gas, the minimum rates of flow and numbers of "effects" required to give stated efficiencies of absorption.

The authors' acknowledgments are due to the Director of Artillery for permitting publication; to Sir R. Robertson and Mr. A. E. Leighton for their interest in the work; and to Mr. H. Swann and Mr. H. Whittaker for their assistance in the experiments.

Discussion.

Sir **Frederic Nathan** said that the papers gave the genesis of the work which had led to a very important step in connexion with the production of propulsive explosives. The recovery of acetone from cordite was well known, but the introduction of an explosive with ether and alcohol as the solvent involved another recovery problem. For the reasons given by the authors, and also more especially owing to the fact that it was impossible to use sulphuric acid in existing recovery plants, it had never become practicable to employ it. Fortunately the value of cresol as an absorbent of ether and alcohol had been realised, and as the result of the experiments described the recovery of very large quantities of alcohol and ether had been made possible, and in that way the cost of our explosives had been reduced.

Sir **Robert Robertson** said that the earlier experiments on the absorption of ether and alcohol by sulphuric acid had shown clearly that this process was inadvisable, at least under the conditions which existed in this country. The necessary dilution of the sulphuric acid used for absorption, before it would part with its ether and alcohol, had constituted an objection, as it involved the reconcentration by heating of large quantities of sulphuric acid. This was to be avoided in the neighbourhood of propellant manufacture, on account of the possibility of fumes from the condensation apparatus getting into the danger area, which in this respect should be kept scrupulously clean. That danger, however, did not arise with the use of cresol. It was from the results of the authors' investigations that they had deduced the conditions and expressions which defined the maximum efficiency of a solvent, not only for the solvents mentioned, but also generally. For cresol the results actually obtained in practice agreed well with those predicted by this work, and in another case known to the speaker an application of the same principles to the absorption of alcohol by water gave a result which was in good agreement as regards percentage of possible recovery with actual results obtained in both experimental and large-scale practice. The principles worked out by the authors should therefore be found useful in connexion with the absorption of vapour by solvents, the main assumption being that equilibrium between absorbent and vapour is achieved. He understood that Dr. Masson was pursuing his investigations on this subject; the absence of the data in this connexion had in the past resulted in many plants being built much larger than was necessary.

Mr. **F. Sproxton** said the authors had referred to the difficulties which occurred when applying his results to large-scale plant, but he had not referred to some almost equally great difficulties which occurred, particularly in the celluloid industry, before this stage was reached, namely, in obtaining a constant concentration of the solvent vapour in the air which had to be dealt with. He thought this was a more difficult problem in the case of celluloid than with cordite, for the reason that there was a larger range of thicknesses in celluloid manufacture. The thinnest material was 0·005 in., and the thickest standard material about ½ in. thick. With the thinnest sheets all the solvent which might be got out had gone in a few hours, and so far it had been almost impossible to find a practicable way of recovering any of this solvent. After the material was booked and weighed there was very little left. He did not think the difficulties were so great in the case of the dope industries, because there they were dealing with large quantities of solvent in comparison with the solid residue. In the case of celluloid there was only about 10% of the raw weight to recover. Although in the celluloid industry there might be a very large number of stoves it was not possible to have one stove for every thickness, and consequently there would be a stove with half the material ready to come out and the other half still giving off vapour. Many of the patentees of methods of solvent recovery had not realised the difficulties antecedent to the actual recovery process.

Dr. **W. R. Ormandy** said the authors had given in a very lucid manner the theory underlying the important practical work which M. Brégeat had done since 1916. Since then a large number of plants had been put up to work with cresol, and if the facts and figures could be obtained from M. Brégeat they would add to the value of the present paper. The most remarkable thing to him in connexion with the work was the apparent capability of cresol to absorb most of the vapours which were used industrially. Was there any connexion between the latent heat of solution and this property of the cresols to absorb a large proportion of the vapours which were present in the air? Obviously, the best liquid for the purpose was the one which absorbed the largest proportion in the liquid and left the smallest proportion in the air. It was a very interesting fact that many of the hydroxybenzene compounds, such as the thymols, which were very insoluble in water, were remarkably soluble in water which contained phenols and cresols, and this rather bore on the curious property of the cresols to dissolve so many of the vapours used industrially.

Mr. **William Macnab** said he believed that the greatest dilution of air with ether and alcohol that could be successfully treated was 5 grms. per cubic metre. In France M. Brégeat's method had been used on a much larger scale than at Gretna, but in both cases it had resulted in a great increase in the recovery. At Gretna it had been a very great success, and had saved a large amount of alcohol. He hoped before long some information would be published on the actual working of the plant in regard to which much of Dr. Masson's work referred.

Dr. Masson, in reply, said that at Woolwich they had measured the vapour pressures of a large number of volatile solvents dissolved in cresol, and in every case the results were such as led him to suppose that even volatile oils such as some of the hydrocarbons could fairly well be dealt with by cresol. That, he believed, was of importance in the rubber industry. He did not suggest that hydrocarbon oils, such as petroleum ether, could be recovered with anything like such a high efficiency as ether and alcohol, except possibly with a rather extravagant use of cresol. Nevertheless, cresol transcended all other liquids which he had tried except melted phenol, which was interesting in connexion with Dr. Ormandy's remarks. Phenol had a greater heat of reaction than cresol with ether. Mixtures of phenol and cresol, liquid at ordinary temperatures, had been considered, but for winter temperatures so much cresol was needed that no useful improvement would be gained. There were other matters, such as the slight volatility of cresol itself, which had to be taken into account, as had been found to be the case at Gretna. Other points which had been studied very thoroughly at Gretna included the increase in the viscosity of cresol when used in metal vessels. He understood that steel was almost the only metal which could be used with cresol; for instance, in one plant, in which lead-lined scrubbers had been used they were corroded through in a week, but these and various other questions had not come within his province. Nevertheless, they could rest assured that, of all the liquids hitherto examined, cresol appeared in general to be by far the best.

Meeting held at Burlington House on Feb. 7, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE EROSION OF BRONZE PROPELLERS.

BY O. SILBERRAD, PH.D.

During the twelve years, 1908—1920, which these researches have occupied, notices of the principal conclusions arrived at in the early part of the work have from time to time appeared in print,[1] but although the β type of alloy to which they led has been universally adopted throughout the world for the manufacture of high-speed propellers, nevertheless no detailed or succinct record of the work has heretofore been made public; it is therefore with this object in view that the following account is now presented.

Prior to 1906 all observed cases of deterioration of ships' propellers appear to have been traceable to chemical corrosion and, with the possible exception of a few isolated cases, to have been confined to cast-iron or steel propellers. Soon after this date, however, numerous instances of deterioration occurred in bronze propellers of high-speed ships. In appearance this new form of deterioration bore a superficial resemblance to the corrosion above referred to, and it appears to have been generally assumed that chemical action was at the root of the trouble in both cases. As a result it was not until 1908, when these researches were commenced, that the phenomenon was submitted to systematic investigation.

In the meantime, as progress in marine engineering rendered greater velocities in ships practicable, the seriousness of the position became more acute, until this deterioration of the propellers was becoming the limiting factor to further developments in the direction of speed; thus, in the case of the Cunard liners, Mauretania and Lusitania, the first set of propellers was practically destroyed after three months' running (see figs. 1—3), whilst high-speed torpedo destroyers have been known to show serious erosion in a single trial run at full speed (see fig. 4). At this juncture Messrs. Charles and P. R. Parsons, of The Manganese Bronze and Brass Co., Ltd., instigated the present researches which have resulted in the discovery of the erosion-resisting alloys that are now used throughout the world for the propellers of high-speed ships[2] and, incidentally, in proving that the deterioration is due to mechanical erosion brought about by a combination of frictional rub with "the action of water broken by evacuated spaces in which no air is present."[3]

Quite recently this subject has again been brought into prominence through the investigations of a sub-committee of the Board of Inventions and Research.[4] The conclusions arrived at by this Committee on the whole confirm the author's earlier observations that the deterioration is primily due to mechanical causes. As regards chemical action, the Committee observe that there is no evidence of this,[5] which is also in accord with the author's investigations.[6] On the other hand, although the conclusions of the Committee as regards the mechanical nature of the deterioration entirely confirm the researches of the author and, indeed, throw considerable additional light on the mechanism of that part of erosion due to the collapse of evacuated spaces, nevertheless their views as to the precise nature of the underlying causes are not, in the opinion of the author, quite in accord with the observed phenomena. Prior to 1912 the author's experiments led him to the conclusion, firstly, that erosion proper is a purely mechanical effect, and, secondly, that this mechanical action was brought about by water broken by intervening evacuated spaces, or vacuum bubbles,[7] coupled with frictional rub of said water.[8]

The Committee would appear rather to hold the view that the former of these two agencies, which they aptly refer to as "water-hammer action," is operative almost to the exclusion of frictional rub: they appear to have arrived at this conclusion (*a*) because erosion does not appear to be the invariable result of velocity, although admittedly it is more likely to occur under the conditions pertaining in high-speed ships; (*b*) because erosion is observed in local patches, sometimes quite near the roots of the blades. The fact that the tips of high-speed propellers are frequently not eroded at all merely indicates that the frictional rub at these points alone is not sufficient to cause erosion. The distribution and nature of the observed eroded areas renders it perfectly obvious that the frictional rub of the water is, as a rule, only active when operating on metal which has been damaged through the collapse of the vacuum bubbles referred to above, or where local pressure and velocity are excessive.

[6] Editorial on the author's work (*Engineering* 1912, p. 33). "An examination of the damaged propellers showed that the eating away was quite different to ordinary corrosion in still water. In that case if dissolution takes place, it is selective in character, the zinc being dissolved, a spongy mass richer in copper being left. No similar phenomena were apparent in the case of the eroded blades. Analysis showed no copper enrichment: the results agreed with the intended composition with extraordinary accuracy."

[7] This apt expression for the evacuated spaces was first used by Mr. Stromeyer: *Trans. Naval Architects*, 1919, 242.

[8] *Engineering*, 1912, 34. Editorial on propeller erosion.

"Dr. Silberrad holds that erosion proper is a purely mechanical effect. . . . The area attacked" (in the case of the Mauretania) "is near the hub. This was of large size, and it seems probable that there was a certain centrifugal action causing a reduction of pressure, and this region of reduced pressure was marked by the erosion. Dr. Silberrad considers that cavitation might occur and in consequence, water broken by intervening evacuated spaces with no air present."

That frictional rub under certain conditions can alone bring about erosion was demonstrated by the author's jet experiments carried on in 1911,[9] and has, in the author's opinion, been further confirmed by the experiments of the Committee themselves, which showed that not only did jets of water produce an etching effect on the surface of propeller metals,[10] but also that rods inserted in jets were "eroded away to a greater or less degree in parts . . . the general conclusion was that the degree of etching of these rods depended chiefly upon the duration of the experiment and the velocity of the water,"[11] and although the Committee's experiments were conducted with sea water, it is nevertheless fairly obvious that this action is mechanical and not chemical, for, firstly, when manganese bronze is subjected to the action of sea water it becomes tarnished all over and seldom shows any signs of etching; and, secondly, the author's original jet experiments,[12] which produced a similar effect, were conducted with fresh water which had been recently distilled, and which is without chemical action on manganese bronze. Hence it appears justifiable to conclude in cases where the whole of the driving face of large propellers is bright and has the appearance of being etched all over when the ship is dry-docked immediately after running at full speed, that this etching effect is in reality erosion, due very largely, if not entirely, to frictional rub. Indeed, referring to this subject in his report to the Committee, Prof. Carpenter says it "may be due to the mechanical wearing away of the metal caused by the rapid flow of water over the surface of the blade."[13] That it has not in general an appearance identical with the more serious patches of erosion is doubtless due to the fact that the latter is brought about by this frictional rub in combination with the passage of water broken by intervening evacuated spaces or vacuum bubbles. The difference in appearance, however, seems to be rather a question of degree: thus, where the rush of water has been extremely violent—as, for example, in the case of the spindle of high-pressure hydraulic valves, the seating of which has become so worn as to permit of the continuous passage of water (see fig. 5)—an effect is produced almost identical with that observed in the case of propellers (figs. 1—3).

As regards the influence of structure, the Committee appear to be of the opinion that there is no evidence showing "any connexion between the structure of a metal and the distribution of erosion."[14] It is true that the precise area attacked is determined by outside influences; nevertheless, the portion of the alloy destroyed is determined largely by the structure of the metal; indeed, frequently the substitution of an alloy of the right structure renders the propeller capable of withstanding these outside eroding influences altogether. It should, however, be observed that the Committee's investigations on this subject appear to have been confined to the examination of a propeller constructed of one of the erosion-resisting alloys which were the outcome of the earlier part of these researches, namely, an alloy of essentially β structure. Further, it should be observed that Professor Carpenter's work on this point does not in fact quite bear out the Committee's conclusion. Thus, he reports "that of these two constituents" (viz., α and β crystals) "it may be predicted that α will be the more easily deformed of the two," and he actually finds two instances of such deformed α crystals. He also shows that a direct application of mechanical force establishes that the β crystals are not subject to distortion and that "they show that any considerable accumulation of deformed α at the surface is not to be expected on account of the small amount present" (in the alloy of the new erosion-resisting type examined by him), "and, further, that such deformation must be confined to α which is not entirely surrounded by β."[15] It was precisely similar observations[16] which led the author in 1908 to recommend the use of an alloy of primarily β structure in the case of the "Mauretania" and subsequently for the manufacture of propellers liable to be subjected to erosive influences in general[17]; and, as Sir William Ramsay observed,[18] "since this alloy has been universally adopted for such purposes it must be admitted that these observations were fairly in accord with facts."

In reviewing the work of the Committee in general as set forth in Sir Charles Parsons and Mr. S. Cook's paper, though it must be admitted that much of the work merely confirms facts which have been generally accepted and utilised in the trade, the Committee have nevertheless rendered a signal service in throwing so much light on the enormous forces operative when evacuated spaces collapse under water, thus very conclusively confirming the phenomena previously observed by the author. It is, however, impossible to agree with their observation that the type of alloy used is unimportant, or that all tendency for high-speed propellers to become eroded can be eliminated through amending the design.[19] In the first place, the Committee only appear to have examined propellers cast of the present erosion-resisting alloys which are the outcome of the author's researches; and, further, erosion is frequently traceable to damage done to the edges of the propellers through contact with steel hawsers, wreckage, etc., namely, causes in no way bound up with the question of design. But even apart from such considerations, the difficulty in arriving at "the right design and position of propeller" for high-speed ships is such that it is obviously desirable to adopt an alloy possessed of as high a specific resistance to erosion as possible; indeed, without some such alloy it seems improbable that anything approaching the present speeds could ever have been reached.

I. *Investigation into the causes of deterioration.*

Chemical examination.—At the commencement of this investigation the idea that the deterioration in question was due to chemical action was so generally prevalent that it was difficult to approach the subject with a truly open mind; a careful chemical examination of the damaged surfaces in a large number of cases, however, entirely failed to supply any evidence of chemical action; there was no sign of any concentration of copper or deficiency of zinc, as would be expected in the event of such severe deterioration being the result of chemical action. As regards composition the alloy proved to be the ordinary high-tension manganese bronze in all the early cases examined; the only possible indication of chemical action at all lay in the observation that the crystalline structure of pro-

[17] Parsons & Silberrad, Eng. Pat. 232 of 1910. In this connexion it is interesting to note that two years later, viz., in 1912, the Gewerkschaft Rubelbronze of Berlin recommended the use of an alloy of β structure as being suitable for "propellers of battleships and other high class steamships," alleging that this bronze was identical with the "bronze C" manufactured by them in 1908. It should, however, be observed that the physical properties of the alloy recommended by them in 1912 do not coincide with those published in respect of their alloy of 1908, with which the alloy they subsequently recommended was supposed to be identical; and, further, that on the strength of this the Gewerkschaft Rubelbronze of Berlin attacked the Austrian equivalent of this patent (Austrian Pat. 53094 of 1910 by Parsons & Silberrad), but were unsuccessful in their suit in spite of the fact that this country was at war with Austria at the time.

[18] Sir William Ramsay, *Engineering*, Nov. 21, 1913.

[19] *Trans. Inst. Naval Architects*, 1919, 247.

pellers was frequently clearly observable over considerable areas, the surface being bright and having the appearance of recent etching when the propellers first come out of the water. It seems probable, however, that this etching also is due to mechanical erosion, for the above phenomenon was only noticeable providing the ship had been running at full speed immediately before dry-docking; the propellers were always observed to be tarnished all over if she had been at rest two or three days previously. Experiments with a view to reproducing this condition were therefore undertaken, and it was found that a precisely similar appearance can be produced by subjecting the alloy to the action of a jet of high-pressure water, whereas on immersing a piece of manganese bronze in sea water it became tarnished rather than etched. Fig. 6 represents a specimen which has been subjected to such a high-pressure jet; the best results were obtained with small direct jets constructed of steel and supplied with water from inverted steel cylinders into which nitrogen at 2000 lb. per sq. in. was forced by means of a three-stage compressor, the water being covered with a layer of B.P. petroleum to prevent solution of the nitrogen.

In order to investigate further the extent to which chemical action plays a part, a sample of manganese bronze cut from one of the wing propellers of the s.s. "Mauretania" was submitted to the action of sea water, the alteration in weight per sq. m. exposed being recorded from day to day. The results are given in Table I., from which it will be observed that the average loss of weight of this particular bronze was 0·28 g. per sq. m. per day. The maximum depth to which the deterioration had reached in the particular propeller from which this sample was cut was $2\frac{1}{2}$ in., from which it will be observed that it would take over 5000 years[20] to effect the observed deterioration by chemical corrosion; and since the deterioration in question was caused in 3 months it becomes self-evident that chemical corrosion is a negligible factor in the deterioration under consideration.

Galvanic action.—No evidence of galvanic action being a factor could be obtained. In all the most pronounced cases examined the protecting zinc plates in the neighbourhood of each of the propellers were in perfectly normal condition, nor was there any electric leak detectable throughout any of the ships examined.

The suggestion made by Mr. Ramsay[21] that local electric disturbances set up through mechanical stresses might be the cause of the deterioration led to the examination of the behaviour of a sample of this same alloy when submitted to a variable stress under sea water. This experiment was carried out by submerging a bar $8\times\frac{1}{2}\times\frac{1}{8}$ in. in sea water, one end of the bar being held rigidly and the other end attached to an eccentric making 4 strokes of 1 in. per minute. The results are incorporated in Table I., below, from which it will be observed that the alteration in weight due to corrosion in this case is only very slightly greater than that suffered by a similar bar of this alloy not under stress; and that in both cases the loss is entirely negligible as a factor in dealing with the severe type of deterioration under consideration.

Physical examination.—Although the above observations were sufficient to constitute fairly conclusive evidence that the deterioration was not due to chemical or galvanic action, they are nevertheless all of a negative rather than a positive nature; it was therefore decided to make full examination of a series of damaged propellers with a view to gaining a further insight into the nature of the operating causes.

Micro-examination of the eroded surfaces of a large number of propellers revealed distinct evidence of deformed α crystals; this was confirmed by cutting pieces from the eroded portions, embedding them in soft solder, and examining them after sectioning and polishing.

In the early days of these researches the propellers examined possessed the normal structure of manganese bronze, namely, essentially an α-structure. In general these samples were remarkably similar and showed deformed α crystals wherever these predominated; cases were also observed of part of the alloy having been washed away, leaving protruding crystals, most of which showed varying degrees of deformation. In a few isolated cases where the proportion of zinc in the alloy had been allowed to get a little above normal the alloy assumed a mixed α and β structure; in these cases it was observed that the β crystals stood up to the erosion remarkably well, whereas the α crystals, where they were not embedded in β, had either been crushed, broken off, or else washed right away. A typical example of such an eroded

---

[20] $10{,}000 \times 2{\cdot}5 \times 2{\cdot}54 \times 8{\cdot}321 \div 0{\cdot}28 \times 365{\cdot}25 = 5109{\cdot}8$ years.

[21] *Engineering*, May 24, 1912.

edge is illustrated in fig. 2, the propellers in question having been scrapped after running less than three months on account of erosion. In this connexion fig. 3 is also interesting as illustrating an α crystal which has been deformed and broken at the point.

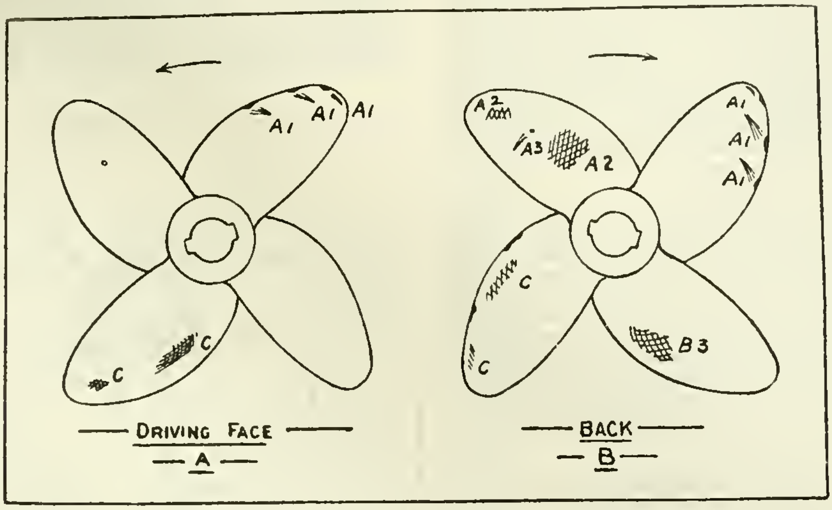

Fig. 7.—(1/100 full size.)
Diagram of 4-bladed propeller showing various types of erosion.

It will be observed therefore that micro-examination of eroded bronze revealed distinct evidence as to the deterioration being mechanical in origin, and also as to the superiority of β crystals in their capacity to withstand this erosion. These conclusions were subsequently very fully confirmed by taking small samples of a very large series of propellers as they were cast, submitting these samples to micro-examination and subsequently inspecting the propellers from time to time as they developed any defect in use. In this way so close a connexion between the microstructure and the capacity to withstand erosion under any given conditions was established that it became possible by merely studying the microstructure of any given propeller to give to it a relative figure of merit which was closely indicative of its capacity to withstand erosion.

Macro-examination.—An exhaustive macro-examination of a large number of eroded propellers was next entered upon, which established, in the first place, that dirt in the castings played little or no part as a determining factor, either as to the position or degree of the erosion produced. In this connexion many cases of unsound castings were examined, and although instances remarkably similar to erosion were found, when propellers having such defects were put to work the cavities in question showed no signs of developing into erosion; indeed, if anything, they assumed a slightly smoother appearance.

In the second place, it was noted that eroded propellers belonged to one of two classes—they were either relatively small propellers running at a high speed (*i.e.*, 600—800 r.p.m.), as in the case of torpedo destroyers; or else they were large propellers transmitting great power, as in the case of battleships or fast liners, as, for example, the "Mauretania," the "Lusitania," the "La France," and the "Imperator."

As regards the areas eroded in the different propellers examined, these were most varied and in the first instance most perplexing, erosion being observed on the boss, base, centre, and edges of the propeller blades. A thorough examination of a very large number of propellers, however, rendered it possible to arrive at a series of generalisations as to the areas attacked and to classify these into three types, each type being traceable to special conditions productive of currents of water, broken by evacuated cavities, or vacuum bubbles, impinging on the areas eroded.

Classification of the various types of erosion.

Type A. *Erosion due to damage done to the propeller.*

Erosion of this type divides itself under three heads:—

Type A. 1. *Erosion due to damage done to the leading edge.*—Whenever the leading edge of a high-speed propeller is bent or deformed an eroded area results on that side of the blade towards which the damaged edge has been deflected. Thus the erosion starting from damage of this sort will be found on the driving face if the leading edge has been bent towards that face (see fig. 7 A), whereas if the damage done to the leading edge has caused the metal to become bent backwards, the erosion will appear on the back of the propeller (see fig. 7 B). Frequently these areas of erosion are deep and very clearly defined, often tailing off in comet-shaped grooves. It thus becomes evident that the contributing conditions which lead to erosion of this type are as follows:—

The leading edge being distorted leaves a trail of water broken with evacuated spaces starting from the distortion on the side towards which the blade has been deflected; as this current of broken water sweeps over the blade the vacuum bubbles therein collapse, and the combined frictional rub and water-hammer action so produced cause the erosion observed. As is to be expected, erosion of this type is generally situated on an arc described from the centre of the propeller and passing through the damaged edge; where exceptions have been observed these appear to be due to deflecting currents influencing the flow of the broken water caused by the damaged edge.

Type A. 2. *Erosion due to damage done to the following edge.*—Deformation of the following edge of a blade is liable to cause a stream of broken water to impinge on the back of the next blade of the same propeller (fig. 7 B). Erosion of this type occasionally covers a considerable area, but is seldom deep; its origin is attributable to causes precisely analogous to those which bring about the A. 1 variety—the distorted following edge leaves a trail of water broken with evacuated spaces which impinges on the back of the next blade; the current in this case is generally more disturbed and, as a consequence, the erosion is less intense but covers a greater area.

Type A. 3. *Erosion due to holes in the propeller* (as when the plug comes out of the shackle hole). Under these circumstances a comet-shaped area of erosion results on the back of the blade (fig. 7 B), the eroded area being on an arc described from the centre of the propeller and passing through the hole. A little consideration will render it obvious that erosion of this type is due to the following causes:—

The water on the driving face of the propeller being under pressure rushes through the shackle hole, thus taking up the rotary movement of the propeller; the jet of water so produced strikes the relatively stationary water behind the propeller, thus causing cavitation in the form of an evacuated space round the jet; the broken water so produced is subsequently swept over the back of the propeller on which the vacuum bubbles collapse, causing the comet-shaped eroded area invariably observed when the plug comes out of the shackle hole of a high-speed propeller.

Type B. *Erosion due to disturbances caused by the propeller itself.*

Three distinct types of erosion arising from disturbances set up by the propeller itself have been observed, namely—

Type B. 1. *Erosion due to high number of revolutions made by the propeller.*—When a propeller of any given design is running at too high a speed erosion appears at or near the root of the driving face (fig. 8). In these cases it would seem that erosion is due to the centrifugal action caused by such rapid revolution, as a result of which water, broken by evacuated spaces, is whirled outwards into areas of greater pressure, thus causing the vacuum bubbles to collapse on the surface of the blade near the root.

B. 2. *Erosion due to stream lines caused by the following edge of the preceding propeller.*—Erosion of this type generally appears as a deep cut on the boss near the back of the blade following, and seems to be confined to propellers with very wide blades having a relatively small diameter and making a fairly high number of r.p.m. (See Fig. 9.)

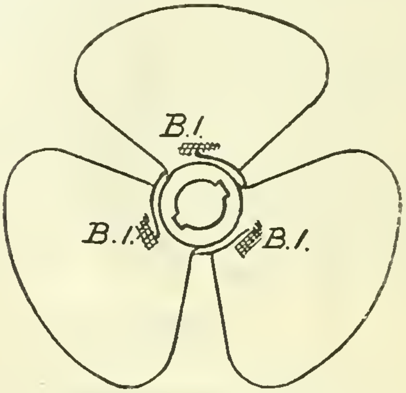

FIG. 8.—(1/25 full size.)
Diagram of 3-bladed propeller showing B1 erosion on driving face.

Type B. 3. *Erosion due to backwash from the sides of the ship.*—This is liable to occur where the wing propellers have insufficient clearance, especially if they turn inwards; in this case the backwash causes broken water to be thrown on to the propellers, thus producing severe erosion (fig. 7 B). Figure 1 illustrates an extreme case of this class, in which erosion to the depth of 2½ in. was caused

TABLE II.

Classification of causes of erosion.

Class.	Cause.	Position and appearance.	Illustration.	Remedy.
		A.—Erosion due to damage done to propeller.		
1	Deformation of leading edge—			
	(*a*) Blade distorted towards driving face.	Comet-shaped groove on driving face starting from deformation.	A_1, fig. 7A.	Avoid contact with hawsers, wreckage, etc. To repair damage trim deflected edge down to the level of surrounding metal.
	(*b*) Blade deformed towards back.	Comet-shaped groove on back starting from deformation.	A_1, fig. 7B.	Do. do.
2	Deformation of following edge.	Area often ill-defined but generally shallow on back of the following blade.	A_2, fig. 7B.	Do. do.
3	Shackle hole being unplugged.	Comet-shaped area on back of blade starting from shackle hole.	A_3, fig. 7B.	Keep shackle hole plugged.
		B.—Erosion due to disturbances caused by the propeller itself.		
1	Propeller of given design running at too high speed.	Clearly defined patch of erosion, generally deep, situated at or near root of driving face.	B_1, fig. 8.	Run propeller slower, using, if need be, geared turbines and larger propellers.
2	Unsatisfactory design of following edges.	Deep cut-like erosion on boss near root of back of propeller blades.	B_2, fig. 9.	Alter design of propeller, particularly following edges of the blades.
3	Backwash from side of ship due to insufficient clearance or propeller turning inwards.	Area often considerable and sometimes deep; generally situated on back of propeller about half way up and towards following edge.	B^3, fig. 7B.	Give wing propellers plenty of clearance and arrange for them to turn outwards.
		C.—Erosion due to influences external to the propeller.		
1	Stream lines of water broken by evacuated spaces produced by a propeller forward of eroded propeller.	On both sides of propeller generally about half way up and towards leading edge, erosion often being deep, especially on driving face.	Fig. 7A.	Alter relative arrangement of propellers.
2	Stream lines of water broken by evacuated spaces produced by "A brackets" forward of eroded propeller.	do. do.	Fig. 7B.	Alter design and arrangement of "A brackets" supporting propeller.
3	Stream lines of water broken by evacuated spaces produced by the ship itself.	do. do.		Alter design of ship.

in three months. As regards position, this type of erosion is generally to be found on the back of the blade, though naturally it varies with the precise position of the seat of the cause.

Type C. *Erosion due to passage of some body forward of the propeller*, which causes a stream of water broken by evacuated spaces to impinge on the propellers. Erosion of this type is generally due to one of the following causes:—

Type C. 1. Stream lines of water broken by evacuated spaces produced by another propeller forward of the propeller in question.

Type C. 2. Stream lines of water broken by evacuated spaces produced by "A brackets" situated forward of the propeller eroded.

Type C. 3. Stream lines of water broken by evacuated spaces produced by the ship itself.

Such erosion generally appears on both sides of the propeller and varies enormously both in shape and intensity. It occurs on the back whenever a stream of water broken by evacuated cavities impinges on the propeller and is due to the collapse of these evacuated spaces on striking the surface in question (fig. 6B). Similar erosion on the driving face is obviously due to the same cause; the streams of broken water on being cut by the propellers suddenly enter an area of high pressures with the result that the evacuated spaces collapse on the driving face at a distance from the leading edge dependent on the peripheral velocity of the propeller at the point of cutting. As a general rule erosion due to this cause will therefore be found on both sides of the propeller, but is likely to be more intense on the driving face than on the back.

For the sake of convenience in reference these various types of erosion have been classified in Table II. under the causes to which they are attributable.

Part II.—*Production of propeller alloys possessing relatively high specific resistance to erosion.*

From the investigations described above the following conclusions may be drawn respecting the nature of this deterioration:—

1. Chemical action is a negligible factor.

2. Galvanic action does not appear to come into play at all.

3. The presence of dirt in the castings has only a slight detrimental effect.

4. The true cause of the deterioration is mechanical and is therefore properly termed erosion, the determining factors being:—

(*a*) The frictional rub of the water.

(*b*) The impinging on the propeller blades of water broken with evacuated spaces which subsequently collapse on the propeller blades, both of which conditions, it will be observed, are more liable to arise in high-speed ships or propellers moving at a high velocity.

It has also been established above that where alloys containing α crystals are exposed to this action, these α crystals are liable to deformation unless they are wholly embedded in β crystals, from which it would appear that a bronze composed essentially of a β structure is best calculated to withstand the deterioration under consideration.

At the date when these researches were commenced, however (1908), β alloys consisting essentially of copper and zinc were regarded as being mechanically unsound; this research therefore next turned upon the problem of discovering suitable additions to copper-zinc alloys of the manganese bronze type which would change them from essentially α alloys to those of β structure without impairing their physical properties in any way. In carrying out this part of the investigation use was made of Guillet's work on complex brasses,[22] wherein he showed that one part of zinc may be replaced by an equivalent quantity of any of a series of certain other metals without affecting the structure of the original copper-zinc alloy. These "equivalents" must not in any way be confounded with the atomic weights of the metals, to which they do not appear to bear any very simple relationship. Thus, 1 part of zinc is equivalent to aluminium 0·16 part, iron 1·1, manganese 2·0, cadmium 1·0, lead 1·0, silicon 0·1, or tin 0·5 part. Making use of these equivalents a large series of alloys possessed of β structure was made; in each case part of a 300-lb. charge was cast in sand and part in chill; test pieces were cut from each, and the alloy thoroughly examined both mechanically and microscopically. As this paper deals essentially with erosion and does not pretend to go into metallurgical problems it is not proposed to give these researches in detail; the following table, however, sets forth a few of the more important results which led to the production of a mechanically sound alloy of β structure, and gives the composition and properties of a series of alloys representative of each step in the research.

Table III.
Development of bronzes.

Composition of alloy.			Composition of corresponding imaginary brass.		Mechanical properties.

	Standard manganese bronze for comparison				33·0	17·0	20	120

All these alloys possessed a homogeneous β-structure with the exception of the standard manganese bronze, which showed strong α-crystallisation. The above figures show that tin in appreciable quantity appears to act very detrimentally on β-alloys. The marked improvement in physical properties caused by the introduction of manganese should be noted, though the presence of as much as 9% renders the alloy troublesome in the foundry. The chief effect of aluminium appears to be to raise the elastic limit. The alloy containing Al, Mn, and Fe may be regarded as the parent of the present erosion-resisting bronzes. The first propellers made of it were cast by The Manganese Bronze & Brass Co. in 1908, for the *Mauretania*. The first alloy of the type of standard manganese bronze was introduced by Mr. P. M. Parsons of The Manganese Bronze & Brass Co. in 1876.

From these results it will be observed that although a copper-zinc brass of purely β structure is not a satisfactory alloy, nevertheless alloys quite equal in mechanical properties to the old-established α bronzes can be produced by introducing small quantities of aluminium, manganese, iron, etc. Having thus established the practicability of producing improved erosion-resisting alloys of this

---

[22] Guillet, *Rev. de Mét.*, 1906, 159.

type, their further development and application followed as a matter of course, and such alloys are now used throughout the world for the manufacture of propellers for high-speed ships. Photomicrographs of some of these alloys are given in figs. 10—15. In No. 10 (tensile strength 34 tons, elastic limit 17 tons per sq. in., elongation 25%) the α crystals are sufficiently protected to render the alloy immune from any but the most severe erosive influences to which marine propellers are subject, whilst the α crystals present render the alloy much more easily repaired or worked than a homogeneous β alloy. Similar remarks apply to a lesser extent to No. 11 (t.s. 30, el. lim. 15·5, elong., 33%), which although essentially an α bronze still has sufficient β crystallisation for protective purposes where the eroding influences are not excessive. Nos. 12 and 13 (t.s. 40—42, el. lim. 20, elong, 17—25%) represent a homogeneous β solution and have the highest possible specific resistance to erosion. No. 14 (t.s. 36—38, el. lim. 18·5, elong. 30—35%), and No. 15 (t.s. 33—35, el. lim. 17·5, elong. 25—30%) have α crystals embedded in β and are excellent all-round propeller alloys. It is noteworthy that although the former of these alloys contains a higher percentage of zinc, it is even less subject to corrosion than manganese bronze (see Table I.); it is suggested that this may be due to the extreme homogeneity of the alloy, which is a practically pure β solution.

The first ship equipped with propellers cast of an alloy of the new type was the "Mauretania." It will be remembered that in three months this ship wore out her first set of propellers, which were cast of the old type of bronze (see fig. 1); the propellers of the new alloy were fitted in January, 1909, and it is interesting to note that the Surveyor for the Germanische Lloyd, on inspecting these new propellers after they had run for six months—*i.e.*, twice as long as the original ones of normal manganese bronze lasted—reported that they were in perfect condition, there was no sign of wasting or erosion, and the surface appeared to be as good in every way as when the castings were first made.

In conclusion I desire to express my thanks to Mr. P. R. Parsons for his most skilful co-operation throughout these researches. My thanks are also due to Sir Phillip Watts, K.C.B., F.R.S., for his valued advice on numerous occasions, to Dr. Desch for his assistance in connexion with the photo-micrographic records, to Mr. A. T. Quelch, O.B.E., Mr. F. G. Martin, The Manganese Bronze and Brass Co., Ltd., Messrs. J. Stone and Co., Messrs. Billington and Newton, Ltd., the Superintendents of the various Admiralty Dockyards, The Cunard Co., Ltd., Messrs. Harland and Wolff, Messrs. Cammell, Laird and Co., Ltd., and Messrs. Alfred Holt and Co., Ltd., for the facilities afforded me on all occasions during the last twelve years when inspecting eroded propellers and otherwise pursuing these investigations.

Discussion.

Mr. A. T. Quelch said that during the past thirteen years he had made 16,000 or 17,000 tons of bronze propellers and propeller blades; a large number of these had been made with the β-alloys referred to in the paper, and he could concur with the author that the erosion was purely mechanical. He had had occasion to examine very many high-speed propellers. In the case of the "Swift"—a very fast scout type of destroyer, designed for 36 knots—difficulty had been found in keeping up the speed for the six hours full-speed trials. Experiments with the design of the propellers had been started. Altogether 26 propellers had been made for that ship, and examination of these had revealed the very curious way in which, as the design was altered, the area of the eroded part moved about, a fact which proved that the erosion was purely mechanical. In that particular case the expanded area of the three blades was actually greater than the disc area, which fact introduced that peculiar cause of erosion, the interference of one blade with another, which produced a deep cut on the back. During the war the greater number of the destroyers built had been built of the geared turbine type, giving reduced speed of the propellers, in the hope that it would put an end to erosion troubles. Soon afterwards, however, serious erosion had been reported to be taking place on the Bruce-Douglas type of destroyer leader. Examination had shown that the greater proportion of this so-called erosion was dirt washed out of the propeller, due to a great extent to the design of the propeller. Unfortunately, the engineer often did not consider whether the designs were good or bad from the founder's point of view. In this particular case the propellers were of such a large surface, coupled with a short boss, that both the leading and following edges of the blades overlapped the top and bottom of the boss. Propellers were cast with the driving face downwards, so that the following edge of the blade was considerably below the level of the bottom of the boss. The gate was put into the bottom of the boss so that the first flow of metal which entered the boss had to run down hill, and there was a considerable disturbance of this metal by eddies etc., and the production of a large amount of oxide. The section of the blade of those particular propellers, about six inches from the tip, was about 6 ft. long by about 1¼ in. thick, so that the dirt had not much chance to get away. The only serious erosion in this particular case was on the back of the blade, almost on the fillet, and it was due, in his opinion, to the very badly designed A bracket. The section of this A bracket was very square, and, in addition, there was a lubricator in the angle of the A bracket, by the boss, which had the effect of throwing a jet of disturbed water on to the propeller, with the result that grooves were eroded in the blade to the extent of 1¼ in. deep.

He would like to ask the author as to the size of crystals in the β structure which could be produced by adding various metals, *e.g.*, Al, Mn, Fe, to the ordinary copper-zinc alloy. There was considerable variation in the size of the crystals, although their general type was the same, and this might have a very considerable influence on the mechanical properties. Whereas quite favourable results might be obtained in an ordinary tensile test piece, when the alloy was exposed to the stresses obtaining in the case of a propeller, in which there was considerable variation in stress and reversals of stress at different times, there might be failure in the material in resisting fatigue, which was most important with any running machinery. He had had very little trouble with the β-alloys, in which he had been particularly interested, but he believed certain troubles had occurred in propellers using alloys of somewhat similar structure where, for no apparent reason, the whole of the blade had broken off. He had recently manufactured some large propellers for Japanese battleships, of turbadium, which weighed, in their finished state, 13½ tons each. One test-piece had been taken from each blade and one from the boss. The elastic limit of all the test pieces actually taken from the first of these propellers was 21 tons, the ultimate strength averaged 41 tons, and the average elongation 20%, which was a good result with a copper-zinc alloy. In the case of these alloys there was not the breakdown at the yield point that there was in steel, but the elastic limit was defined as such a stress as would produce a permanent set of 0·003 in. Since making these propellers he had made a smaller propeller of a β-type of alloy, but arrived at in a different manner from turbadium, the object being to get a little more stretch or ductility in the alloy. In this case the test piece taken from the propeller showed an elastic limit of 18 tons, an ultimate strength of 38 tons, and 27% elongation, with a cold bend test on a 1 in. square bar between 12 in. points of support of over 90° without fracture. With regard to the propellers of the "Mauretania" and "Lusitania," he thought they were inclined to give a little too much credit to the alloy. The original propellers on both these vessels had been of the built-up type, *i.e.*, the blades had been cast separately and bolted on to the boss, so that the external conditions would be rather worse than in the solid propeller. The design of solid propellers eventually adopted was very different, and it was a little difficult when comparing the results in resisting erosion to say how much credit was due to the alloy and how much to the altered design of the propeller. In the case of the Tribal class of destroyers built about 1910, propellers had been made of exactly the same design, some of ordinary manganese bronze and some of turbadium, and the great advantage in having the β-type of alloy, from the point of view of resisting erosion, had been evident. There was still some slight erosion, but it was very difficult to produce an alloy which would have the necessary mechanical properties to withstand the arduous service of a propeller in constant work, where there were very many stresses introduced, especially in the case of light-draught boats, like destroyers, and at the same time be the best structure to resist erosion. In the case of the "Hood," for instance, the finished weight of each propeller was about 19½ tons, and in the actual manufacture 30 tons of metal had to be dealt with. It would therefore be realised what a very big problem it was to produce an alloy which would meet all the mechanical tests and at the same time satisfy the very arduous conditions of propeller running and also offer a high resistance to erosion.

Mr. H. **Talbot** said that the author had brought out two points which, in his (the speaker's) opinion, were almost conclusive evidence in favour of the mechanical explanation. The first was the existence of what was practically a critical velocity of erosion, above which the rate of deterioration was especially marked; the second was the fact that equally resistant alloys contained metals of the same chemical family in proportions which had no connexion with their chemical combining weights.

Dr. **Silberrad**, in replying, said that he quite agreed with the observations respecting the influence of altering the shape and design of any given propeller on the position and nature of erosion produced; indeed the observance of such cases had contributed very materially to the classification of the different types of erosion. With regard to the tendency of homogeneous β-alloys to solidify in large crystals, very little seemed at present to be known about the particular combinations which influenced this. Cases where alloys on solidification formed crystals as much as two inches long and several pounds weight had come before his notice, and in such cases, as a rule, a very slight alteration in composition had been found to cause the alloy entirely to change its properties in this respect. In that case the alloy was very easily broken, not with one single hit, but when subjected to continuous vibration. One of his exhibits was a sample from a propeller made of an alloy which showed this tendency; it had broken off short in use. By taking Guillet's equivalents it was possible to predict the influence of various metals on the alloy to some extent and thus obtain satisfactory mechanical results. He was never able, however, to get any idea at all as to what effect an alteration in composition would have on the tendency to form large crystals. That appeared to resolve itself into a question of trial and error, and the experiments ran into hundreds before the final results were obtained. But actual experience had proved that the crystals should not be too large, and further, the presence of small α crystals which could be regarded as embedded in the β solid solution was advantageous. Such an alloy would resist erosion almost as well as a pure β alloy and at the same time had the advantages of an α alloy, which was able to stand fatigue better. Moreover, this alloy of mixed structure could be handled much better in the foundry. Propellers in use get knocked against dock gates and hawsers, and thus not infrequently suffered severe damage, to repair which was much more troublesome in a pure β alloy than in the case of an alloy of mixed α β structure.

Another difficulty which took a good deal of overcoming was that of determining in what proportions the various ingredients for any given alloy should be taken in order to produce the desired composition when making comparatively large castings; for in operations of the type here dealt with it was no uncommon thing to have to run 20—30 tons of bronze at once, and when it was realised that alloys of this type alter in composition through loss of zinc, oxidation of manganese, and elimination of aluminium the whole time that they were in the reverberatory furnace and whenever they came into contact with air it would be seen that it was not easy so to adjust things as to arrive at an alloy varying not more than 0·1% or at most 0·2% in zinc, or an equivalent quantity of one of the substituting metals, which in the case of aluminium meant working to within ⅙th of 0·2%. But these difficulties, like most others, had given way before persistence. The problem had started by being apparently a fairly simple one, because he had expected merely to find chemical corrosion, but, as the paper showed, this was far from being the case, and the work had involved something like 12 years' research.

MR. J. H. HOSEASON IN THE CHAIR.

THE PREPARATION AND PROPERTIES OF 1.3.5-TRINITROBENZENE.

BY L. GUY RADCLIFFE, M.SC.TECH., AND ALAN A. POLLITT, M.SC.TECH.

The preparation of trinitrobenzenes presents interesting features in the light of the use of 1.3.5-trinitrobenzene as an explosive, but the literature relating to this subject is rather meagre, and for this reason the following research was undertaken.

Over a year ago experiments were made by one of us having for their object the determination of the conditions under which 1.3-dinitrobenzene could be further nitrated to form the trinitro derivative. In general, successful nitrations resulted in the production of the well-known 1.3.5-isomer, m.p. 121° C., but occasionally a trinitrobenzene of m.p. 61° C. was obtained, and this was at first thought to be the 1.2.4-compound described by Hepp (Annalen, **215**, 362) and Lobry de Bruyn (Rec. Trav. Chim., **9**, 190), though this compound is stated to melt at 57·5°.

It was soon found that this result could not be repeated at will, and numerous carefully conducted

---

* Publication of this paper was deferred at the request of the Ministry of Munitions.

experiments have so far entirely failed to establish the conditions under which the trinitrobenzene of m.p. 61° can be produced.

A study of the properties of this new trinitrobenzene has caused us to modify the opinion that it was 1.2.4-trinitrobenzene, inasmuch as it has been found possible to convert the compound melting at 61° into the ordinary symmetrical 1.3.5-trinitrobenzene, m.p. 121°, by several simple methods. The facts appear to favour the assumption that 1.3.5-trinitrobenzene can exist in two forms which differ widely in their melting points. Hepp (Annalen, **215**, 345) obtained 1.3.5-trinitrobenzene of m.p. 121°C. by heating 40 g. of 1.3-dinitrobenzene with a mixture of 300 g. of crystallised, fuming sulphuric acid and 120 g. of highly concentrated nitric acid (the exact strength of each is not stated), at first for one day at 80° C., and then for a further period of two days at 120°. The product was isolated by pouring the mixture into cold water, collecting the precipitate and washing it, first with water and then with dilute sodium carbonate solution, and finally crystallising the product from alcohol. Darst made the same substance by a very similar method.

Claus Becker (Ber., **16**, 1597) obtained 1.3.5-trinitrobenzene from 2.4.6-trinitrotoluene by heating it to 180° with fuming sulphuric acid, carbon dioxide being evolved during the process. Furthermore, the same trinitrotoluene can be oxidised to trinitrobenzoic acid, and this latter when heated with water yields trinitrobenzene.

EXPERIMENTAL.

Symmetrical or 1.3.5-*trinitrobenzene.*

In the earlier attempts to prepare this substance mixtures of fuming nitric acid and fuming sulphuric acid (up to 60% SO_3) were used, but even with a large excess of nitric acid and prolonged times of heating the dinitrobenzene was not nitrated. Further experiments were made with 100% nitric acid prepared by distilling a mixture of the 95% acid with 26% oleum. In the first of these nitrations 25 g. of dinitrobenzene was dissolved in 50 g. of oleum (26% SO_3) and 20 g. of nitric acid (approximately 1½ mols. excess) added in small quantities at a time, the flask being kept cool during the mixing. The mixture was then gently heated for three hours at 110° C. in a wide-necked flask over a small flame and appeared to boil gently. The product was poured into water, washed, and crystallised once from alcohol; it formed plates or leaflets, m.p. 61° C., which proved on analysis (*cf. infra*) to contain 99·8% of trinitrobenzene. A 30% yield of the new compound was obtained. On repeating this experiment, using larger quantities, the product melted at 121° C., and was the ordinary symmetrical trinitrobenzene. Another experiment was made in which the quantities were 50 g. of dinitrobenzene, 75 g. of nitric acid (100%), and 125 g. of oleum (26% SO_3). The two acids were mixed and heated to 110° C. and the powdered dinitrobenzene added gradually over a period of 1½ hours, after which the mixture was heated for a further 6½ hours at 110°—120° C. The product was isolated as usual, and on crystallising from alcohol plates of the *s*-trinitrobenzene, m.p. 121° C., were obtained; analysis indicated 100·2% of trinitrobenzene, the yield being 45% of the theoretical. In an attempt to increase the yield the same quantities as in the last experiment were used, and up to the completion of the addition of the dinitrobenzene the method of procedure was the same. At this point, however, a further quantity of mixed acids was added, consisting of 50 g. of oleum (26% SO_3) and 35 g. of the nitric acid; the mixture was maintained at 110°—120° C. for 6½ hours, as in the last experiment. A 56% yield of trinitrobenzene, m.p. 121°, resulted, its purity corresponding to 99·97% trinitrobenzene.

A repetition of this method, using oleum containing 60% of SO_3, in place of the 26% oleum, gave a yield of 60% of the usual *s*-trinitrobenzene; moreover, the time required was reduced to a total of 6 hours. In these experiments it was observed that a considerable quantity of the nitric acid was being lost by escaping from the flask, and therefore further nitrations were conducted under a reflux condenser, with the result that the loss of nitric acid was to a large extent prevented and the yield of *s*-trinitrobenzene slightly increased, *viz.*, to 63%. Another series of experiments was made in which the reflux condenser was used, and, in addition, the reacting mixture was mechanically stirred throughout the experiment. In the first stage 50 g. of dinitrobenzene, 75 g. of nitric acid (100%), and 125 g. of oleum (60% SO_3) were used, followed by 50 g. of oleum (60% SO_3) and 35 g. of nitric acid (100%); working under these conditions a yield of 71% of *s*-trinitrobenzene, m.p. 121°, was obtained.

It has not been found possible to improve on this yield, as the use of higher temperatures increases the risk of the reaction getting beyond control, and if the time of the nitration is increased beyond about eight hours there is a reduction in the yield due apparently to the oxidation of the nitro compound.

At this stage it will be convenient to describe the nitrations which yielded a trinitrobenzene of m.p. 61°. In one experiment 25 g. of dinitrobenzene was dissolved in 50 g. of 26% oleum, 20 g. of 100% nitric acid was slowly added, and the resulting mixture heated for three hours at 110°, the product isolated melted at 61°, and analysis showed it to be a pure trinitrobenzene. The experiment was repeated several times, in detail, but on each occasion the resulting compound was pure *s*-trinitrobenzene, m.p. 121°, and numerous other nitrations failed to give the compound of m.p. 61°.

In an attempt to effect an economy in the amount of nitric acid used in the above method 45 g. of dinitrobenzene was dissolved in 125 g. of oleum (26% SO_3), 20 g. of nitric acid (100%) added, and the mixture heated for three hours at 110°. On isolating the product, 26% of trinitrobenzene, m.p. 61°, purity 99·89%, was obtained, but again the repetition of the experiment gave the compound melting at 121°. These methods were frequently repeated and only very occasionally gave a product melting at 61°.

The failure to reproduce the experiment giving the compound melting at 61° seemed to indicate that some accidental trace of a catalyst might be causing its occasional formation, and therefore the effects of certain possible catalysts were tried, using the same conditions and quantities as in the two experiments just described.

First, a small quantity (0·5 g.) of flowers of sulphur was added to the nitration mixture, but beyond giving a slightly better yield of the ordinary *s*-trinitrobenzene it had no effect. Additions of ferric oxide, manganese dioxide, and urea produced no visible effect, the product being always the compound melting at 121°. It seemed possible that the presence of a trace of a reduced nitro compound, such as a nitraniline, might influence the nitration; to test this dinitrobenzene was mixed with a small quantity of sodium bisulphite before dissolving in the oleum, but this had no effect.

Whilst discussing the effect of catalysts the following interesting observation was made with regard to the effect of light on nitration. At a certain period it was found that the yields were not so good as usual. It was thought that as the windows of the laboratory had been darkened, at the request of the military authorities, by being covered with a blue wash, this subdued light might be the cause of the diminished yields, and when further nitrations were carried out in front of the open window and in direct sunlight the original yields were obtained.

Another series of attempts was made to prepare the trinitrobenzene melting at 61° by using different strengths of oleum ranging from 20 to 60% SO_3, increasing the strength each time by 10% SO_3, the quantities being 25 g. of dinitrobenzene, 20 g. of nitric acid (100%), and 100 g. of oleum. In each experiment the nitric acid was added to the solution of dinitrobenzene in oleum and the mixture heated under a reflux condenser for three hours at 110°—120° C., with continuous mechanical stirring The experiments gave without exception the variety melting at 121°, and the yields, though increasing with the strength of the oleum, varied very slightly. All manner of variations of these methods were tried, but in no case was the compound of m.p. 61° C. obtained. With the higher strengths of oleum it is not safe to exceed 120° C., especially when using a reflux condenser, as control over the reaction is very easily lost, but when using 20% or 30% oleum a temperature of 150° C. may be safely employed; furthermore, increasing the time beyond a certain limit causes loss of material and diminution in the yields.

It was now decided to alter still further the conditions of nitration, and with this object ordinary concentrated sulphuric acid (96% H_2SO_4) was used and sufficient phosphoric anhydride to take up the water in the sulphuric acid and also that produced during the nitration, with an additional 10% in excess of this theoretical amount: 37 g. of phosphoric anhydride was dissolved in 50 g. of sulphuric acid and 20 g. of dinitrobenzene dissolved in this mixture; the resulting solution was heated to 110° in an open flask and 12 g. of 100% nitric acid added from a tap funnel. After the addition of all the nitric acid the contents of the flask were heated for 3 hrs., attaining a maximum temperature of 150° C. after 1½ hrs., and maintaining this for the remainder of the time; no nitration occurred. A further 8 g. of nitric acid was added and the mixture again heated at 150° for a further 2 hrs.; a yield of 25% of *s*-trinitrobenzene, m.p. 121°, was obtained.

The experiment was repeated, starting with 20 g. of nitric acid instead of the 12 g. used at first in the previous attempt; the acid was added in three instalments of about equal volumes, the mixture being heated for 1 hr. to 130° after the first addition, for 1 hr. to 135° after the second, and for 3 hrs. to 150° C. after the third. This temperature was maintained for the remainder of the nitration. Although this method differs only slightly from the previous one, yet on isolating the product a yield of about 30% of the trinitrobenzene of m.p. 61° was obtained; analysis showed it to have a purity of 100·3%. During the nitration an oily layer formed, which solidified on cooling. It contained all the trinitrobenzene admixed with a very little unchanged dinitrobenzene, whilst the solid isolated from the residual mixed acid consisted almost entirely of unchanged dinitrobenzene. The formation of this oily layer has been observed in all the experiments in which phosphoric anhydride was used, no matter whether the compound produced melted at 121° or 61° C. This experiment was repeated exactly as detailed above, and again a 30% yield of the trinitrobenzene of m.p. 61° was obtained. Further repetitions, however, gave the compound of m.p. 121° C., and it has not been found possible to obtain further quantities of the compound of m.p. 61° C. by this method. No reason is advanced in explanation of these failures.

For the analysis of the products Knecht and Hibbert's method (see "New Reduction Methods in Volumetric Analysis." Longmans) was used, the trinitrobenzenes being dissolved in alcohol, reduced with titanous chloride solution, and the excess of the latter estimated by titration with iron alum.

The two varities of trinitrobenze are very similar in colour, being almost white, and both crystallise from alcohol in plates or leaflets made up of needles. Both forms are much less soluble than *m*-dinitrobenzene in alcohol; on crystallising the product isolated from a nitration, the first crop of crystals is almost pure trinitrobenzene, and by removing the second crop as soon as needles of dinitrobenzene begin to appear, a product is obtained which when once recrystallised is pure trinitrobenzene. This method of separation and purification is still easier if carbon tetrachloride is used instead of alcohol; the trinitrobenzenes are difficultly soluble in the former, whilst dinitrobenzene is comparatively very soluble. The trinitrobenzenes are easily soluble in ether and acetone and very soluble in benzene; both varieties are very slightly soluble in hot water and insoluble in cold water. The trinitrobenzenes dissolve in ammonia and caustic alkalis giving a deep red coloration, which is discharged by acids; they are not immediately affected by sodium carbonate or bicarbonate, but react slowly, producing a deep wine-coloured solution. The modification melting at 61° reacts with sodium bicarbonate in alcoholic solution much more slowly than does the variety melting at 121°. The colour is due to the formation of salts. By careful heating the ordinary form, m.p. 121°, may be sublimed, but it has not been found possible to sublime the variety of m.p. 61°.

With a view of establishing the constitution of the compound melting at 61°, the addition compounds of the two trinitrobenzenes with aniline were prepared. The molecular compound formed by adding aniline to the 1.2.4-trinitrobenzene, of m.p. 57·5°, is a red crystalline substance, m.p. 84°, whilst that obtained from 1.3.5-trinitrobenzene, of m.p. 121°, is also in the form of light red crystals of m.p. 124°. The aniline compound of the two trinitrobenzenes melting at 121° and 61°, as prepared by us, was made by adding aniline to each of the compounds and recrystallising the products from benzene; in both cases light red crystals were obtained, and from each variety the compound had the same melting point, viz., 124°. This remarkable result, wherein two compounds of widely different melting points gave an addition product with aniline having exactly the same melting point, dispersed the idea that the compound melting at 61° was 1.2.4-trinitrobenzene. On regenerating the trinitrobenzenes from the aniline-addition compounds by means of dilute hydrochloric acid each compound gave the same variety of trinitrobenzene, m.p. 121°. In this way the remarkable fact, that the trinitrobenzene melting at 61° could be converted into the well-known variety melting at 121°, was established. J. J. Sudborough (J. Chem. Soc., 1901, 522) has described the addition compounds of *s*-trinitrobenzene (m.p. 121°) with α- and β-naphthylamine and their resolution by means of acetyl chloride. We have prepared the naphthylamine compounds of the trinitrobenzenes of m.p. 121° and 61° C., and find that both these varieties give a compound with α-naphthylamine having m.p. 214° and with β-naphthylamine, m.p. 162°—the same figures as given by Sudborough. The trinitrobenzenes obtained by decomposition of these addition compounds melted at 121° C. in each case. These remarkable results lead to the conclusion that two forms of *s*-trinitrobenzene exist, and that the less stable form melts at 61° and is converted by simple reactions into the stable form, m.p. 121° C.

The conversion of the less stable into the more stable form was not accomplished by adding a crystal of the ordinary *s*-trinitrobenzene to a saturated alcoholic solution of the compound of m.p. 61°, but when equal volumes of the saturated solutions in alcohol of the two varieties were mixed and then fractionally crystallised only a compound of m.p. 121°—122° could be obtained. Heating the compound of m.p. 61° for some time just above its melting point, either alone or in strong sulphuric acid solution, failed to bring about the conversion into the ordinary variety.

The molecular weights as determined by the Landsberger-Walker method, using acetone as solvent, were identical for both varieties, corresponding to a trinitrobenzene. The two varieties of trinitrobenzene were separately reduced with the calculated amount of strong titanous chloride solution and excess of hydrochloric acid in quantities sufficient to give a dinitroaniline from each of them; each variety yielded the same dinitro-aniline, in the form of bright yellow needles, m.p. 159°. Bader (Ber., 24, 1654) obtained 3.5-dinitro-aniline as yellow needles, m.p. 159°, by reducing 1.3.5-trinitrobenzene with ammonium sulphide; we have also reduced the two varieties of *s*-trinitrobenzene by the same method and obtained 3.5-dinitro-aniline, but the yield is not so good as that obtained by reduction with titanous chloride.

The nitrophenylenediamines and the triaminobenzenes were also prepared from each variety of the trinitrobenzene; the products appeared to be identical in each case.

From the above experiments there appears to be little doubt that *s*-trinitrobenzene can exist in two forms, and that one form is less stable than the other; it has not been found possible to control the conditions under which the less stable form is occasionally produced, but further investigations are in progress, and it is hoped that these points will soon be cleared up. In conclusion we desire to express our thanks to Mr. S. Medofski, B.Sc.,Tech., for his assistancce in some of the later parts of this work.

ADDENDUM.

Since reading the above paper the behaviour of trinitrobenzene melting at 61° and 121°, respectively, has been determined according to the method suggested by N. V. Sidgwick (Chem. Soc. Trans., 1915, **107**, 672), and we are indebted to S. Medofski, B.Sc.,Tech., for carrying out the experiments recorded below. Benzene was used as the solvent and its freezing point was determined, then the trinitrobenzene melting at 61° was added until the freezing point, which at first fell steadily, was constant. The trinitrobenzene melting at 121° was then added and the freezing point again determined. The depression of freezing point by trinitrobenzene of m.p. 61° was 2·474° (solubility 85·0 g. per litre), and the depression by the mixture of trinitrobenzenes, m.p. 61° and m.p. 121°, was 2·468°. It is evident, therefore, that the concentration of the solution has not increased by the addition of the compound melting at 121°, and that, according to Sidgwick, the forms are polymorphic.

THE RELATIVE ACTIVITY OF VARIOUS ALLOTROPIC FORMS OF SULPHUR TOWARDS CAOUTCHOUC.

BY D. F. TWISS AND F. THOMAS.

The investigations in recent years of the allotropic forms of sulphur capable of existence within the range of temperature used in ordinary vulcanisation, naturally prompt enquiries as to a possible difference in the activity of these various modifications of the vulcanising agent. The forms most likely to be involved are (*a*) $S\lambda$, the modification represented by ordinary crystalline sulphur, (*b*) $S\mu$, the insoluble modification constituting part of genuine "flowers of sulphur" and corresponding with the viscous constituent of molten sulphur, and (*c*) $S\pi$, a more brightly coloured and more soluble variety, present in a small proportion with much $S\lambda$ in the equilibrium mixture yielded by ordinary sulphur at temperatures a little above its melting point; the proportion of $S\pi$ increases markedly if the temperature is raised to 140° or higher (Aten, Z. physik. Chem., 1912, **81**, 257; 1913, **83**, 442; **86**, 1. Proc. K. Akad. Wetensch., Amsterdam, 1918, **20**, 824).

Tests made with mixtures of rubber with soluble sulphur ($S\lambda$) and insoluble sulphur ($S\mu$) respectively, under ordinary technical conditions, indicate that the vulcanising effect of these two varieties is practically the same (Twiss, Annual Reports of the Progress of Applied Chemistry, 1919, **4**, 327); this result, however, is probably to be attributed to the rapid change of $S\mu$ at such temperatures into the equilibrium mixture consisting mainly of $S\lambda$ with some $S\pi$ (Beckmann and others, Z. anorg. Chem., 1918, **102**, 201; **103**, 189).

Between 128° and 168° C. the temperature coefficient of the chemical reaction between rubber and sulphur, *i.e.* the proportion by which the rate is increased on raising the temperature 10° C., is surprisingly constant, and in view of the alteration of the composition of the equilibrium mixture with rise of temperature, the comment has been made that this is indicative of comparable vulcanising capacity on the part of the modifications present (Twiss and Brazier, J., 1920, 125 T).

Although the difference observable between the forms of sulphur naturally existent at ordinary vulcanising temperatures is thus shown to be relatively slight, it must be remembered that under such conditions the sulphur will undergo fusion and then rapidly yield the equilibrium mixture. If the temperature could be maintained much lower, the rate of attainment of equilibrium could be reduced and the increased persistence of each form would afford greater opportunity for observing any difference in vulcanising capacity. The use of a suitable vulcanisation catalyst, *e.g.*, aldehyde-ammonia, enables experiments to be made at a sufficiently low temperature. It is a little unfortunate that the powerful organic catalysts generally should be basic substances such as also tend to catalyse the mutual inter-conversion of the sulphur allotropes, but, as is demonstrated by the results now submitted, the disturbance from this direction is not sufficient to mask completely the sought effect.

In the first set of experiments the varieties of sulphur used were (*a*) a high grade finely powdered sulphur soluble in carbon bisulphide and consisting entirely of $S\lambda$, and (*b*) an extracted sublimed flowers of sulphur 93% insoluble in carbon bisulphide and consisting mainly of $S\mu$. Mixtures were made of each of these with selected pale crêpe rubber of known rate of vulcanisation; the composition in each case was rubber 90 parts, sulphur 10 parts, and aldehyde-ammonia 1 part. In order to ensure as closely comparable composition and conditions as possible, the sulphur in both cases was first mixed with an equal weight of the rubber and the composition of each stock checked before introducing the correct amount of each into the final mixtures. Similarly the aldehyde-ammonia was first mixed with 9 times its weight of the rubber so as to increase the accuracy with which equal proportions of this "stock" could be introduced into the two batches of equally "worked" rubber. Vulcanisation was effected, with the two mixtures simultaneously, at 98°, 108°, and 118° C. Figure 1 shows the rate of vulcanisation as indicated by the gradual reduction in extensibility of the two mixtures at the respective temperatures; the transverse dotted lines mark the approximate position of the "optimum tensile strength" where this was observed. Figures for combined or residual free sulphur are not given because their satisfactory determination in the ordinary way is impossible in the presence of $S\mu$ (see Twiss, J., 1917, 789).

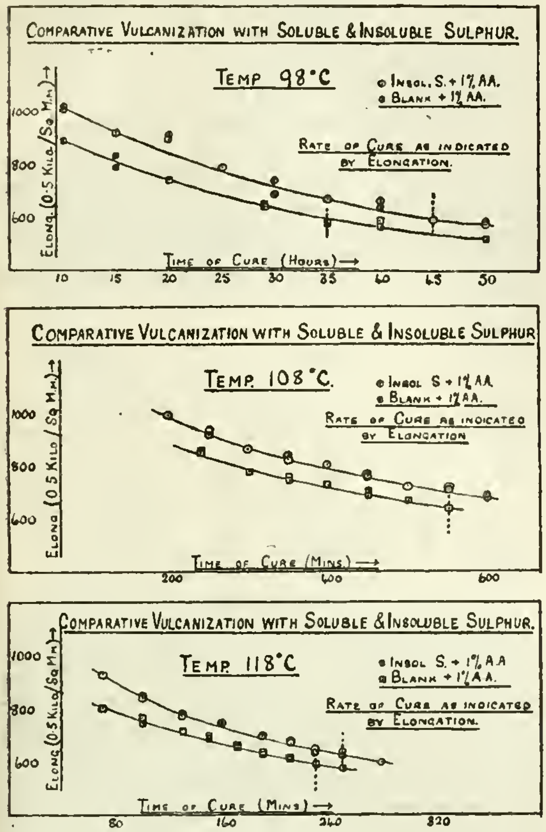

Fig. 1.

It will be noted that under the conditions of these experiments the vulcanising effect of $S\mu$, particularly at the lowest temperature, is definitely inferior to that of $S\lambda$.

Taking an extensibility of 700% as a standard for comparison, the difference in the rate of vulcanisation of the two mixtures is clearly seen from the respective periods required, and the more rapid conversion of $S\mu$ into $S\lambda$ with rise of temperature is reflected in the corresponding decrease in the temperature coefficient.*

	Rate of vulcanisation.				
	$S\mu$ (93%).		$S\lambda$.		
	Time required.	Temp. coefft.	Time required.	Temp. coefft.	Relative effect, $S\mu : S\lambda$.
98° C.	32 hours	—	23 hours	—	1 : 1·4
108°	550 mins.	3·5	440 mins.	3·1	1 : 1·3
118°	185 mins.	3·0	140 mins.	3·1	1 : 1·3

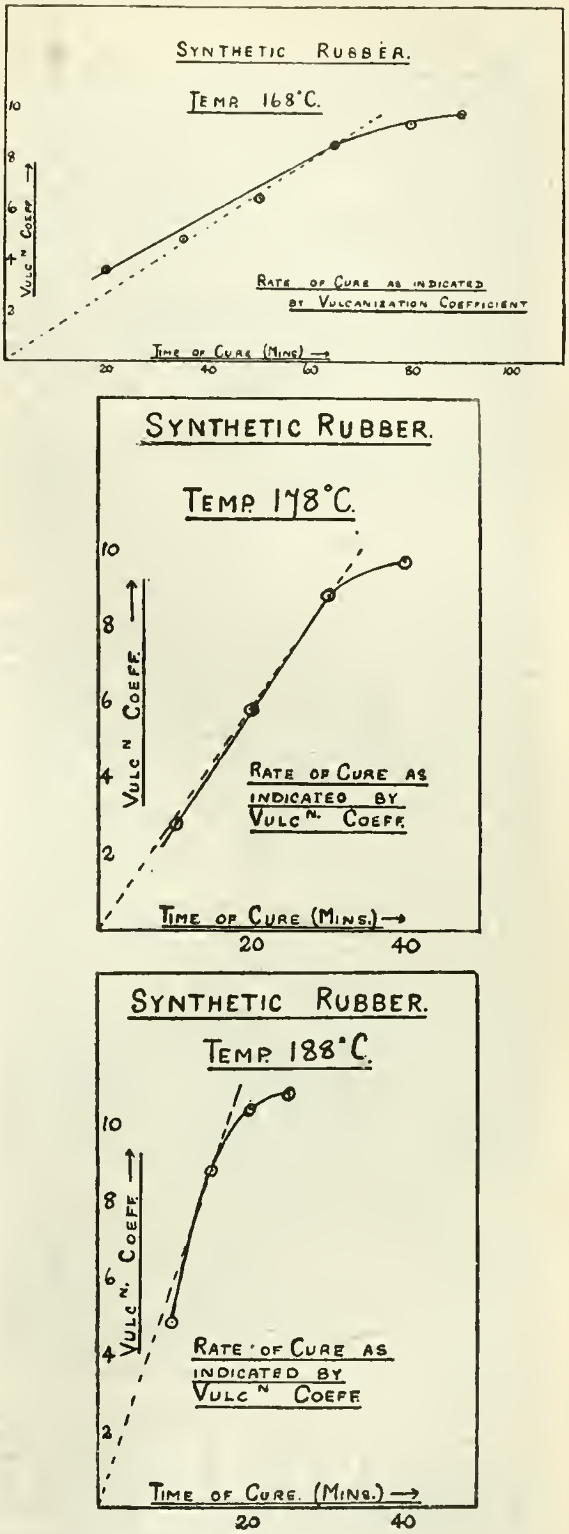

Fig. 2

An experiment with similar mixings of the same rubber and two forms of sulphur in the same proportions, but without the catalyst and at 148°, confirmed the earlier observations (Twiss, *loc. cit.*) as to the closely comparable effectiveness of the $S\mu$

---

* In these experiments vulcanisation was effected uninterruptedly for the full periods, the temperature of the oil bath being maintained constant for the whole of the time. The greater value of the temperature coefficient obtained previously with $S\lambda$ for the interval 98°-108° C. (Twiss and Brazier, *loc. cit.*) is to be ascribed to the fact that the earlier experiment at 98° C. was made in two stages, with the result that the vulcanisation would be retarded somewhat on account of the partial separation of sulphur from solution in the rubber half-way through the experiment.

and Sλ at this temperature, the relative effectiveness calculated in the same way as above being 1:1·06.

These results as a whole demonstrate that at the ordinary vulcanising temperatures, *e.g.*, 148°, Sμ changes so rapidly into Sλ that no appreciable difference can be detected in the rate of vulcanisation, the effect in each case being that actually produced by Sλ. At lower temperatures it is possible to detect a distinctly feebler effect in the mixture containing Sμ. The possibility that this difference may be characteristic not of Sμ but of Sπ, which is formed together with Sλ from the less stable Sμ at such temperatures, is hardly in accord with the almost identical effect observed at 148° C. (see above) and with the results given below. In all likelihood therefore the difference arises from the Sμ itself and is probably not explained completely by the lower solubility of this form of sulphur.

From the constancy of the temperature coefficient of the reaction between ordinary sulphur and rubber at 138°—168° C., over which range Sλ gives rise to an increasing proportion of Sπ, it would appear that Sπ and Sλ are of almost equal activity in this direction. This result is of interest in view of Aten's observation (Z. physik. Chem., 1914, 88, 321) that Sπ retards the action of Sλ on silver and mercury.

There appeared to be some hope of obtaining more evidence of the activity of Sμ relative to Sλ by making vulcanisation experiments with rubber at higher temperatures, at which sulphur is known to undergo a marked change in molecular complexity probably corresponding with a rapidly increasing proportion of Sμ in the equilibrium mixture (Beckmann and others, *loc. cit.* Kellas, Trans. Chem. Soc., 1918, 113, 903. Smith, Proc. Roy. Soc. Edin., 1905, 25, 588, 590; Smith and Carson, *ibid*, 1906, 26, 352). Unfortunately with ordinary rubber the chemical change accompanying vulcanisation would then be too rapid for convenient examination, and recourse was therefore had to the use of synthetic rubber which, as is well known, is relatively sluggish in vulcanisation; the sample used was of "methyl-rubber," *i.e.*, polymerised dimethylbutadiene, which was free from artificial catalysts and "elasticators." On account of the hardness of the vulcanised products obtained with such synthetic rubber, no physical tests were possible and the rate of reaction was followed only by the gradual disappearance of sulphur into combination. The composition of the original mixture was sulphur (Sλ) 10·4%, methyl-rubber 89·6%. Experiments were made at 168°, 178°, and 188° C., the results being as given in figure 2.

It is remarkable that the disappearance of most of the sulphur into combination appears to follow the approximately rectilinear course already observed with natural rubber (Skellon, Rubber Industry, 1914, 172; van Iterson, Comm. Netherland Gov. Inst. for Advising Rubber Trade, 1918, 7, 247); if, as suggested by van Iterson, this is due to autocatalysis it is evident that the non-caoutchouc constituents of natural rubber are not responsible.

The results are not quite as smooth as could be desired, but if comparison is made of the time required for the attainment of the various degrees of vulcanisation at different temperatures, the temperature coefficients in each case are greater for the interval 168°—178° than for 178°—188°.

The apparent slight increase in the temperature coefficient during the progress of the reaction appears to indicate the existence of a very brief initial period of greater reactivity. This may be due to the fact that the sulphur initially is composed practically entirely of Sλ, which rapidly undergoes conversion into the less active equilibrium mixture; it might, however, be caused by the presence in the synthetic rubber of a small proportion of some more active material. There is no such regular alteration observable in the figures calculated in a similar way from the experiments with ordinary rubber and sulphur at 138°—168° C. (Twiss and Brazier, *loc. cit.*).

A better comparison of the temperature coefficients is probably given by the ratio of the tangents of the angles included between the horizontal axis and the line (dotted in Fig. 2) between the origin and the point representing the end of the "rectilinear" course of the vulcanisation process. This method of comparison likewise shows a smaller increase in the rate of reaction for the second interval.

	Time (mins.).			Temp. coefft.	
Vulcan. coefft.	168°.	178°.	188°.	178°-168°.	188°-178°.
4	25	14	—	1·8	—
5	34	18	10	1·9	1·8
6	43	21	11	2·0	1·9
7	52	24	12	2·2	2·0
8	61	28	14	2·2	2·0
9	73	31	15	2·4	2·0
angle	33°	56°	71°	—	—
tan.angle	0·65	1·48	2·90	2·3	2·0

The smaller coefficient for the higher temperature interval suggests that the sulphur equilibrium mixture at the higher temperature is relatively less effective than the equilibrum mixture existent at the lower temperature; as the difference in the composition of the two equilibrium mixtures will be a smaller proportion of Sλ and a greater proportion of Sπ and Sμ at the higher temperature, and as the earlier considerations lead to the view that the effectiveness of Sπ is very little different from that of Sλ, it follows that the results again indicate a somewhat inferior vulcanising capacity for Sμ. It must be remembered, however, that the observed differences in such experiments, based on the relative activity of interchangeable modifications of a chemical substance, will be diminished by the tendency of the equilibrium automatically to adjust itself as the more active form disappears.

Although these results indicate a difference between the activity of Sμ and of Sλ or Sπ, the outstanding fact is not the existence of this difference but its relatively small magnitude. The three forms are of such diverse general characteristics that much greater differences might have been expected. Under the conditions of ordinary technical practice indeed, the possibility of alteration in the relative proportions of the various modifications of sulphur is not likely to form an appreciable disturbing factor in vulcanisation, and the only instance of any special form of sulphur (as such) showing special vulcanisation features appears to be that possibly involved in the recently discovered method of treating raw rubber with sulphur dioxide and hydrogen sulphide.

For the experiments recorded above, use was made of the very convenient oil-bath method of vulcanisation.

Meeting held at Burlington House on January 3, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE SMITH CONTINUOUS SYSTEM OF CARBONISATION.

BY GEORGE H. THURSTON, M.I.E.E., A.M.S.M.E.

The carbonisation of coal has been fully dealt with in this country but up to the present, so far as the author is aware, no complete description has been given of the system designed and perfected by Mr. Charles H. Smith, of New York, or of the plants constructed on this system and producing a smokeless fuel called "Carbocoal" at the rate of 550 tons per day. One of these plants situated at Irvington, New Jersey, has been in constant operation for the past two years.

The Smith continuous system is a combination of low- and high-temperature carbonisation, and the inventor has retained all the advantages connected with the high oil recovery in the former, and in addition has succeeded in increasing the yields of tar and sulphate of ammonia by means of the latter, at the same time producing a free-burning smokeless fuel that stands rough handling with a minimum of loss.

In order to obtain low operating costs on a carbonisation plant it is essential that the process should be continuous, and lost time reduced to a minimum. Full advantage must be taken of labour-saving machinery and manual labour eliminated as much as possible. To carry out this effectively necessitates the construction of a plant capable of dealing with at least 200,000 tons of coal per annum. The importance of these features is fully realised in the United States, and in the 150,000-ton carbocoal unit of the 1,500,000-ton plant built at Clinchfield, Va., for the International Coal Products Corporation of Virginia, to operate the Smith process, labour-saving devices are used to the utmost extent. This plant commenced producing in July, 1920, and is working smoothly.

An objection frequently raised to the fuel obtained from low-temperature carbonisation is its friability and bulk, which make its transport difficult and costly. "Carbocoal" is carried on the railways in the United States at the same rates as coal, and is not subject to these disadvantages.

In the Smith continuous system of carbonisation the coal, which is crushed to pass a ⅜ in.-mesh screen, is subjected to a primary carbonisation at a temperature of about 480° C. to reduce its volatile content to a uniformly low figure, whereby it is converted into a friable residue containing 7—10% of volatile matter, called "semi-carbocoal." The period of this process is 2—3 hours, and the operation is continuous.

After passing through the retort, the material is ground and mixed with a suitable percentage of pitch and briquetted. The briquettes, which contain about 15% of volatile matter, are then heated to 1000°—1100° C., which drives off all but 3 or 4% of the volatile content and leaves them firm and hard. The quality of the briquettes is influenced by the ash content of the coal, but since this is evenly distributed throughout the mass, the clinkering of the fuel during combustion is absent except when the ash has a very low fusion point, and it has been found that, although the coal loses 12% of its calorific value by carbonisation, the actual heating efficiency of Carbocoal—referred to the coal from which it is made—is 94%.

The tar recovered from the primary retort and by scrubbing the gas contains the usual oils and ammonium sulphate found in tar recovered by the low-temperature process. The yield, owing to the low temperature employed, is high, the actual quantity recovered and its value naturally depending on the constituents of the coal. The tar recovered from the secondary carbonisation contains a large percentage of heavy oil and pitch, and when distilled considerably increases the total yield of ammonium sulphate.

The gas produced in the Smith system varies in quality and quantity; that from the primary retort has a calorific value of 650—700 B.Th.U. per cb. ft., and the quantity distilled from a 35% volatile coal is between 5600 and 6700 cb. ft. per ton. In the secondary retort the gas has a value of 350—400 B.Th.U. and the yield is about 4480 cb. ft., or an average total of 10,630 cb. ft., with a calorific value of about 548 B.Th.U. In the present stage of development, the system, after supplying all the demands, furnishes a surplus of 2240 cb. ft. of gas.

Description of plant.

By referring to Fig. 1, which illustrates a typical flow diagram of a plant laid out to produce "Carbocoal" by the Smith continuous system of carbonisation, it will be seen that the coal is delivered into the track hopper or storage bin, *a*, and transported by means of the belt conveyer, *b*, to the hopper of the coal crusher, *c*, which reduces it to about ⅛ in. size; the fine coal is then raised by the elevator, *d*, and distributed by means of the conveyor belt, *e*, to the hoppers, *f*, which automatically feed the primary retorts, *g*, a detailed description of which will be given later (see also Figs. 2, 3, and 4). The black, friable, spongy mass formed in the primary retort is conveyed by means of the paddles in the retort to the discharge orifice, where it is deposited in pieces not over 6 in. in size in the water-jacketed discharge hopper, *h*, situated immediately below the retort. From this it is fed by the worm, *i*, to the conveyor, *j*, which transfers it to the storage bin, *k*.

The mass is then fed by means of a feeder conveyor, *l*, to the crusher, *m*, where it is broken up to ⅛ in. or less, after which it is raised by the elevator, *n*, to the mixer, o, in which it is mixed with 8—10% of its weight of liquid pitch, stored in the vessel, *r*. The mixture then goes to the "fluxer," where the two materials are intimately mixed in conjunction with steam which melts the pitch, and passes from there into a briquetting press, *q*, of the roll type. The raw briquettes are then passed to the storage bin, *u*, by means of a cooling conveyor, *t*. This conveyor is of sufficient length to enable the briquettes to be completely set by the time they arrive at the storage bin, and they are thus ready for the secondary carbonisation. Underneath the briquetting press is a second conveyor, *s*, for recovering the fines made from the press and returning them to the fluxer, so that only whole briquettes are carried to the storage bin. The briquettes are taken from the storage bin by means of a lorry car, *v*, and deposited in the secondary retort, *w*, where the final carbonisation is completed.

The high-temperature retort illustrated in Fig. 5 is a modification of the inclined gas retort; the modification consists of the compartments being made rectangular in place of the usual D shape; the retort has three compartments each containing two carbonising chambers that are charged and discharged by gravity.

The temperature to which the briquettes are subjected is approximately 1090° C., which expels practically all the volatile matter. The time occupied in this operation is about six hours per charge. The briquettes are then discharged by gravity into the car, *x*, transferred to the loading station by means of the track, *y*, and quenched with water, and are then ready for despatch.

The Smith retort.

The retort invented by Mr. C. H. Smith constitutes the most important link in the carbonisation system developed by him. The retort, which is cylindrical and about 18 ft. long, has an inverted heart shape (see Fig. 2). It is constituted of individual blocks of carborundum containing a special asbestos-packed tongue-and-groove expansion joint. Carborundum was selected after long and extended trials, in which retorts constructed of other refractory material and metal were used. When its heat-conducting and wearing qualities are taken into consideration it is considered to be the best material for the purpose that has been discovered up to the present. The end walls of the retort are of cast iron lined with firebricks and contain the necessary openings for the feed and the paddle shafts, which are parallel with the axis of the retort. The shafts pass through asbestos-packed stuffing-boxes, forming part of the cast-iron covers on the end walls, and are carried by substantial sleeve bearings. The paddles for stirring the material and moving it through the retort have a radius of 2 ft. 3 in., and the clearance between the end of the paddles and the carborundum muffle blocks is ¾ in. The paddles, which are bolted to the 12-in. shaft, are mounted alternately, so that each paddle wipes the opposite shaft, and its face is inclined sufficiently to push the material through the retort. The shaft makes one revolution in eight minutes, and the power required is 2 B.H.P. It has been found in practice that the speed can be considerably accelerated if it is considered desirable to stir up the coal to a greater extent. Under average operating conditions it is the practice to keep the retort about half full, which provides ample room for intumescence of the coal without interfering with its operation.

The feeding is accomplished by means of a single screw conveyor running in a closed pipe; the packing of the material is depended on for the necessary gas seal. The conveyor is driven by a motor, and the average power taken is about 5 B.H.P. The regulation of the feed is effected by starting and stopping the motor by means of contacts mounted on the paddle shaft gear wheel.

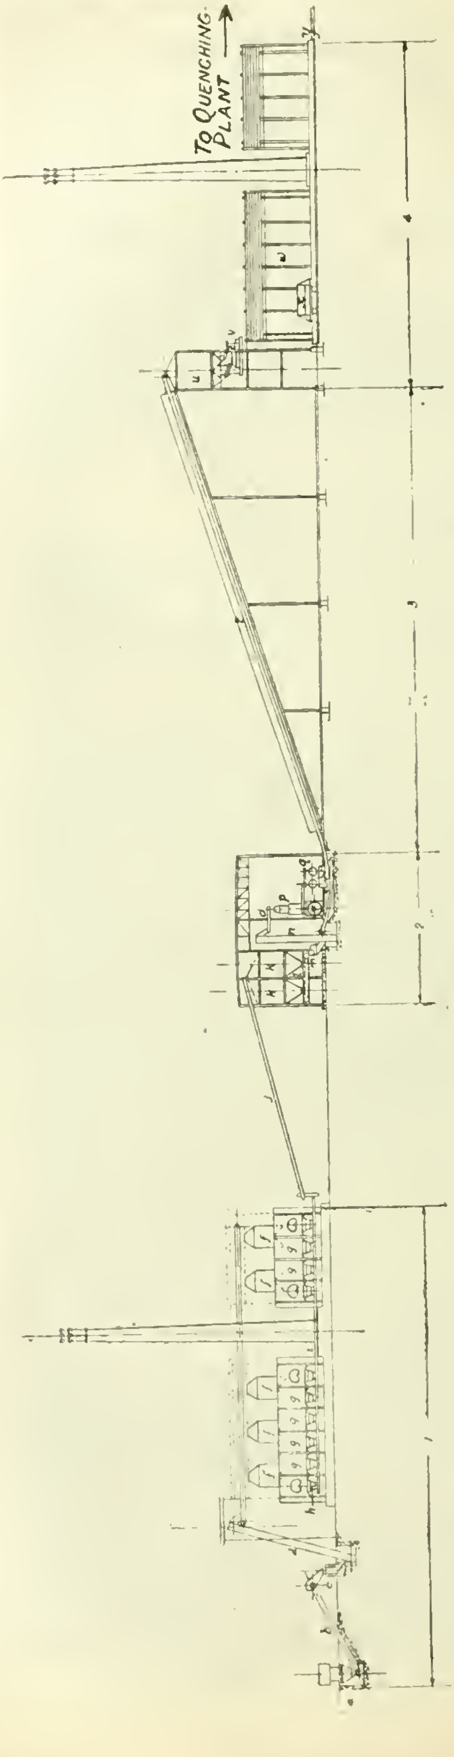
The apparatus for discharging the material is situated at the bottom of the retort, and consists of arms mounted on a revolving shaft, which serves to break up the product as received from the retort and deliver it in a suitable condition to a screw conveyor operating in a water-cooled pipe turned up at the end to form a gas seal.

Stripped gas is used for heating; the burners are placed in the flues of the brick setting surrounding the retort, which also contains the usual recuperative features for pre-heating the air by means of the heat in the waste gases. Sufficient heat is maintained in the retort so that the outgoing carbonised product has a temperature of about 480° C. When treating American coal containing 35% of volatile matter and 0·72% of moisture the retort has a capacity of one ton per hour.

Products of distillation.

The products of distillation pass out at the top of the retort and are not subjected to any increase in temperature, so that the tar obtained possesses all the characteristics of a low-temperature tar, and the yield is exceptionally good, as will be seen from the following results obtained from a ton of typical high volatile Pittsburgh coal:—

Briquettes.	Primary furnace.	Secondary furnace.	Total 70% dry.
Gas, cb. ft.	5600	4480	10,080
Tar (30% tar acids), galls.	22·4	5·6	28
Sulphate of ammonia, lb.	2·24	20	22·24



Carbocoal process—Flow diagram—Raw coal to finished briquettes.

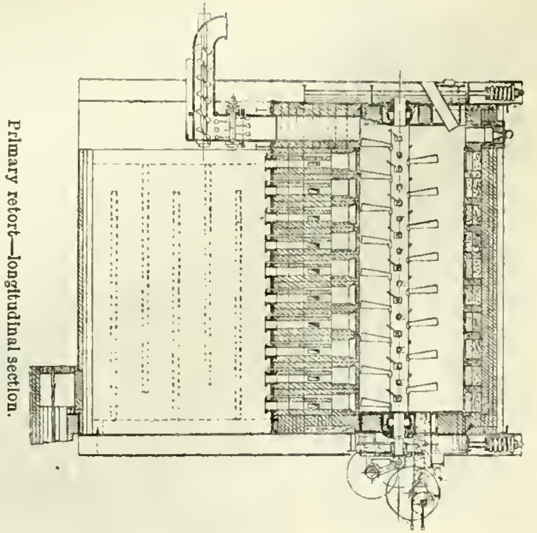
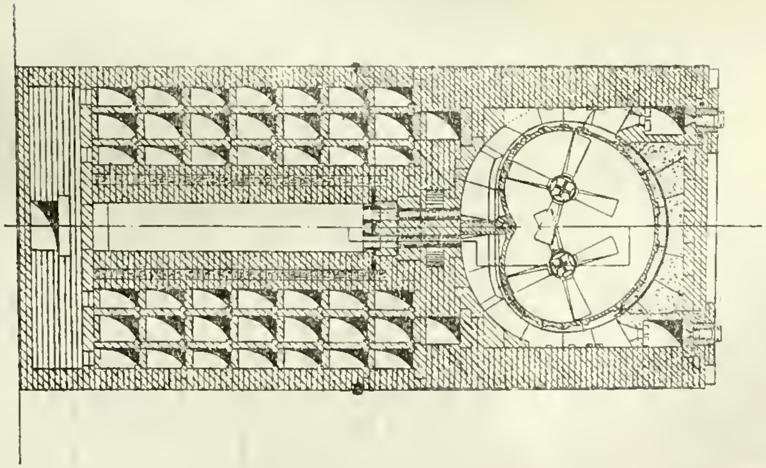
Fig. 1.



Primary retort—longitudinal section.

FIG. 2.



Primary retort—cross-section.

FIG. 3.

The 28 gallons of tar when distilled gives a yield of 18·6 gallons of distillate, the remainder being pitch, which is used in making the briquettes.

If, on investigation, it is found profitable to "crack" the tar into motor spirit, naphtha, tar acid, and fuel oils, this can be accomplished by the installation of the usual by-product plant. It is estimated that all the necessary heat and power required for the by-product plant will be furnished by the 2240 cb. ft. of surplus gas obtained from the carbonising process. The by-product plant is well known, and as it does not form an integral part of the plant it is not the intention to devote any further space to its description.

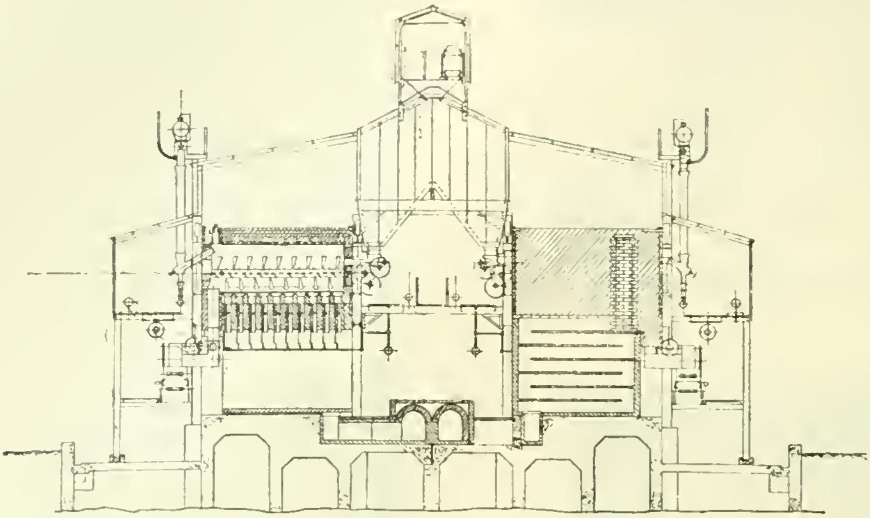
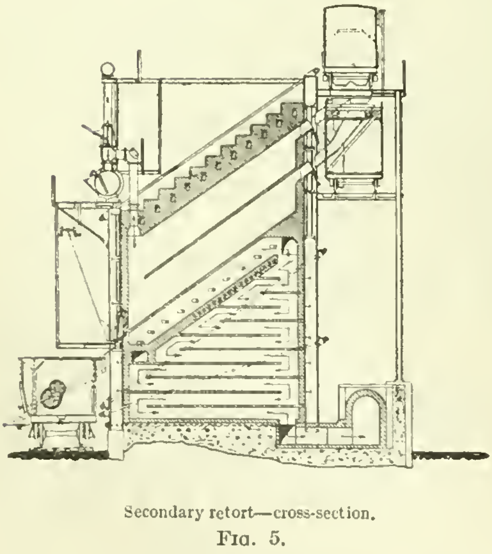
Pre-heating.

That the Smith retort is capable of dealing successfully with a great variety of fuels can be seen by referring to Table I., and there is no apparent reason why British fuel should present any greater difficulties than those already treated in the retort. It is obvious that the results obtained from the different kinds of fuel will vary, and that careful investigation is necessary before laying out a plant.



Primary retorts—general cross-section.

FIG. 4.



Secondary retort—cross-section.

FIG. 5.

The investigation may point to the necessity of washing the coal, with the possibility of having to subject it to preliminary drying for the purpose of driving off the moisture before being fed into the primary retort. To accomplish this a simple form of dryer has been designed by Mr. Smith. In this device the waste gases from the retort are passed through it on the way to the chimney. By means of this the moist coal is heated to 150° C., and the period of distillation in the primary retort is reduced proportionately. In addition a considerable amount of moisture is eliminated from the gas by this pre-heating, and as this does not have to be removed from the tar, the work performed in the more expensive unit is reduced to a minimum.

Use of Carbocoal in boilers, furnaces, and blast-furnaces.

Judging from the published reports of tests made by the United States Navy Department, carbocoal, when burnt in the furnace of a Babcock and Wilcox boiler, compared favourably with the coal from which it was made. The tests indicated that one pound of Carbocoal evaporated 9·09 lb. of water from and at 212° F., as against 9·59 lb. of water for the coal it was derived from. Similar tests were also made on a horizontal tubular boiler at the Fosdick Machine Tool Company's works. The fuels used were bituminous slack, having a calorific value (dry) of 14,120 B.Th.U., as against 12,470 B.Th.U. for carbocoal. The relative evaporation was 6·59 lb. and 7·34 lb. of water per hour from and at 212° F.

Carbocoal has also been tried with success in a locomotive. One very valuable feature of the briquettes is their great strength, which has been obtained without sacrificing their porosity. This feature enables the fuel to be roughly handled and transported long distances with a minimum of loss due to breakage. Recent tests have demonstrated that it has all the advantages of coal as a powdered fuel and at the same time is immune from spontaneous combustion. This, in addition to its occupying very little more space than an equal weight of coal, makes it an excellent bunker fuel for marine work. The hardness of carbocoal and its great strength when subjected to heavy pressure make it suitable for use in the blast furnace; this is of considerable importance, as it indicates that a fuel suitable for metallurgical purposes can be produced by means of the Smith system from coal which the coke oven is incapable of dealing with.

Tests to ascertain the crushing strength of carbocoal made by Messrs. Kalmus, Comstock and Wescott, Inc., Industrial Research Engineers, of Boston, U.S.A., in conjunction with Dr. Walter Runge, of the International Coal Products Corporation, indicate that the average crushing strength was 943 lb. per square inch at a temperature of 1400° C.; the crushing strength of coke at room temperature was 944 lb. per square inch. The apparent specific gravity of both carbocoal and coke was found to be 0·973 at room temperature.

Discussion.

Dr. W. R. **Ormandy** said that the plant described appeared to him to resemble the Del Monte retort with two stirrers instead of one, whilst the soft coke was made into high-temperature coke. As far as he could gather, in this process the gases given off by low-temperature distillation were added to those given off by high-temperature distillation, and a large amount of pitch was added to the coke. With the Del Monte process, in which a continuously moving worm was working in a sticky mass of good Durham gas coal, there would result a soft, friable coke, which would be very porous. If that coke were mixed with pitch and heated to 1090° C., there was strong presumptive evidence that a hard coke would result, which would probably stand the pressure of the blast furnace. The description of the Smith process led him to think that an effort was being made to claim the advantages both of low- and high-temperature distillation. If the process gave a hard coke this would not have the advantages which were attached to low-temperature coke, which would ignite readily and was an admirable fuel for ordinary household use. The harder coke might be better for metallurgical purposes, and would probably be very suitable for steam raising, and it would certainly be better for transport purposes. On the whole, however, it did not seem to him that there was a great deal of novelty in this beyond the attempt which had been forecasted by many writers, to get over the difficulty of the soft, fine coke produced by a really low-temperature process by briquetting it, and then reheating the briquettes in this semi-continuous process. It was interesting to find that, although the primary process was to be carried out at a temperature not exceeding 480° C., the inventor did not seem to have found that an iron retort was satisfactory, and had resorted to the use of carborundum. That material had been used years ago by Dressler for making the combustion tube of his continuous ceramic furnace; in this, however, it was used, with a similar sort of expansion joint, at a temperature of 1500°—1700° C., where a metallic material could not be used. He failed to see what advantage there was in the use of a carborundum tube in the place of an iron tube in the present system. It seemed to him also that the Del Monte system of taking the gas off from a number of points from the top of the retort was an advantage compared with using the carborundum retort with the gas exhaust at one end, so that the products of distillation were exposed for a much longer time to the temperature of the inside of the hot retort.

Dr. R. **Lessing** said that the process appeared to be working on a fairly extensive scale. He believed the American Government had given a grant in connexion with the plant. He agreed with Dr. Ormandy that there might be features of the process which could not be claimed to be novel, but to-day that was really not the question in low-temperature carbonisation. It was rather a question of applying well-known principles in a workmanlike fashion, and, what was more important, in a manner which was based on scientific investigations, because what was missing to-day was the scientific data on which plants could be constructed. Until these data were obtained in a great mass for any number of coals, and, what was equally important, he ventured to think, in connexion with the materials of which retorts had to be made, the progress which was desired would not be made. We knew next to nothing to-day of the conductivity of coals under the conditions under which large masses had to be carbonised, and it was this question of conductivity that was responsible for all the failures that had been experienced hitherto. They had to deal with a problem in which a great deal of heat had to be forced into a material which was less conducting than the coke or semi-coke obtained at high temperature, and this had to be done from a lower starting point in order not to decompose the material at the walls of the retort to the same extent as at high temperature. They had to deal, therefore, with a very much less steep heating gradient, and that was the crux of the failures hitherto experienced. Until these matters had been thoroughly thrashed out in a scientific manner there was very little hope of getting this problem really solved. On the other hand, there was not the slightest doubt that the problem was one worthy of solution, and any money spent in this direction, provided it was done on really scientific lines, ought to produce results of great economic value.

Mr. E. **Lawson Lomax**, referring to the quality of the oils produced by low-temperature carbonisation processes, said that all the advocates of these processes claimed to get so many gallons of oil per ton of coal carbonised. They did not, however, say what kind of oil it was nor whether it was free from water when measured. From his experience in handling these oils he had found that most of them were very difficult to refine, and also it was very difficult to get accurate readings of the quantities, owing to the fact that so much water was held in suspension. At the present time, and having regard to our present knowledge of the chemistry of these oils, they could not be classed as having any value except for fuel purposes, and therefore in most cases the values assigned to them by the advocates of the various processes were fictitious. The figure of 20 to 30 cents per gallon mentioned in connexion with the Smith process was a very high one for fuel oil to-day. A large amount of research work would have to be carried out on these oils before they could be refined profitably, and that work should be done before the processes were brought on the market.

Mr. E. B. **Edwards**, replying on behalf of the author, said that one of the differences between the Smith retort and the Del Monte retort was that the latter would not handle a swelling coal, whereas the Smith retort would handle coking or non-coking coals. The use of the carborundum linings was found necessary, owing to the high temperature in the heating flues; metal linings for the retorts would not withstand the temperature. By this process it was possible, by stirring the coal in the retort, to have a very high temperature in the flue and at the same time to have a low temperature in the retort itself. This gave a high capacity to the retort, which worked at the rate of 1 ton per hour continuously day in and day out. Another reason for the use of carborundum was its high conductivity. In reply to a statement by Dr. Ormandy, Mr. Edwards said that the fuel was now being used and sold in large quantities for the same purposes for which anthracite was used and had also been used in open grates and anthracite stoves in England. It was only after long scientific investigations and research work at the plant at Irvington, and based on its results, that the commercial plant at Clinchfield was erected. The trouble with low-temperature processes in England at the present time was that the processes were non-continuous, with the result that it was necessary to have low temperature in the flues, and it took about twelve hours to carbonise a charge of coal. The material must be agitated in order to release the gases and reduce the time of carbonisation; in America they were using a continuous retort in which the material was agitated by means of the paddles on the shaft. With regard to the question of the oils and their disposal, it was found in America that after distilling the tars, there was no difficulty in disposing of the oils. They had been able to get toluol and benzol by a very simple cracking process; in fact, the United States Government looked into the process during the war and gave a grant for the purpose of installing a cracking plant. It was proved that toluol and benzol could be manufactured to meet with the Government requirements for making TNT and picric acid.

Meeting held at Sydney on November 10, 1920.

MR. R. W. CHALLINOR IN THE CHAIR.

THE INFLUENCE OF SODIUM CHLORIDE AND SODIUM SULPHATE ON THE SOLUBILITY IN WATER OF SODIUM β-NAPHTHALENESULPHONATE.

BY W. TERNENT COOKE.

The two systems water—sodium β-naphthalenesulphonate—sodium chloride or sodium sulphate have been investigated over the temperature range 25°—65° C. at atmospheric pressure.

The sulphonate was made by heating together 1 g.-mol. of powdered naphthalene with slightly more than 1 g.-mol. of sulphuric acid (93% H_2SO_4) to 180° C. for 3—4 hours. After cooling, and diluting to about 1 litre, 2 g.-mols. of common salt was added dissolved in about 1 litre of water. The precipitated sulphonate was fractionally crystallised until free from sulphate and chloride. It did not melt below 275° C. and was quite neutral to litmus. The sodium sulphate was used in the anhydrous form; the sodium chloride was Kahlbaum's purest fused salt.

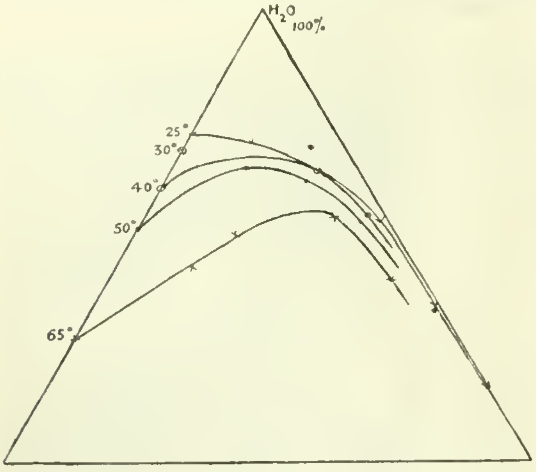

FIG. I.

The two thermometers used were found not to differ by more than 0·1° from standards in the laboratory. Up to 50° C. the temperature was kept within 0·1°, and at 65° to within 0·2°.

Weighed quantities (0·2—5 g.) of sulphonate and of either sulphate or chloride were mixed with 10 c.c. of water in small glass vessels which were immersed in a thermostat and agitated for about 24 hours. Samples of the liquid were then withdrawn through a small filtering plug of cotton wool into a pipette jacketed with hot water, and the weights of the solution and of the salts left on evaporation were ascertained. The salts were dried at a temperature up to 150° C., trials having shown that the sulphonate is unaffected at this temperature. The dried salts were quantitatively analysed for sulphate and chloride, respectively, by precipitation as barium sulphate, or by titration with standardised silver nitrate solution, using chromate as indicator. Trials with known amounts showed that both these methods are accurate when sodium chloride, or sulphate, is mixed with an equal weight of sulphonate. Incidentally, the solubility of the sulphonate alone had to be determined as only one value, that at 23·9° C., could be found (Thorpe, Dict. Appl. Chem., 1912, III., 574). The solubilities of the sulphate and chloride were taken from Landolt and Börnstein's tables.

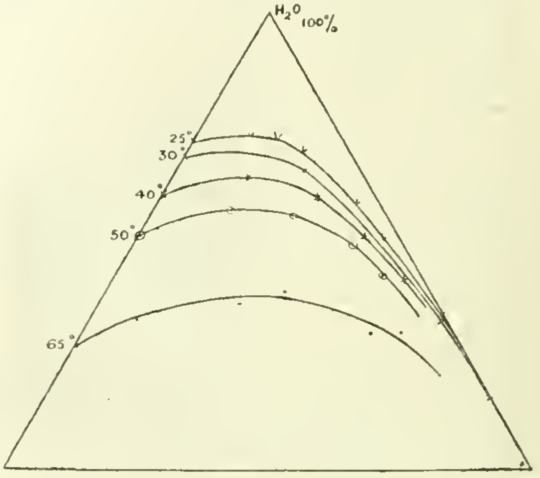

FIG. 2.

In one experiment a mixture of 1·5 g. of β salt. 0·3 g. of sodium chloride, and 10 c.c. of water was shaken together for 24 hours at 65° C.; 5·2668 g. of solution was filtered off, and this weight of liquid left 0·6003 g. of mixed salts on evaporation. These salts required silver nitrate solution equivalent to 0·1544 g. of NaCl. Therefore 0·4459 g. of β salt was present. The solution contained therefore:—Water 4·6665 g. (88·57%), β salt 0·4459 g. (8·47%). sodium chloride 0·1544 g. (2·93%). The results obtained are shown in the accompanying diagrams.

The curves show that the solubility of the β salt is reduced practically to zero when the concentration of the inorganic salt reaches about 10 g. in 100 g. of solution, especially at lower temperatures. The figures are derived from experiments made by using the β salt in excess and gradually increasing the amount of inorganic salt. Applying the ordinary method of graphical analysis to this three-component system, and from the appearance of the insoluble residues, the residue in each case is found to be the organic salt. The curves, therefore, represent the solubilities of the organic salt in solutions of the inorganic salts. An attempt was made, at 25°, to find the point of intersection of the curve shown in the figure with the curve representing the solubility of sodium sulphate in presence of the β salt. Two experiments were made at 25° using excess of both salts. The evaporated filtrates left 1·1444 and 1·302 g. of residue respectively, which residues yielded barium sulphate equivalent to 1·1284 and 1·2835 g. of Na_2SO_4 respectively, showing that the influence of the β salt on the solubility of the sulphate is practically negligible. The point of intersection lies, therefore, practically on the solubility curve of the sulphate.

The above work was carried out in the Chemical Department of the University of Queensland, and I desire to thank the authorities of that University, and especially Prof. B. D. Steele, for granting me every facility for work. I am also indebted to Prof. Steele for the interest he took in the research.

The University, Adelaide.

Communications.

THE ESTIMATION OF COCONUT AND PALM-KERNEL OILS IN FAT MIXTURES IN WHICH BOTH OILS MAY BE PRESENT.

BY W. N. STOKOE, B.SC., A.I.C.

It is common knowledge that the estimation of coconut and palm-kernel oils in mixtures when both are present is a matter of great difficulty owing to the similarity in composition of the two oils. Coconut oil, however, is richer than palm-kernel oil in the lower fatty acids, as is indicated by its higher Polenske value. Further, the insoluble fatty acids from coconut oil which distil over in the Polenske test are liquid at room temperature, whereas the volatile acids obtained from palm-kernel oil under the same conditions are solid. This difference suggested a possible method for the identification and estimation of the respective oils.

Several methods for the estimation of coconut and palm-kernel oils in mixtures have been described in the literature. Burnett and Revis (Analyst, 1913, 38, 255) have devised a method which depends on the relative solubility of the barium salts of the insoluble volatile acids in alcohol of definite strength. The temperature of turbidity on cooling is observed, palm-kernel oil giving a higher figure than coconut oil. Mixtures of the two oils are stated to give "turbidity temperatures" proportionately intermediate between the extreme values given by the pure oils. This method is expensive owing to the quantity of strong alcohol required, and has the disadvantage that the solution of the barium salts in alcohol is seldom perfectly clear, and the exact "turbidity point" is often difficult to judge accurately. A second method devised by Blichfeldt (J., 1919, 151 T) depending on the m.p. of the insoluble volatile acids has been published; in the preliminary work preceding this investigation a modification of this method was tried, but without success. After further experiment the following method was devised.

In the standard Reichert-Polenske process, after distilling 110 c.c. the liquid is cooled and the insoluble acids collected on a filter; the condenser tube is rinsed down with 20 c.c. of warm water (30°—40° C.), which is poured over the filter. The filter paper is washed with warm water (30°—40° C), and as soon as the last drop of water has drained through several capillary tubes (internal diameter of 1 mm.) are filled to the depth of ½ in. with the now melted acids. Two of the tubes are immediately attached, one on either side, by means of a small rubber band, to a thermometer graduated to read 1/10°, and the thermometer fitted into a test tube by means of a cork having a hole through which the thermometer is placed. The tube is supported in a beaker containing ether, the surface of which should be above the level of the acids in the capillary tubes. A rough idea as to whether the bulk of the acids is from palm-kernel or coconut will have been obtained from the appearance of the acids in the original Reichert-Polenske distillate. If the acids are solid at ordinary temperature it is necessary to warm the ether to about 30° C. A gentle stream of air is forced through the ether by means of a foot bellows so as to lower its temperature gradually, the rate of cooling being so adjusted that the temperature of the ether is 2° C. below that registered by the capillary tube thermometer. As the cooling progresses the fatty acids will become slightly cloudy, then a distinct "seeding" or crystallising will occur. At the first appearance of crystals the temperature is noted. This "seeding point" is quite definite and sharp. At this point the acids in the capillary tubes appear liquid with a number of tiny white crystals along the sides of the tube. It is important in performing the test that the rate of cooling should be regular.

The following tables show results obtained by this method. As was to be expected, there is a slight variation between the figures obtained for samples of different origin. The oils used in the mixtures were made by mixing equal quantities of the different individual samples in order to obtain an average result:—

Mixtures containing only coconut and palm-kernel oils.

Coconut.	Palm-kernel.	"Seeding" point. ° C.	Average.
%	%		
85	15	11·8 11·6 11·6 11·9 11·6 12·0 12·0	11·8°
75	25	13·5 13·4 13·2 13·2 13·2 13·5 13·2 13·0	13·4°
60	40	15·7 15·3 15·6 15·6 15·4 15·3 15·3 15·6	15·5°
50	50	16·9 17·0 16·8 17·0	16·9°
40	60	17·9 17·9 17·9 18·0	17·9°
25	75	19·6 19·4 19·4 19·5	19·5°
10	90	21·6 22·0 21·7 22·0	21·8°

Four samples of coconut oil of different origin and the same number of palm-kernel oil were examined. The highest figure for the "seeding point" of coconut oil acids was 11·4° C. and the lowest 9·9°; average 10·75. The figures for palm-kernel acids were: highest, 23·2°; lowest, 22·05°; average, 22·75° C.

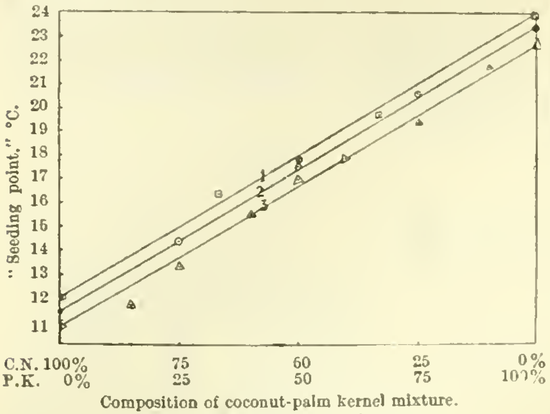
Mixed fats containing 30% oleo, 10% cottonseed oil, 60% coconut or palm-kernel oil or mixtures of them.

Relative proportions of coconut and palm-kernel oils	"Seeding" polot. ° C.	Mean.
Coconut 100%	11·3 11·6 11·3 11·3 11·5 11·4	11·4°
Palm-kernel 100%	23·5 23·7 23·5 23·7	23·6°
Coconut 75%, palm-kernel 25%	14·5 14·0 14·5 14·1	14·3°
Coconut 50%, palm-kernel 50%	17·6 17·6 17·5 17·5	17·55°
Coconut 25%, palm-kernel 75%	20·4 20·9 20·6 20·4 21·0 20·3	20·6°

Mixed fats containing 50% oleo, 20% cottonseed oil, 30% coconut or palm-kernel oil or mixtures of them.

Relative proportions of coconut and palm-kernel oils.	"Seeding" point. ° C.	Mean.
Coconut 100%	12·0 12·0 12·0 11·9 12·0 12·0	12·0°
Palm-kernel 100%	24·0 24·0 24·0 24·1	24·0°
Coconut 33⅓%, palm-kernel 66⅔%	20·0 19·6 19·9 19·8 20·1 19·5 19·8 19·7	19·8°
Coconut 50%, palm-kernel 50%	17·8 17·2 17·8 17·7 18·2 17·3 17·6 17·8	17·7°
Coconut 66⅔%, palm-kernel 33⅓%	16·6 16·2 16·2 16·4 16·2 16·4	16·3°

It will be observed that the presence of other fats raises the "seeding point," but that, roughly speaking, parallel lines are given on the graph. Thus in the analysis of an unknown fat mixture it will be necessary first to ascertain the approximate quantity of the coconut group of fats present by determining the saponification value and the Reichert-Polenske value. Reference is then made to the corresponding line or intermediate line if necessary on the graph diagram, and from this the relative proportions of coconut and palm-kernel oils are read off.



1. 30% C.N. and P.K. in mixture.
2. 60% C.N. and P K. in mixture.
3. 100% C.N. and P.K.

The method can be readily carried out as an extension of the standard Reichert-Polenske method, the contents of the capillary tubes being added to the alcoholic solution of the remainder of the insoluble acids and the whole being titrated as usual to obtain the Polenske value.

The following table shows results obtained on margarine samples of known composition :—

Relative proportion of C.N. & P.K. in sample.	Sapon. value.	Reichert-Meissl.	Polenske.	"Seeding" point. ° C.	Relative proportion of C.N. & P.K. indicated.
Palm-kernel 100%	228·7	4·05	6·1	23·5	100% P.K.
Palm-kernel 100%	208·2	1·36	1·3	24·0	100% P.K.
Coconut 100%	223·7	5·01	6·40	11·8	100% C.N.
Coconut 100%	246·3	7·15	13·0	11·5	100% C.N.
Coconut 50%, palm-kernel 50%	244·1	5·61	11·2	16·9	51% C.N., 49% P.K.
Coconut 25%, palm-kernel 75%	228·1	4·35	7·30	20·6	26% C.N., 74% P.K.

HYDROGENATION IN THE NAPHTHALENE SERIES.

BY F. M. ROWE.

A communication on dihydronaphthalene by Straus and Lemmel (Ber., 1921, **54**, 25) has drawn my attention to an error inadvertently introduced into my paper on this subject (J., 1920, 241 T) when it was written from the laboratory note-books. It is stated that both 1.4- and 1.2-dihydronaphthalenes were purified by means of their mercuric acetate compounds, whereas actually it was only the former of these compounds that was purified in this manner. My assistant, Miss Levin, attempted to purify 1.2-dihydronaphthalene by this means, but found that the mercury compound formed, of high melting point and insoluble in boiling benzene, did not yield the hydrocarbon when treated with acid, although this compound was not examined further at the time. Straus and Lemmel have now found that mercuric acetate exerts an oxidising action on 1.2-dihydronaphthalene, forming 1.2-dihydroxytetrahydronaphthalene, and that the insoluble mercury compound is Hg.O.CO.CH$_3$.

The only satisfactory method by which the purity of 1.2-dihydronaphthalene may be ensured consists in its conversion into the dibromide, which is purified by recrystallisation, followed by the removal of the bromine atoms.

THE VULCANISATION OF RUBBER.

In a letter dated January 22 to the Editor (see also India-Rubber J., 1021, **61**, 177), M. A. Dubosc claims that he had already anticipated Peachey's discovery of the possibility of vulcanising rubber by the action of sulphur dioxide and hydrogen sulphide at the ordinary temperature (see Peachey and Skipsey, J., 1921, 5 T). In 1915 (*cf.* India-Rubber J., May 1, 1915) M. Dubosc had suggested that, of the various allotropic modifications of sulphur, only the colloidal form is able to vulcanise rubber. Chemically pure rubber is known to undergo vulcanisation only with great difficulty, the presence of the natural resinous and protein impurities being essential to the change, which is also aided by the addition of metallic oxides such as magnesium oxide or litharge. M. Dubosc's view of the vulcanisation process was that the resinous matter first reacts with part of the ordinary sulphur present, with formation of hydrogen sulphide, whilst any oxidised rubber or metallic oxide in a similar manner gives rise to sulphur dioxide; these gases, in solution in the rubber, then react with formation of water and sulphur, the latter being produced in the active "monatomic or colloidal" condition capable of effecting vulcanisation.

Mr. Peachey (India-Rubber J., 1921, **61**, 163) replies that the new process is one of "cold vulcanisation" operating at the ordinary temperature, whereas the above theory referred to the ordinary process of hot vulcanisation; in a critical review of M. Dubosc's claim, he questions the accuracy of certain of the assumptions and directs attention to the facts that not only would any sulphur present during hot vulcanisation be in the molten condition, but that for the production of a pure ebonite containing 32% of combined sulphur, the volume of sulphur dioxide and hydrogen sulphide necessary according to above theory would be approximately 100 and 200 times respectively that of the rubber.

THE EROSION OF BRONZE PROPELLERS.

(See J., 1921, 38—45 T.)

Colonel N. **Belaiew** wrote that he had been particularly struck by the similarity between the erosion of propellers and the erosion of guns. In both cases the process of erosion seemed to be divided into two phases—the preliminary, and the final. In the case of a propeller, this preliminary phase, according to Dr. Silberrad, consisted in the "water-hammer" action of water broken by vacuum bubbles; in the case of a gun, according to Tschernoff (Proc. Int. Assoc. Testing Materials, 1912, 2, A, 121), it consisted in the thermal action of the gases on a thin film of the metal on the internal surface of the gun-tube. The next stage, or the actual erosion, in both cases was due to mechanical causes only, being caused either by frictional rub of the water (on the propeller), or by the frictional rub of the particles of the gases (as in guns) forcing their way out of the tube. He (Colonel Belaiew) felt inclined, therefore, to endorse the author's view that after the surface of the propeller had been damaged by any of these agencies, further erosion was chiefly caused by the frictional rub of the water. He also thought that, just as in guns, the influence of structure was considerable, and that whilst, according to the Committee report, there might be no "connexion between the structure of a metal and the distribution of erosion," the wearing away of the metal was largely determined by the structure of the metal. The problem of structure was more complex in guns, where the gases had a certain hardening effect, and where the initial structure might therefore be altered considerably; in propellers the position was more simple, and only resolved itself into the question, as the author rightly pointed out, of finding an alloy with the most suitable initial structure.

THE PHOSPHATES OF NAURU AND OCEAN ISLANDS.

BY THOMAS STEEL.

The only detailed analyses of different types of the phosphates from these islands with which the author is acquainted have been published by C. Anderson (Records Australian Museum, Sydney, 1903, 5, 13), who gives descriptions of ten specimens, mostly from Ocean Island, with analyses of four. Anderson's descriptions and analyses agree well with some of those detailed in this paper. F. R. C. Reed (Geol. Mag., 1903, 10, 298) describes the physical appearance of a series of specimens from Ocean Island, which agree precisely with several of the author's samples, and gives an analysis by Voelcker of a specimen described as "hard rock," which shows 4·5% of magnesia. As will be seen from the descriptions following, there is a considerable variety of types. For the specimens, which were selected with the special view of being representative, the author is indebted to his brother, Mr. F. W. Steel, who was resident on Nauru for some time. Most of the samples are from Nauru, but the Ocean Island phosphates are of precisely similar character.

Description of specimens.

1. A beautiful, compact, pale grey rock of uniform very fine texture, closely resembling the porcelain of which Wedgewood mortars are made. Fracture conchoidal, not stratified.

2. Extremely porous, sintery mass in which coral structure is well preserved, the vertical ribs in the the coral tubes being clearly defined. Bears a strong resemblance to a mass of calcified sponge.

3. Somewhat porous, in shape like coarse branching coral, but no organic structure could be detected. Some specimens are hollow, the interior being thickly lined with interlacing vermiform processes, whilst others are solid, being filled with a mixture of similar processes and of oolitic grains.

4. A breccia, consisting of small oolitic grains and rough angular fragments loosely cemented.

5. Similar to 1, but in fine layers of dark and light grey.

6. Coarse and fine loose water-worn grains and pebbles. May be described as a mixture of pisolitic and oolitic grains; grey.

7. Similar to 6, but the grains are black, being coated with a skin of humus easily rubbed off. This constitutes the surface "soil," 4 to 6 inches in depth. Ocean Island.

8. Compact, surface smooth, somewhat resembling grey flint.

9. Thin, brown layers like banded agate, dark and light brown. Very hard and dense. Breaks with a splintery fracture.

10. This sample bears a striking resemblance to a mass of commercial gum benzoin. Brown, with angular white enclosures.

11. Black, compact trachyte-like, of oolitic structure. Bears a strong superficial resemblance to a piece of dolerite. Weathers white on outer surface.

12. A hard, grey, massive rock, having numerous vesicles lined with brown material, like 10, and small spheres of same substance.

13. Resembles coarse, grey sandstone, composed of oolitic grains loosely cemented.

14. Like dense limestone, with numerous large white shell casts.

15. Fine columnar structure of coral, adherent to dense limestone. Columns about $\frac{1}{8}$ inch in diameter, with vertical radial septa dividing the tube into a series of sectors. Coral part only taken for analysis.

16. Buff and white diffusely banded, compact rock, dense and hard. From reef. Ocean Island.

17. Small sample, showing in vertical section flattened double coral tubes, each element of the double tube being about $\frac{1}{16}$ inch in diameter. The septa of the tubes are very prominent and well preserved, forming a series of superimposed closed cells, in depth about equal to their diameter. Not analysed, but high in phosphoric acid.

Unless otherwise stated, all the samples are from Nauru Island.

Only traces of iron or alumina were present in any of the samples. Varying small amounts of fluorine occur in many of the samples.

The original source of the phosphoric acid is generally conceded to have been the accumulations of guano from the colonies of sea-birds using the islands as nesting places.

Most of the samples bear evidence of having undergone considerable metamorphosis and of having been deposited either from solution or as sediment. Only two samples, 2 and 17, of those high in phosphoric acid, retain any organic structure. Of the others, 14 and 15 exhibit the remains of shells and coral respectively, but these are dolomites containing only a small proportion of phosphoric acid.

The four samples analysed by Anderson are high in phosphoric acid, and of these two are described as displaying organic structure, coral, or shell.

It is not possible to offer any opinion as to the extent to which coral has entered in the course of formation of the various types described above, but it is possible that the deposits devoid of organic structure may have been formed direct from guano without the intervention of coral. When dead coral is submerged in sea water it becomes dolomitised by reaction between the calcium carbonate of the coral and magnesium chloride of the water, producing such samples as 14 and 15. Where the supporting rock consisted of such dolomite, the phosphatic basis of the guano, after the loss of the organic constituents by decay and leaching, may have undergone transformation by solution and redistribution without in any way affecting the inert underlying rock. Doubtless carbon dioxide in percolating rain water would materially assist in the transformation of the phosphate.

Fresh coral has been reported to contain from 0·28 to 0·84 % of calcium phosphate. Fresh coral is stated (Watts' Dict. Chem., II., p. 84) to contain about 1 % of magnesia and 2·1—9·4 % of organic matter, the remainder being calcium carbonate.

The analysis of the above phosphates show that part only of the phosphoric acid is present as calcium phosphate ($Ca_3P_2O_8$), the relative proportions of constituents indicating the presence of a varying proportion of tetracalcium phosphate ($Ca_4P_2O_9$). The author has observed this in other natural phosphates, and, quite recently, in the deposit of "tartar" from the teeth of man, sheep, ox, and other animals (Steel, Proc. Linnean Soc. N.S. Wales, 1920, 324).

The question of origin was the subject of an important lawsuit in Melbourne some years ago. A firm of chemical manufacturers claimed that a cargo of phosphate from Ocean Island should be classed as guano owing to its reputed bird origin. Guano was admitted free of wharfage, whereas a charge of one shilling per ton was levied by the Harbour Trust on minerals, under which category they placed the "rock phosphate" of Ocean Island. The verdict of the court was in favour of the Harbour Trust.

Mr. F. W. Steel has furnished the following notes from his observations when resident on Nauru:—

"The substructure of both islands is hard dolomite without trace of coralline structure, containing embedded fossil shells. The coral pinnacles among which the phosphate deposit is found come up to the present surface and in a number of places project beyond to a considerable height, notably two large masses in the centre of Nauru, which attain a height of about 100 ft. above ground level. The highest point of the island of Nauru is stated to be about 250 ft. above sea-level. On Nauru are a number of caves in the dolomite rock; these are evidently shrinkage cracks and show but slight stalagmitic structure. In places the surface layer of the dolomite seems to have been partly phosphatised, but this may be merely a layer of phosphate deposited thereon from solution.

Around Ocean Island is a raised beach or rough flat of very limited extent, where in places are numerous pinnacle masses of coral, evidently the remains of the coral structure, and which are very rough and sharp through weathering. The pinnacles embedded in the phosphate, on the other hand, show smooth surfaces with layers of phosphatised coral. It is extremely probable that the shore pinnacles were originally surrounded by phosphate which has been subsequently washed out by the sea, as on the flat reef on Ocean Island there are numerous 'pipes' of phosphate of pisolitic structure projecting from the surface, the grains being cemented together with phosphate. These, being formed by the filling in of 'blowholes' in the coral and being harder than the latter, have remained when the surrounding coral was removed by wave action. The "pipes" stand up to as much as three feet above the reef level. The flat reef is submerged at each high tide. The sand of the beaches is all coral *débris*, shells, etc."

Meeting held at Queen's Hotel, Leeds, on January 17, 1921.

DR. L. L. LLOYD IN THE CHAIR.

THE PRESENCE OF NITRATES IN THE LEAVES OF TREES GROWING NEAR PICRIC ACID WORKS.

BY B. A. BURRELL, F.I.C., AND G. W. DOUGLAS.

In the production of picric acid by the nitration of phenolsulphonic acid large quantities of oxides of nitrogen are evolved. During the war considerable volumes of these gases sometimes escaped from the nitrating sheds to the detriment of any vegetation that might be in the vicinity.

In 1916 one of us was consulted in respect to such damage, and during that and subsequent years we examined numerous samples of leaves taken from trees growing near to a large picric acid works.

When the wind was blowing from the works to the agricultural land (about ½ a mile distant) on which the damage had and was taking place, the distinctive smell of the nitric fumes was easily perceptible.

The district was well wooded and the damaged trees could be easily recognised, the leaves being dry, shrivelled, and falling readily. When the trees were in clumps, those nearest to the works showed the most damage, those behind being to a certain extent protected. Where the trees were growing behind a wall situated between them and the works, the portion immediately behind the wall did not show material damage, whereas that portion which projected above the wall and to which the gases could obtain direct access was obviously damaged.

The beeches appeared to suffer the most, sycamores, elms, and oaks being more resistant. A certain amount of sulphuric acid vapour also escaped from the works from time to time, but not to anything like the same extent as the oxides of nitrogen. The sulphurous vapour would no doubt contribute to the damage, but this is more difficult to determine as sulphates occur naturally in all vegetation* whereas nitrates do not† though according to Wiley they occur in considerable quantity in the tobacco plant.‡ In this connexion it has been stated that the tobacco plant is particularly injured by nitric acid, and that next to all herbaceous plants, trees generally suffer.§

Our experiments were made on leaves which had been air dried in a room where they could not come into contact with nitric fumes.

Ten grams of the leaves, free from twigs &c., were placed in a clean dry stoppered bottle, 200 c.c. of distilled water was added, and the bottle and contents were gently agitated at frequent intervals for ½ hr., when the aqueous extract was poured off, the leaves remaining in the bottle were drained for a specified time, the drainings being added to the decanted liquid and the bulk made up to 200 c.c. Known quantities (generally 10 c.c.) were taken for the detection and estimation of nitrates, only those methods being used which were capable of estimating minute quantities of nitrates in the presence of comparatively large quantities of nitrogenous organic matter.

§ A. W. and M. W. Blyth, "Poisons." 1906, 4th Ed., p. 110.

Phenolsulphonic acid method.—There was no difficulty in detecting the presence of nitrates, but for quantitative purposes the process was not satisfactory, the colour produced being of a much browner tint than that of the standard ammonium picrate solution, and when the solutions were allowed to stand for a short time a greenish tint began to develop which made comparison still more difficult.

Indigo method.—This was also found unreliable for quantitative purposes.

Brucine method.—The results quoted were all obtained by this method, which was found to be well suited for the purpose. The process is due to West Knights,¶ and is based upon the well-known reaction of brucine with nitrates, a deep red colour being produced on evaporation to dryness in the presence of a small quantity of oxalic acid. The residue thus obtained is dissolved in a small quantity of water, the solution filtered, and the colour compared with that of a solution containing a known quantity of nitrate.

A standard solution of potassium nitrate is prepared by dissolving 0·721 g. in distilled water and making up to a litre: each c.c. of this solution is thus equal to 0·0001 g. of nitric nitrogen. 10 c.c. of the solution is evaporated to dryness on a water bath and 3 c.c. of a 1% solution of brucine in alcohol and 0·5 c.c. of a saturated solution of oxalic acid are added to the residue, which is again evaporated to dryness. A little distilled water is then added to dissolve the residue and the volume made up to 100 c.c. Each c.c. of this solution = 0·00001 g. of nitric nitrogen.

One example of the damaged leaves of a sycamore may be given. The extract from 0·5 g. of leaves was treated as described, the final solution being filtered to remove any calcium oxalate and then diluted to 50 c.c. in a Nessler cylinder; 7 c.c. of the standard red solution was required to match the colour given by 10 c.c. of leaf extract. Then 0·00001 × 7 × 200 = 0·014% of nitric nitrogen.

The following is a list of results obtained:—

TABLE A.

				Nitric N. %	Nitric acid %
No. 1	Beech (damaged			0·056	0·252
„ 2	Elm	„	¼ mile from works	0·072	0·324
„ 3	Elm	„	near to No. 2	0·012	0·054
„ 3a	Sycamore	„	Leaves fallen to the ground	0·060	0·270
„ 4	Beech	„		0·050	0·225
„ 5	Sycamore	„		0·084	0·378
„ 6	Ash	„		0·024	0·108
„ 6a	Grass	„	From edge of a manhole from which nitric fumes escaped at intervals	0·032	0·144
„ 7	Beech	„		0·036	0·162
„ A	Beech (damaged side)			0·018	0·081
„ A1	Beech (same tree as A, undamaged side)			—	—

A sycamore, an elm, and an ash from the same estate, but some distance from the works and which from their position could not have been exposed to the nitric fumes, were all undamaged and did not contain any traces of nitrates. (These samples were taken in August, 1916.)

TABLE B.

Results in parts per 100. (Samples taken July, 1918.)
These trees are not included in Table A.

			Nitric N.	*Total acid.	Chlorine.	Sulphur trioxide.
No. 1	Sycamore	(damaged)	0·014	0·799	0·62	0·78
„ 2	„	(undamaged)	—	0·517	0·38	0·46
„ 3	Elm	(damaged)	0·044	1·17	0·96	1·12
„ 4	Elm	(undamaged)	—	0·90	0·68	0·38

* Total acid expressed in terms of sulphuric acid.

The damaged and undamaged sycamores were 12—15 yards apart, while Nos. 3 and 4 were from the same tree, No. 3 being exposed to fumes, No. 4 being protected by a wall.

In addition we have tested the leaves from elm, elder, hawthorn, and plane trees growing in Springfield Mount, Leeds, and from ash, beech, elm, and sycamore trees growing at Ilkley, and have in all cases proved the absence of nitrates. In none of the leaves, either damaged or undamaged, could we find any trace of nitrites.

DISCUSSION.

MR. W. McD. MACKEY suggested that the effect of fumes on a leaf would depend on the surface of the latter; he would expect a smooth leaf to be more immune than one with a rough surface. He asked if the shrivelling effect observed might not have been due as much to sulphur oxides as to the oxides of nitrogen.

MR. BURRELL, in reply, said that the difficulty with regard to sulphuric anhydride was that all leaves contained an appreciable quantity of sulphate, and no definite line could be drawn between the natural amount and an abnormal amount sufficient to cause damage. No such difficulty occurred with nitrates.

Communications.

THE ACTION OF HYDRAZINES ON CELLULOSE ACETATES.

BY W. LEIGH BARNETT, B.SC., A.I.C.

The object of this investigation was to determine whether phenylhydrazine and *p*-bromophenylhydrazine form any definite chemical compounds with cellulose esters, which compounds might be comparable with simpler hydrazones. Under normal conditions cellulose has not been known to react with phenylhydrazine to give well-defined products, owing no doubt to the inertness of the cellulose complex, and to the fact that it is insoluble in ordinary solvents which are used in the case of simpler ketones. Again, it is possible that the cellulose complex is held together by oxygen linkages, and until these linkages are broken and the cellulose complex degraded the ketonic or aldehydic groups cannot function as such. Consequently no phenylhydrazones of cellulose are formed by reason of the enforced inactivity of these latent groups. It was considered that the problem could be attacked by first of all forming cellulose esters, made by the author's method (J., 1921, 8 T), so as to ensure the minimum of degradation of the complex, and then treating these esters with the hydrazine. The fact that these esters are readily soluble in many solvents obviously simplifies the problem. It is clearly of importance that the cellulose esters utilised in this research should be made in such a way as to preclude the possibility of dissociation of the parent complex, otherwise the initial ester, being of lesser magnitude than the cellulose complex, would show an enhanced reactivity due to the degradation which it had undergone.

If dissociation of the cellulose complex, $(C_6H_{10}O_5)_n$, occurs, and if this is brought about by rupture at the oxygen linkages freeing more and more ketonic groups as the value *n* grows less, then at the same time there will be a progressive increase in the amount of phenylhydrazine reacting with the ketonic group to form hydrazone. Taking the case of cellulose triacetate, which can be written as $[C_6H_7O_2(CH_3CO_2)_3]_n$, and supposing for any value of *n* there be one ketone group only, the complex can be written in the form, $C_{6n}H_{7n}O_{2n-1}O(CH_3CO_2)_{3n}$, and the corresponding phenylhydr-

---

¶ Analyst, 1881, 56-58.

azone will be $C_{6n}H_{7n}O_{2n-1}C_6H_5NH.N(CH_3CO_2)_{3n}$. In the case of the *p*-bromophenylhydrazone the general formula will be similar as shown by $C_{6n}H_{7n}O_{2n-1}C_6H_4BrN_2H(CH_3CO_2)_{3n}$. The nitrogen and also the bromine content of these compounds will vary inversely as the value of *n*. Conversely, if by experiment the least amount of bromine, and nitrogen, be ascertained, and if these quantities be definite together with the properties of the specific compound under observation, irrespective of the mode of preparation, it should be possible to fix on a value for *n*, and hence get some indication of the molecular complexity of the cellulose complex.

The results obtained from a large number of experiments both with di- and triacetylcellulose, and also phenylhydrazine and *p*-bromophenylhydrazine, indicate that it is possible to obtain a series of definite compounds containing nitrogen (and halogen) in quantities corresponding with the amounts expected from cellulose acetates calculated according to the general formulæ given above, provided that the value *n* be chosen suitably. These hydrazones have definite melting points, and also exhibit the normal characteristics of ketose hydrazones. The experimental methods adopted were such as to eliminate the possibility of the purified products being merely adsorption products of the hydrazine by the cellulose ester colloid. Essentially the method consisted in treating a solution of the cellulose acetate in a suitable solvent with the hydrazine, under different conditions of temperature and time of duration of the treatment, followed by removal of the solvent and excess hydrazine, and then exhaustive purification of the product by repeated solution, precipitation, filtration, and washing the number of re-precipitations of the substance depending on its properties.

The following solvents were employed for the initial solution of the cellulose acetate:—Aniline, chloroform, glacial acetic acid, o-toluidine, nitrobenzene, pyridine, and phenol. The cellulose acetates used were made by the author's method (*loc. cit.*), from filter paper, cotton wool, and bleached cotton yarn.

As important differences exist between acetylcellulose phenylhydrazones and the bromophenylhydrazones they will be treated separately.

Acetylceltulose phenylhydrazones.—It was found possible to obtain the same acetylcellulose phenylhydrazone starting from different cellulose triacetates, irrespective of the initial properties, and also of the mode of operation in the preparation of the hydrazones. The final products form, as a rule, amorphous powders, which may be coloured from a whitish-grey to a very pale yellow or light brown. All these substances are soluble in hot alcohol, but in different degrees. The solubility is apparently influenced by the solvent employed in the first part of the reaction. The temperature at which the treatment of the cellulose acetate with the phenylhydrazine is carried out has less influence on the nature of the product than the solvent, and to a lesser extent the time of heating. An important physical difference between the phenylhydrazones obtained from the triacetate from paper and cotton was noticed. If the product in the form of an amorphous powder, which is not perfectly freed from traces of alcohol used in the final washing in the purification process, be placed in an oven to dry at 100° C., the whole mass rapidly coalesces and assumes the appearance of a transparent yellow resin. These resinous masses are hard, brittle, and flaky. In alcohol they give solutions similar to shellac varnishes. Evaporation of the alcohol from thin films of the solution leaves hard, glossy, transparent, but somewhat brittle, films. Whether the product be in the form of an amorphous powder or resin, it possesses a well-marked melting point, at which unstable viscid brown liquids are formed. The melting points appear to be associated with the solubility in alcohol, and not with the complexity of the compound, as deduced from the nitrogen content. Thus the most soluble product obtained (1·02% N, m.p. 229° C.) was of the resinous type, and was made from a filter paper cellulose triacetate. The next in order of solubility had 4·16% N, m.p. 238° C. Several compounds less soluble in alcohol melted at 245° C., although the nitrogen content varied between 0·76 and 4·44%, the same samples giving concordant figures. The least soluble products melted about 262° C., the nitrogen content being 0·90—1·78%. All these compounds dissolve easily in acetone, giving clear solutions from which they can be precipitated unchanged by suitable means. This latter fact shows that there is no possibility of these substances being adsorption products, otherwise the acetone would react with the liberated phenylhydrazine in the usual manner.

In the case in which chloroform is used as a solvent for the cellulose acetate, followed by digestion with phenylhydrazine, the reaction is complicated by the formation of a crystalline substance which separates in very fine, glistening plates. This was found to be due to the action of the chloroform on the hydrazine. Steps had therefore to be taken to eliminate the possibility of contamination of the cellulose derivative by this crystalline substance, which was separated and investigated separately. (Details of this substance will be given in a separate paper.)

Experimental.—The method adopted consisted essentially in first dissolving the cellulose acetate in the chosen solvent, which was generally warmed to facilitate solution, and when complete solution had occurred the phenylhydrazine was added, after which the mixture was heated to the boiling point for known periods of time. The solvent was then removed by suitable means depending on its nature. In the case of chloroform this was effected by mixing with excess of water and distilling off the chloroform on a water-bath. In the case of aniline, nitrobenzene, etc., after mixing with water the excess of solvent was removed by steam distillation. The remaining products were filtered off, washed, pressed, and then repeatedly dissolved in hot alcohol (under a reflux condenser), followed by cooling to precipitate the substance in a fine powdery form, filtration, washing with alcohol, and then redissolving in more alcohol, and re-precipitation. This process was repeated until the melting point of the product was constant. Generally from eight to twelve re-precipitations from alcohol were employed, the number depending on the nature of the product, and its solubility in alcohol. In some cases it is necessary to use mixtures of alcohol and ether or of alcohol and water for the final stages in the purification.

Table I.

Nitrogen in phenylhydrazones from diacetates and triacetates.

	Diacetates. %	Triacetates. %
1.	8·33	7·48
2.	4·81	4·20
3.	3·38	2·94
4.	2·60	2·25
5.	2·12	1·83
6.	1·78	1·54
7.	1·55	1·33
8.	—	1·17
9.	—	1·04
10.	—	0·94
11.	—	0·86
12.	—	0·79

From Tables I. and II. it will be seen that the carbon and hydrogen content will vary to a far less extent than the nitrogen value for different members of the series contained therein. Hence in the greater number of preparations only the percentage of nitrogen was ascertained. In a few doubtful cases the carbon and hydrogen figures were determined, and of these the hydrogen figure is the more reliable.

The experimental results are collected in Table II. for the sake of brevity. Table I. gives the nitrogen figures for the theoretically possible compounds from the di- and triacetates respectively for various values of *n*.

TABLE II.

Ester.†	Solvent.	Time. hrs.	M.p.	N. % found.	*n*	N. % (calc.)	Form.

Tri.F.P.	Aniline	3	262	2·78	3	2·94	R.
Tri.C.W.	Nitrobenzene	9	265	1·51	6	1·54	P.

† F.P. stands for cellulose acetate from filter paper, B.C. that from bleached cotton, and C.W. that from cotton wool. Time= time in hours that mixture was actually heated. *n* is the value which is found to correspond with the nitrogen figure, from Table I. Form.—R=resin. P=powder. All samples marked P could not be induced to show the resinification phenomenon.

* The solution was allowed to stand for several hours after heating.

In determinations of the melting points of these substances the temperature must be raised rapidly, as is common in the case of phenylhydrazones of simpler compounds. They all show an initial softening about 12° C. below the actual melting point, when they decompose simultaneously. A marked shrinkage in volume accompanies the initial softening.

Acetylcellulose p-bromophenylhydrazones. — It was considered that these substances would possess more marked physical properties than the corresponding phenylhydrazones. They were made in a similar manner. The final products were amorphous powders, varying from almost white to dark brown in colour. No signs of resinification were observed in any case, even when cellulose acetate derived from filter paper was employed. Initial subjection of the filter paper before acetylation to vigorous chemical purification, such as treatment with bromine or chlorine, followed by sulphurous acid, and then washing until free from impurities, did not give rise to resinous products. The melting points of these substances are sharper than those of the corresponding derivatives from the same acetylcellulose and phenylhydrazine. Further, in most cases no pronounced preliminary darkening occurs before the melting point is reached, although decomposition takes place at the melting point. In most cases these substances melt at higher temperatures than the simpler acetylcellulose phenylhydrazones. At the same time, the solubility in alcohol is less than the corresponding solubility in the simpler series. As may be expected, the results of analysis, based on the bromine content, indicate that the reaction is a progressive one, the composition of the bromophenylhydrazone produced becoming simpler on prolonged treatment before the reaction is checked. The application of heat for a short time during the reaction causes a more rapid breakdown of the complex than occurs when the mixture is allowed to stand for some time without much heating. The degradation of the complex does not proceed to such an extent as in the case of the phenylhydrazones. This is shown by comparison of the bromine content as found with that possible calculated from the general formula for triacetate products, $C_{6n}H_{7n}O_{2n-1}Ac_{3n}C_6H_4BrN_2H$ This is indicative of a much further resolution of the cellulose acetate by phenylhydrazine than by *p*-bromophenylhydrazine. The difference of solubility of the products in alcohol also points to the same conclusion, for in general the greater the solubility the greater the degradation of the complex. Again, the melting points are higher, and in most cases are round about 287° C., and the subsequent thermal decomposition is similar to the mode in which degraded cellulose acetates decompose on heating. As the degradation of the complex increases so the melting points decrease, exactly as shown in the parallel case of the simpler hydrazones.

Experimental.—The method of preparation and purification was similar to that outlined for the acetylcellulose phenylhydrazones. The results obtained are shown in Table III.:—

TABLE III.

Ester.*	Solvent.	Time, hrs.	m.p.	Br % found.	Br% (calc.)	*n*	Colour
BCI	Aniline	48	243	1·07	1·085	25	L.Y.
FPS	Acetic acid	22	245	3·57	3·66	7	C.B.
FPS	Acetic acid	5	265	2·66	2·62	10	R.B.
FPS	*o*-Toluidine	5	266	1·72	1·68	16	R.B.
FPS	Nitrobenzene	10	272	2·96	2·90	9	C.B.
BCI	Acetic acid	8	273	1·88	1·90	14	L.B.
FPS	Chloroform	18	278	1·01	1·01	27	L.Y.
FPI	Pyridine	17	278	2·80	2·90	0	L.B.
FPI	Phenol	4	287	0·77	0·76	36	L.B.
FPS	Nitrobenzene & acetic acid	1	287	1·08	1·085	25	L.Y.
FPI	Aniline	4	287	1·15	1·13	24	L.Y.
FPI	Acetic anhydride	16	287	1·65	1·68	16	L.Y.

* BCI refers to cellulose acetate from bleached cotton, insoluble in acetone, and FPS to cellulose acetate from Swedish filter paper, soluble in acetone. Time=actual time of heating in hours. *n*=the value of the compex coefficient which is used for the purpose of calculating the theoretical Br % from the general formula already quoted. Under the heading "Colour."—L.Y.=light yellow, C.B.=chocolate-brown, R.B.=reddish-brown, L.B.=light brown.

These results are indicative of the manner in which the complex cellulose is degraded by progressive resolution into simpler groups of the same empirical composition, but which contain active ketonic groups.

THE EFFECT OF APPARATUS ERRORS ON THE ACCURACY OF VOLUMETRIC ANALYSES.

BY VERNEY STOTT, B.A., F.INST.P.

The object of the present note is to examine in detail how the results of volumetric analyses are affected by inaccuracies in the apparatus used. The errors due to other sources will be briefly indicated also. In attempting to arrive at a numerical estimate of the inaccuracy due to the errors in the apparatus involved it will be assumed that the apparatus used has the maximum errors permissible under the N.P.L. Class A tolerances,* and that the apparatus is used without applying any corrections to the nominal capacity.

Errors in preparation of a solution for analysis.

The usual procedure is to dissolve a known weight of the substance to be analysed (or the whole of one

---

* The tolerances allowed on Class A apparatus are given in a pamphlet, "Volumetric Tests on Scientific Glassware," published by the National Physical Laboratory in November, 1919.

constituent from a known weight of the substance) and to make up the solution to a definite volume in a measuring flask. We will assume that the flask used is inaccurate by an amount equal to the N.P.L. Class A tolerance. If the strength of the solution were to be calculated by taking the nominal capacity of the flask as its true capacity, then a percentage error would be introduced equal to the N.P.L. Class A tolerance expressed as a percentage of the nominal capacity of the flask. The Class A tolerances correspond on the average to an error of $\pm 0{\cdot}03_3\%$, assuming flasks of capacity 100 c.c. to 1000 c.c. to be used.

Errors in preparation of standard solutions.

(A) Where a pure chemical is available a known weight may be dissolved and the solution made up to a definite volume in a measuring flask. The error in such a case would therefore be $\pm 0{\cdot}03_3\%$, as above. This procedure is, however, not always possible, and other methods have to be adopted.

(B) *Standard acid solutions.*—The strength of standard acid solutions most frequently used is *N*/10. Such a solution may be prepared as follows: A solution which is approximately *N*/1 is first made. Then a weighed quantity (2 g. is a convenient amount) of pure anhydrous sodium carbonate is dissolved in any convenient quantity of water, and the volume of the acid solution required to neutralise this is determined by titration. The normal acid is then diluted to *N*/10. Assume 2 g. of sodium carbonate to be taken, and approximately 42 c.c. of the normal acid to be required to neutralise it. If the 42 c.c. were measured from a Class A burette it may be in error by ±0·04 c.c., *i.e.*, by $\pm 0{\cdot}09_5\%$. The dilution to *N*/10 would probably be performed (I.) by delivering 100 c.c. of *N*/1 acid from a pipette into a 1000 c.c. flask; (II.) by delivering 100 c.c. of *N*/1 acid twice from a pipette into a 2000 c.c. flask; or (III.) by delivering 200 c.c. of *N*/1 acid from a pipette into a 2000 c.c. flask.

The errors would be:—

	I.	II.	III.
Possible pipette error ..	±0·05 c.c.	±0·10 c.c.	±0·08 c.c.
flask error ..	±0·20 c.c.	±0·35 c.c.	±0·35 c.c.
	±0·25 c.c.	±0·45 c.c.	±0·43 c.c.
i.e.	$\pm 0{\cdot}02_5\%$	$\pm 0{\cdot}02_3\%$	$\pm 0{\cdot}02_1\%$

The error in dilution may hence be taken as $\pm 0{\cdot}02_3\%$.

Combining this with the burette error, we obtain $(\pm 0{\cdot}09_5 \pm 0{\cdot}02_3)$, *i.e.*, $\pm 0{\cdot}11_8\%$, as the total possible error.

(C) Decinormal oxidising solutions may be checked directly against a known weight of sodium oxalate, and in this case there would be no dilution errors. For example, 0·5 g. of sodium oxalate would be oxidised by 74·6 c.c. of *N*/10 potassium permanganate solution. If the 74·6 c.c. were measured with a Class A 100 c.c. burette the possible error would be ±0·08 c.c., *i.e.*, $\pm 0{\cdot}10_7\%$. With half quantities and using a 50 c.c. burette the percentage error would be the same.

(D) *Indirectly determined standard solutions.*—Some standard solutions can only be standardised indirectly against a chemical of known and very high order of purity. The following is a method of standardising a sodium thiosulphate solution which will serve as an example. A potassium permanganate solution standardised as above (and therefore liable to an error of $\pm 0{\cdot}10_7\%$ due to assumed inaccuracy of apparatus) could be used to liberate iodine from an excess of potassium iodide solution. The apparatus error involved would be that of the pipette used to measure the potassium permanganate solution. If a 50 c.c. pipette were used this error would be ±0·07%. The average percentage error for pipettes of capacity from 25 to 100 c.c. would be 0·08%. The error using a 50 c.c. pipette is therefore sufficiently typical. In titrating the liberated iodine against the *N*/10 thiosulphate about 50 c.c. of the latter would be required and be liable to an error of ±0·01 c.c.

The total percentage error is therefore $0{\cdot}10_7 + 0{\cdot}07_0 + 0{\cdot}08_0 = \pm 0{\cdot}25_7\%$.

The mean of the errors in the above four cases (A—D), *i.e.*, ±0·12%, is very close to the values for B and C, which are cases of very frequent occurrence, and therefore, although the mean has in itself no particular significance, it will be convenient to use this figure as the percentage error in standard solutions when this value is required in considering errors in the various types of analyses dealt with below.

Errors in analyses of Type I.

When a known weight of substance is dissolved and the whole solution titrated against a standard solution, the error of the burette used for the titration is involved. Taking 30 c.c. as an average quantity of standard solution to be used and a 50 c.c. burette as the most commonly used size, we have a possible error of ±0·04 c.c. on 30 c.c., *i.e.*, $\pm 0{\cdot}13_3\%$. To this must be added the error of the standard solution, viz., ±0·12%, and we thus obtain ±0·25% as the total error due to inaccuracy of the apparatus used.

Errors in analyses of Type II.

In this case a solution is made up to a known volume and an aliquot portion taken for titration against a standard solution.

The errors in making up to known volume and taking an aliquot part vary from $\pm 0{\cdot}20_0\%$ with a 100 c.c. flask and a 10 c.c. pipette to $\pm 0{\cdot}05_7\%$ with a 2000 c.c. flask and 200 c.c. pipette. We may reasonably take ±0·10% as the error arising in measuring off an aliquot portion. To this must be added the burette error in the titration and the error in the standard solution, and we thus get the total error as follows:—Pipette and flask errors, ±0·10%; burette error, $\pm 0{\cdot}13_3\%$; error in standard solution, ±0·12%; total, $\pm 0{\cdot}35_3\%$.

*Errors in analyses of Type III.**

This may be described as the excess method, and involves the use of two standard solutions.

Suppose A and B to be the two standard solutions and C the solution whose strength is required.

To take a particular case, suppose 50 c.c. of A is equivalent to 50 c.c. of B, and that when 50 c.c. of B is added to 50 c.c. of C. 30 c.c. of A is required to complete the neutralisation of B. Thus 20 c.c. of B is equivalent to 50 c.c. of C.

The errors involved are as follows:—The strength of the solution A added from the burette in the first case to 50 c.c. of B, and in the second case to 50 c.c. of B and 50 c.c. of C need not be known. The solution A simply serves to give the ratio 20 c.c./50 c.c. obtained from the burette readings. This ratio may be in error by 0·2%. The error in taking an aliquot portion of C would also be involved, and the error in the assumed strength of B, and in measuring the amount of B taken from the test. The total errors would therefore be:—Error in ratio of burette readings, 0·2%; in making up C and taking a portion, 0·1%; in measuring B (average pipette error), 0·08%; in standard B, 0·12%; total, 0·50%.

If C were a solution of the whole of a constituent from a weighed portion of a substance, *e.g.*, a solution of the phosphorus from a weighed quantity of steel, then the error in taking an aliquot portion would not arise and the above value would reduce to 0·40%.

---

* The bismuthate method of determining manganese in steel is an example of Type III.

Summary of errors in typical cases.

The errors in the cases considered are summarised in the table below :—

	Type I.	Type II.	Type III.
Standard in error by ±0·03%	±0·16%	±0·26%	±0·41%
" " " " ±0·11%	±0·24%	±0·34%	±0·49%
" " " " ±0·26%	±0·39%	±0·49%	±0·64%

The mean of the values given in the above table is ±0·38%. The value ±0·4% may therefore be taken as an average value for the greatest error which may arise in a volumetric analysis due solely to inaccuracies in the apparatus used, it being assumed that the apparatus used has the maximum errors allowed under the N.P.L. Class A tolerances.

Significance of above error.

The figure ±0·4% represents the possible range of the total error due to inaccuracies of the apparatus used, and not the probable error in any particular case. The figure assumes all errors to be cumulative, whereas they may be compensating, *i.e.*, the figure relates to the worst case which may arise.

The probability of the errors being cumulative as regards sign is $1 \div 2^{n\ 1}$ where *n* is the number of pieces of apparatus used. For example, using a flask, pipette, and burette, the probability of the errors being cumulative is ¼. Hence, unless more than five or six different pieces of apparatus are involved, the probability of the errors being cumulative as regards sign cannot be considered small.

The probability of the errors in the apparatus having the maximum value allowed under the Class A tolerances cannot be assigned a definite value. It should be noted, however, that the Class A tolerances represent a high standard of manufacture, and that in ordinary commercial grade apparatus larger errors than the maximum allowed under the above tolerances are quite likely to occur.

Another important point is the significance which the above error would have in the final form in which the results of the analysis are expressed. In a large number of instances the object of a volumetric analysis is to determine the percentage of one constituent of the substance under examination. If there is x% of the constituent present, and the error in its determination due to the cause considered above is n% of that constituent, then the error expressed as a percentage of the whole substance is $nx/100$%. Thus on a 10% constituent the average maximum value of 0·4% derived above for the error in the volumetric determination would be 0·04% when expressed as a percentage of the whole substance.

The same matter may be viewed in a slightly different manner as follows :—If a 10% constituent is determined volumetrically and the result is required correct to the first decimal place, then the total errors from all causes should not exceed ±0·05% of the whole substance, *i.e.*, 0·5% of the 10% constituent.

We have seen that the errors due simply to the apparatus used being inaccurate to the extent of the N.P.L. Class A tolerance may amount to 0·4% of the constituent, taking an average of the maximum values.

It is clear, therefore, that when a constituent is to be determined to an accuracy corresponding to 0·5% or even to 1% of the percentage of the constituent present, the errors of the apparatus used are a factor requiring careful consideration.

Other sources of error.

(1) *Errors in weighing.*—These should be negligible if proper precautions are taken.

(2) *Errors of manipulation.*—Such are: (*a*) incorrect setting of liquid meniscus on graduation marks of pipettes and flasks or incorrect reading of position of liquid surface in burette; (*b*) not strictly adhering to standard methods of delivering liquid from pipettes and burettes; (*c*) loss of liquid by splashing etc.

The errors under (*a*) may be placed at approximately from 1/5th to 1/10th of the N.P.L. Class A tolerances. The errors under (*b*) are not likely to be more than 1/4th the N.P.L. Class A tolerances when standard apparatus is used. The errors under (*c*) should, of course, be negligible.

(3) *Errors due to uncertainty of end-point.*—This varies with the method of observing the end-point. With ordinary indicators as generally used, the value 0·03 c.c. should cover this source of error.

(4) *Errors due to temperature differences.*—If standard solutions are made up within one or two degrees of 15° C., and solutions are allowed to assume room temperature before titration, no serious errors need arise from this cause.

(5) *Chemical errors.*—Under this heading come such sources of errors as the partial oxidation of ferrous iron to the ferric state before the addition of the standard oxidising solution, the incomplete separation of closely allied elements, etc. Such sources of error are of a different nature from those dealt with above, and relating as they do to particular methods do not properly arise in considering errors common to volumetric analyses in general.

(6) *Uncertainties in the accepted values of the atomic weights.*—These again are of a particular nature beyond the scope of the present paper.

General conclusions.

Excluding such causes as (5) and (6) just given, it is interesting to frame some estimate of the probable percentage error arising from the other causes just enumerated. No exact figure of general application can be given. In the opinion of the author a minimum estimate would be 0·4%. To assign a maximum figure is more difficult. Twice or three times the minimum would be a fairly reasonable estimate, but the question is one on which it is impossible to be precise.

Finally it has been shown that 0·4% may be taken as a fairly representative average of the maximum errors which may arise in volumetric analysis due solely to apparatus errors when using apparatus accurate within the N.P.L. Class A tolerances, but used without applying corrections.

A more debatable conclusion is that a minimum estimate of the errors from other sources is also approximately 0·4%.

THE EROSION OF BRONZE PROPELLERS.

CONTRIBUTION TO DISCUSSION.

Mr. WILLIAM RAMSAY (of Messrs. Cammell Laird and Co., Ltd., Birkenhead) wrote that Dr. Silberrad's paper (J., 1920, 38 T) was of special interest to him as he had been engaged on the same work for some twenty years. Although Dr. Silberrad and the "Propeller Committee" appeared to be satisfied that the cause of the defect has been definitely settled as a purely mechanical action, others were not so convinced that the correct explanation had been given. The "Propeller Committee" had consisted of Sir Charles Parsons and a number of engineers and naval officers who, although of very high rank in their own professions, were hardly fitted to decide on a metallurgical or chemical question. The only other member who could deal with the matter in an authoritative manner had been Prof. H. C. H. Carpenter. On the strength of a number of somewhat unconvincing experiments the Committee had decided that the defect was due to water-hammer action, the metal being broken away by impact and not by frictional wear or erosion. However weak their experimental evidence had been in favour of water-hammer action, it had certainly proved the erosion theory to be a fallacy.

Dr. Silberrad's claim that his alloy had overcome the defect was not, in his opinion, fully proved, his (the writer's) own experience being that such propellers were no better than those made of the old manganese brass. In his article on the subject published in "Engineering," May 24, 1912, several photographs of the defect appeared, all of which had been taken from blades of the Silberrad alloy, and a large stock of such propellers had been discarded as unsafe. It was not safe to rely on the presence or absence of copper concentration on the corroded surfaces for evidence of chemical action. In the conditions under which high-speed propellers worked such removal of zinc or copper concentration was impossible. Some recent work of his own had shown that this phenomenon was entirely due to redeposition of copper from the corrosion product, and if the latter were swept away as formed no redeposition of copper took place.

He had carried out many erosion tests on similar lines to those of Dr. Silberrad, but using a high-pressure jet of Mersey water. In no case had he been able to obtain more than a slight roughening of the disturbed surface layer of metal; the extent of the action appeared to depend very largely on the manner in which the surface of the metal was prepared. If, however, the jet was made the negative and the metal the positive of a circuit supplying a small current such as might exist between stressed and unstressed metal, interesting results were obtained. At low water pressures the metal became coated with corrosion product, and the current fell off almost to nothing in a short time. At a higher pressure the corrosion product was washed away, and the metal (brass) was seen to be coated with redeposited copper. At still higher pressure this copper was removed and the corroded surface became bright and of the natural colour of the metal. Further, the loss in weight was invariably greater than that demanded by the current supplied; in one case the excess corrosion amounted to over 800%, though as a rule it was from 50% to 200%. Specimens corroded in the above manner reproduced in miniature all the features of a corroded propeller blade. No distinction could be drawn between α-brass and β-brass or one containing both phases. Pure metals behaved similarly, and, as one might expect, aluminium and zinc appeared to suffer most. Further investigation into the matter was required, but it appeared to him that such combined action might be sufficient to account for propeller deterioration.

Dr. Silberrad's tests on stressed and unstressed brass showed a small but consistently greater loss on the stressed material. A high-speed propeller blade, however, instead of being stressed four times per minute, probably suffered alternating stresses of the order of 800 per minute and possibly a much higher frequency, and had Dr. Silberrad or the "Propeller Committee" approached these conditions in their experiments it was possible that their results and conclusions might have been very different.

The practice of backing metal with soft solder for sectioning for micro-examination was, in his (the writer's) experience, open to objection, and he was surprised that Dr. Silberrad had not found many more distorted α-crystals. There was a growing suspicion among micro-metallurgists that even such a mild process as polishing a comparatively soft metal such as brass distorted the surface layer of crystals to some slight extent even under the amorphous polish layer. This was sometimes seen in an exaggerated form at the filed or sawn edges of a section. Embedding in solder, Wood's alloy, or in electro-deposited copper did not entirely prevent this, and crystals were frequently torn completely out at the junction of the two metals. The presence of distorted crystals at the edge of a fracture or a surface such as Dr. Silberrad had examined should therefore be accepted with certain reservations.

When the turbine had first been used for marine propulsion, owing to the high shaft speed and other considerations, it had been considered necessary to cut down blade weight to the lowest limit, the result being that at top speeds (about 800 revs. per minute) considerable "whipping" of the blade had ensued. Whether this was the cause of the trouble or not was still doubtful, but the use of stiffer blades had reduced the defect and, he understood, eliminated it in some cases. The present tendency to increase efficiency by reducing shaft speed by the intermediary of single or double reduction gear and stiffer propellers had practically removed the trouble, and to this extent The Manganese Bronze Co. and other equally good propeller founders might fairly claim that their alloys were erosion-proof.

The references to Sir William Ramsay called for some explanation. Sir William admittedly had not been an authority on the subject, and had intervened simply because someone had attributed the present writer's views on the subject to himself owing to their names being the same. The opinions which he had volunteered as to the universal use and success of the new alloy had been formed entirely on Dr. Silberrad's statements and not from first-hand knowledge of the subject. The continued use of Sir William Ramsay's name in that connexion therefore appeared to be unnecessary.

Joint Meeting of the Society of Chemical Industry and of the Institution of Mechanical Engineers.

Held at the Institution of Mechanical Engineers on March 4, 1921.

DEGASSING AND PURIFICATION OF BOILER FEED-WATER.*

BY PAUL KESTNER.

(*Abstract.*)

The problem of feeding boilers with water in such a way that they will run for long periods under steam without scale or corrosion has not been completely solved up to the present. The old lime and soda purifying apparatus has been improved and reduced in size, and heat has been applied to accelerate the process, but even with these improvements some kinds of water have proved refractory, scale being formed, or in some cases a concentrated solution of soda being produced in the boiler. A process has, however, been devised which prevents the formation of mud and incrustation completely. It consists of continuous blowing-down, used in conjunction with the hot purification process. Hot purification processes result in increased speed of reaction, more rapid evolution of dissolved gases, diminished viscosity of the water (resulting in more rapid settling of the precipitate), decomposition of alkaline-earth bicarbonates, and decreased solubility of calcium sulphate.

The usual method adopted to remove the sediments from boilers is to blow off the water periodically, but this necessarily involves loss of heat. To be effective, blowing off must take place to the extent of a large actual quantity of water, though the amount is small in proportion to the total contents of the boiler. In the continuous blowing down process, instead of sending the blow-off direct into the drain a relatively small quantity is removed from the boiler continuously at its lowest point and is passed through a feed-water heater of the direct contact type where it gives up its heat, the mud being deposited in a reservoir below the heater; the water in cooling loses a certain proportion of the salts which had been retained in solution and is then mixed with the feed-water and returned to the boiler. For example, the boiler may be blown down to the extent of 20% of its contents in an hour, *i.e.*, its contents are renewed every five hours; this ensures the elimination of all mud that has been produced before it has had time to accumulate. When the feed-water is purified by means of sodium carbonate, this reacts with the calcium bicarbonate, forming sodium bicarbonate, which is decomposed in the boiler into carbonate; a certain amount of sodium hydroxide is also formed in the boiler as a result of the hydrolysis of the sodium carbonate. In the continuous blowing down process, therefore, the feed-water is continuously supplied with a solution of sodium hydroxide and carbonate. If the quantity of water removed from the boiler in a given time is calculated so that it contains the quantity of soda necessary for the purification of the water entering the boiler in that time, it will not be necessary to add any sodium carbonate to remove the temporary hardness of the water.

The apparatus illustrated in Fig. 1 has been devised to use a blow-down on the described principle. It consists of a steam separator, S, which the blow-down enters in the form of a mixture of steam and water. The liquid from the blow-down falls into a central reservoir, P, in which it gives up its heat to the water surrounding it in the annular chamber, B, into which it is decanted. The steam from the blow-down rises in the reheater, R, in which it heats the feed-water, which thus loses a part of its bicarbonate. The heated water falls through the tube, T, and mixes with the blow-down as it leaves the central chamber, and then rises in the annular chamber, B, in which precipitation and settling take place. The purified water then passes through the filter and enters the boiler. The soda is distributed in the apparatus by means of a water meter, J, which admits it in proportion to the new water (make-up feed). The valves, V and V¹, allow the mud to be separated.

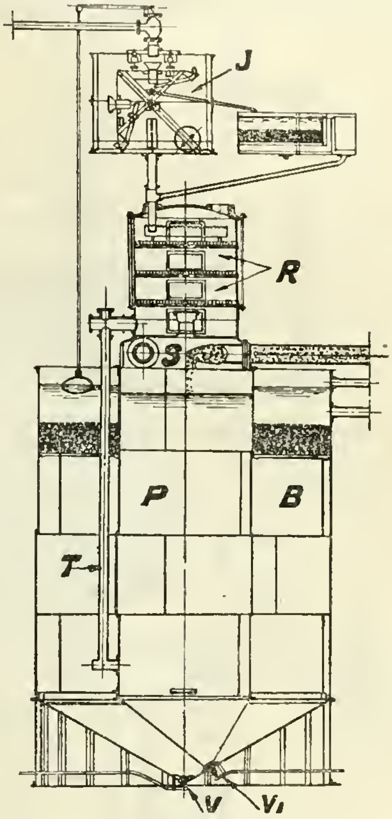

Fig. 1.

The blow-down must be arranged at the lowest possible level on the boiler without risk of emptying it. A simple arrangement (Fig. 2) is recommended by which, when the water of the boiler falls below a certain level, the siphon action of the blow-off is broken. At this moment steam leaves by the inlet and gives warning by sounding a whistle. In any case it is impossible to empty the boiler by the continuous blow-down. On the pipe of the continuous blow-down and the outlet from the boiler a reducing valve is placed, which reduces the pressure of the blow-down from that of the boiler to a pressure of 1—2 kg. per sq. cm. (15—30 lb. per sq. in.) before it enters the purifier. A meter, fitted with a regulating valve, is placed at the outlet of the boiler.

---

* The full paper will appear in an early issue of the Proceedings of the Institution of Mechanical Engineers.

The proportions of the blow-down are calculated according to the temperature to be maintained in the purifier, and the rate of blow-down depends on the working pressure of the boiler. The temperature at which purification is effected should not be less than 70° C.

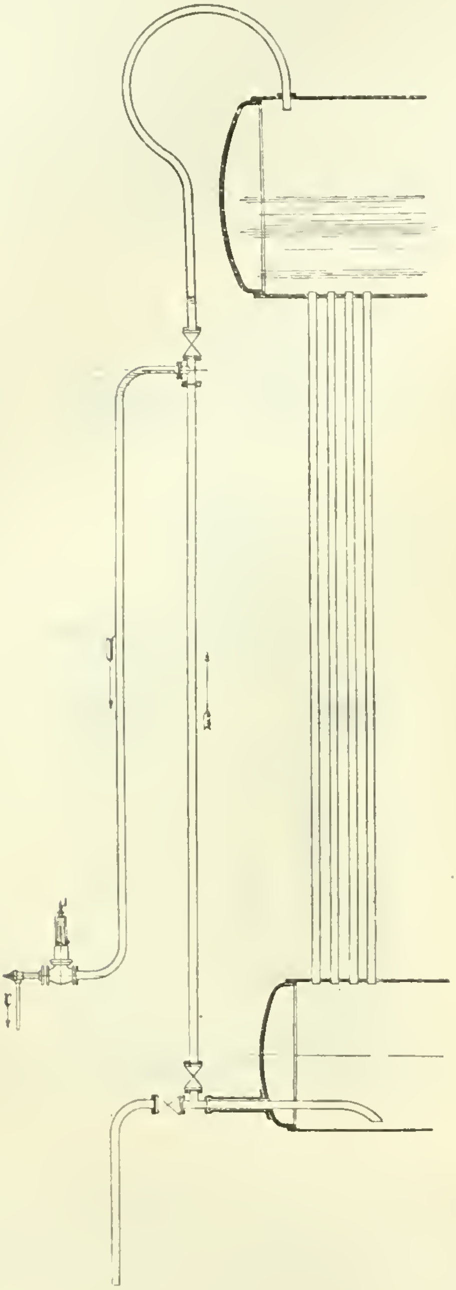

FIG. 2.

In central stations using distilled water small amounts of soluble salts are carried over by entrainment, so that the salts gradually become concentrated in the water. Boilers working with distilled water therefore require to be blown down occasionally, the amount removed being usually 1—2 %, which is replaced by distilled water. Even when an evaporator is used the continuous blowing-down method can be adopted; a certain amount of saline or impure water can be drawn from the boilers and passed into the evaporator, which returns it to the boiler after it has been freed from the greater portion of its salts. By means of continuous blowing-down, in conjunction with degassing, a complete closed water circuit can be established in a central station using distilled water.

In the case of boilers using distilled water corrosion can only be produced by oxygen dissolved in the feed-water and set free in the boiler, and the effect is greater with intermittent working.

In the case of boilers using purified water other factors have to be considered before coming to a conclusion. The corrosive effect of saline solutions increases in proportion to the concentration up to a critical point at which it attains a maximum; the effect then decreases rapidly as the concentration increases. In practice, after a few hours, a boiler using purified water will have already attained a concentration fully one hundred times the critical amount, so that corrosion cannot be attributed to this cause. Electrical action may have some influence on corrosion, but it is not of great importance. Electrolytic dissociation occurs much more easily in a dilute than in a concentrated solution, and is of little importance in connexion with corrosion.

Hydrolysis may have more important effects, particularly in the case of magnesium chloride, which gives rise to the production of hydrochloric acid. Fortunately, this salt only occurs occasionally, and its effects are sufficiently well known for special care to be given where it is present. Carbon dioxide alone has only feeble action on iron, but in presence of oxygen the metal is attacked much more rapidly. Oxygen comes into play still further when the water contains salts capable of combining with oxygen and forming unstable oxygen compounds which can part with their oxygen to form other oxides.

Thus it appears that it is the solution of atmospheric oxygen in water that is the chief cause of corrosion, whether the feed is distilled water or purified water. This is supported by the fact that corrosion is often more serious in boilers using distilled water, in which dissolved oxygen can be the only agent, than in boilers using purified water. The remedy is simple, namely, the elimination of the dissolved oxygen.

The solubility of air in water follows Henry's law. At ordinary temperatures and pressures 18 c.c. of nitrogen and 35 c.c. of oxygen form saturated solutions with 1 litre of water. The quantities of each dissolved from air are therefore: Nitrogen: $0{\cdot}8 \times 18 = 14{\cdot}4$ c.c.; oxygen: $0{\cdot}2 \times 35 = 7{\cdot}0$ c.c. The air dissolved in water will therefore contain, roughly, 33% of oxygen. Laboratory tests have shown that the quantity of oxygen dissolved in water varies slightly with the nature of the water, and soft water absorbs more than fresh water, and soft water more than hard water. Distilled water absorbs 7·8 c.c. per litre at 20° C., 2·1 c.c. at 100° C. The water supply of Paris contains 6·06 c.c. per litre at 20° C., 4·3 at 55° C., and 2 c.c. at 100° C.

When water is heated supersaturation occurs. No gas is evolved up to a temperature of 75° C. Air is only driven off continuously when the water is agitated continuously from the commencement of heating. When water that has been boiled is cooled the inverse takes place; a litre of water absorbs, for instance, 2·3 c.c. at 44° C. and 3 c.c. at 20° C.* If the water is agitated in air the false state of equilibrium is disturbed, and the water becomes saturated up to 6 c.c. of oxygen. The water resulting from the condensation of steam in the air contains 4 c.c. of oxygen per litre at 60° C. The same quantity of water of condensation exposing only a small surface to the air contains only 3 c.c. of oxygen per litre at the same temperature.

The determinations of dissolved oxygen have been made by the following modification of Winkler's method: The water is introduced into a 2-litre flat-bottomed flask through a tube dipping into a small quantity of paraffin; 1 g. of manganese sulphate is added and the flask is immediately closed by a rubber stopper fitted with a funnel having a stop-cock and a glass tube connected by rubber tube to another glass tube of larger diameter, carried on a stand. It is possible, by raising or lowering the tube, to change the pressure in the flask and to cause liquid contained in the funnel to be drawn into the flask. When the manganese sulphate is dissolved, 5 c.c. of sodium hydroxide solution is introduced through the funnel and the flask is shaken. After a quarter of an hour the absorption of oxygen by the manganous hydroxide is complete. Two c.c. of a 50% solution of potassium iodide (free from iodate) is introduced through the tube fitted with the funnel, followed by 20 c.c. of concentrated hydrochloric acid. The flask is shaken until the precipitate has dissolved and the amount of iodine liberated is determined by titration with standard sodium thiosulphate, preferably of such strength that 1 c.c. = 1 c.c. of oxygen.

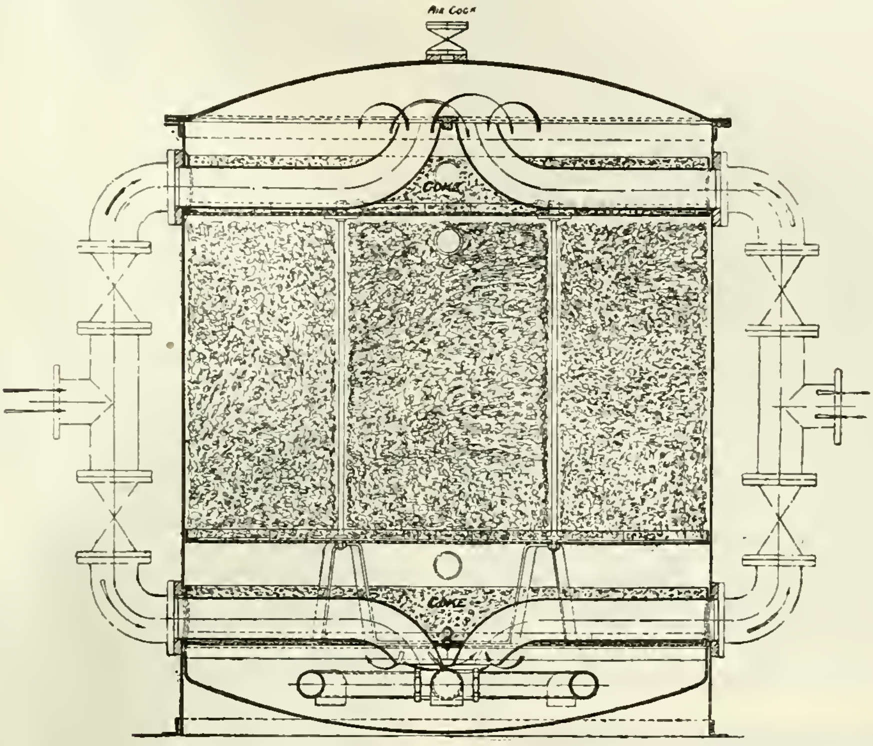

Fig. 3.

The removal of the oxygen dissolved in water may be effected either by physical methods or by chemical methods, or by the two combined. The principal physical methods are agitation of the water, heating, and reduction of pressure. These three methods may be used either separately, or in the majority of cases, in combination. Of the chemical methods the only one to be considered is the action of highly oxidisable iron, which absorbs the oxygen from the water before entering the boiler.

Agitation of the water is used in various appliances in the form of fine spraying or circulation through channels of varying section, or by passing the current of water over an uneven surface. These can only have the effect of preventing supersaturation at the particular temperature and pressure. Even if the temperature of the water is raised to 100° C. the solubility of the gases cannot be neglected. Heating, however, produces a great improvement in the condition of the water entering the boiler. A vacuum would give better results still if it could be used at a very high temperature, but the vacuum cannot be very high, otherwise the water would boil. A large German company which makes an apparatus using these three methods simultaneously states that water treated by this process still contains some milligrams of oxygen that cannot be removed by a very high vacuum and by reheating. Nevertheless, the physical removal of gases diminishes the percentage of oxygen in the feed-water and retards the corrosion.

All chemical methods of removal of gases in actual use consist in passing the water over iron. If the iron has a sufficiently large surface, if it is of a kind readily oxidised, and if the water is circulated sufficiently slowly, all the oxygen can be eliminated.

Laboratory experiments have shown that manganese accelerates the oxidation of iron, and a suitable manganese cast-iron for the purpose has been found.

In commercial appliances, when the coating of oxide becomes very thick, the removal of the oxygen may become considerably slower, but under the most unfavourable conditions water leaving such apparatus is found to contain less than 0·5 c.c. of oxygen per litre.

To avoid the retardation of the oxidising process by the deposit on the iron the Kestner Co. has designed an apparatus based on the observation that if the oxidised iron is allowed to remain at rest for a day the red deposit will become greenish-black owing to the reduction of the ferric hydroxide by the iron. This reaction takes place in the middle of the reducing agent—that is, in the presence of iron and in the absence of oxygen. The product is easily removed from the iron by washing, and, moreover, is capable of further absorbing oxygen to form ferric hydroxide.

The Kestner apparatus (Fig. 3) consists of a column of iron turnings placed between two filters with an intake and outlet for the water at each end of the apparatus, in such manner that the direction of flow of the water can be reversed at regular intervals, and an arrangement for allowing steam to be admitted at the base for cleaning.

The column of turnings is of such quantity that one-half only is in action, and that the gases are removed when the water has reached half the height. At the end of the day the direction of flow is reversed. The consumption of iron turnings varies from 1 to 3 g. per cb. m. of water.

Whatever may be the method employed for removing the gases, it involves a circuit of water closed from atmospheric contact if it is to give a large output. It is therefore advisable that the tanks in which the water is retained should be as well enclosed as possible, and that on the whole pipe system there should be a small positive pressure.

In such a system the only place at which the entry of air should be possible is the condenser in which the vacuum is produced. The tightness of the condenser should therefore be very carefully tested, and the water should pass through the gas remover immediately before entering the boiler.

The study of continuous blowing down and of degassing has led to the conception of a complete circulation system for a central station using distilled water, in which one boiler evaporates the purified water coming from the purifier and supplies steam that passes with that generated by the other steam boilers to the steam main. The steam passes through turbines, is condensed, and re-enters the boilers as distilled water after it has passed through the degassing apparatus. All the boilers are blown down, and the amounts blown down are passed collectively through the purifier. The purified water is returned to the distilling boiler after it has passed through a special degassing appliance.

The boiler containing the water to be purified thus furnishes the supply to the boilers working with distilled water in the form of steam. It is only necessary to provide an overflow reservoir to enable any excess of purified water to be re-introduced into the circuit if such excess should be produced. All the boilers can be fed either with purified water or with distilled water, which enables any desired boiler to be used for distilling.

DR. H. W. BROWNSDON IN THE CHAIR.

THE PREPARATION OF ZIRCONIA FROM BRAZILIAN ORE AND A NEW METHOD OF DETERMINATION.

BY E. C. ROSSITER, A.C.G.I., F.I.C., AND
P. H. SANDERS, A.I.C.

In the extraction of zirconia in a pure state from its ores one of the chief difficulties is the complete separation from iron and alumina. This paper describes a simple method for this separation and one which has been found to give practically quantitative results.

The method is based on the precipitation of the zirconia as a basic sulphate in which the ratio of zirconia to sulphuric acid is expressed by the formula $5ZrO_2,2SO_3$. A similar method has been proposed by K. Leuchs (G.P. 285,344, 1915) in which a basic sulphate of the formula $7ZrO_2,3SO_3,14H_2O$ is precipitated; Leuchs has modified this method (G.P. 295,246, 1916) so as to obtain a crystalline basic sulphate of the formula $3ZrO_2,2SO_3,6H_2O$. Both these products are claimed to be free from iron, but the yield is not stated. A similar method is described by the Pennsylvania Salt Manufacturing Co. (E.P. 153,113) in which a crystalline basic sulphate of the composition $5ZrO_2,3SO_3,13H_2O$ is obtained by adding the requisite proportion of sulphuric acid to a solution of the oxychloride; this basic sulphate is claimed to be substantially free from iron, titanium, and silica, but again the yield is not stated.

The ore used in the present investigation was from Brazil; it was ground fine in a porcelain ball mill before being used; during the grinding it was found that about 50% was much softer than the remainder and this was separated; on further grinding a small residue amounting to 0·8% remained unground. These three portions were analysed separately and gave the following figures:—

Analysis of the ore.

	Softer portion.	Hard portion.	Very hard residue.
ZrO_2	65·00	75·10	74·30
SiO_2	24·48	18·50	17·28
Fe_2O_3	4·90	1·75	4·80
Al_2O_3	4·30	4·05	2·70
Loss on ignition	1·25	0·50	0·50
	99·93	99·90	99·58

The ore also contained traces of titanium and manganese and gave a slight indication of thorium.

When this ore is extracted with hydrochloric acid for 3 days at room temperature only 41% of the iron and alumina is dissolved. When extracted at 100° with hydrochloric acid only 45% of the iron and alumina is dissolved and 0·25% of the zirconia.

Decomposition of the ore.

Two methods of decomposing have been examined, namely fusion with caustic soda and fusion with acid sodium sulphate (nitre-cake).

Fusion of the ore, previously ground to flour fineness, with its own weight of caustic soda at a final temperature of about 600° C. yields a product which, after extraction with hot water, is soluble in hydrochloric acid to the extent of 80% of the ore. Fusion of the ore with four times its weight of nitre-cake yields a product which on extraction with water yields a solution containing 50% of the ore.

Since, as will appear later, it is necessary to obtain the zirconia in solution as oxychloride in order to separate it completely from the iron and alumina, fusion with caustic soda is preferred. 50 g. of the zirconia ore is mixed with 50 g. of caustic soda and fused in an iron crucible; foaming occurs and the mixture is continually stirred until it becomes a granular powder; the temperature is then raised to just visible redness. The fusion takes 2 hrs. The product is thrown hot into 1½ l. of water, filtered, and the residue washed free from alkali. The insoluble residue is then treated with hydrochloric acid and the mixture evaporated to dryness on the water bath. The product is then extracted with hot water and filtered. The insoluble residue after the fusion process amounts to 19—20% of the ore used, and contains 61·55% ZrO_2, 29·32% SiO_2, 1·10% Fe_2O_3, 1·80% Al_2O_3, 5·90% loss on ignition. The solution contains zirconium oxychloride, and iron, alumina, titanium, manganese, etc.

Precipitation of the zirconia.

The solution of the chlorides is diluted to 1½ l., treated with a slight excess of sulphurous acid over that required to reduce the iron salts (about 100 c.c. of saturated SO_2), and heated to boiling. *N*/1 Sulphuric acid is then gradually added in amount equal to that theoretically required to replace the chlorine in the oxychloride or until the mixture becomes quite thick; after a short time the whole of the zirconia is deposited as basic sulphate. This precipitate is easy to filter, and settles rapidly; it is, however, very bulky, and we prefer to wash it by decantation. Five washings by decantation in a glass cylinder of 6 l. capacity reduce the soluble impurities to 0·3% of the amount originally present. The precipitate is then drained on a filter. The wet precipitate gives only the faintest indication for iron when tested with thiocyanate, and therefore contains less than 1 part in 100,000.

To obtain zirconia from the basic sulphate it may be either dried and ignited, or suspended in water, treated with alkali, and the hydroxide washed, dried, and ignited. The zirconia obtained contains 98—99% ZrO_2, the remainder being silica and a small quantity of alumina. The above precipitation as basic sulphate is practically quantitative, and affords a ready means of determining zirconia in the presence of iron and alumina.

Zirconia is precipitated from the boiling solution of its oxychloride by sulphuric acid alone, and also by sulphurous acid alone, but the precipitates are usually very difficult to filter and wash, and in no case have we been able to obtain a complete precipitation under these conditions. The exact action of the sulphurous acid has not been determined; it was added in the first instance to prevent the precipitation of iron, which always comes down in small quantity with the zirconia in the absence of sulphurous acid.

Properties of the basic zirconium sulphate.

The basic zirconium sulphate when dried at room temperature or at 100° C. has the appearance and colour of clear amber. The sample dried at room temperature contained 51·92% ZrO_2, 13·53% SO_3, and 34·53% H_2O, corresponding with the formula $5ZrO_2,2SO_3,22{\cdot}6H_2O$. The sample dried at 100° contained 65·36% ZrO_2, 17·03% SO_3, and 17·80% H_2O, corresponding with the formula $5ZrO_2,2SO_3,9{\cdot}3H_2O$. It loses water progressively as the temperature of drying is raised. After drying at 100° it is easily soluble in concentrated sulphuric acid, slightly soluble in hydrochloric acid, and completely decomposed by prolonged boiling with sodium carbonate or ammonia. When ignited it blackens and is decomposed to the oxide. Before drying it is easily and completely soluble in hydrochloric acid, and when this solution is evaporated on the water-bath crystals of zirconium oxychloride are obtained, the mother liquid containing zirconium sulphate.

The hydroxide prepared by suspending the undried basic sulphate in ammonia is easily soluble in hydrochloric acid, and this solution when concentrated on the water-bath and allowed to crystallise yields the oxychloride $ZrOCl_2,8H_2O$, crystallising in slender needles. An analysis of this oxychloride gave 38·20% ZrO_2, 21·87% Cl_2, whereas the formula requires 38·12% ZrO_2, 22·12% Cl_2.

The basic zirconium sulphate described above has all the properties of the 5:2 basic zirconium sulphate described by Rodd (Chem. Soc. Trans., 1917, 111, 396), except that the hydrate when dissolved in hydrochloric acid yields the normal oxychloride. No trace of Rodd's 5:4 basic zirconium chloride was observed. Rodd also describes a basic sulphate obtained by adding sulphuric acid to a dilute solution of zirconium oxychloride previously boiled for 6 hrs.; this basic sulphate on analysis gave figures corresponding with those of the 5:2 basic sulphate, but after drying the salt was insoluble in sulphuric acid and was unattacked by ammonia, and is therefore different from the 5:2 basic sulphate described above, and also from Rodd's 5:2 basic sulphate.

Attempts to make Rodd's 5:4 basic zirconium chloride according to the method described by him always resulted in obtaining the ordinary zirconium oxychloride $ZrOCl_2,8H_2O$. Nor were we able to prepare a 5:2 basic sulphate which was different from that described above.

The determination of zirconia in the presence of iron and alumina.

Since the precipitation as basic sulphate described above was apparently quantitative, this reaction was examined to determine under what conditions it could be used in controlling the process of manufacture. Tests on a solution of zirconium oxychloride of known strength indicated that in order to obtain quantitative results, 7 c.c. of sulphurous acid solution and 2 c.c. of *N*/1 sulphuric acid should be used for each 0·2 g. of ZrO_2, and that the solution should be diluted to at least 150 c.c. for each 2 c.c. of sulphuric acid. The difficulty to be overcome in the presence of iron is the quantity of sulphuric acid formed in the reduction of the ferric salts to ferrous by the sulphur dioxide. Good results were obtained in the presence of iron in the proportion of 1 part of Fe_2O_3 to 3 parts ZrO_2 by proceeding as above and, by modifying the method, complete separation from quantities of iron oxide up to 3½ times that of the zirconia. Attempts were made by neutralising the solution with ammonia after the reduction, but the results were high on account of some iron being precipitated along with the zirconium basic sulphate.

By the following method, however, good results were obtained. The solution used contained 0·1906 g. ZrO_2 and ferric chloride equivalent to 0·7 g. Fe_2O_3, diluted to 150 c.c.; 25 c.c. of sulphur dioxide solution was added and the mixture boiled until the iron was reduced. It was then neutralised with ammonia, 10 c.c. of sulphur dioxide solution and 2 c.c. of *N*/1 sulphuric acid added, and the liquid again boiled. The precipitated basic sulphate was filtered off, washed, and redissolved in hydrochloric acid. This solution was evaporated just to dryness to remove excess of acid, the residue dissolved in water, and the zirconia again precipitated with 10 c.c. of sulphur dioxide solution and 2 c.c. of *N*/1 sulphuric acid. The ignited precipitate weighed 0·1900 g. and was quite white (error, 0·31%).

With much larger proportions of iron the method does not give good results since the basic sulphate is somewhat soluble in the ammonium sulphate and chloride formed during the neutralisation.

Research Laboratories,
The British Cyanides Co., Ltd.,
Oldbury.

Discussion.

Mr. **Bradford** said that the method appeared to have some points of resemblance with the patented method of Rodd. The difficulty of separating zirconia from baddelyite and other ores and obtaining a pure sample was exceptionally great. He had devised a method quite different from that of the National Physical Laboratory in which ore was opened up by means of hydrofluoric acid; the extraction was carried out on an industrial scale, and he obtained zirconia which was dead white. He was interested in the quantitative separation of titanium from zirconia, and would welcome information on this point. Experiments showed that the presence of iron, alumina, titanium, etc., did not interfere with the quantitative determination of zirconia, if the latter was determined by means of "cupferron" as elaborated by Thornton and Haydon.

Mr. F. H. Alcock suggested that an effective method for opening up refractory ore was by fusing with calcium oxide or with potassium hydrogen sulphate.

The Chairman suggested the opening up by fusion with acid sulphates as leading to a possible simple analytical method when insoluble sulphates were involved. In dealing with rich lead alloys, especially those containing a few per cent. of antimony, he had found direct fusion with potassium acid sulphate and subsequent treatment of the melt with water a rapid means of obtaining the insoluble sulphate, and, indirectly, especially convenient for the titration of antimony in the filtrate.

Mr. Rossiter, in reply, said the process was very similar to that described by Rodd, the chief difference being in the use of sulphurous acid. Rodd, in his paper, pointed out that the precipitation of the basic sulphate depended upon the previous history of the solution of zirconia, but the previous history of his solution was not given. A very complete account of analytical methods for opening up and analysing zirconia ores had been given by Lundell and Knowles (J. Amer. Chem. Soc., 1920, 42, 1439). The separation of zirconium from titanium was not complete by the method described. Sodium salts were used in preference to potassium salts in opening up the ore because zirconia formed difficultly soluble salts with potassium salts. The solution obtained by fusing the ore with acid sodium sulphate and lixiviating the product would on boiling give a basic zirconium sulphate precipitate, providing it was nearly neutral, but this precipitate would most probably be difficult to filter and wash, it would not settle, and would not be free from iron. It was difficult to obtain anything like a quantitative separation of zirconia as basic sulphate from an acid solution; that was the reason why, after the ore had been opened up by caustic soda and the part insoluble in water extracted with hydrochloric acid, it was necessary to evaporate the excess of acid completely before dissolving in water. Without doing this it was impossible to effect a good precipitation of the basic sulphate.

MR. JOHN ALLAN IN THE CHAIR.

THE ORIGIN, DEVELOPMENT, AND VALUE OF THE THALLEIOQUIN REACTION.

BY WM. BEAMONT HART, F.I.C.

(*Abstract.*)

An investigation as to the analytical value of the thalleioquin reaction was carried out by the author in the year 1909, but the results as to its quantitative value were of such a negative character that they were not considered to be worthy of publication at the time; in view, however, of later published work, they appear to have some importance.

The earliest published record of the green coloration produced by the addition to a quinine solution of chlorine water followed by ammonia is made by H. A. Meeson (Phil. Mag., 1835, 158), who gave its sensibility as 1 in 8750. In Merck's "Reagentzien Verzeichnis" Manson's reaction for morphine and quinine is mentioned, but from the description and references it is quite evident that the name "Manson" is a misprint for "Meeson." Brandes and Leber, 1839, gave the name of dalleiochin or thalleioquin to the green product, hence the name of the reaction.

The reaction has been developed in various ways too numerous to detail here, by substitution of bromine for chlorine or by different methods of liberating halogen, to a sensitiveness of 1:20,000.[1]

Attempts have been made to use this reaction for the colorimetric determination of quinine, using varying quantities of halogen per quinine molecule: Trimble[2] used 38 atoms of chlorine; Léger[3] used 13 atoms of bromine, and states that the method is useless; Vondraseck,[4] using potassium bromate and hydrochloric acid, assumed that with modification and practice it could be used; La Wall used from 10 to 40 atoms of bromine from potassium bromate and hydrobromic acid per mol. of quinine.[5]

From the figures given by Trimble and Léger—the only data found up to 1909—it appeared that the amount of halogen used was excessive and variable. The present author therefore investigated the reaction to determine more minutely (1) the exact conditions necessary, (2) its limit of sensitiveness, and (3) if it were possible to base a quantitative method on it, using bromine as the halogen.

The following solutions were used: (1) Quinine as sulphate, at dilutions 1:1000 to 1:200,000; (2) bromine water, freshly made; and (3) ammonia, 5% solution. Preliminary trials showed that the shade of colour produced depended on (1) the quantity of bromine, (2) time of action of bromine before addition of ammonia, and (3) deterioration of colour by standing after reaction is obtained.

Quantity of bromine.—In all, eleven dilutions were treated with increasing amounts of bromine, starting with 0·75 and increasing by 0·75 up to 12·75 atoms per mol. of quinine, ammonia being added after similar times of action, the solutions made up to a total volume of 25 c.c., or 2¼ inches in the tube, and the colour shade noted, with the following results:—

With quinine solutions 1:1750 or stronger, and with 6 or more atoms of bromine per mol. of quinine, before ammonia addition, a yellow precipitate is obtained.

With increase of bromine and addition of ammonia the colour proceeds from blue, blue-green to yellow-green and yellow; finally this yellow disappears, except in solutions 1:5000 or stronger.

The strongest colour depth is obtained with 6 atoms of bromine shown consecutively in dilutions 1:1750 to 1:1,200,000; at 1:1000 this maximum appears somewhat earlier with 5·25 atoms of bromine, but the difficulty of comparing colours of precipitates may account for this.

The stronger the quinine solution, the earlier does the yellow shade of green appear; at 1:1000 to 1:10,000 it appears before and extends longer in the series after the maximum colour is attained.

Contrary to a published statement[2] that no green precipitate is obtained in quinine solutions of greater dilution than 1:1000, these results show at 1:5000, with 6 atoms of bromine, a decided cloudiness; at 1:2500, with the same amount of bromine, a precipitate; at 1:1750 this precipitation begins at 0·75 atom, is distinct at 2·25 atoms, and increases up to the addition of 6 atoms of bromine.

During the addition of ammonia, at dilutions of 1:1000 to 1:5000, a pink coloration is first obtained, which appears earlier with increase of quinine concentration; in every case, when the solution is alkaline, this coloration changes to green on standing.

With increase of bromine, at dilutions of 1:1000 to 1:5000, during addition of ammonia, white fumes appear, which with increase of quinine appear earlier in the series; these fumes were noted with bromine present to the extent of about 0·023 g. per 100 c.c. of solution in excess of the 6 atoms per quinine molecule.

Time of action of bromine before addition of ammonia.—Experiments were now made to find the influence of definite intervals of time of action of bromine before addition of ammonia, the intervals chosen being immediate (five seconds), one minute, and five minutes, with the following results: With immediate action, and addition of ammonia till the solution is alkaline, the best results are obtained with stronger solutions, down to 1:40,000, according to the amount of bromine present; with one-minute action weaker solutions give the best results; action of bromine for five minutes reduces the resultant colour strength, but in the weaker solutions (1:40,000 downwards) this is still of deeper shade than with the corresponding dilutions with immediate action.

Colour-strength deterioration.—Trials made for this purpose showed that the green colour fades to some extent, but not very materially up to five minutes.

The following conclusions are drawn from the above results: (1) Excess of bromine and its prolonged action are detrimental to the production of the thalleioquin reaction, 6 atoms of this halogen for one minute being ample for strongest colour depth; (2) with quinine solution 1:1000 to 1:20,000 the reaction commences in presence of 0·75, at 1:40,000 to 1:80,000 in presence of 1·5 to 2·25, at 1:120,000 in presence of 3, and at 1:200,000 in presence of 6 atoms of bromine per mol. of quinine; (3) as a qualitative reaction, by making a few preliminary trials it can be made very sensitive, the limit being 1:250,000 in a depth of liquid 2¼ inches (of course, the greater the depth the greater will be its sensibility); for quantitative work, with so many variables, no credence of even approximate accuracy can be assigned to the reaction, except under very strict conditions and in very dilute solutions, as shown.

Bromine absorption in aqueous solution.—Attempts were made to determine the bromine absorption of quinine in aqueous solution for 5, 10, and 20 minutes' action with 2·5, 5, and 11·5 atoms of bromine per mol. of quinine, using quinine at 1:1000 and bromine water at one-tenth saturation, the excess of bromine being titrated with thiosulphate after addition of potassium iodide. The results obtained showed that although four atoms of bromine appears to be the maximum quantity absorbed, and this is constant for five minutes, yet any excess over two atoms is only loosely held and appears to be slowly given up again.

The earlier workers (Andre, Brandes, etc.) did not find chlorine in their product; Commanducci,[6] by varying the time of action of chlorine, obtained two new red products even in alkaline solution—a statement at variance with the present author's bromine results. Comstock and Koenigs,[7] by extracting their quinine dibromide with water and separating by means of ammonia, did not obtain any thalleioquin reaction. Buraczewski and Dziurzynski,[8] on treating their quinine pentabromide with water not above 40° C., filtering and adding ammonia to the filtrate, obtained a white flocculent precipitate which soon became emerald-green and contained bromine, and they state that it is probably identical with the substance formed in the thalleioquin reaction. Christensen,[9] by progressive chlorination of quinine, obtained (1) quinine hydroxychloride and dichloride, in which the vinyl group is saturated and which give the thalleioquin reaction when chlorine followed by ammonia is added to the slightly acid solution; (2) with 4 atoms of chlorine, an unstable base, 5-chloro-6-hydroxycinchonine hydroxychloride, which gives the thalleioquin reaction on treatment with an oxidising agent, a substance that combines with chlorine, and ammonia; (3) with 6 atoms of chlorine, an unstable base, 5-dichloro-6-ketocinchonine hydroxychloride, which liberates two atoms of iodine from potassium iodide for the one active chlorine present and therefore probably contains the group $—CO.CCl_2—$ in the quinoline nucleus, with consequent conversion into the group —C(OH):CCl—. This base gives the thalleioquin reaction on addition of ammonia only; the green product on drying leaves a residue of chloro-5.6-diketohydroxycinchonine, the group $—CO.CCl_2—$ being replaced, in presence of ammonia, by the —CO·CO— group.

As far as is known, then, the action of chlorine or bromine on quinine in dilute aqueous acidified solution is similar, and the products, beyond the dihalogen stage, that can be formed during or can give rise to the thalleioquin reaction, are numerous. The author attacked the problem from the analytical standpoint, and his conclusion, in 1909, that 6 atoms of halogen are required for the full reaction, is confirmed by the later results of Christensen; these also explain why, in the results of the bromine absorption in aqueous solution, apparently not more than four atoms as a maximum are absorbed, whilst actually six atoms take part in the reaction, the two atoms of iodine set free being determined as unabsorbed bromine. It follows, then, that quinine may be determined from its bromine absorption for five minutes in the manner stated: 1 c.c. $N/10$ Br = 0·0081 g. quinine.

It is possible and probable that the progressive halogen action runs concurrently to some extent; that is to say, part of the halogen is preferably used in further conversion of the intermediate products than in full conversion of quinine into intermediate products; this would explain why the thalleioquin reaction is obtained, though not to the full extent, by the action of much less than six atoms of bromine per mol. of quinine. Christensen's statement that the intermediate product, 5-chloro-6-hydroxycinchonine hydroxychloride, gives the reaction by treatment with an oxidising agent, a substance that combines with chlorine, and ammonia, may explain the mechanism of the delay in the final green colour production by Vogel's reaction (1850) and also by Battandier's reaction (1904), since we have the three essentials, time only being necessary; to some extent this also applies to Kletzinsky's reaction (1854), though in this case a further change probably occurs. During the early stage of this investigation the use of a solvent, such as amyl alcohol, for the green product suggested itself, but from the above results it was not thought to be of any value.

Discussion.

The Author, replying to a question, said that it was not practicable to estimate the colour depths by the absorption spectra or by the colorimeter, owing to the rapid changes of colour of the solutions and the large number of experiments being carried out at the same time.

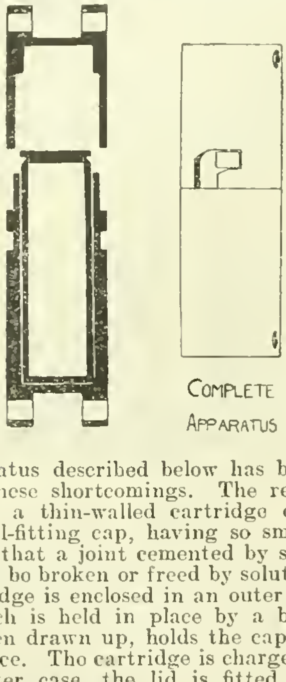
NOTE ON AN APPARATUS FOR SODIUM PEROXIDE FUSIONS.

BY H. J. HODSMAN, M.B.E., M.SC., F.I.C.

The method of fusion with sodium peroxide for converting insoluble combustible matter into a form suitable for ordinary analytical operations is finding many applications, *viz.*, in the determination of sulphur, chlorine, and phosphorus. The forms of apparatus described hitherto have not been free from objection and even risk in handling, especially to the novice, for the reaction is mildly explosive. In some methods the risk is increased by immersing the apparatus more or less completely in water. Screwed threads are liable to seize, making the apparatus difficult to open. The trouble is accentuated if any of the melt solidifies in the threads. Firing by means of heated wires or pellets is erratic, especially to the inexperienced.



The apparatus described below has been designed to avoid these shortcomings. The reaction vessel consists of a thin-walled cartridge of steel tube with a well-fitting cap, having so small a surface of contact that a joint cemented by solidified melt can readily be broken or freed by solution in water. This cartridge is enclosed in an outer cylinder, the lid of which is held in place by a bayonet catch which, when drawn up, holds the cap of the inner tube in place. The cartridge is charged and placed in the outer case, the lid is fitted on, and the apparatus is supported inclined in a clamp and heated at the base for a few minutes over a Bunsen flame until firing has occurred. Alternatively, the apparatus may be placed in a muffle. After cooling, the lid is removed, the cartridge withdrawn, its contents are extracted with water, and the analysis can be proceeded with by the methods in vogue for the determination in question. The outer tube and cover are extended at both ends and bored for the insertion of a rod which facilitates opening. This is unnecessary when the apparatus is properly used. The apparatus can be opened while hot if desired.

Fuel Department, Leeds University.

Discussion.

Mr. W. McD. Mackey said that when using sodium peroxide in a Roland Wild calorimeter very high results had been obtained in a number of cases, which he attributed to the possible presence of free sodium in the peroxide.

Mr. D. McCandlish asked if the peroxide fusion method could be used for the determination of arsenic in fuels, and also whether the author prescribed any special degree of fineness for the powdered fuel.

The Author, in reply, said that he had not come across any sodium peroxide which contained free sodium, and he suggested that Mr. Mackey's high results might have been due to leakage of water into the crucible. The peroxide fusion method was especially useful for the estimation of sulphur in coal, but there was no apparent objection to using it for arsenic determinations. He had used it for the estimation of phosphorus in coke. As regards the fineness of the coal powder no special precautions were needed if the powder and peroxide were well mixed. The fact that the whole apparatus was directly heated in a Bunsen burner made it unnecessary to have such an intimate and homogeneous mixture as was required in a sodium peroxide calorimeter. In the author's experience the peroxide calorimeters of Parr gave fairly satisfactory results for the ordinary grades of coal.

Communication.

THE HYDROLYTIC ALKALINITY OF PURE AND COMMERCIAL SOAPS.

(*See* J., Feb. 28, 1921, 27—29 T.)

Mr. R. G. Saraiya writes as follows:—On p. 29 T, under "Sodium carbonate," it is said:—"Simmons states that 'sodium carbonate has an irritating effect . . . and must only be present to a very small extent in a toilet soap, usually not exceeding 0·15%.' The experiment gave a concentration of hydroxyl ion in 0·15% sodium carbonate *solution* at 25°, amounting to 0·0010 *N*. . . . Thus a maximum alkalinity recognised as permissible is about 0·001—0·002*N* OH′ . . ." Now, Simmons refers to 0·15% of sodium carbonate on the *soap*. The determination of the hydroxyl concentration in the above experiment was made on a 0·15% solution of sodium carbonate. Hence it seems scarcely justifiable to conclude from this experiment that "a maximum alkalinity recognised as permissible is 0·001—0·002*N* OH′." It would be interesting in this connexion to find the OH′ concentration in aqueous solution of a pure soap containing 0·15% (on the soap) of sodium carbonate."

Mr. T. R. Bolam writes in reply:—"We are indebted to Mr. Saraiya for having pointed out the obvious slip in the short final paragraph dealing with sodium carbonate, which fortunately leaves the experimental data and the paper itself otherwise unaffected. 0·15% sodium carbonate in a soap in the usual technical units amounts to about 1·6% of excess of alkali in the form of carbonate when expressed in chemical equivalents. The data show that sodium carbonate taken alone is much more hydrolysed than an equivalent quantity of soap. Previous data show that in *N*/20 or *N*/10 sodium palmitate solutions the alkalinity is 0·0011 to 0·0014 *N* OH′, and that when to these solutions there is added 1 or 2% (in equivalents) of sodium hydroxide the concentration of hydroxyl ion is increased by about half the normality of the excess of alkali added. This would indicate that addition of even these small quantities of sodium carbonate would increase the hydroxyl concentration of 1% soap solutions by an appreciable fraction."

DR. D. S. JERDAN IN THE CHAIR.

INVESTIGATIONS ON THE RANCIDITY OF BUTTER AND MARGARINE FATS.

BY W. N. STOKOE, B.SC., A.I.C.

Of all the problems which those concerned with the manufacture of fatty foods have to face the question of the occurrence of rancidity, either in the raw materials or the finished article, is probably the most acute. During the warm summer months in particular the manufacturer is constantly haunted by the possibility of his goods going wrong within a short time, in spite of meticulous care during manufacture, and each year an astonishingly large quantity of unsaleable goods finds its way eventually to the soapmaker. It is, therefore, of paramount importance that this problem should be carefully studied, and a thorough insight gained into the conditions causing and favouring the occurrence of rancidity.

A considerable amount of work has already been done and published on this subject, but even yet the nature of the chemical changes covered by the term rancidity is but little understood, and on many points there is still considerable diversity of opinion.

The rancidity of pure fats is now generally understood to be due to a product of hydrolysis and oxidation, and it is usually characterised by the loss of the natural sweetness and flavour of the fat, the formation of compounds of unpleasant odour and taste and a development of acidity in the fat. However, the acidity of a fat is in no way a measure of its rancidity or non-rancidity, for it is possible to have examples of fats showing extremely low acidity and yet being very rancid, whereas other cases may occur in which the fats show a much higher free fatty acid content and yet are perfectly sweet and non-rancid.

In commercial oils and fats the chief causes influencing rancidity seem to be the action of moisture, air, and light, assisted by traces of lipolytic enzymes which may be present in the oils. Generally speaking vegetable oils and fats are free from these enzymes owing to the comparatively high temperature to which the oil is subjected during refining. It is a fact, though, that under certain conditions lipolytic enzymes can withstand a considerably higher temperature than the usual thermal destruction point of enzymes without being destroyed.

Animal fats, on the other hand, being rendered at a low temperature, contain traces of enzymes derived from the tissues of the animal. The presence of enzymes will largely depend on the care taken to ensure separation of tissue.

The first stage in the development of rancidity is hydrolysis, which, however, may be very slight and scarcely capable of detection by chemical means; then oxidation and a multitude of other reactions take place. Some observers state that the oxidation of the glycerol set free in the initial hydrolysis is the actual cause of the rancid taste.

It has been thought that micro-organisms are the cause of rancidity, but in pure fats this is not the case, for organisms introduced into the fat quickly die. In butter and margarine the case is different, for here there is adequate nidus for the development of the organism. Ritsert[*] found that pure lard was not turned rancid by bacteria, aërobic or anaërobic, and this result has been confirmed by other workers. Duclaux[*] showed that micro-organisms play no part in the production of rancidity, for the fats being insoluble in water cannot afford nutriment to the cells. The present author's experiments have confirmed this view, though it would appear that a slight hydrolysis does occur in the case of the fat-splitting organisms.

A culture was taken from a sample of rancid margarine showing a free fatty acid content of 1·84%, and the principal organisms present plated out and obtained in the pure culture state. Samples of pure fats were procured and inoculated with the pure cultures. In these experiments the organisms used were a mould, *Penicillium glaucum*, and a bacillus, *B. fluor. non-liq.* After a week the free fatty acid was determined in a portion of the inoculated fats, the remainder being replaced in the incubator. After a second week the acidity was again determined.

TABLE 1.

Inoculated with Penicillium glaucum.

Oil or fat.	Free fatty acid.	After 1 week.	After 2 weeks.
	%	%	%
(*a*) Coconut	0·078	0·085	0·085
(*b*) Palm kernel ..	0·078	0·085	0·085
(*c*) Lard	0·20	0·22	0·23
(*d*) Oleo	0·25	0·26	0·26
(*e*) Prem. jus	0·16	0·19	0·19
(*f*) Groundnut	0·28	0·28	0·29
(*g*) Soya bean	0·19	0·10	0·19
Control 1—Coconut ..	0·078	0·078	0·078
Control 2—Oleo ..	0·34	0·34	0·36

Note.—The free fatty acid is expressed in terms of oleic acid. In all cases the odour and taste were unimpaired.

Table 1 shows the free fatty acid determinations on the fats inoculated with *Penicillium* and two uninoculated controls. The figures for the fats inoculated with *B. fluor. non-liq.* are similar. The results show a slight increase in acidity, whereas there is no appreciable increase in the control samples. As far as taste and odour were concerned the fats had apparently not deteriorated in any way. The fat remaining after the second series of determinations was emulsified with nutrient media and placed in the incubator. In each case after a few days a growth of the mould organism was obtained, showing that the spores of the mould remained fertile in the oil. This point will be referred to again later.

It appears probable that the vegetative cells live for a short time in the fat while the organism uses up its reserve material. In this period the organism presumably secretes a small quantity of lipase which is able to cause a slight hydrolysis of the fat. It is, of course, well known that with enzyme-secreting organisms the maximum amount of enzyme present in the plant is obtained when the plant begins to utilise its reserve material. It is then that the enzyme is best able to diffuse from the cells of the plant.

The rancidity of butter and margarine is almost wholly caused by the action of micro-organisms, which find in these substances a suitable medium for their growth and propagation. To a certain extent the development is restrained by the use of preservatives such as salt and boron compounds, but at best these are but feeble antiseptics in the quantity usually found or allowed in foodstuffs.

The kinds or forms of rancidity which occur are several and may be classified into divisions depending largely on macroscopic appearance, odour, and taste.

---

[*] Inaug. Dissert., Berlin, 1890.

[*] Ann. Inst. Pasteur, 1887; Comptes rend., **102**, 1077.

(1) *The fat having a stale greasy taste and odour, but not discoloured or visibly affected in any way.* Instances of this type of rancidity are found principally with pastry margarines, *i.e.*, margarines of a hard nature containing mostly fats of high m.p. These are, as often as not, churned with water only, not milk. This case is comparatively simple, and is really analogous to the rancidity of a pure fat, where the rancidity changes are due to air, light, and moisture, possibly assisted or accelerated by the action of traces of lipolytic enzymes present in the fats. The author has attempted to determine whether or not fats rancidify more quickly than the same fats previously heated to a temperature sufficient to destroy any enzyme present. These experiments were, however, unsatisfactory, and although a good many figures were obtained it would be unwise to attempt to draw any conclusions from them. Generally speaking heated oils increased in free fatty acid content more rapidly than the unheated oils, so that enzyme action is altogether out of the question as far as these experiments go. Of course pastry margarines which contain, as a rule, a major proportion of premier jus or stearine, require to be churned at a high temperature approaching the thermal destruction point of enzymes, and it would therefore be expected that any enzyme present would be considerably weakened, if not totally destroyed. In general the flavour of animal oils and fats is impaired by heat.

Samples of margarine rancid in the form just referred to were invariably old and in most cases had been unduly exposed to air and warmth. The fat had a stale taste and tallowy odour, but did not show an abnormal acidity on analysis. The outside of the margarine was much more affected than the inside.

The "tallowiness" of old butter is another instance of this form of rancidity, seeing that it is not caused by biological conditions, but by the action of air and light.

It seems that this characteristic tallowiness of rancid fats and rancid butter is an oxidation effect. Hunziker and Hosman* suggest that glycollic acid is formed from the glycerol produced by the initial hydrolysis and that the glycollic acid then combines with fatty acids, so producing the unpleasant flavoured compounds. The presence of lactose intensifies the oxidation effect since it leads to excess of glycollic acid. Light does not appear to be essential to the oxidation but has an accelerating effect. Oxidation is accompanied by a decrease in the iodine value.

(2) *The "perfume" form of rancidity.* For want of a better description this form of rancidity, ocurring frequently in margarine, may be termed the "perfume" rancidity. A strong distinctive aromatic odour is produced which is not at all offensive, but the rancid fat has a vile pungent taste.

This form of rancidity is most obnoxious, for it can occur in margarines only a few days old. The margarine may appear perfectly good and wholesome and yet have this most objectionable taste and powerful odour. In more advanced stages of this rancidity the margarine is often discoloured and patchy, but it is usually the early stages with which one has to deal.

In the investigation of this problem a number of rancid samples were procured and biological cultures prepared from each, after which the principal organisms present were isolated in the pure culture state. At this point one fact became evident, namely, that in every case mould organisms, principally *Penicillium* species, were present. Another noticeable feature is the fewness of the lactic acid organisms present on the plates. Analysis of the fat of the samples showed that in every case in which this type of rancidity was observed the fat contained a proportion of coconut oil, palm kernel oil, or both. This directly confirmed manufacturing experience, which always associated coconut oil with and blamed it for this trouble.

It was next decided to prepare media containing pure oils and to inoculate tubes of the special media with the organisms isolated in the former work. The media were prepared by emulsifying nutrient lactose, gelatin, and agar with sterilised fats, and in this way media were made up containing respectively coconut, palm kernel, and other common fats. Tubes of these media were inoculated with the different organisms previously obtained and incubated at 68° F. Table 2 shows the results obtained.

TABLE 2.

Incubation: 7 days at 68° F.

Organism.	Wild yeast.	*B. acidi lactici.*	*Sarcina lutea.*	*Penicillium glaucum.*
Coconut oil media	No odour	No odour	Putrid odour. Decomposition of nitrogenous matter.	Very strong "perfume" odour.
Palm kernel oil media	No odour	No odour	Do.	Strong "perfume" odour, same as C.N.
Media containing oleo and lard.	Slightly rancid odour.	No odour	Do.	Musty odour
Media containing cotton seed oil	Very slight odour suggesting staleness	No odour	Do.	Slight musty odour.
Media containing arachis oil.	Do.	No odour	Do.	Do.
Media containing soya bean oil.	Do.	No odour	Do.	Do.

It will be observed that only the coconut and palm kernel media produced the "perfume" in question, and that the organism concerned was *Penicillium*. Later on a sample of babassu fat was examined in the same way, and was found to give a similar result to coconut and palm kernel. These results were confirmed by repetition using samples of oil of various origin. In every case the mould *Penicillium glaucum* was able to produce this "perfume" rancidity with coconut and palm kernel oils. Up to the present *Penicillium glaucum* was the only mould organism experimented with, seeing it was the principal organism found in the samples examined. Subsequently, however, other mould organisms were isolated from rancid butter and margarine. Pure cultures of these were prepared in the usual way.

Table 3 shows the effect of cultivating the various common mould organisms on media containing coconut oil and butter fat.

It appears from this table that species of *Penicillium* and *Aspergillus* alone can produce the "perfume" odour, but that hydrolysis occurs to a greater or less degree in each case.

The "perfume" odour is not produced with butter fat.

It will be noticed that *Oidium lactis* liquefied the media. This, of course, only occurs in the case of acid media.

In a recent paper on this same subject, H. C. Jacobsen,* who has worked along similar lines, states that the ester odour of rancid coconut oil appears only under microbic influence. He finds

---

* J. Dairy Sci., 1917, 1, 320.

* Folia Microbiologica, Deel V., Afl. 2 (Nov., 1918).

further that only the following moulds have this capacity:—*Penicillium glaucum*, *Aspergillus* spec., *Mucor* species, *Clasterosporium* species, *Hormodendron* spec., *Phoma* spec., and *Cladosporium butyri*. *Oidium lactis* does not cause rancidity.

TABLE 3.

Incubation: 7 days at 68° F. Coconut oil (a), f.f.a. 0·07% lauric. Butter fat (b), f.f.a 0·33% oleic.

Organism.	Coconut oil media.	(a)	Butter fat media.	(b)
	Observations.	F.f.a.	Observations.	F.f.a.
		%		%
Oidium lactis	Cheesy, not unpleasant odour, gelatin liquefied.	13·6	Strong cheesy odour.	10·3
Penicillium glaucum	Strong "perfume" odour, gelatin liquefied, fat discoloured.	6·1	Slight odour of butyric acid, also somewhat mouldy odour.	3·1
Aspergillus glaucum	Strong "perfume" odour, gelatin liquefied.	6·8	Rancid odour, somewhat masked by smell of mould.	5·2
Botrytis cinerea.	Musty earthy odour, gelatin not liquefied.	4·7	Odour very slight, not distinctive.	4·8
Cladosporium oidium	No appreciable odour, gelatin not liquefied, fat discoloured; black.	2·0	Slightly stale odour, fat much discoloured.	6·5
Mucor mucedo	Earthy odour, gelatin not liquefied.	9·6	Stale odour of rancid butter.	6·8

Fatty acid expressed as (*a*) lauric acid, (*b*) oleic acid.

Jacobsen does not state the precise organism used in his experiments. Certainly *Botrytis cinerea*, *Cladosporium oidium*, and *Mucor mucedo* did not produce the "perfume" form of rancidity.

Experiments were next undertaken to attempt to determine the conditions favouring the production of this "perfume" rancidity.

Influence of the composition of the media.

The following media were prepared, sterilised and emulsified with various oils and fats as before. (*a*) Nutrient broth—peptone, flesh, lactose. (*b*) do., no sugar. (*c*) Nutrient gelatin, no flesh, dextrose. (*d*) Milk. (*e*) Whey soured by pure lactic acid ferment. (*f*) Casein. Portions of these media were inoculated with the pure cultures previously prepared and incubated for a week at 68° F. (20° C.).

Tables showing the individual observations were not drawn up, but briefly the principal points observed were:—

(1) In every instance the growth of species of *Penicillium* or *Aspergillus* upon media containing coconut or palm kernel oils produced the "perfume" form of rancidity.

(2) Of the two oils coconut seems to be the more susceptible; throughout the whole series of observations, as far as could be ascertained, the odour from the coconut media was stronger than from the palm kernel, though identical in character.

(3) The influence of sugar in the media is noteworthy; in absence of sugar the odoriferous substance is not so readily produced.

(4) Mould spores did not readily germinate in the soured whey media, probably owing in some measure to its nitrogen deficiency, but with the casein media there was a prolific mould growth and corresponding rancidity in the course of a few days.

Further experiments were next undertaken to ascertain the effect of acidity or alkalinity of the media. Table 4 shows the relative quantities used and the results of the experiments.

TABLE 4.

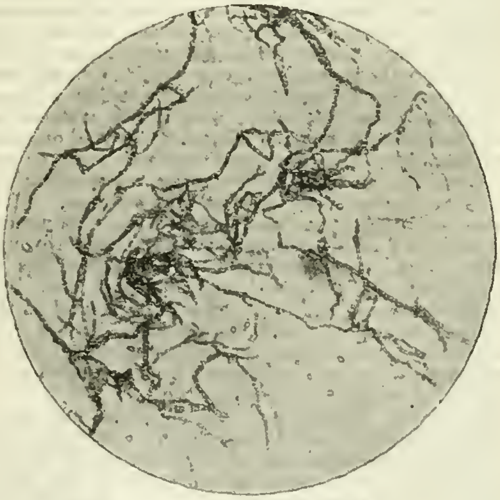
Organism: Penicillium glaucum. Media: Coconut oil (f.f.a. 0·07%), gelatin lactose.

Acidity or alkalinity of media.	Observations after 7 days incubation at 68° F. (20° C.).	F.f.a. as lauric acid.
		%
2½% *N*/10 HCl.	Abundant mould growth; media liquefied, "perfume" odour; fat discoloured green.	4·9
5% *N*/10 HCl.	Less mould growth; media not liquefied; "perfume" odour; discoloration very slight.	2·0
5% *N*/1 HCl.	Much growth of the mould; odour very slight; fat orange coloured.	4·2
5% *N*/10 NaOH	Abundant growth; strong "perfume" odour; gelatin liquefied.	5·4
5% *N*/1 NaOH.	Less luxurious growth; gelatin liquefied; odour very slight.	3·2

The experiments are not very conclusive, but it would appear that the "perfume" is produced even in presence of 5% of *N*/1 acid. In presence of a similar quantity of alkali the perfume is produced to a small extent, but in both cases a considerable hydrolysis of the fat takes place.

The influence of temperature.—This is, of course, very marked. Warmth accelerates the growth of the organism, and for this reason it is really only in summer that the problem of the occurrence of this rancidity is accentuated. In winter the preservatives present in margarine are usually sufficient to restrain undue propagation of the organisms present.

Samples of margarine showing this "perfume" form of rancidity are invariably more rancid at the outside than the inside. As often as not the inside is perfectly sweet and fresh. In more advanced stages the rancidity does penetrate right down through the bulk, but invariably it will be found that the outside is the more decomposed. The free fatty acid content is always found to be much higher at the outside. The "perfume" rancidity is always accompanied by fat splitting to a greater or less degree. This is, of course, to be expected seeing that both *Penicillium* and *Aspergillus* are lipase-secreting organisms. Microscopical examination of the rancid margarine often reveals the presence of mycelia which penetrate through the fat (see Fig. 1).



Thin layer of rancid fat showing disintegrated mycelium of the mould organism. (× 50, unstained.)

FIG. 1.

The mycelia are often much disintegrated and in samples but slightly rancid their presence is sometimes extremely difficult to detect. The amount of the compounds produced giving the strong perfume is exceedingly small. Steam distillation of 200 g. of a rancid margarine only yielded less than 0·1 c.c. of the odoriferous substances.

The question as to the mechanism of the action of this form of rancidity now arises. Apparently air assists the action if not necessary to it. Does lipase so act on coconut and palm kernel oils to produce the effect in question; or is the lipase of the *Penicillium* and *Aspergillus* organisms peculiar to itself; or is another independent enzyme responsible for the acceleration of the change? When coconut or palm kernel oil rancidifies through the usual agency of air, light and moisture the "perfume" is *not* produced; there is produced, on the other hand, the usual stale greasy taste and odour common to rancid fats. Clearly then an additional factor enters into consideration.

In the first instance a solution containing lipase of vegetable origin was prepared from castor oil seeds. Germinating seeds were ground up in a mortar with a 5% sodium chloride solution containing 0·2% potassium cyanide, the whole being allowed to stand after the operation for 24 hours. The filtered solution was then ready for the experiments. Portions of coconut and palm kernel oil were mixed with the enzyme solution, four drops of carbon tetrachloride added, and the test mixtures kept for given periods of time at a temperature of 68° F. In a series of experiments the time, concentration and proportion of enzyme liquid were varied. In all cases hydrolysis of the fat took place to a greater or less extent, sometimes considerable, but there was no production of aroma or "perfume" whatsoever, showing that the lipase alone as prepared from castor seed is incapable of producing the effect in question.

Attempts were next made to prepare the enzyme or enzymes of the mould *Penicillium glaucum.* Several methods were tried without success, but the following method proved fairly satisfactory. A wide vessel was filled to a depth of about ½ in. with a medium made by emulsifying coconut oil with a gelatin lactose medium. This was liberally sown with spores of the organism and placed in the incubator. After several days a luxurious growth of the mould completely covered the surface of the medium. The latter was then gently warmed to melt it completely and enable the mould plant to be lifted bodily out of the liquid. It was then transferred to a vessel containing distilled water, which was replaced in the incubator. A small amount of the original medium adhered to the plant and was more or less dissolved by the water, forming a substratum for the organism of very low nutritive value. After several days the plant was removed from its watery bed and the liquid filtered several times through cotton wool until free from cellular elements as determined by microscopical examination and incubation tests. Addition of strong alcohol to the solution produced a slight opalescence. Tested with tincture of guaiacum and hydrogen peroxide, a positive reaction was obtained, but the boiled solution failed to give the reaction.

The liquid containing the enzymes was next mixed with sterilised coconut oil in varying quantities with the addition of four drops of carbon tetrachloride, and the tests set aside in the incubator at a temperature of 68° F. A control was also prepared, in which the enzyme liquid had previously been boiled. After a week it was found that the "perfume" odour had been produced and that the fat tasted very rancid, but the control was still sweet to taste, and there was no suggestion of the "perfume" odour. A similar series of tests with the further addition of lactose was made, the results of which confirmed the former. If anything the "perfume" odour was stronger in the last experiments. A similar test with the addition of lactose was made with the castor oil seed lipase solution, but there was no formation of the "perfume" rancidity. Table 5 shows the results obtained, using 10 g. of coconut oil in each case.

TABLE 5.

—	10 c.c.	Present		1·12
—	20 c.c.	Present		2·38
—	20 c.c. Boiled.	Present	No odour; taste still quite sweet and fresh.	0·16

It will be observed that the extent of the hydrolysis brought about by the enzyme is roughly proportional to the quantity of enzyme liquid used.

These results appear to indicate that the "perfume" form of rancidity of the coconut group of oils is brought about by an enzyme secreted by certain of the mould organisms acting probably in conjunction with the lipase secreted by the same organism. Up to the present I have not succeeded in preparing this enzyme apart from lipase, nor yet obtained much reliable information concerning its action. It seems, however, to provide a subject for an interesting piece of biological research. Jacobsen in his paper, already referred to, calls the "perfume" produced an "ester odour," and appears to regard it as due to esters of some of the volatile acids. In this he seems to have been mistaken, for although there may be traces of esters present in the substances produced, undoubtedly the greater part is a ketone or mixture of ketones. About 75% is methyl nonyl ketone, and this is accompanied by methyl heptyl and methyl undecyl ketones. By steam distilling a culture of *Penicillium* grown on a medium containing coconut oil a small quantity of these odoriferous substances was obtained in a comparatively pure state. The distillate gave a strongly positive reaction for ketones, but was negative to tests for aldehydes.

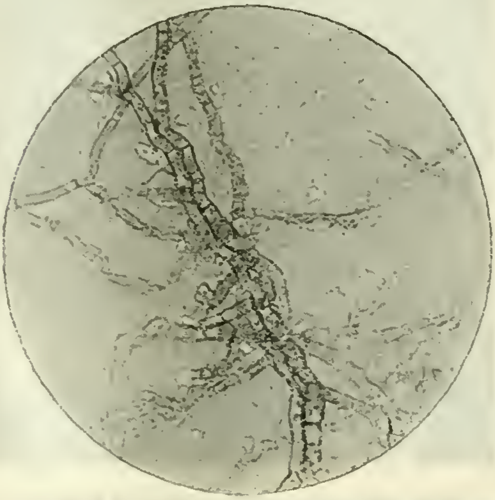
3. *Rancidity where there is a marked discoloration of the butter or margarine.*

As already indicated, fats in the advanced stages of perfume rancidity often show discoloration. The yellow colour of the fat loses its natural brightness and sometimes the fat tends to lose its colour. Sometimes darker coloured patches are formed. Some time ago dimethylaminoazobenzene was largely used to colour margarine, but of late it has been more or less superseded owing to the action of rancidifying fat upon it. The dye invariably tended to change its shade to a pinkish hue as the formation of free acidity proceeded.

The discoloration of the rancid margarine may take the form of black irregular patches, blue patches, or large spreading pink to red areas dotted over the bulk of the margarine (this must not be confused with the dye effect already mentioned). Sometimes one form predominates, sometimes another, or they may occur together in the same sample.

All these effects are caused by the growth of micro-organisms. In some cases the organisms are moulds, in others, bacteria or yeasts. By making cultures from the rancid samples showing these effects the responsible organisms were isolated and studied for identification.

The black patches as a rule do not extend to any depth; they are merely surface colonies of the organism. In such cases the rancidity is localised, only the surface layer being affected. The appearance of the fat is repulsive, but the taste is only slightly affected and no odour is produced. The organism causing this trouble is a species of *Cladosporium*, and by smearing the surface of butter or margarine with a culture of the organism the discoloration could be closely imitated. Examination of discoloured portions of the fat under the microscope shows the mycelium of the organism (see Fig. 2).



Discoloured (black) portion of margarine from surface showing mycelium of *Cladosporium*. (× 400, unstained.)

FIG. 2.

Blue-green patches are caused by *Penicillium glaucum* or like species. Here the rancidity is not so localised for the mycelium of the plant seems to be able to penetrate right down into the fat. Considerable hydrolysis takes place and the effect on the coconut group of fats has already been discussed. In absence of these fats usually a mouldy taste and odour predominate. Examination of the fat shows the mycelium of the organism—often very disintegrated. Owing to the disintegration it is usually impossible to identify the organism at this stage. In many cases it is sufficient to place a very small particle of the fat on a microscope slide and press out flat with a cover slip and then examine with a $\frac{1}{6}$ in. objective. In less advanced stages of the rancidity it may be necessary, however, to use a larger quantity of the fatty matter and to dissolve away the fat with a solvent. The residue can then be mounted, stained if desired, and examined.

Aspergillus species and other common moulds and fungi produce grey to blue-black discolorations, but these organisms do not occur so frequently in butter or margarine. *Penicillium* species are by far the most common.

The red discoloration is caused by one or two organisms obviously of the chromogenic class as well as by certain wild yeasts. At least three different organisms of this nature, *B. prodigiosus*, *S. rosea*, and *M. roseus*, were isolated and identified in the course of this investigation. These are able to cause hydrolysis of the fat to a considerable degree, but no specially marked deterioration in flavour occurs. There is no odour produced.

There are quite a number of other organisms to be found in rancid butter or margarine. Many of these, if not all, are able to hydrolyse the fat to a greater or less degree. In some cases the deterioration in flavour of the fat is marked, in others the taste is but slightly affected. The following organisms were isolated and identified in the course of the work:—*B. fluorescens liq.* and *non-liq.*, *B. proteus* species, *B. coli*, *B. putrificus*, *Bact. punctatum*, *M. luteus*, *S. lutea*, wild yeasts, and torulas, besides a considerable number of species of micrococci and sarcina which were not positively identified. *Sarcina urea* was found on several occasions. In general the organisms belong to the saprophyte class of bacteria.

In the rancidity changes set up in butter and margarine by these organisms, not only is the action on the fat to be considered; there is further the action on the protein matter of the butter or margarine which may be converted into products conferring an obnoxious flavour and aroma on the sample.

It is now well known that the lactic acid organisms themselves have an effect on the keeping properties of butter. Butter prepared from pasteurised cream keeps better than butter prepared from soured cream, other conditions being equal.

In general it is at present impossible to dogmatise as to the definite chemical changes produced by the organisms either in respect to fat or to protein matter; also it is impossible to catalogue rancidity-producing organisms, and in many cases, owing to insufficient description, it is very difficult to identify organisms found.

Just recently a sample of rancid margarine, purple in colour, was examined, from which moulds of the *Penicillium* species were isolated as well as a large fission fungus so far unidentified.

In butter yeast organisms are often found. The action of these is very interesting and possibly capable of being developed to a useful end. A small amount of fat splitting proceeds, and a medium containing coconut oil increased in acidity from 0·1% to 0·8% in a month when inoculated with the organism. A slight, rather pleasant fruity odour is produced alike in most neutral fats. It seems also that certain acid-resisting yeasts have the property of associating themselves with the lactic acid organisms, whereby the life of the latter is prolonged. This appears to have considerable bearing on the flavour-keeping properties of butter and margarine, and samples prepared using mixed cultures under appropriate conditions remained sweet, fresh, and of good flavour for several months, although kept under usually unfavourable conditions.

These investigations have demonstrated the vital necessity of preventing the contamination and invasion of butter and margarine by undesirable rancidifying organisms. A thorough examination into the possible sources of contamination during manufacture was carried out, and in the course of this work some very interesting facts were revealed.

1. *Contamination from air, utensils, machinery, etc.*—This is very important, but it can be reduced to a negligible quantity by thorough cleanliness in manufacturing processes and by sterilising and disinfecting the air in the factory, all utensils, etc.

2. *Raw materials.*—This is perhaps the most serious question of all. Hitherto raw materials have been judged as regards quality on taste, odour, and chemical analysis. As a result of an exhaustive bacteriological investigation it was found that the usual tests are of little value if the oils are not sterile to begin with, owing to the germination of the spores once the material is manufactured and mixed with nitrogenous matter. In addition to the usual tests, therefore, a bacterio-

logical examination of the raw materials used in margarine manufacture is strongly advocated. During the past two years several hundred samples of commercial oils and fats have been submitted to a bacteriological examination. Of these less than 5% proved to be sterile, some 10—20% contained not more than 6 spores per c.c., but the majority simply teemed with spores of mould, mucor, and other spore-forming organisms. Invariably liquid oils were worst in this respect, and so far not a single perfectly sterile sample has been found. Hardened fats proved to be sterile, or practically so; coconut and palm kernel oils were usually fairly sterile, that is to say contained less than 10 spores per c.c., but nevertheless some very bad samples of these oils were encountered.

Animal fats are fairly sterile, but many samples were found to contain bacteria spores rather than mould spores. The vegetable oils usually contain mould, mucor, and fungi rather than bacteria spores.

The following organisms were found to occur most frequently in the oils and fats:—*Penicillium* species, *Aspergillus* species, *Cladosporium* species, *Botrytis cinerea*, *Mucor* species, and a few common sporulating bacteria.

The most satisfactory method of making a bacteriological test on oils and fats was found to be as follows:—Portions of 1 c.c. and 2 c.c. of the oil or just melted fat are withdrawn from the sample by means of sterilised pipettes and run into tubes of nutrient sugar gelatin, the latter being melted. The mouth of the tube having been "flamed," a sterilised stopper is quickly inserted and the mixture of oil and medium violently shaken to produce an emulsion. This is finally poured out into a cold Petri dish, when it will be found that the emulsion sets before any separation of oil or fat occurs. The Petri dishes are then placed in the incubator at a suitable temperature and examined after two or three days, when a count of the colonies present may be taken.

The question of the origin of the mould spores in the oils and fats naturally arises. It would be expected, naturally, that any spores pre-existing in the crude oil would be destroyed during the deodorising process in which high temperatures are employed. It was thought desirable actually to investigate and check this point, seeing that autoclave conditions do not obtain during deodorising, but rather a vacuum is employed. In carrying out this work the author was indebted to several well-known firms of oil refiners who allowed him to visit their works and draw samples at various stages of the refining and deodorising processes, and in particular to one firm who took an active part in the work. The samples so drawn were tested as described. The investigation yielded some remarkable results, which, briefly, were as follows:—

(*a*) Mould spores existing in the oil prior to deodorising are not invariably destroyed during the process even at a temperature as high as 150°—170° C., the temperature being maintained for several hours. Many spores are destroyed, however, the count being invariably much less after deodorising than before.

(*b*) Mould spores can remain in a fertile condition in oils for a very long time, only awaiting favourable conditions for development and propagation.

(*c*) Where filtration is carried out after deodorising, the oil is liable to infection from air and from the filter cloths.

(*d*) The quality of the seeds or nuts or crude oil has a good deal to do with the relative sterility of the finished oil. With carefully picked seeds or nuts the oil, even before deodorising, is very free from spores so that the deodorised oil has a better chance of being sterile, or approximately so, than in the too frequent case where the seeds or crude oil are of inferior quality. Undoubtedly the quality of the seeds and nuts largely governs the number of spores in the finished oil.

(*e*) The use of wooden barrels or containers is much to be deprecated. It is practically impossible to sterilise the wood, and there is always danger of mould development on the wood if it should become damp and have access to air. Further, the canvas which is put on the bungs of the barrels teems with mould spores (see Fig. 3).

Canvas from bungs of barrels embedded in nutrient solution after germination of spores. (Natural size.)

FIG. 3.

With regard to (*a*) it is difficult to explain the undue resistance of the mould spores to such great heat, and no reference or mention of such a high temperature could be found in the literature. It is to be noted, however, that the oil is heated under dry conditions and under reduced pressure, both factors being usually additive so far as resistance of the spores to heat is concerned.

3. Leaving now the question of sterility of oils and fats and the containers, there remain to be considered the parchment paper and wrappers used for the finished margarine or butter. Many tests were made on all kinds and makes of paper, and in not a single instance was the paper found to be sterile, usually much the opposite. Mould spores, chiefly *Penicillium* and *Cladosporium* species, and various bacteria organisms abound. Figs. 4 and 5 show two tests made on different grades of paper. When such paper is used on margarine or butter the necessary dampness and nidus for the propagation of the organism is at once supplied. It is then only a question of time before dark green or black spots (colonies) make their appearance, ruining the butter or margarine as a saleable article.

Throughout the work, lasting nearly two years, the utmost precautions were taken to ensure freedom from contamination, either in drawing the samples or in making the tests; in many cases a sterile chamber was used when the sample required to be opened, even momentarily. One important point resulting from these investigations has had to be omitted for commercial reasons, viz., the question of actually preparing a perfectly sterile oil without injuring its flavour or neutrality in any way.

Nothing but the utmost care and bacteriological cleanliness and sterile materials can help the margarine makers to put out a good, regular, butter-like product, which will keep its clean taste for a reasonable time. There is no doubt that failure to realise these conditions is largely responsible, not only for the tendency to rancidify, but for the variations in quality of butter and margarine with which we are so familiar.

London Section.

Meeting held at Burlington House on March 7, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

FACTORS INFLUENCING THE NUTRITIVE VALUE OF LARD AND LARD SUBSTITUTES.

BY J. C. DRUMMOND, D.SC., F.I.C.

Until comparatively recently the food value of oils and fats was regarded almost entirely from the calorific standpoint, and accordingly most of the experimental work was devoted to determining what percentage of the total calorific value of each product could be absorbed by the digestive system of the mammalian organism. The discovery of the vitamins* by Hopkins in 1912, and the subsequent differentiation by later workers of three individual substances of this type has, however, led to a very fundamental change in our conceptions of the rôle of fats in the diet.

It has been shown that many naturally occurring fats, particularly those of animal origin, may serve as valuable sources of one of these indispensable, but as yet unidentified, dietary components, the so-called fat-soluble A or vitamin A.

Our earlier researches led us to believe that oils of vegetable origin are practically devoid of this valuable component, whereas the majority of animal oils and fats show its presence. (Earlier literature given by Halliburton and Drummond, J. Physiol., 1917, 51, 235.)

As a result of improvements in the technique for conducting tests for the presence of the vitamin A, this view has been somewhat modified in a recent paper (Drummond and Coward, Biochem. J., 1920, 14, 668), where it is shown that there is no hard and fast line between the vegetable and animal oils and fats when they are regarded from the standpoint of vitamin content, and that there are many factors which may influence the amount of this substance present.

In this paper it was pointed out that the chief factor determining the presence of the vitamin in animal products is the diet which the animal has been receiving. Apparently the vitamin A cannot be synthesised by the animal body, so that only when the diet contains ample supplies of this constituent can appreciable amounts be demonstrated in the tissue fats.

Quite early in the study of the vitamin present in certain edible oils it was observed that lard appeared to be devoid of this important constituent (McCollum and Davis, J. Biol. Chem., 1913, 15, 167), and on many occasions subsequently this observation was confirmed by other investigators.

In a recent summary of the knowledge concerning the vitamins, the author wrote "no entirely satisfactory explanation of the deficiency of lard has yet been advanced" (Special Report No. 38, Medical Research Council. H.M. Stationery Office, 1919). Researches carried out since this statement was made have, however, provided what is regarded as a satisfactory solution to the question.

Before proceeding to describe the investigations on the food value of lard and lard substitutes from the point of view of vitamins, reference may be made to a few experiments which the author made some time ago on the digestibility of these products.

---

* It is proposed to employ the term "vitamins" for these substances of unknown character rather than "vitamines" proposed by Funk, since the latter word implies, according to the Chemical Society's system of nomenclature, that the substances are of a basic nature. There is no evidence that this is so and they should therefore be classified as substances of unknown constitution (see Drummond, Biochem. J., 1920, 14, 660).

The digestibility of lard and lard substitutes.

The majority of edible oils and fats are well digested and absorbed by the mammalian alimentary tract, and it is very unusual to encounter a low coefficient of digestibility. There is a general opinion that the chief factor governing this coefficient is the melting point of the fats, and to a certain extent this appears to be correct, but it is doubtful whether the question is quite as simple as this. In the author's experiments all the samples of lard and of substitute lards which were investigated gave a high coefficient of digestibility.

TABLE I.

Sample.	Approx. m.p. °C.	Length of trial. Days.	Average coefficient of digestibility. %
Neutral lard I.	37·5°	10	97·7
" " II.	37°	10	98·2
Hardened cottonseed oil, lard substitute I. ..	40°	7	96·1
Hardened oil, lard substitute II.	38°	10	97·2
Lard substitute A (compound lard)	36°	7	96·4
Lard substitute B (compound lard)	37°	7	96·7
Lard substitute C ..	37°	7	97·5

These results confirm records by other investigators. On the basis of the old theories regarding the food value of fats, therefore, there would be little to choose between any of these products.

The newer knowledge of the vitamin content of oils and fats has taught us how erroneous such a conclusion may be, and accordingly a study of the vitamin content of the lards and lard substitutes was initiated. The technique of conducting these feeding tests is now so much improved that results of a roughly quantitative nature may be obtained provided very great care is taken (see Drummond and Coward, Biochem. J., 1920, **14**, 661). This biological method of testing is of course necessary in the absence of any chemical or physical means of estimation.

The vitamin content of lard.

Recent researches have demonstrated that the amount of vitamin A present in the body fat of an animal is determined to a great extent by the diet which the animal has received.

Apparently the animal organism does not possess the power to synthesise this peculiar substance, but can store up a reserve in certain localities such as the body fat when a surplus is provided in the diet. There did not therefore appear to be any reason why the pig should differ from other species in this respect. In collaboration with Capt. J. Golding, D.S.O., of the Research Institute for Dairying, University College, Reading, and Dr. S. S. Zilva, of the Lister Institute, experiments were made to throw light on these points.

At the outset it was evident to us that the usual dietaries on which pigs are raised in this country are in the majority of cases low in vitamin A. It therefore appeared quite feasible to argue that the growth of the pigs might demand most or all of the accessory factor in the diet, leaving little or no surplus for storage in the fatty tissue.

To test this point experimentally batches of young pigs were reared on dietaries some of which were practically devoid of the vitamin A, whilst others supplied ample amounts of that substance. These experiments have been fully described in a previous communication (Drummond, Golding, Zilva, and Coward, Biochem. J., 1920, **14**, 742).

Certain animals from each lot were slaughtered after several months on the special diets when they had reached the size of porkers (about 180 lb.), and samples of leaf fat (peri-nephritic fat) and back fat were removed. By means of the biological method these fats were tested for the presence of the vitamin A, and the results proved to be most interesting.

Briefly this method of testing is carried out as follows:—Young animals, usually rats (since many standard data have now been collected for this species), are fed upon an artificial dietary which has been rendered as free from vitamin A as is possible. Upon this diet they are usually able to grow for a short time, presumably whilst they are utilising the reserves present in their own tissues, but after the elapse of a few weeks this growth ceases and the health and weight of the animals decline.

If at this point the diet is supplemented with the foodstuff to be tested the resulting effect on the health and growth of the animal is in the majority of cases dependent on the amount of the vitamin in the added substance. If no vitamin is present the decline of the young animals proceeds to a fatal termination, but on the other hand a recovery of health and a resumption of growth will indicate the presence of the accessory substance A. With the improvements in technique it is now possible to obtain roughly quantitative data by this method, but it is much to be hoped that a chemical or physical method will soon be available so that a much greater degree of accuracy will be attainable.

By this method the samples of fats removed from the various batches of pigs were tested, and it was found that the body fats of swine fed on dietaries supplying ample supplies of the vitamin A contained that substance, but that its presence could not be demonstrated in the fats derived from the animals fed on the foods deficient in vitamin A.

It was therefore apparent to us that the pig resembles other species concerning which data are available in possessing the power to store supplies of the vitamin A in its body fat under suitable conditions.

The next step in the investigation was to ascertain why the majority of samples of lard contain no detectable trace of the accessory constituent. We were fortunate in obtaining the co-operation of Messrs. Harris and Co., of Calne, Wiltshire, at this stage of the work, and must express our appreciation of the very valuable help which they so readily rendered. From material which they placed at our disposal it was possible to show that the average samples of pig fat used in lard manufacture in this country contain small but appreciable amounts of the vitamin A.

The processes of lard manufacture were examined next in order to ascertain whether destruction of the vitamin occurs.

The destruction of the vitamin A at high temperatures was at one time believed to be due to the heating alone (Steenbock, Boutwell and Kent, J. Biol. Chem., 1918, **35**, 577; Drummond, Biochem. J., 1919, **13**, 81), but more recently it has been shown that temperatures up to 120° C. do not inactivate the vitamin unless there is contact with air or oxygen. It would appear, therefore, that the destruction is probably due to changes of an oxidative nature (Hopkins, Biochem. J., 1920, **14**, 725; Drummond, Biochem. J., 1920, **14**, 734; Zilva, Biochem. J., 1920, **14**, 740).

The older methods of lard manufacture, which still exist in many places, are essentially modifications of the original farmhouse process in which the fat is rendered at low temperature and separated in a simple manner from the connective tissue and water which forms the lower layer of the melted material.

Such a process would not bring about much oxidation, and accordingly it appeared probable that lards prepared in this manner would retain most of the vitamin present in the original fat.

Products of this type are usually termed "butcher's lard" or "home rendered lard."

This we have found to be true by actual experiments. Good recovery curves were shown by animals fed on a sample of pig fat and also on a lard prepared from this fat by a very simple rendering process in which the minced fat was melted in a steam jacketed pan at a temperature of approximately 70° C. The melted fat is stirred very little beyond what is necessary to obtain a satisfactory separation of the layers by adding salt, etc., and the clear, upper layer is merely run off and packed after being subjected to a simple straining or filtration.

Such a product appears to be as rich a source of the vitamin as the original crude fat. Very little lard is prepared by this type of process in Great Britain, but a similar method appears to be used extensively in America for preparing the products known as "Neutral lards Nos. 1 and 2" (Lewkowitsch, 5th Edn., 1914, Vol. 2, p. 689). It is therefore rather surprising that American observers have not frequently encountered samples of lard containing the vitamin. Only quite recently has attention been drawn to such a product by Daniels and Loughlin (J. Biol. Chem., 1920, **42**, 359) in the United States, but they advanced no explanation of their results.

It would seem probable, since these investigators took considerable trouble to check sources of error in their experiments, that they were working with lard prepared by a simple rendering process from pig fat containing comparatively a large quantity of the vitamin.

By far the largest proportion of lard made in this country is prepared by processes which involve a certain amount of aeration at high temperatures. Stirring takes place during the melting, and after the separation of the layers the fat is stirred at a temperature of about 102° C. for some 10—15 minutes to remove moisture. The dry fat is then frequently passed through filter presses before packing.

An active sample of pig fat was found to have lost practically the whole of its vitamin A after being converted into lard by such a process. It therefore appears probable that any technical process involving the contact of the hot fat with air or oxidising agents used for bleaching purposes will considerably lower the nutritive value of the product. The effect of filtration has not been investigated.

Lard substitutes.

(*a*) *Compound lards.*—Two products of this type were examined in an earlier investigation (Halliburton and Drummond, J. Physiol., 1917, **51**, 235) and were found to contain no detectable traces of the vitamin A. Naturally the presence or absence of the vitamin will depend on the nature of the constituent fats

Both the products investigated were composed mainly of cottonseed oil and oleo-stearin. Experiments on cottonseed oil show that the highly refined edible oil is usually deficient in the vitamin, but nothing is yet known as to the value of the crude oil or of the possible changes which may occur in the vitamin content during the refining processes. These questions are now being systematically studied in collaboration with Dr. Zilva.

Oleo-stearin also appears to be generally deficient in vitamin A. Beef fat normally contains appreciable quantities of this indispensable dietary constituent (Osborne and Mendel, J. Biol. Chem., 1915, **20**, 379), and these observers found on crystallisation of beef fat from alcohol that the vitamin is concentrated in the mother liquors together with the glycerides of lower m.p. This explains why in the process of separating oleo-stearin from premier jus the greater part of the vitamin passes through with the expressed oleo oil. The usual process of oleo oil preparation would hardly be likely to affect the amount of vitamin present.

Considerable variations in the vitamin content of oleo oil may be encountered, but these are in all probability due to the seasonal variations in the diets of the animals. Oleo-stearin is practically always of very low vitamin value. The nutritive value of compound lards will therefore be much influenced by the vitamin content of the constituents employed in its compounding.

(*b*) *Lard substitutes prepared from hardened fats.* In a recent publication it was shown that a sample of whale oil which possessed a fairly high value as a source of the vitamin A was rendered completely inactive by being "hardened" at high temperatures (Halliburton, Paton, Drummond, and others, J. Physiol., 1919, **52**, 325; also Drummond, Biochem. J., 1919, **13**, 81). This was at the time attributed to the high temperature at which hydrogenation was carried out, but this opinion must now be modified in view of the more recent work on the stability of the vitamin to high temperatures in the absence of air or oxidising agents. The cause of the inactivity of the hardened fats from the vitamin standpoint has not been definitely ascertained, but a number of such products, both of animal and vegetable origin, have been examined in this laboratory recently and have shown no trace of the vitamin.

It is therefore not surprising that we have found several samples of lard substitutes prepared on a basis of hardened fats to be devoid of the growth-promoting factor, an experience which has also been encountered by investigators in America (see McCollum, Simmonds, and Pitz, Amer. J. Physiol., 1916, **41**, 361).

Summary.

1. The food value of lard and lard substitutes cannot be estimated solely in terms of digestibility and coefficients of utilisation. Such products are usually well absorbed by the alimentary tract.

2. The nutritive value of lards and lard substitutes may be largely determined by the amount of the so-called vitamin A present.

3. The diet of the pig is the chief factor determining the amount of the vitamin present in the body fat.

4. In the manufacture of lard from a pig fat rich in the vitamin avoidance of aeration or close contact with air or oxidising agents at high temperature will prevent loss of the active substance.

5. Compound lards do not usually contain any appreciable amount of the vitamin A. This is because the constituents most frequently employed (*e.g.*, cottonseed oil, ground nut oil, and oleo-stearin) are almost devoid of that substance.

6. The vitamin content of beef fat is dependent on the diet of the animal. In the manufacture of oleo-stearin from premier jus the vitamin passes through with the lower m.p. fractions into the oleo oil.

7. Samples of hydrogenated fats of animal and vegetable origin were found to be inactive from the standpoint of vitamin A, as also were samples of lard substitutes prepared on a basis of such fats. The cause of the destruction when it occurs has not yet been ascertained.

DISCUSSION.

The CHAIRMAN said that the results put forward by the author were of great importance, and tended to show the strong instinct which mankind had for consuming natural fats where possible. Work of this kind showed that there was something more than flavour which determined the desirability of eating butter in preference to margarine and similar artificial products.

Mr. E. R. **Bolton** said that some twenty years ago it was an achievement to produce absolutely tasteless edible vegetable oils. Then the bacteriologist, by suitable cultures of bacteria, had introduced butter flavour into the fat, and now the biologist showed us that the presence of vitamins was necessary to perfect the oil for food. It would be desirable to find a method whereby the manufacturer could first separate the vitamins from oils, then carry on the refining process, and re-introduce the vitamins which otherwise would be destroyed by the process. It would be interesting to have experimental evidence as to how far the vitamins were destroyed by the process of heating necessary to produce clarification, and whether it was really exposure to oxygen, or heat, or both together, which had the detrimental effect. The process of refining oils in this country necessitated the chemical removal of the free fatty acids, followed by treatment at a very high temperature, but there was little or no exposure to oxygen. If, therefore, vitamins were destroyed in this process the destruction was not, in his opinion, due to oxidation. Olive oils were not usually exposed to high temperatures or to oxidation, and it would be interesting to have a comparison of the vitamin content in edible olive oil and in refined oils.

Dr. G. W. **Monier-Williams** said that one interesting point was the very high vitamin content of cod-liver oil and whale oils. Terrestrial animals apparently derived their vitamins from vegetable sources. The vitamin content of butter fat was higher in the spring when the cows were grass-fed than in the winter when they were largely stall-fed. From what sources did the whale and the cod obtain their store of vitamin? Presumably it must originate with the marine "plankton," the unicellular organisms which formed the ultimate food material of all marine animals. If so, it would be interesting to trace the course of these vitamins from the organisms in which they were originally formed, through the various marine animals, until they were ultimately deposited in such relatively large amounts in cod-liver and whale oils.

Mr. H. F. E. **Hulton** asked whether the lard had been given to the rats in the natural state or cooked. If previously fried the vitamin content might be very much reduced, and he thought the rat experiments should therefore be carried out with lard as usually consumed, since, unlike butter, it was not eaten as bought.

Mr. T. **Thornley** asked if hydrogenation was the only process to which the whale oil had been subjected. It was difficult to hydrogenate whale oil without some previous refining on account of catalyst poisons being present in the whale oil, and it might have happened that some of the refining processes had destroyed the vitamins. He further asked if simple hydrogenation of an unrefined oil at a low temperature had been shown to destroy vitamins, in view of Sekine's work showing that the vitamin content of commercial cod-liver oil, poor in vitamins, was increased by hydrogenation at a low temperature.

Captain **Golding** said that his share in these experiments had been in the pig-feeding trials. Not only was there a great rise in the curve of growth of the animal when a sow was given cod-liver oil after it had practically ceased to grow on a diet deficient in fat-soluble A, but there was also an improvement in the general well-being of the sow after the change of diet which figures fail to indicate. Crude cod-liver oil was not particularly palatable, but the pigs took it readily. Pigs which had been kept on a diet deficient in fat-soluble A would endeavour to make good the deficiency by eating grass. These observations showed that the question of taste, to which the Chairman had referred, was really a very natural guide, particularly in the animal world.

Mr. A. E. **Parkes** inquired whether the process of curing pork for conversion into bacon had any effect on the vitamin content.

Dr. **Drummond**, in reply, said that the refining and deodorisation of oils were part of the investigations now in hand. It was realised that the only way to get reliable information was to take the oils from the starting point and follow them through every stage of manufacture, testing them at each stage. Every such test took some three months to complete, and might necessitate the employment of two or three dozen animals, so that it was a tedious and expensive method. The questions of refining, the removal of the fatty acids, bleaching and filtering through various materials, deodorising, high-pressure steaming, etc., were being worked out. With regard to olive oil, he had not yet made controlled investigations, although in one case he had found evidence of a certain amount of vitamin A in a sample of crude olive oil. His information as regards this oil, however, was scanty. He agreed with Dr. Monier-Williams that it was extraordinary how the cod was able to store such a large amount of vitamins in its liver. The chief types of fish of the white variety—the cod type—appeared to store large quantities of vitamins in the liver, but in the other type of fish, the herring type, the vitamins appeared to accompany the fat distributed in the muscle tissue. He believed that in the case of the cod and the whale, the vitamin was derived primarily from simple marine organisms, and he hoped to go to north Norway, with some colleagues, to find out how the cod obtained its vitamins. It might be that the amount of vitamin produced in marine plants was far higher in proportion than with the ordinary land plant. An eminent marine biologist was accompanying the trip to Norway to throw light on this aspect of the problem. The question of summer and winter butter had been worked out in the preliminary stage, and it had been found that grass-fed cattle in the summer gave milk which possessed a higher vitamin-content than milk from cattle during the winter when the feeding was stall-feeding, such as cake, etc. With regard to the cooking of lard and the experiments on the rats, the experiments were carried out not so much to find out the food value of the fat as consumed, but to settle whether the pig could store vitamin in its fat, and how the vitamin was affected by the technical processes of extraction and refining. Further experiments were in progress. He had tested a sample of crude whale oil before and after hydrogenation. It was possible that the oil had also been refined, but as yet there was no knowledge of the effect of these processes, particularly of the removal of the free fatty acids. Low-temperature work had not yet been carried out. He had not seen the paper referred to by Mr. Thornley, but if the destruction actually occurred by oxidation, it was quite feasible that the vitamin might, perhaps, be restored by a corresponding reduction process.

THE STABILITY OF BENZOYL PEROXIDE.

BY ROBERT CROSBIE FARMER.

Benzoyl peroxide is of industrial interest as an oxidising agent, and has been utilised in several directions under the name of Lucidol. It was introduced by the Verein. Chem. Werke of Charlottenburg as a fixing agent in technical microscopy. It is a powerful antiseptic (Loevenhart, Bull. Comm., 33, 471; Year Book of Pharmacy, 1906, 95), and has been used for the treatment of burns and ulcers. It has a slight anæsthetic action when applied externally. Its internal use has been given up on account of its poisonous action on the blood (Fränkel, "Die Arzneimittelsynthese"). Its physiological action on dogs was examined by Nencki and Zaleski (Z. physiol. Chem., 1899, **27**, 487).

Benzoyl peroxide acts as a drier towards linseed and other drying oils (Krumbhaar, Farben-Zeit., 1913, **18**, 1280), and has some application for bleaching oils (G.P. 214,937. See also Utz, Chem. Rev. Fett- und Harz-Ind., 1912, **19**, 70, 128, 151; Farben-Zeit., 1912, **17**, 2105).

Benzoyl peroxide has a limited application for explosive purposes; since its temperature of explosion is low, its use for electrical detonators acting at low tension has been patented (E.P. 23,450 of 1912).

The compound has generally been assumed to be quite stable for handling and storage. Its behaviour on warming led the author to examine more closely into its stability, and the results given in the present paper indicate that some care should be taken when dealing with dry benzoyl peroxide.

For the preparation of benzoyl peroxide in larger quantities the autoxidation of benzaldehyde does not proceed readily, but the action of sodium peroxide on benzoyl chloride (Nencki and Zaleski, *loc. cit.*) was found satisfactory. The crude product melts at about 98° C., but on crystallisation from alcohol the pure compound of m.p. 103°—104° is readily obtained. It is practically insoluble in water, and almost insoluble in petrol, but dissolves readily in benzene and most organic solvents. It is gradually attacked by warm ammonia, forming benzamide and ammonium benzoate. Sodium hydroxide gradually dissolves it with formation of sodium benzoate.

Very little information has been published regarding the stability of benzoyl peroxide. It is known to decompose vigorously on melting in a capillary tube, and Orndorff and White found that molecular weight determinations at the boiling point of benzene were inaccurate owing to decomposition (Z. physik. Chem., 1893, **12**, 68).

Tests made by the author at the Research Department of the Royal Arsenal, Woolwich, are given below by the permission of the Director of Artillery. The stability was measured by means of the velocity of evolution of gas in a vacuum, by the standard method used for testing high explosives, as described by the author (Chem. Soc. Trans., 1920, **117**, 1432). The benzoyl peroxide used in these tests was of German origin, and showed the correct melting point for the pure substance. It will be seen that the decomposition proceeds with an acceleration, indicating autocatalysis. For comparison it may be stated that the main high explosives, such as picric acid and trinitrotoluene, show no measurable gas evolution at 100°, whilst tetryl gives only about 0·06 c.c. per g. in 100 hours.

Vacuum stability tests.

(i.) Test at 49° C. Benzoyl peroxide m.p. 103·5°—104° (5 g.) previously dried for 100 hours in a vacuum to remove all volatile matter.

Hours	0	50	100	150	200	250	300
c.c. of gas (corr.) .	0	0·37	0·93	1·37	2·53	3·55	4·63

(ii.) Tests at 80°. Benzoyl peroxide as above (1 g.)

Hours	0	5	10	15	20	24
c.c of gas (corr.) (*a*) ..	0	0·55	1·20	2·10	3·60	6·40
(*b*) ..	0	0·60	1·35	2·40	4·10	7·45

(iii.) Tests at 100°. Benzoyl peroxide as above. (*a*) 5 g. of peroxide exploded within 30 minutes, breaking the glass apparatus, but without injury to the metal bath. (*b*) 1 g. of peroxide was heated first to 80° in a vacuum and showed a similar rate of decomposition to the above tests at 80°, namely, 0·31 c.c. of gas in 3 hours. The temperature was then raised to 100°, and explosion occurred within 1 hour.

This instability is confirmed by observations on the behaviour of benzoyl peroxide made at this laboratory, which may be summarised as follows:—

Tests at atmospheric pressure.

(i.) When 1 g. of the crude peroxide was heated at 100° a mild explosion occurred after 30 minutes, but the glass tube was not broken. (ii.) One gram of the peroxide, crystallised from alcohol, was heated at 100°. A mild explosion occurred after 1 hour; the glass tube was broken, but the bath was not damaged. Similar explosions were observed on heating pure benzoyl peroxide under water at 100°. (iii.) 7 g. of the crude peroxide was kept at ordinary temperature in a dish in a vacuum-desiccator over sulphuric acid. After 8 hours the peroxide exploded with a sharp noise and destroyed the desiccator. The remains of the peroxide formed a charred mass. (iv.) Slight explosions were observed on grinding dry benzoyl peroxide in a mortar.

The gas evolved on decomposition was carbon dioxide and amounted to approximately one molecule per molecule of benzoyl peroxide. In every case the decomposition was accompanied by an odour similar to that of phenyl benzoate.

Safeguards against explosion.—Wet benzoyl peroxide has shown no explosive tendency at ordinary temperatures, and the manufacture thus appears to be without danger, so long as the compound is not allowed to become dry. In order to prepare a non-explosive dry product, salts were mixed with wet peroxide, and the mixtures dried at 50°. A mixture of 1 part of benzoyl peroxide and 4 parts of sodium chloride decomposed gradually without explosion when heated to 130°. When a flame was applied to a heap of the mixture, the peroxide burned out gradually, but on removing the flame the burning ceased. The benzoyl peroxide can be extracted with benzene from the salt mixture and gives the correct melting point. After keeping the mixture at 45°—50° C. for 20 days, the benzoyl peroxide on extraction still gave approximately the correct melting point. Experiments with ammonium phosphate gave similar results, but the sodium chloride mixture appeared less inflammable of the two.

Summary.—Benzoyl peroxide has explosive properties in the dry state, and drying should be avoided, where possible, in the manufacture. This instability applies both to the crude and the pure compound. The peroxide can be rendered immune against explosion by mixing it in the wet condition with excess of salt and drying the mixture. On warming, the substance decomposes gradually with evolution of gas, and the decomposition is autocatalytically accelerated. Storage of the peroxide under warm conditions is therefore to be avoided.

Hackney.

Discussion.

Dr. H. P. Stevens asked the author how far purity affected stability. Some time ago he had made some experiments with benzoyl peroxide for vulcanising rubber, but he had not taken any particular care in purifying it. A small quantity had been left standing in a watch glass in a dry, warm place 4 or 5 feet above a gas stove, and it had exploded without being touched. He had mixed benzoyl peroxide with rubber without difficulty by keeping it wet. He wondered whether a carefully purified product would be more stable.

Dr. M. O. Forster asked if it exploded when hammered.

Dr. Farmer replied that he had not given it very vigorous hammering. Purity did not, in his experience, affect the stability particularly. He had had the material in a state of great purity, and also in various degrees of impurity, but the time that it would stand heating seemed to be about the same. It did not seem to undergo any increase in stability on purifying. In the case mentioned by Dr. Stevens, possibly the benzoyl peroxide had become very dry by the gradual heating, and so had become more sensitive to heat.

Dr. Stevens said that in his case the benzoyl peroxide had been mixed on warm rollers heated to 50° or 60° C., and a little spot of benzoyl peroxide had got on this roller and dried, and exploded without any friction.

Newcastle Section.

Meeting held at Middlesbrough on March 7, 1921.

DR. J. H. PATERSON IN THE CHAIR.

THE MANUFACTURE OF ALCOHOL FROM COKE-OVEN GAS.

BY C. F. TIDMAN.

The conversion of the ethylene present in coke-oven gas into alcohol and its derivatives was dealt with by my late chief, Mr. Ernest Bury, at a meeting of the Cleveland Institution of Engineers in December, 1919 (see J., 1920, 94 A). The present paper contains a record of the work that has been carried on during the last twelve months on this subject. The suitability of alcohol as a fuel has already been established, and some figures which will be given in a later part of this paper will indicate how far these claims will hold when the power alcohol has been obtained synthetically from coke-oven gas.

Berthelot (1854) is generally credited with the discovery that ethylene could be fixed as ethyl-sulphuric acid, which can then be hydrolysed to alcohol, although Henry Hennell indicates in a paper communicated to the Royal Society in 1827 that he had identified sulphonvinic acid in quantity of sulphuric acid given him by Faraday, which had absorbed eighty times its volume of olefiant gas, or, in other words, 5% of its weight of ethylene. In a paper published the following year he states that this sulphovinic acid decomposed into sulphuric acid and alcohol. Fritsche seems to have investigated in 1897, and more thoroughly in 1912, the application of this synthesis to industry, but when he found that 12 cubic metres of scrubbing surface was required per cub. m. of gas treated per minute he decided that the large scrubbing plant necessary would render the proposal unworkable. In the work we have conducted at Skinningrove we have decided that not only surface, but turbulent contact plays a part in deciding the speed with which ethylene will combine with sulphuric acid. While Fritsche seems to have worked along the lines of pressure, we have considered temperature and turbulence to be essential factors in successful and rapid absorption. Since the publication of Mr. Bury's work on this subject, a patent has been taken out by a Belgian firm, where success seems to have been attained by the use of catalysts such as vanadic and tungstic acids.

With very few data at our disposal the problem was attacked at Skinningrove under the direction of Messrs. Bury and Ollander. The first point was to determine the most suitable temperature of absorption, and to this end absorptions were carried out at temperatures 160°—165°, 95°—100°, and 85°—90° C. respectively. The absorption apparatus consisted of two lead pots in series provided with stirring gear and containing 95% R.O.V., through which the coke-oven gas was passed in series. At 85°—90° C. it was found that there was 0·25% of carbon in the acid, showing that even at this temperature decomposition was occurring, while at 160°—165° C. the acid used soon became gelatinous, while the exit gas contained a good deal of sulphur dioxide. Fig. 1 shows the progress of the absorption at temperatures below 85°. The figures for these absorptions were obtained by using towers packed with fused silica as absorbers. From these data the best temperature of absorption was considered to be from 60° to 80° C. Four lead towers, each 4 ft. 6 in. by 3 in. diam., jacketed by a cylinder 5 in. diameter, arranged in series, were packed with broken fused silica in such a way that the ratio of free space to packing space was as 2:5. The total capacity of the towers was 1 cb. ft., of which 5/7 cb. ft. represented solid packing material. Sulphuric acid containing 95·4% H_2SO_4 was fed down the towers by means of a siphon and carried to the top at intervals. During the first few experiments acid was fed down the tower continuously in the smallest continuous stream possible (at the rate of about 30 c.c. per minute), but later experiments showed that this was not necessary, since after flushing down the towers the acid flow could be stopped and the absorption continued without appreciable alteration for an hour. In one experiment, for example, the inlet gas contained 1·70% of ethylene; after 5 minutes' absorption the outlet gas was found to contain 0·60% of ethylene. The acid flow was then stopped and the percentages of ethylene in the exit gases were found to be as follows: 10 min., 0·60%; 15 min., 0·64%; 20 min., 0·64%; 60 min., 0·66%. A repeat experiment gave almost identical figures.

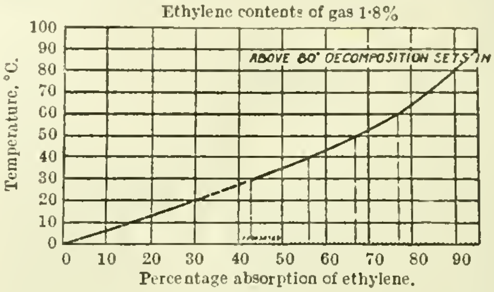

Fig. 1.

Variation of absorption of ethylene with temperature.

In the first absorption experiment carried out, desulphurised gas was passed through a bubbler containing 80% sulphuric acid. The primary object of this scrubber was to remove moisture and any higher homologues of ethylene (propylene, butylene, etc.). In the gas produced under the conditions existing at Skinningrove, however, the presence of the higher homologues has not been observed, although doubtless these exist in small quantities. During the course of an experiment in which a gas richer in ethylene than coke-oven gas was used—viz., gas driven off from beech-wood* charcoal, which had been placed in the gas stream—a white, crystalline solid separated out on the 80% acid; this was found to have the empirical formula C_5H_8, m.p. 126° C., b.p. 250°—255° C. With this solid was associated a second solid containing oxygen and of the probable empirical formula C_5H_8O; it had a very characteristic sweet taste, which persisted in the mouth for hours. Even using ordinary coke-oven gas a certain amount of solids settles out in the preliminary bubblers, but these are easily separated and can be discarded, although further investigation may prove them to be of value.

After the gas had left the scrubber containing 80% acid it was passed through the experimental towers just referred to at the rate of 5—6 cb. ft. per hour, and at the commencement the absorption was as high as 90% of the ethylene entering the system. The experiment was made a continuous one and lasted 145 hours. The average speed of the first 440 cb. ft. of gas was 5·6 cb. ft. per hour, while the average absorption of the ethylene was 90%. The speed of the next 320 cb. ft. was 4·8 cb. ft. per hour, with an average absorption of 65%. The total quantity of acid (95·4% H_2SO_4) used was 3000 c.c. With a gas space in the towers of 2/7 cb. ft. and a gas speed of 5·6 cb. ft. an hour, the time of contact of gas with acid was thus 3·1 minutes, during which 90% of the ethylene present was absorbed. These data multiplied up to plant size, where the daily carbonisation is 800 tons, would suggest the use of nine scrubbing towers, each the size of the ordinary benzol scrubber, *i.e.*, 10 ft. diam. and 80 ft. high. Of these nine towers practically the volume of six would be occupied by packing material, the function of which is to give surface and turbulence. To give surface alone, special packing material was used at Skinningrove in plant experimental towers, but although a large surface was provided, allowing three minutes' contact, 80—90% absorption of the ethylene was not obtained.

Keeping in mind these facts, a series of experiments was carried out in a flask of 1950 c.c. capacity filled with dry desulphurised coke-oven gas. The flask was heated in a water-bath until the temperature of the gas was about 80° C., hot acid (300 c.c.) was added and the flask covered with a non-conducting material and vigorously agitated, to afford adequate surface contact, for periods varying from ½ to 3 minutes. Further experiments were carried out using 5% of silica with the 95·4% sulphuric acid. The results obtained are shown in Fig. 2, from which it is seen that the addition of silica increases the absorption by approximately 5%. The function of the silica is not quite clear, but it appears to have a catalytic action and not merely a surface effect, since during the first few experiments on the small laboratory towers the absorption was particularly good, while a much later experiment, using the same towers, showed a falling off in percentage absorption, conditions remaining exactly the same except that the silica packing was coated with a slime of lead sulphate. In the experiments just described the addition of silica greatly increased the amount of froth formed on the surface of the acid, this giving much better contact between gas and acid.

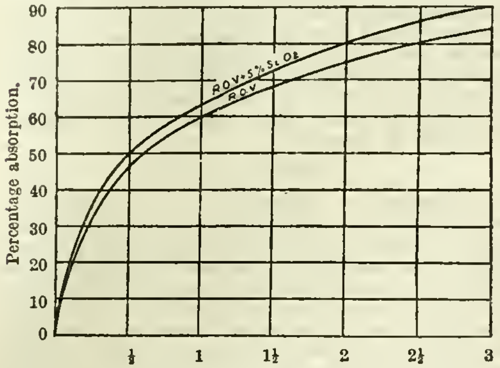

Fig. 2.

Speed of absorption 80° *C.* 95·4 %. H_2SO_4.

From the figures quoted it will be seen that for 3 minutes' contact by either method—towers or direct agitation in flask—the percentage absorption is 90%, so that whichever method of scrubbing is finally adopted—*i.e.*, towers or mechanical washer—it should be possible to remove 70—80% of the ethylene by allowing 2½—3 minutes' contact.

Spraying the acid into the gas has also been tried, but difficulties occurred in maintaining the required temperature and also in the blocking of the sprays. It was decided that this type of scrubber was not suitable. However, certain forms of mechanical washers give practically the spray effect without the disadvantages of blocking of small jets as used in sprays.

The next point to be determined is how nearly sulphuric acid can be saturated with ethylene before it will cease to act as an efficient absorber. Mr. Bury stated that 18% of the acid radicle is available for ethylene absorption, *i.e.*, 95% sulphuric acid (R.O.V.) would continue to absorb ethylene until reduced to 77% H_2SO_4. We have since found, however, that acid already saturated 18% would still continue to absorb ethylene in a mechanical agitator, 30% of the ethylene present being absorbed in 2½ minutes.

A mechanical washer would have the advantage over a tower scrubber system in that the size of the plant would be much reduced, and the power required to drive such washers is not great, considering the power required for pumping and the inconvenience of periodically cleaning a tower scrubber. The absorption product contains free alcohol in addition to sulphuric acid, ethyl hydrogen sulphate, and diethyl sulphate. This was apparent from the results of a trial run on the experimental plant. From analyses of the gases from each scrubber it was seen that No. 1 scrubber gave a shortage when distilled for alcohol, but scrubbers 3 and 4 each yielded more alcohol than was indicated by the gas test. In a number of tests the free alcohol has been as high as 50% of the total yield. It was therefore decided to recover the alcohol by distillation under reduced pressure, first allowing distillation to proceed without steam, and admitting steam when the temperature of distillation increased so that the speed of distillation was maintained. The following figures indicate the procedure. The acid was first diluted to 64% H_2SO_4 by the addition of water. Under a vacuum of 26½ in. distillation commenced at 94° C., the highest temperature recorded being 146°. The alcohol distilled over satisfactorily, and no frothing took place. The finished acid, which was free from alcohol, free or combined, showed 80% H_2SO_4.

The method suggested earlier for recovery of the alcohol was to use a counter-current flow of acid and superheated steam. Over short periods this method was satisfactory, but after a time large amounts of froth were produced which passed into the condensing system.

The bulk of the alcohol obtained from this process is in the form of a 15% distillate, any weaker distillate obtained being used for diluting the acid to the strength required for distillation *in vacuo*. The production of strong alcohol from this weak distillate is hardly within the scope of this paper, since the distillate is of a very similar strength to that obtained by fermentation. The alcohol itself, however, is very interesting in view of the impurities present. These are not important when the alcohol is to be used as fuel, since the alcohol burns completely—indeed, it has been considered possible that the Revenue authorities may even accept the spirit as sufficiently denatured to pass into use without the addition of other substances; certainly the crude spirit is much less potable than methylated spirit. The alcohol, however, possesses an objectionable odour, which persists in other products made from it. For example, chloroform made from by-product alcohol was reported to satisfy B.P. requirements only after treatment with hot concentrated sulphuric acid to destroy the odorous substances, the washing process reducing the bulk 10%. In preparing strong alcohol from the weak distillate it had been noted that the weak distillate was often cloudy but became clear on heating, showing that the substance present was more soluble in hot than in cold alcohol. Repeated distillations from the 80% alcohol left a residue which on cooling deposited a white, crystalline solid, which was found to be diethylene disulphide (m.p. 111° C., uncorr.). In addition to this impurity a yellow oil containing about 15% of sulphur was found on the surface of the weak distillate. Both forms of impurity were present in largest amount in the first scrubber. Since only a small quantity of the oil is available and it has a wide range of boiling point, it has not been possible to fix definitely the exact substance present. A further difficulty in that diethylene disulphide is very soluble in this oil and consequently it is difficult to obtain the oil free from this substance.

In using an 87% alcohol as fuel without any attempt to remove impurities, quite good results have been obtained in a number of practical trials. In one trial with a 4 h.p. Triumph machine (total weight just over 700 lb.) the following results were obtained:—No. 1 Shell petrol, 64·6 miles per gall.: 50% benzol, 50% alcohol, 78·50 miles; alcohol, 58 miles per gall. A trial with denatured alcohol made from coke-oven gas on a Buick car also gave satisfactory results. The presence of diethylene disulphide appeared to give rise to no bad results.

The diethylene disulphide is derived from the hydrogen sulphide in the coke-oven gas, which contains 6 g. of H_2S per cb. m. The gas for use in the small alcohol plant at Skinningrove is subjected to the ordinary bog iron-ore system of purification. To instal such a system for dealing with 8 million cb. ft. of gas per day is out of the question, since both in capital outlay and labour the cost would be prohibitive. Again, it is very difficult to rid a gas entirely of sulphur compounds by using bog iron-ore purifiers. An alternative method has therefore been devised depending on the well-known reaction between hydrogen sulphide and sulphur dioxide. At first gaseous sulphur dioxide, obtained by the action of acid on sodium bisulphite, was admitted into the gas stream, and the mixture passed up a packed tower. By admitting rather less sulphur dioxide than was theoretically necessary to decompose the hydrogen sulphide it was hoped to precipitate the bulk of the sulphur in the tower, thus producing a gas containing only a small amount of undecomposed hydrogen sulphide which was to be removed by a bog ore purifier. In practice it was found that when the amount of sulphur dioxide present was short of that required very little decomposition took place. The admission of a small quantity of steam gave very little improvement, and passing the mixed gas through hot tubes also failed to remove the sulphur. It was therefore decided to try to desulphurise the gas by the countercurrent system, using sulphur dioxide in solution. This method was found to be quite successful, the gas being easily purified when a large excess of sulphur dioxide was present. The exact excess necessary will no doubt depend largely on the plant itself. Much of the excess of sulphur dioxide is carried forward in the gas stream, but it can easily be removed by scrubbing with water. The sulphur produced in this process is deposited in the form of a mud which can be easily separated from the liquid.

Mr. Bury has pointed out that at a coking plant such as that at Skinningrove, with its 120 Otto regenerative ovens, the make per week, allowing 70% absorption and 70% recovery, would be 9280 gallons of absolute alcohol. When pure gas is used and the alcohol is recovered by distillation under reduced pressure we may easily expect an 80% recovery, while using an acid stronger than 95% R.O.V. we may expect the 70% absorption of the ethylene to be increased. It would not be difficult to obtain, say, 98% H_2SO_4 if instead of erecting a sulphuric acid plant with an acid concentrating plant an oleum plant were installed. The 80% acid left after dealcoholation would form a very good absorbent for the SO_3, while the additional acid thus made would be used for benzol washing etc. The scheme at Skinningrove has been worked out using an acid of 95% H_2SO_4, *i.e.*, R.O.V., but we have noted that an increase of 1 or 2% acidity is of advantage. When using acid of 93% H_2SO_4 we have found that the absorption falls off very rapidly. The figures given by Plant and Sidgwick (J., 1921, 14 T), using concentrated ethylene, show that while 93·1% acid increases in weight 20·8% on absorbing ethylene, 95·8% H_2SO_4 increases 28%. At some point between 95·8% and 98·1% we get a decided increase in the amount of diethyl sulphate formed, while when free sulphuric anhydride is present carbyl sulphate is formed—a substance not hydrolysable by alcohol. When using R.O.V. 95% (approximately) we have not found diethyl sulphate to be formed, although in certain of the crude alcohols produced on the experimental plant traces of the characteristic odour of diethyl sulphate have been noticed. We have also found it advisable to place one or two acid bubblers before the 80% sulphuric acid scrubber to avoid the formation of a substance like pitch, which may easily block the scrubber. When the bubblers are used this tarry product separates out on the surface of the acid and can be removed from time to time. We have not yet determined the composition of this deposit, but in a preliminary examination we have found that it is only partly soluble in water. The soluble portion gives a deep-green solution, and when freed from acid forms a soapy solution giving a persistent film when air is blown through it.

In conclusion, I desire to express my thanks for the sympathetic help and encouragement received from the heads of the Skinningrove Iron Company, Mr. Alfred Hutchison, and Mr. Coulson. I also wish to acknowledge the great help received from Mr. Ralph Robinson, B.Sc., Mr. G. M. Harrison, and Mr. K. L. Brown.

Discussion.

The **Chairman** suggested the desirability of research into the possibility of using the hydrocarbons of coke-oven gas (which contained a total of 30%) as a source of fuel rather than selecting one small and unimportant constituent for conversion into fuel. The sulphur problem was an extremely serious one having regard to the effect of the sulphur compounds upon the fuel tanks and exhaust apparatus of an engine, and any process devised for the manufacture of power alcohol would have to produce a material practically free from sulphur compounds.

Dr. G. **Weyman** thought that there should be no great trouble or expense involved in removing hydrogen sulphide, as gasworks were able to make a profit on oxide purification. Gasworks had necessarily to remove every trace of hydrogen sulphide, and there was no trouble in dealing with 10 or 20 million cb. ft per day. He was not sure if oxide purification plant would not be less expensive than the scrubber system of removing excess of sulphur dioxide which Mr. Tidman had mentioned. In an older process the last trace of sulphur dioxide was removed in an alkaline washer. The reaction between sulphur dioxide and hydrogen sulphide was most interesting, but extremely complicated. There were other sulphur compounds besides hydrogen sulphide which might cause the trouble referred to.

Dr. J. T. **Dunn** suggested that if it were necessary to have the final product free from sulphur, attention would have to be given to the removal not alone of hydrogen sulphide, but of the other sulphur compounds which accompanied it in the gas.

Mr. A. **Trobridge** said that many years ago he had had considerable experience in separating the last traces of hydrogen sulphide from gas in connexion with the development of the Chance process for the recovery of sulphur from alkali waste. Large quantities of hydrogen sulphide had been passed through the Claus kilns, and it had been necessary to determine the exact proportion of air necessary to give the maximum yield of sulphur; it had been found impossible to obtain an exit gas free from either hydrogen sulphide or sulphur dioxide. The United Alkali Co. had had a similar experience recently at their Gateshead works. He thought that the use of sulphur dioxide for removing the hydrogen sulphide from coke-oven gas did not hold forth much promise, and that some other method should be devised.

Mr. J. E. **Christopher** said that he had been in touch with a plant in which sulphur was recovered from waste gases, the best yield being obtained when the final gases showed signs of both H_2S and SO_2. If either were present alone the yield was diminished. He foresaw difficulty in introducing alcohol recovery apparatus in many existing coke plants, but the question should be considered more especially in regard to new plants. Had Mr. Tidman any experience of this particular process in dealing with gas from a low-temperature carbonisation scheme? A very high yield of motor spirit would be expected in that case, and if it could be established it would undoubtedly bring low-temperature schemes more into prominence.

Mr. A. **Hutchinson** said that the paper was really a report of progress in the conversion of a process which had proved a success on a small laboratory scale to a semi-manufacturing scale, with a view to finding the most economical plant for large-scale manufacturing, so as to keep down the capital expenditure to a minimum. So far, the experiments had proved entirely successful, but the number of towers required to complete the extraction of the whole of the ethylene by means of sulphuric acid was so considerable that they were now turning their attention to a small experimental plant designed by Dr. Davidson, which had been successful in ammonia absorption, and, it was hoped, would prove equally so in ethylene absorption. If this proved to be the case, a very considerable saving in capital cost would be effected, and there was every likelihood of the manufacture of alcohol being a paying proposition. He did not think that the sulphur compounds would have any detrimental effect in the use of the alcohol for internal combustion engines, motor cars, etc. Experience at Skinningrove with large gas engines using gas containing a certain amount of sulphur was that the engines were themselves in no way affected by the sulphur. When the waste gases were cooled in water, however, the acid solution affected the exhaust pipes.

Mr. H. **Crowe** said that at Skinningrove they had run their large gas engines on blast-furnace gas only, which contained only traces of sulphur. They had also for many years run these engines on a mixture of blast-furnace gas and coke-oven gas containing a considerable quantity of sulphur. No ill-effects from the sulphur were felt in the engine until at the point, just past the exhaust valve, where water was injected to cool the exhaust pipes and deaden the noise of the exhaust. From this point onwards, all along the exhaust pipes and silencers, rapid corrosion took place. Large gas engines were more satisfactorily run on pure blast-furnace gas than on a mixture of blast-furnace gas and coke-oven gas.

Major **Scott** said that he did not think the action of sulphur on the interior of internal combustion engines would be at all serious. He had run gas engines on blast-furnace gas and gas from gas producers and had found no bad results in the cylinders. Corrosion was liable to take place in the exhaust pipes owing to moisture being present.

Mr. **Tidman**, in reply, said that after removing the diethylene disulphide from a sample of crude alcohol by means of mercuric chloride, the resultant spirit was pronounced by the visiting Excise officer to be equal to grain spirit. His work had all been carried out on gas produced under coking conditions as at Skinningrove, where metallurgical coke was the main product, and had not extended to low-temperature carbonisation. He suggested that such substances as thiophen would be removed in the wash oil of the benzol scrubbers, and so would not trouble the alcohol system. Replying to Mr. Trobridge, Mr. Tidman said that when removing the hydrogen sulphide by means of sulphur dioxide solution in the experimental towers referred to, the gas from the exit of the last tower contained no sulphur dioxide.

GUANIDINE CARBONATE AS A STANDARD ALKALI.

BY A. H. DODD, B.A., A.I.C.

Sodium carbonate is very generally used for the preparation of standard alkali solutions, but it is open to several objections (*cf.* Rimbach, Ber., **26**, 171; Higgins, J., 1900, 958; North and Blakey, J., 1905, 396).

During the last three years guanidine carbonate has been used in this laboratory for making up standard alkali solutions, and has been found to possess certain definite advantages over sodium carbonate. Thus it can easily be freed from inorganic impurities, it contains no water of crystallisation, and, when pure, it is non-hygroscopic.

No reference to its use as a standard reagent has been found in the literature, although Grossmann and Schuck (Chem.-Zeit., **30**, 1205) have suggested its determination by titration with standard acids and recommend it as a powerful alkali to precipitate zinc, etc.

Guanidine carbonate, $[NH{:}C(NH_2)_2]_2.H_2CO_3$, is a strong "mon-acid" base; the hypothetical guanidonium hydroxide from which it is derived approximates in strength to the alkali hydroxides, and is stronger than the tetra-substituted ammonium hydroxides (Ostwald, J. prakt. Chem., (2), 33, 367). The heat of neutralisation of the free base is 14·12° C. per g.-mol. (Morrell and Bellars, J. Chem. Soc., 1907, 1012).

The carbonate as ordinarily prepared from guanidine thiocyanate, *i.e.*, from ammonium thiocyanate as starting material, is not to be recommended. Generally it is hygroscopic and contaminated with ammonium and potassium salts. In any case the purification is costly, and the yield of carbonate from thiocyanate, using potassium carbonate and alcohol extraction, is only 70% (Volhard, J. prakt. Chem., (2), 9, 10).

The product made from dicyanodiamide, *i.e.* from calcium cyanamide as raw product, is extraordinarily pure, and should be obtainable for a few shillings a pound.

Guanidine carbonate is precipitated from its aqueous solution by addition of alcohol, and it is best to make use of this fact to obtain the analytical reagent. Two precipitations from its aqueous solution and washing with 80% alcohol yield small white crystals which, after drying at 110° C., show a purity of 100% if tested with standard acids, and can be stored in a well-stoppered bottle and used without further treatment for standard alkali for works use. Samples left covered but exposed to the atmosphere for 14 days in a warm corner of the laboratory did not gain in weight appreciably. Beautiful colourless crystals weighing up to 3 g. can be obtained by slow evaporation from water, but although they are anhydrous they would not, however, be used for analytical work, since they are liable to occlude impurities and a small quantity of water.

Although it is generally admitted that $N/1$ solutions are not sufficiently accurate for analytical work, it is nevertheless the usual practice of acid manufacturers to sell their acids on the acidity of a weighed quantity against $N/1$ caustic soda, itself standardised against $N/1$ acid checked against $N/1$ sodium carbonate.

Accordingly, a $N/1$ solution of guanidine carbonate (90·07 g. per litre) has been compared with $N/1$ sodium carbonate and $N/1$ potassium hydroxide (from mercuric oxide and potassium iodide). The strength of the sulphuric acid was about 0·957 N. The sodium carbonate was Kahlbaum's "pro analysi" dried at 100° C. Solutions were all used at 15° C. in vessels calibrated at that temperature. The following results in g. per l. are the mean of three observations:—

	Sodium carbonate.	Guanidine carbonate.	Potassium hydroxide.
Methyl orange	46·853 ..	46·816 ..	46·91
Congo red	46·67 ..	46·76 ..	47·1
Alizarin red	46·72 ..	46·76 ..	46·78

The acid when standardised against caustic soda itself standardised against $N/1$ hydrochloric acid (by Gay Lussac's method) with phenolphthalein as indicator gave a result of 46·893 g. per litre. These figures show that the testing of sulphuric acid by means of guanidine carbonate instead of sodium carbonate is accurate enough for routine works practice.

Guanidine carbonate has also been used for the standardisation of $N/10$ sulphuric acid. Carbon dioxide was not removed, as is advisable for accurate work. The following table gives the factor of approximately $N/10$ sulphuric acid, each being the mean of three observations:—

Indicator.	Guanidine carbonate.	Sodium carbonate.
Methyl orange	1·0075 ..	1·0081
Alizarin red	1·0049 ..	1·0075
Congo red	1·0060 ..	1·0075

The higher figures with methyl orange are possibly due to a slight acid reaction of the carbon dioxide.

It thus appears that guanidine carbonate should prove a satisfactory and convenient reagent for acidimetry. It merits a more minute investigation, using more delicate indicators, such as bromothymol blue, which are now available.

THE PREPARATION AND PROPERTIES OF 1.3.5-TRINITROBENZENE.

BY L. G. RADCLIFFE AND A. A. POLLITT.

(This J., 1921, 45 T.)

Dr. W. H. Gibson, of York Street Flax Spinning Co., Belfast, wrote as follows:—The evidence produced by the authors for the existence of a less stable form of *s*-trinitrobenzene melting at 61° C. fails to convince me. It appears to me that on the occasions when this material was obtained the conditions were such as to favour incomplete nitration, and the low yields recorded support this view. It not infrequently happens that in the trinitration of benzene a mixture of di- and tri-nitrobenzenes is obtained, which is not easily separated by crystallisation, and which gives a product melting in the neighbourhood of 60° C. It seems possible that Messrs. Radcliffe and Pollitt really obtained this mixture, and the behaviour they observed on preparing the aniline and naphthylamine addition compounds is consistent with this, as they do not state that they obtained a quantitative conversion of the unstable to the stable form through the addition compound, nor do they state that they got equal yields of addition compound from equal weights of the two forms. It may be, then, that only a separation of the 1.3.5-trinitrobenzene in a mixture of di- and tri-nitrobenzenes was effected. The analysis of the unstable form by the Knecht and Hibbert method is stated to correspond with pure trinitrobenzene, but it seems unfortunate that this was not confirmed by a nitrogen determination carried out in the usual manner. Quantitative conversion of one form into the other would, however, be the most convincing proof of the existence of this unstable form.

Mr. Radcliffe replied as follows:—I fear that in condensing the paper certain details have been left out, but we made many experiments involving fractional crystallisation of the product melting at 61° using different solvents, but entirely failed to resolve it or indeed change its melting point; further, we thought at the time that it might be a mixture, and the experiments with aniline etc. and regeneration were done most carefully and with due regard to the quantitative recovery of the trinitrobenzene. I find, from the original notes, that we used several different methods for the determination of nitrogen, and these gave results pointing to the compound being a trinitrobenzene.

Meeting held at Leeds on November 8, 1920.

DR. L. L. LLOYD IN THE CHAIR.

OCHRE STREAMS OF THE VALLEYS OF THE DON AND LOXLEY.

BY J. HAWORTH AND J. EVANS.

Ochre waters may be defined as natural waters in which salts of iron occur in solution. In most cases such waters deposit iron oxide or ochre on the banks and bed of the stream. They may be conveniently sub-divided as:—(1) Chalybeate waters, which occur either as waters containing carbon dioxide and iron bicarbonate, together with other salts, or as saline acidulous chalybeates containing chiefly sodium sulphate and iron bicarbonate. (2) Waters containing chiefly sulphates of iron.

The chalybeate waters seldom contain large quantities of iron (8 to 15 parts per 100,000). They emanate from strata containing iron in the form of carbonate, which in the presence of carbon dioxide forms the soluble bicarbonate. It is not, however, proposed to deal further with this class of waters, but rather with the second class, which are common in the neighbourhood of Sheffield.

Waters containing sulphates of iron are frequently found in all districts where coal workings exist or where outcrops of the coal measures occur. The streams in valleys draining areas in which coal measures are exposed frequently bear marked indications of the presence of iron salts by the brown and red deposits of ochre on the beds of the streams and by the brown colour of the water.

During the course of certain investigations respecting the water supplies of the city of Sheffield the authors made extensive examinations of the contributory streams to the rivers Loxley and Don. The river Loxley is a tributary of the Don, and the watersheds are divided by a precipitous ridge in which outcrops of the lower coal measures occur at numerous points and are exposed. Beneath the lower coal measures beds of ganister and fireclay occur. These are worked at numerous points on both sides of the ridge, the products being largely used in the Sheffield industries. The mining operations consist usually of driving levels or adits into sides of the valleys at different levels where the outcrops occur, and water drains from these forming streams which flow down to the river. There are also other streams flowing from the slopes of the valley, but a casual observation shows that the streams from the mines or ganister pits all contain salts of iron and deposited ochre, whereas the remaining streams contain no iron.

The physical appearance of the ochre streams is very striking. In some cases the water is clear but coloured, the colour varying from pale yellow to a deep reddish-brown; in other cases the water is turbid through the presence of iron hydroxide, but in all cases heavy deposits of iron hydroxide or basic iron sulphate are present.

Between two points in the Loxley Valley about two miles apart, some twelve streams were carefully examined. The following analytical figures (see table) are typical for the water from one of the streams.

The acidity in terms of sulphuric acid varies from 8·57 to 155·57 parts per 100,000, and the total solids in solution from 47·0 to 521·0 parts per 100,000. It will be seen from the analyses that the water initially contains iron chiefly as ferrous sulphate, which at the point of discharge to the river has undergone practically complete oxidation.

	Parts per 100,000.		
	(1)	(2)	(3)
Total solids	260·7	410·0	521·6
Solids in suspension:			
Total	5·7	Nil.	Nil.
Mineral	3·5	—	—

Acidity (as H_2SO_4) ..	49·0	78·4	112·7
Iron, total	23·1	13·4	53·0
„ ferric	20·3	10·2	33·0
„ ferrous	2·8	3·2	20·0
Hardness (as $CaCO_3$) ..	146·8	200·3	—

	Ochre water at entrance to ganister pit. Bower Plantation.	Ochre water taken at point of entry into river.
	Parts per 100,000.	
Total solids	64·0	506·0
FeO	8·6	68·2
Fe_2O_3	22·4	64·9
CaO	15·0	19·0
MgO	17·3	14·4
SO_3	125·7	223·6

The source of the iron salts is without doubt ferric sulphide (iron pyrites) between the layers of the coal strata. Specimens of the shale and coal when first exposed show distinct layers of pyrites in the course of oxidation; in splitting the layers perfect crystals of transparent calcium sulphate in the form of selenite, $CaSO_4,2H_2O$, may be observed. This substance also finds its way into the water, as the analyses indicate.

The waters issuing from the mines contain ferrous and ferric sulphates and free sulphuric acid, the primary oxidation products of pyrites. In the streams further reactions occur producing the heavy red deposits which consist of ferric oxide and basic ferric sulphates. In some cases the banks consist of this deposited ochre for several inches in depth.

The ochre deposits have their origin in several ways: (1) Direct oxidation and the production of ferric hydroxide; (2) alkaline surface waters joining the stream; (3) the action of iron bacteria, which grow profusely in such waters.

The first two methods of deposition are purely chemical; the third is of considerable interest. Water containing iron salts, even in very minute quantities, forms a very suitable medium for the growth of the organisms commonly referred to as "iron bacteria"; two common varieties of these are *Crenothrix polyspera* and *Leptothrix ochraceæ*. As little as one part of iron in 2 to 3 millions of water is sufficient to permit the development of these organisms. The organisms decompose the salts of iron, depositing the iron in the form of ferric oxide, the liberated acid then attacking the iron of the water pipes. Serious corrosion may occur in this manner.

In the case of ochre streams such as those under consideration the organisms deposit the ferric oxide and the streams become acid. The organisms have very high chemical energy and are able to oxidise ferrous salts many times the weight of their own cells. They are remarkable by reason of the fact that their existence is maintained largely by inorganic salts and the presence of only minute quantities of organic matter is necessary. In the case of the two rivers mentioned the usual flora and fauna are entirely absent.

It will be apparent that the industrial users of waters of rivers into which ochre streams discharge must be subject to great inconvenience and expense. Such waters must be neutralised and softened before use, or serious corrosion of boilers, pipes, tanks, and iron and steel work will generally occur.

In the case of the rivers under consideration a pure stream of water is within two miles rendered practically unsuitable for industrial use of any kind, except after treatment. Such discharges cannot in any way be controlled or purification insisted upon, as waters draining from mines are specifically excluded from control of rivers authorities under the various Rivers Pollution Prevention Acts.

DISCUSSION.

Mr. W. McD. **MACKEY** mentioned the case of a water supply containing traces of iron as bicarbonate, which after flowing about 100 yards in a shallow stream, became free from iron.

Mr. C. P. **FINN** gave an instance of an ochre water derived from a disused coal pit, which, unlike the waters tested by the authors, was invariably alkaline. It was quite clear when first pumped, but immediately commenced to precipitate ochre when turned into the stream. In twelve months about 100 yards of pump main was reduced in effective diameter from 10 in. to 2 in. by the deposit.

The **CHAIRMAN** instanced a water supply at Blackburn which contained a small amount (some 0·3 part per 100,000) of iron, which was sufficient to cause "iron spots" on dyed fabric. Its elimination was attended by considerable difficulty, attributed to the presence of the tannin substances. It had finally been found necessary to harden the water, soften it, and then treat with permutit.

Dr. **CHAPLIN** said that in his experience with Wakefield water organic matter high in nitrogen delayed the softening process, and the organic matter tended to keep iron in solution.

Mr. **EVANS**, in reply to a question, said that the determination of acidity in the presence of iron was difficult, and that so far the authors had found no method that was entirely satisfactory. With reference to bacterial deposits in water mains, he recalled the trouble experienced in conveying water from Lake Vyrny to Liverpool, which had been overcome by efficient filtration at the lake.

Mr. **HAIGH JOHNSON** said he had found that the bacterial growths in cast-iron water mains were generally confined to places where manganese was present, and he concluded that manganese was essential for the development of these bacteria.

Mr. A. R. **TANKARD** suggested that the acidity in presence of iron might be estimated by titration with standard lime-water, using phenolphthalein as indicator.

Dr. **LLOYD** thought that it might be better to replace the phenolphthalein by Congo red dyed a pale shade on silk.

Mr. **LOWSON** mentioned the hydrogen sulphide method for estimating free acid in the presence of iron.

Mr. **HAWORTH** said that manganese was always present in small quantities in the waters they had examined.

Communications.

SOME METHODS OF PURIFICATION OF *o*-TOLUENESULPHONAMIDE.

BY PHYLLIS VIOLET McKIE.

In the preparation of saccharin from toluene two nearly related routes (Fahlberg, G.P. 224,386, *et seq.;* and Lange, G.P. 57,391 *et seq.*) may be followed. In the Fahlberg procedure the initial stage gives rise to a mixture of *o*- and *p*-sulphochlorides in the ratio of 60:40, while in the alternative Lange process a mixture of *o*- and *p*-sulphonic acids in the same ratio is obtained. The essential difference is that separation of the *ortho* and *para* derivatives is performed in the latter process at the sulphonic acid stage, and in the Fahlberg process partly at the chloride, partly at the amide stage. By partial separation of the chlorides a mixture containing 70% *o*- and 30% *p*-sulphonic chloride is obtained, and these proportions are maintained during the subsequent amidation.

Several methods have been devised by which the proportion of *para* component in this 70/30 *o*-*p*-amide mixture can be reduced:—(1) Precipitation by acids from alkaline solution (G.P. 76,881, 1892). (2) Separation based on the fact that of the crystalline salts formed with alkalis, that of the *ortho* compound is the less soluble (G.P. 77,435, 1894). (3) Precipitation from alkaline solution by ammonium salts (G.P. 154,655, 1903). A fourth process, which involves the transformation of the amides again into the sulphonic chlorides, has also been used (G.P. 133,919, 1902).

In no case do these patents claim complete separation. A certain amount of *o*-toluenesulphonamide, still mixed with 7—10% of *para* component, and hence of only 90—93% purity, is extracted, while the residual mother liquor contains, besides the bulk of the *p*-toluenesulphonamide, a varying proportion—up to 30%—of the *ortho* isomer. Oxidation of the mixture containing only 90% *ortho* compound thus produces a saccharin of equal impurity.

On the other hand, separation of the *ortho*- and *para*-toluenesulphonic acids in the Lange method of preparing saccharin produces an acid containing already 90% of *ortho* compound. Subsequent chlorination and amidation of this acid thus yields a crude *o*-toluenesulphonamide mixed with only 10% *para* compound.

It was the object of this investigation to examine and test a number of simple methods of freeing the *o*-toluenesulphonamide from this 10% of *para* derivative, which remains after the preliminary separation of the 70/30 mixture by the patented processes. Especial emphasis is laid on the avoidance of loss of *o*-toluenesulphonamide in the purification.

Crystallisation from water.

(The solubility in water of *o*-toluenesulphonamide is 1 part in 958 parts at 9° C.; *p*-toluenesulphonamide, 1 part in 515 parts at 9° C. Klason, Vallin. Ber., 1879, 12, 1851.)

One recrystallisation of the crude (90% pure) amide mixture from water sufficient to retain the whole of the contained *p*-toluenesulphonamide in solution yields 80% of *o*-toluenesulphonamide of 97—98% purity.

TABLE I.

Initial mixture.		Recrystallised material.	m.p.	Purity.
5 g.			150°	90%
	1st	4 g.	155°	98%
	2nd	3·6 g.	155·2°	98·3%
	3rd	3·06 g.	155·5°	99·2%

Only by fractional sublimation *in vacuo* could the melting point be raised above that obtained by a third recrystallisation from water. (The melting point of pure *o*-toluenesulphonamide is 156·3° C. McKie. Chem. Soc. Trans., 1918, 113, 799.)

Precipitation by acids from alkaline solution.

In considering the separation of *o*- and *p*-toluenesulphonamides from alkaline solution, or the extraction of the solid amides by aqueous alkali, two opposing factors have to be taken into account. Of the two amides the *ortho* compound is the less soluble, as is also the sodium salt of the *ortho* amide, but *o*-toluenesulphonamide should, by virtue of its configuration, possess the greater "acidity" (*cf.* *o*-chlorobenzoic and *o*-nitrobenzoic acids, which are much stronger acids than the corresponding *para* derivatives).

The solid toluenesulphonamide mixture, containing 90% *ortho* and 10% *para* derivative, was dissolved in a solution of one mole of 8—10% sodium hydroxide. Addition of acids of varying strengths and in varying proportions precipitated corresponding amounts of solid toluenesulphonamide, which was collected, dried, and weighed in a Gooch or alundum crucible. As there is always a slight loss in the steam oven, the solid was dried over sulphuric acid *in vacuo* at 50° C.

(i) *Acid equivalent to one-tenth of o-toluenesulphonamide:*—Addition of acid equivalent to one-tenth of the o-toluenesulphonamide brings out almost completely pure *ortho* compound, largely independent of the hydrion concentration of the acid. Except for very low concentrations of hydrion, solubility is the most powerful factor, and hence the less soluble—the o-toluenesulphonamide—is precipitated only very slightly contaminated with *para* derivative. But with such a slightly ionised acid as carbonic acid the relative acidities of the two toluenesulphonamides come into play, though solubility is still dominant, hence a small amount (3% by carbonic acid) of *p*-toluenesulphonamide is precipitated.

TABLE II.

5 g. of mixed toluenesulphonamide, containing 10% *p*-toluene sulphonamide, in 1 mole (1·17 g.) NaOH in 15 c.c.

Acid equivalent to *p*-toluenesulphonamide added in 10 c.c. of water.

Acid.	Hydrochloric	Acetic.	Carbonic.
Wt. amide precipitated ..	0·53 g.	0·5263 g.	0·4820 g.
Melting point	156°	155°	154·5°
% *o*-toluenesulphonamide in precipitate	99·5	98	97

(ii) Experiments were made in which amounts of hydrochloric and acetic acid equivalent to 70% of *o*-toluenesulphonamide were added to solutions of mixed amide containing 10% of *para* compound, in one mole of 8—10% sodium hydroxide. After standing for some hours the precipitated solid was filtered off. A second and third separation was obtained by addition of acid respectively equivalent to 15% and 9% of o-toluenesulphonamide.

TABLE III.

	Hydrochloric acid.	Acetic acid.
Wt. mixed amide, m.p. 150°	5 g.	5 g.
Acid=70% of o-amide.		
Amide precipitated ..	3·2 g.	3·158 g.
Melting point ..	154°=(96% *o*-amide)	156°=(99·5% *o*-amide)
Acid=15% of o-amide.		
Amide precipitated ..	0·65 g.	0·65 g.
Melting point ..	150°=(90% *o*-amide)	155°=(98% *o*-amide)
Acid=9% o-amide.		
Amide precipitated ..	—	0·489 g.
Melting point ..	—	149°=(87·5% *o*-amide)

As will be seen from the table, the weaker acid, acetic, gave a precipitation of *o*-toluenesulphonamide, containing only 0·5% of *para* component, and representing 65% of the total amide originally used. By addition of acetic acid equivalent to a further 15% of *o*-toluenesulphonamide a solid still containing 99% of *ortho* component was obtained.

On the other hand, the strong acid, hydrochloric acid, gave in the first separation a solid containing 3% of *p*-toluenesulphonamide, and in the second (using acid equivalent to 15% *o*-toluenesulphonamide), a mixture containing 10% of *para* derivative. Hence it is obvious that too high a concentration of hydrion so puts back the ionisation of each of the amides that their relative acidities cease to be operative, and the amides are precipitated in a proportion dependent solely on their relative solubilities.

Extraction of the solid mixture by alkali.

The solid toluenesulphonamide mixture was ground up with the requisite quantity of aqueous alkali at a temperature of 50° C., and shaken at that temperature at intervals for three hours. It was then left at room temperature for sixteen hours, after which it was filtered.

A comparison on these lines between sodium hydroxide and sodium carbonate showed conclusively that the weaker alkali, sodium carbonate, effects a cleaner separation than does the stronger sodium hydroxide, and the recovery of pure o-toluenesulphonamide is therefore higher.

TABLE IV.

10 g. mixed toluenesulphonamides, containing 10% *p*-toluenesulphonamide. m.p. 150°.

	NaOH.	Na_2CO_3.
Alkali (conc. 1·17%)=*p*-amide	0·234 g.	0·308 g.
Amide undissolved	8·74 g.	9·374 g.
Melting point	152·5°	153·5°
% o-amide in undissolved amide	93·5	95

If the concentration of the alkali be increased, relatively more *p*-toluenesulphonamide is extracted, and hence the undissolved amide contains a higher proportion of *ortho* compound. But the loss (dissolved material) increases with increase of concentration, so that the higher the concentration of the alkali, the less is the total remaining amide (*v.* Table V). While at a concentration of 7·7% alkali, extraction with two moles of sodium carbonate yields a slightly purer o-toluenesulphonamide than does a concentration of 2·3%, nevertheless the percentage of dissolved solid is double that at the lower concentration.

TABLE V.

Effect of concentration.

Mixed amide taken, 10 g. (90% *o*-amide). m.p. 150°.

Concentration of Na_2CO^3.	1·17%.	2·3%.	7·7%.
Undissolved amide ..	9·38 g.	9·28 g.	9·02 g.

Loss	3%	4%	6%

Extraction of the solid mixture with aqueous alcohol.

(1 part o-toluenesulphonamide dissolves in 28 parts of alcohol, 1 part *p*-toluenesulphonamide dissolves in 13·5 parts of alcohol at 5° C. Klason, Vallin. *Ibid.*)

The mixed toluenesulphonamides were ground up with 96% alcohol, sufficient to dissolve the whole of the contained *p*-toluenesulphonamide. A residual solid representing 83·8% of the total material, but containing only 95% of o-toluenesulphonamide, was thus obtained.

The use of 50% aqueous alcohol is more successful. The undissolved amide, which represents 93·5% of the *o*-toluenesulphonamide, in the original mixture, consists of 98% of *o*-toluenesulphonamide and 2% of *p*-toluenesulphonamide.

Table VI.

10 g. mixed toluenesulphonamide, containing 1 g. *p*-toluenesulphonamide.

	96% alcohol.	50% alcohol.
Amide undissolved	8·38 g.	8·403 g.
Melting point	153·5°	155°
o-amide in undissolved amide	95%	98%

Purification by partial oxidation.

In that process of oxidation of o-toluenesulphonamide to saccharin in which *o*-toluenesulphonamide in excess of potassium permanganate is used (E.P. 3563, 1903), the excess amide is isolated as completely pure o-toluenesulphonamide. Any *p*-toluenesulphonamide present is oxidised to *p*-sulphaminobenzoic acid. Application of this procedure as a means of purification of a 90% mixture of o- and *p*-toluenesulphonamides was highly successful. 90—94% of the *o*-toluenesulphonamide was obtained in a high degree of purity. In the process saccharin of a like degree of purity, equivalent to 5—9% of *o*-toluenesulphonamide, is also isolated. Hence the total loss—unrecovered material—is only the 10% represented by the initial *para* component.

Economically, however, the loss of permanganate necessitated by this procedure is an important factor. The saccharin isolated represents only 60% of the potassium permanganate reduced.

Table VII.

10 g. mixed toluenesulphonamide, containing 1 g. *p*-toluenesulphonamide.
Potassium permanganate equivalent to 1 g. *p*-amide = 1·84 g.
Unoxidised amide = 8·1 g. m.p. 155·5° = 99·2% *o*-amide
Saccharin .. .. = 0·93 g. m.p. 226° = 0·87 g. ..
Loss—*i.e.*, unrecovered material .. = 1·03 g.

The *o*-amide is represented by 99·2% of 8·1 g. unoxidised = 8·0595 g. and saccharin equivalent to 0·87 g., or a total of 8·9295 g. Hence the loss of *o*-toluenesulphonamide is 0·07 g.

Conclusions.

Consideration of the results of the various methods of separation of *o*- and *p*-toluenesulphonamides shows that certain processes stand out as yielding a product of greater purity and with a minimum loss.

In every case final purification, brought about by repeated recrystallisation from water, followed by sublimation *in vacuo* is required.

The highest degree of purity which can be obtained is effected by precipitation by acetic acid of 70% of the o-toluenesulphonamide from an alkaline solution of the mixed amides; a product containing 99·5% of o-toluenesulphonamide is thereby obtained. But the loss involved is very high—30% of the *ortho* compound.

Purification by partial oxidation gives, on the whole, the most satisfactory results. A product of a high degree of purity—99%—is obtained, and including the saccharin which is isolated, represents the whole of the valuable *o*-toluenesulphonamide, a fact of immense importance in the manufacture of saccharin. But the many and lengthy operations involved, and the fact that for every one part of *o*-toluenesulphonamide recovered 0·216 part of potassium permanganate is destroyed, and of this 40%, or 0·086 part, is not accounted for by any product isolated, somewhat detracts from the advantages which this method possesses.

For simplicity and rapidity of manipulation, combined with a good yield of *o*-toluenesulphonamide of a high degree of purity, one extraction of the mixture with 50% aqueous alcohol (1 part of mixed amide to 5 parts of 50% alcohol) is to be recommended. By this means 90·7% of the o-toluenesulphonamide of 97% purity is extracted.

Extraction of the mixture with a moderately concentrated solution of sodium carbonate, while it does not effect such a clean separation (the *o*-toluenesuphonamide is of only 96% purity), brings out almost the whole of the *ortho* compound; a loss of but 2—3% is involved.

On these grounds, together with its low cost and ease of manipulation, it may be suggested as an admirable means of separating mixtures containing more than 10% *para* compound, and even of the "⅔—⅓" mixture obtained in the Fahlberg saccharin process.

I desire to express my indebtedness to Professor Orton, under whose direction this work has been carried out.

THE VOLATILE OIL FROM THE LEAVES OF THE "WILD PIMENTO" OF JAMAICA.

BY O. D. ROBERTS, F.I.C.

The genus *Pimenta* includes two species which are well known in commerce as sources of volatile oils. These are (1) *P. officinalis*, the unripe fruit of which yields ordinary pimento or allspice oil, whilst the leaves also furnish an oil of similar composition; and (2) *P. acris*, from the leaves of which commercial oil of bay is obtained.

Two volatile oils from the leaves of sub-varieties of *P. acris* have also been examined, viz., oil of *P. acris* var. *citrifolia*, Kostel, which is said to contain an appreciable quantity of citral, and oil from a form of *P. acris*, known as "Bois d'Inde anise," which has a characteristic anise-like odour.

The oil which is the subject of the present investigation differs widely in composition from any of the above oils, and has an odour recalling that of spike lavender oil. It is derived from the leaves of a species of pimento found in Jamaica, both in the woods of Upper Clarendon at an altitude of 2000—2500 feet, and in the Dry Harbour Mountains. The tree attains a height of 40 feet and its trunk a diameter of 1 foot. The species is locally known as "Wild pimento," and has been named *Amomis* (=*Pimenta*) *jamaicensis*, Britton and Harris, by the Government botanist.

Leaves distilled in Jamaica were stated to have yielded 0·49% of oil. A sample of the oil received at the Imperial Institute from the Director of Agriculture of Jamaica in 1918 was pale yellow, and had an odour somewhat resembling that of the oil of *Lavandula spica*. It had the following constants: sp. gr. (15°/15° C.) 0·8895; α_D^{22} (in a 100 mm. tube) = −6° 0′; $n_D^{20} = 1{\cdot}471$; acid value 2·4; ester value before acetylation 4·2; ester value after acetylation 129·4. The oil was soluble in 2·5 volumes of 70% alcohol at 15° C., becoming cloudy with 6 volumes.

The following results were obtained in a systematic investigation of the oil.

Free acids: Indication of the presence of caproic and acetic acids.

The free acids were extracted from the oil by shaking it with a dilute solution of sodium carbonate. On acidifying the solution and extracting with ether, an amount equivalent to about 0·2% of the original oil was obtained. This acid liquid was distilled in a current of steam, when there separated in the distillate a small quantity of an acid substance having an unpleasant odour resembling that of caproic acid. After separation from the aqueous portion of the distillate, this substance was converted into its silver salt, of which 0·1270 g. gave 0·0617 g. Ag (Ag=48·6%). Silver caproate contains 48·4% Ag. The aqueous portion of the distillate was saturated with calcium chloride, washed with ether, and again distilled in a current of steam. The distillate contained a readily soluble acid; 0·1023% of its silver salt gave 0·0657 g. Ag (Ag=64·2%). Silver acetate contains 64·6% Ag.

Aldehydes.

On shaking the oil with a saturated solution of sodium hydrogen sulphite, combination to the extent of about 0·1% of the original oil took place. The substance thus removed from the oil had a rather pleasant odour, and was aldehydic in character, for it responded to Schiff's rosaniline test. The amount of liquid obtained was not sufficient for further investigation.

Phenols. Absence of eugenol.

The original oil, after the foregoing treatment with sodium carbonate and sodium hydrogen sulphite solutions, was extracted with a 3% solution of sodium hydroxide. A phenolic liquid was obtained which amounted to about 0·1% of the original oil. This substance had a slight phenolic odour, and produced a reddish-violet coloration with a solution of ferric chloride, but no evidence of the presence of eugenol was obtained.

Fractional distillation of the oil.

Before proceeding with the fractional distillation of the oil remaining after the removal of the abovementioned traces of free acids, phenols, and aldehydes, the oil was hydrolysed by boiling it with alcoholic potassium hydroxide. After the greater portion of the alcohol had been removed by distillation, sufficient water was added to effect the separation of the oil, which was extracted with ether, the ethereal solution was washed and dried, the ether removed, and the oil submitted to repeated fractionation. The following fractions were obtained:—

	Per cent. calculated on the original oil.	Range of boiling point.		Sp. gr. (15°/15° C.)	α_D^{20} 100mm. tube.	n_D^{20}
		Under 14 mm. pressure.	Under atm. pressure.			
1.	32	75°– 80°	175°–190°	0·8750	−8·25°	1·4720
2.	42	80°– 95°	190°–205°	0·8677	−3·74°	1·4670
3.	4	95°–110°	205°–220°	0·8808	−2·30°	1·4705
4.	6	110°–125°	220°–235°	0·9010	−3·80°	1·4865
	Residue 16	—	—	0·9592	Too dark to obtain a reading.	1·5205

Identification of cineol.

The fraction boiling at 175°—190° C. was a colourless limpid liquid, having a camphoraceous odour. On treating it with a 50% solution of resorcinol, an absorption of 47% was obtained, equivalent to 15% of the original oil. The remaining oil was separated from the clear resorcinol solution, and the latter was then subjected to distillation with steam. The colourless oil, which separated in the distillate, had the characteristic odour of cineol, was optically inactive, had sp. gr. (15°/15°) 0·9270, and furnished a pale greenish-white iodole addition compound, which melted and decomposed at 116° C. It was evident therefore that the portion of this fraction absorbed by the resorcinol solution consisted practically entirely of cineol.

Identification of α-phellandrene.

The part of this fraction (175°—190°) which was unabsorbed by the resorcinol solution was distilled over sodium under reduced pressure, and a colourless mobile oil was thus obtained which had sp. gr. (15°/15°) 0·8520, α_D^{22} (in a 100 mm. tube) = −11° 42′; b.p. 172°—179° (uncorr.). A portion of this oil, treated with sodium nitrite and glacial acetic acid, gave the characteristic reaction of phellandrene. The nitrite, after crystallisation from methyl alcohol and chloroform, melted at 112°—113° C., thus establishing the presence of α-phellandrene in the oil.

Identification of dipentene.

From another portion of the above oil, boiling at 172°—179°, a fraction boiling at 176°—179° was obtained, which furnished a tetrabromide melting at 124° C., thus proving the presence of dipentene.

Identification of linalool.

The fraction boiling at 190°—205°, which was the largest fraction obtained, consisted of a colourless liquid, with a pronounced odour of linalool. Almost the entire fraction boiled at 197°—198° C.; this portion had sp. gr. (15°/15°) 0·8693, α_D = −3° 39′, n_D^{20} = 1·4655, which are the characteristic physical constants of linalool. A portion was gently oxidised with chromic acid mixture, and the resulting oil, after purification by distillation with steam, was treated with sodium hydrogen sulphite solution. From the solid bisulphite compound thus produced, citral was liberated, which was recognised by its odour, and identified by the preparation of crystalline α-citryl-β-naphthacinchoninic acid, m.p. 200° C. From these results it is evident that this fraction consisted almost entiredy of *l*-linalool.

The small fraction boiling at 205°—220° C. was a colourless liquid, possessing a pleasant aromatic odour. The alcoholic nature of this fraction was evidenced by its almost complete esterification when treated with acetic anhydride; the combination which took place on heating a portion with phthalic anhydride was, however, almost negligible, thus indicating that the substance consisted of a tertiary alcohol. It was clear that this fraction also consisted largely of linalool, and no definite indication of the presence of any other alcohol was obtained.

Identification of geraniol.

The fraction boiling at 220°—235° consisted of a colourless liquid, possessing a faint rose-like odour. When a few drops of this fraction were oxidised with chromic acid mixture the strong odour of citral was developed. The fraction, diluted with an equal volume of benzene, was heated for several hours with phthalic anhydride. The acid phthalic ester thus formed was converted into the sodium salt which, on saponification and simultaneous distillation in a current of steam, furnished an oil having the characteristic odour of geraniol. The presence of geraniol was confirmed by the formation of geraniol diphenylurethane, m.p. 80°—81° C.

The fraction boiling above 235° was brown and rather viscous. It was evident that it contained resinous decomposition products, consequent upon distillation of the oil under atmospheric pressure. With the object of ascertaining whether any characteristic sesquiterpene was present, this fraction was heated on the water bath for some weeks with sodium under reduced pressure. The oil was then distilled off under 15 mm. pressure. There was thus obtained a colourless oil, with a slight balsamic odour, having sp. gr. (15°/15°) 0·9320, and boiling between 245° and 290° (uncorr.) at atmospheric pressure. Its high density, wide range of boiling point, and the fact that the oil was still slowly attacked by sodium, showed that appreciable quantities of oxygenated compounds were still present. The amount of oil was too small to permit of any further investigation of this fraction.

Summary.

The results of this investigation of the volatile oil from the leaves of *Amomis jamaicensis* have shown that its composition is approximately as follows:—Terpenes, including α-phellandrene and dipentene, 17·0%; cineol, 15·0%; aldehydes, undetermined, 0·1%; alcohols, chiefly *l*-linalool with some geraniol, 38·3%; esters, as linalyl acetate, 1·5%; phenols, undetermined, 0·1%; acids (acetic and caproic in the free state), 0·2%; residue probably containing sesquiterpenes, 27·8%.

A NOTE ON A SPECIAL SLIDE RULE FOR CALCULATION OF "WET" AND "DRY" WEIGHTS OF DAMP MATERIAL.

BY R. SCOTT.

The necessity for a simple, rapid, and accurate method of calculating the "wet" and "dry" weights of nitrocellulose batches led to the construction in this laboratory of a calculator which has proved useful, and the principle employed seems to offer a wider scope for practice.

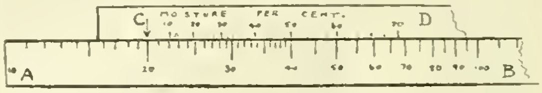
A slide rule may be used in many cases where a nomographic or alinement chart has been suggested for routine calculations. It is easily constructed and easily manipulated, and the time required for the calculation is reduced to a few seconds.

In handling a batch of damp material it is customary to have a sample submitted for determination of moisture which is expressed as moisture per cent. of the damp material. There is now required the amount of "wet" material to give a specific amount of "dry" or the "dry" content of a certain amount of "wet."

The calculation is given by

$$D \times \frac{100}{100-M} = W$$

where D = dry weight, W = wet weight, and M = moisture per cent. This is of tho general form XY = Z and capable of slide rule or nomographic treatment.



To make the slide rule the frame scale, A B (see fig.), was divided in the usual logarithmic manner but the slide scale, C D, was divided proportionally to log. 100/(100—M) between suitable limits of M, each division being marked with its appropriate value of M. The frame scale, A B, was extended beyond the point marked 100 by a length equal to the total length of the slide scale.

For wet weight determination the zero mark on C D is placed opposite the division on A B corresponding to the "dry" weight, and the "wet" weight read off opposite the division on C D marked with the moisture content. For "dry" weight determination the process is reversed.

A convenient distance between the points marked 10 and 100 on the frame was found to be 1000 mm.

The wooden frame and slide were constructed in the carpenters' shop and made so that C D could be moved easily along A B. The scales were glued to the wood and coated with celluloid varnish. The whole apparatus measured 4′ 9″ × 3½″ × ¾″.

The accuracy of the instrument, assuming careful construction, will depend on the scale on which it is constructed and the number of divisions introduced. The calculator in use has a total maximum apparent error due to size of scale divisions of 0·56 lb. dry weight on 100 lb. of dry material, but this is due to errors accumulating in the same direction. In practice the reading of figures may be made to approximations, where necessary, between divisions, and the error thus maintained well within the limit.

It is easy to modify the slide scale to read weights where a certain percentage of moisture is allowed, as in air-dry material. The slide in this instance would be divided proportionally to log. (100—*a*)/(100—M), where *a* is the percentage of moisture allowable.

In general a similar instrument should be useful for rapid calculations of the type $a = x.f(y)$, with the slide scale divided in proportion to log. f(y).

By using several slides, equations of the type $\phi(a) = F(x).f(y) \ldots$ may be solved by dividing the frame scale proportional to log. $\phi(a)$ and slide scales proportionally to log. F(x) and log. f.(y). . .

Communications.

SOME PROPERTIES OF TETRANITRANILINE (TNA).

BY B. J. FLÜRSCHEIM, PH.D.

Since the appearance of the first publications on TNA[1] many authors or patentees have dealt with the subject. Additional information of value has resulted in some cases, whereas erroneous or incorrect statements have been made in others, and it may therefore be useful to give a brief review of the subject on the basis of seventeen years' personal experience. The present communication will therefore deal with the constitution and reactions of TNA, its density and colour, stability, physiological properties, power, and sensitising properties, and certain points connected with its manufacture. Of the tests recorded below, in all of which, unless otherwise stated, merely water-washed, unrecrystallised TNA manufactured on plant scale has been used, Nos. 2, 4—8, 14—16, 22, 26—29, 42, 43, 49—51, 58—60, and 64 were carried out by Allied and associated Governments, Nos. 9, 21, 25, 30, 35, 56, 57, 62, 63 (partly), by explosives manufacturers, Nos. 44, 52, 55, and 61 by ordnance manufacturers, Nos. 3, 10—13, 17—20, 23, 24, 31—34, 36, and 63 (partly) by the author, and the remainder are quoted from the literature on the subject.

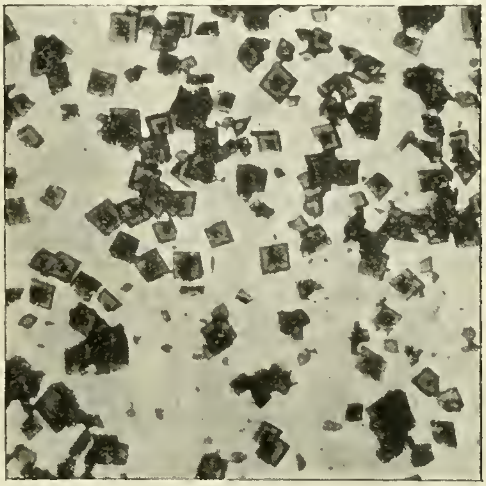
I.—CONSTITUTION AND REACTIONS OF TNA.

TNA was first prepared and analysed by the author in 1904, and the work was partially repeated by his assistant, T. Simon, in 1906. The determination of the positions occupied by the nitro-groups was carried out by the author in 1910, both by synthesis from derivatives of aniline containing a second nitro-group in an ortho- or para-position with regard to the amino group,[2] and by the conversion of TNA into compounds already known, notably trinitroresorcinol[3] and trinitro-*m*-phenylenediamine.[4] It was thus definitely proved that the nitro-groups occupy the positions 2.3.4.6, that the 3-nitro-group is mobile,[5] also that all are real nitro and not nitrite groups, for otherwise ammonia could not transform TNA to trinitro-*m*-phenylenediamine, but only to an ammonium salt of an aminophenol.

In order to test the nitro-formulation of the mobile group in the 3-position, Van Duin[6] recently reduced TNA by means of titanous chloride, and his results confirmed the already well-established fact. It had already been stated[7] that the mobile nitro-group can be replaced by numerous other radicles—for instance, by reaction with alcohols, phenols, or amines—and that the amino-group can be acetylated, and acetyltetranitraniline, trinitroaminophenol, -anisol, and -phenetol had been described. These compounds were again prepared by Van Duin,[8] as well as some of the amines.[9].

II.—DENSITY AND COLOUR.

The true colour of TNA is a strong yellow, which always appears in the ground material. Larger crystals, however, exhibit a deeper hue, varying, according to the mode of preparation, from an intense yellow to greenish. The micrograph obtained by Col. C. G. Storm, at the U.S. Bureau of Mines at an enlargement of 34 diameters, reveals a flaw in the crystals, and under the microscope the centre of the crystal, with the flaw, appears yellow, the transparent surrounding portion green.



Crystals without a flaw can be obtained under certain conditions of nitration, and these, under the microscope, appear entirely transparent and green. According to the method of nitration the material in bulk, as separated from the spent acid, therefore appears—without a flaw—greenish, and has an absolute density of quite 1·9, or more or less yellow, with a corresponding decrease of the density to anything between 1·9 and 1·86. This observation is chiefly due to Dr. Beardsley, of Bound Brook, N.J.

The absolute density of TNA therefore equals that of ammonium perchlorate (1·89). The absolute densities of all other organic high explosives and of ammonium nitrate lie approximately between 1·6 (nitroglycerin) and 1·77 (trinitrochlorobenzene).

III.—STABILITY AND REACTIVITY.

As early as 1914 W. Macnab,[10] on the basis of several years' personal experience, was able to state that TNA "combines an exceptional explosive power with aromatic stability." Indeed, no TNA which the author has examined since its discovery in 1904, including even the very first impure samples, has proved unstable in the sense of being unsafe to handle or store. But to produce a material capable of satisfying all the more or less sensitive tests (which were really intended, not for purely aromatic products like TNA or TNT, but for wholly or partly aliphatic nitro-compounds capable of catalytically accelerated spontaneous decomposition, such as nitrocellulose, nitroglycerin, tetryl, etc.) has required the accumulated experience of several years, but has now been achieved on a commercial scale and without any purification of the material other than washing with water.

[10] Lectures on explosives, Institute of Chemistry, pp. 25, 60 (1914).

Typical examples of different TNA stability tests are given below, and the results are subsequently interpreted and compared with those obtained from other nitro-explosives.

A.—Abel test.

From each test the approximate percentage of NO_2 which would be evolved per year if the measured initial rate were maintained has been calculated by Robertson and Smart's formula.[11]

No. 1, carried out by Van Duin and Van Lennep[12] with TNA prepared with KNO_3, and re-crystallised from acetic acid. Used 10 grams in closed containers of 29·3 c.c. capacity, heated without test paper; times given are those after which an inserted starch-zinc iodide test paper is coloured in 30 seconds.

Temp.	Time.	NO_2% per year.[13]
70° C. ..	3 hrs. ..	0·044
60° C. ..	26 ,, ..	0·0051
50° C. ..	404 ,, † ..	0·00033
32° C. ..	1512 ,, ..	0·000087

† 2 samples out of 4.

No. 2, heated with test paper according to standard American Abel-test method, temperature 65·5° C.—

(*a*) Standard plant TNA, dried on plant scale 6 hrs. at 80° C. in a partial vacuum of 26—27 in. (4 samples): 4 hrs. 13 min. *plus*; NO_2<0·0007% per annum.

(*b*) Similar material, original moisture content 0·22%, dried only 1 hr. at 80° C. at ordinary pressure, tested a few days after manufacture: 30, 50, 51 min.; NO_2 av. 0·02% p.a.

(*c*) Same material as (*b*), not dried: 17, 26, 41 min.; NO_2 av. 0·05% p.a.

(*d*) Similar material, not dried, after 9 months' ordinary storage (3 samples): Slight test after 68 min., no increase of tint in further 33 min.; NO_2 0·009% p.a.

(*e*) Same material as (*a*), after adding a drop (*ca.* 5% of water): 12½, 12½ min.; NO_2 0·26% p.a.

(*f*) Same material as (*c*) after re-drying for 1 hr. at 100° C.: 60 min. *plus*; NO_2 <0·01% p.a.

No. 3. Plant TNA, which had been stored 6½ years, with a moisture content of 0·49%, was used and American Government potassium iodide test paper:—

(*a*) Pre-dried 4 hrs. at 60° C., whereby moisture was reduced to 0·26%. 10 g. TNA, test tube of 39 c.c., temp. 95° C., heated with moist test paper: av. 15 min.; NO_2 0·05% p.a. at 95° C.

(*b*) Pre-dried 4 hrs. at 95° C., 10 g. TNA, temp. 95° C., test tube 39 c.c., heated with moist test paper: av. 32 min.; NO_2 0·011% p.a. at 95° C.

(*c*) Pre-dried 4 hrs. at 95° C., 2 g. TNA, heated by Van Duin and Van Lennep's method, without test paper, test tube 25 c.c., 24 hrs. at 100° C.: av. 1 min.; NO_2 0·013% p.a. at 100° C.

(*d*) Same as (*c*), 6½ hrs. at 100° C.: av. 3 min.; NO_2 0·016% p.a. at 100° C.

(*e*) Same as (*c*), 6 hrs. at 100° C.: av. 4 min.; NO_2 0·013% at 100° C.

(*f*) Same as (*e*), but only 0·1 g. TNA, 2 hrs. at 130° C.: av. 1⅓ min.; NO_2 2·5% p.a. at 130° C.

(*g*) Same as (*f*), preheated 14 hrs. at 130° C., heated 2 hrs. at 130° C.: av. 3 min.; NO_2 1·1% p.a. at 130° C.

B.—Manometric and gravimetric heat tests.

No. 4. Gas evolution *in vacuo* of plant TNA after about 10 months' ordinary storage. Pre-dried, before test, for 4 hrs. at 60° C., 18 hrs. at 80° C.: 1st hour, 0·60 c.c. per g. per hr. at 120° C.; 2nd, 0·25; 3rd, 0·16; 4th to 7th, 0·11; 8th to 11th, 0·09; 12th to 15th, 0·07; 16th to 19th, 0·06; 20th to 30th hour, 0·052 c.c.

No. 5. Same material after about 45 months' storage. Pre-dried 18 hrs. at 30°—40° C., 2 hrs. at about 90° C.: 1st hour, 0·65 c.c. per g. per hr. at 120° C.; 2nd 0·28; 3rd, 0·24; 4th to 7th, 0·16; 8th to 11th, 0·10; 12th to 15th, 0·075; 16th to 19th, 0·06; 20th to 30th hour, 0·044 c.c.

No. 6. The same material as No. 5, after grinding and water-washing, then pre-drying as in No. 5, gave results practically identical with those of No. 5.

No. 7. Same material as No. 4, similarly predried: 1st 16 hrs., 0·034 c.c. per g. per hr. at 100° C.; 17th to 32nd, 0·020; 33rd to 48th, 0·015; 49th to 64th, 0·0125; 65th to 80th, 0·0112; 81st to 96th, 0·0106 c.c.

No. 8. TNA from an experimental run on a small plant scale, in which a mixed acid had been used containing about 2% more water than specified for standard TNA. Pre-dried 18 hrs. at 30°—40° C. and 2 hrs. at 90°—100° C.: first ½ hr., 8·8 c.c. per g. per hr. at 120° C.; ½ hr.—3 hrs., 1·28; 4th to 19th, 0·25; 20th to 27th hrs., 0·15 c.c.

No. 9. TNA made on an experimental scale[14]: 1st 4 hrs., 0·11 c.c. per g. per hr. at 120° C.; 5th to 8th, 0·075; 9th to 12th, 0·045; 13th to 16th, 0·035; 17th to 20th hrs., 0·030 c.c.

No. 10. The loss of weight of TNA (same material as No. 4, pre-heated 3 hrs. at 96° C.) was found to be as follows:—At 130·5° C., first 2 hrs., 0·113% per hr.; 2 hrs. to 9h. 40m., 0·031%; 9h. 40m. to 17h. 20m., 0·017%; 17h. 20m. to 25 hrs., 0·012%. Thereafter at 105·5° C., first 5½ hrs., 0·0012%; 5½ to 10½ hrs., 0·0012% p. hr. The same material (preheated 3 hrs. at 96° C.) lost 0·113% per hr. at 130·5° C. for the first 2 hrs., and thereafter 0·0048% per hour at 106° C. for 5 hrs. The same material (preheated 3 hrs. at 96° C.) lost 0·021% per hr. for the first 5 hrs. at 106° C.

No. 11. The same material as No. 8 (pre-dried 3 hrs. at 96° C.) during the first 2 hrs. lost 0·454% per hr. at 130·5° C.; 3rd to 4th hr., 0·130%; 5th to 6th hr., 0·108%.

No. 12. To ascertain whether aminopicric acid—the only non-volatile product formed by hydrolysis of TNA—has any effect on the change of weight of the latter when heated, a mixture of 95% of standard TNA and 5% of aminopicric acid was heated at 130° C. The % per hour decrease was identical with that obtained with the same TNA by itself. Aminopicric acid by itself, after 4 hrs.' preheating at 95° C., lost during the first 4 hrs. 0·075% per hr., and during the 5th—8th hrs. 0·048% at 130° C.

No. 13. The % per hour decrease of a mixture of 95% of TNA and 5% of aminopicric acid remained the same when the composition was finely ground to ensure intimate mixing.

C.—Fume (German) Test. 135° *C.*

No. 14. TNA was found to withstand the test (no fumes) for 60 hrs. *plus.*

No. 15. TNA which had been further dried on plant scale at 80° C. for 6 hrs. in a partial vacuum turned the blue litmus paper to a neutral pink (3 samples) after 34 min. without bleaching the dye. A fresh paper inserted thereafter was turned pink in 72 mins. (3 samples). The test paper did not lose its sensitiveness. The TNA gave no fumes and did not smell of acid.

TNA which had been pre-dried in the laboratory for 2 hrs. at 100° C. and then allowed to cool for 1 hr., turned the paper, at 135° C., to a neutral pink after 43 mins. (1 sample), and 63 mins. (1 sample). There were no fumes or acid smell.

---

[11] J., 1910, 132.

[12] Rec. Trav. Chim., 1920, **39**, 163; Van Duin, Utrecht, Thesis, 1918.

[13] As zinc iodide test paper is more sensitive than KI paper (*cf* Marshall," Explosives," 2nd ed., p. 660) these figures are somewhat too high.

[14] A diagram of this test has been published in Z. ges. Schiess- u. Sprengst., 1913, **8**, 185.

D.—Storage test at 90° F. (32° C.)

No. 16. Explosives for authorisation in Great Britain must withstand this test for six weeks.[15] TNA is on the British Home Office list of authorised explosives of January 1st, 1920, in Class 3, Division 2.

E.—Storage test at 75° C.

No. 17. TNA withstands this test, not only for the 48 hrs. prescribed by the International Commission for Unification of Explosives,[16] but for an indefinite period.

F.—French litmus tests.

No. 18. Moist neutral litmus paper is not reddened by TNA in 5 days at the ordinary temperature.

No. 19. Dry blue litmus paper is not reddened by TNA in 36 hrs. at 96° C.

No. 20 (test prescribed by French railways). Neutral litmus paper is not reddened by 100 c.c. of water with which 1 g. of TNA had been shaken for ½ hr. at 15° C.

G.—Behaviour toward metals.

No. 21. Experiments already recorded[17] have shown that TNA, whether wet or dry, does not attack steel, iron, tin, copper, brass, lead, aluminium, or zinc in 14 days at the ordinary temperature.

No. 22. TNA (moisture about 0·2%) was packed in copper caps, sealed with paraffin, and stored for 28 months at 90°—100° F. Both the TNA and the surface of the metal remained unaltered.

H.—Behaviour towards inorganic nitrates.

No. 23. 40 parts of TNA and 60 parts of commercial ammonium nitrate, neither of which had been specially pre-dried, were ground together and stored for seven years, under a glass jar, at ordinary temperature and in daylight, and excluding atmospheric moisture. No interaction had taken place, since the mixture was separated into its unchanged components by means of benzene or water.

No. 24. Compressed cartridges containing 50% of "yellow" TNA from an early experiment on semi-plant scale, 10% of potassium nitrate, and 40% of barium nitrate[18] were stored for 28 months at the ordinary temperature, with access of air moisture, and during part of this period in daylight. They remained unchanged.

I.—Resistance to water, solubility, and hygroscopicity.

No. 25. Wet TNA as manufactured retains about 20—25% of water on a vacuum filter, and less than 10% on a centrifugal. TNA with 20—25% of water was generally dried at a temperature rising slowly from 40° to 60° C. for about 24 hrs. at atmospheric pressure, or about 8 hrs. in a vacuum dryer. Its acidity was determined, both before and after drying, according to a method specified by two of the Allied and associated Governments, in which 10 g. of TNA is allowed to stand for ½ hr., with occasional shaking, in 150 c.c. of neutral water, whereafter it is filtered and twice washed with 20 c.c. of water, the united filtrates being titrated with $N/50$ sodium hydroxide, using 15 drops of a 0·5% phenolphthalein solution as indicator. The acidity obtained for standard "green" TNA generally amounted to about 0·2% calculated as H_2SO_4, and was the same before and after the drying. There is therefore no measurable hydrolysis during drying, since this would produce aminopicric acid—a strong and non-volatile acid—which would result in a higher acidity in the dry, as compared with the wet material.

No. 26. *Exposure to own moisture on storage.* The official report states: "On a sample of TNA, Lot No. 3/16, inspected in August, 1916, for . . . . I determined the acidity at that time to be 0·015%. After 9 months' dark storage of this sample, at laboratory temperature, I again determined the acidity and found it to be 0·017%. This apparent increase in acidity is within the limit of experimental error. The amount of mosture (about 0·2%) ordinarily present in TNA of regular plant manufactured does not therefore cause any decomposition of the material."

No. 27. *Acidity of TNA stored with excess of water in the absence of light.* Three tests were made as follows: 10 g. of a composite sample of ordinary green TNA was placed with 150 c.c. of neutral water in sealed rubber-stoppered bottles in a dark room and shaken occasionally and the acidity tested as described in No. 25 with the following results:—

After	Acidity.	Increased acidity per day.
1 day ..	0·0195% ..	—
2 days ..	0·0231 ..	0·0036%
15 " ..	0·0341 ..	0·0008
21 " ..	0·0354 ..	0·0002

The above indicated that, in the dark, the acidity obtained with water is due to the gradual liberation of the occluded sulphuric acid. In further tests, in which TNA, as manufactured was allowed to stand with water for 6 mins., the acidity with unground TNA was found to be 0·034% and with the finely ground substance 0·063%. It is stated in the official report that these figures and the results of tests Nos. 28 and 29 show that the acidity is due to the removal of occluded sulphuric acid, since if it had been due to decomposition of the TNA the figures for "increased acidity per day" would have shown a rise or at least remained steady.

No. 28. *Prolonged exposure to excess of water in daylight.* A blend of green and yellow TNA, original acidity 0·0232%, showed the following increases of acidity: After 1st 24 hrs., 0·0209%; 24—48 h., 0·0270; 48—72, 0·0092; 72—96, 0·0256; 96—120, 0·0228; 120—168, 0·0392; 168—192, 0·0110; 192—216, 0·0147; 216—264, 0·0287; 264—312, 0·0140; 312—336 h., 0·0094%. Average increase of acidity per 24 hrs., 0·0159%. Two other samples showed an average increase of acidity per 24 hrs. of 0·0163% and 0·0139%. The daily variation in the increase of acidity appeared to depend somewhat on the changes of temperature. That the TNA, through the action of water at ordinary temperature, does not undergo any change that would affect its quality is demonstrated, the official report adds, by the fact that the three samples after the above tests had m.p. 212·5°, 213·0°, and 213·0° C. respectively.

No. 29. The sample of TNA which had been stored with excess of water for 13 days without complete exclusion of light was dried at 60° C. and then heated for one hour at 100° C.

(*a*) Abel test at 65·5° C.; 3 specimens. The test paper was not coloured in 1 hr. 50 min., whereupon the test was discontinued.

(*b*) Heat test at 136°—140° C.; 4 specimens. The first indication on the litmus paper of a change from blue to neutral pink appeared after 17 minutes. After an additional 58 mins. (viz., a total heating of 1 hr. 15 min.) the papers had entirely changed to a neutral pink, with the exception of a strip on the margin of each, which had originally been more intensely blue than the rest of the paper, and which

[16] Orig. Comm., Int. Cong. Appl. Chem., 1912, **25**, 311.

[17] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[18] These cartridges were exhibited by W. Macnab in his lecture on Explosives (*loc. cit.*).

remained blue. The TNA gave no fumes and did not smell of acid.

These tests are, states the report, in the case of the Abel test as good as, and in the case of the 136°—140° C. test better than the results obtained with the same sample before storage with water.

No. 30. Prolonged exposure to a smaller amount of water in daylight, at ordinary temperature. 10 g. of TNA with 4 g. of water were left for 33 days, then washed and filtered. The filtrate showed 0·054% of acid. 10 g. of TNA which had been shaken with water for a few minutes, then washed, gave 0·03% of acid (*cf.* No. 27).

No. 31. Prolonged exposure to excess of moisture in partial daylight. TNA as used in test No. 8, but with 10% of water and an unusually large amount of sulphuric acid remaining after perfunctory washing in the plant, was left in a stoppered amber bottle, on an open shelf, for 35 months. When dried thereafter—without any previous washing—its melting point, when compared, by simultaneous heating, with that of a sample of the same material which had been carefully washed and dried a few days after manufacture, as well as its appearance (colour etc.) were found to be unchanged.

No. 32. *Solubility of TNA in water.* One g. of finely divided TNA was shaken for ½ hr. with 100 c.c. of water at 13° C. in order to remove traces of mineral acid and soluble impurities introduced by the factory water-wash. The material was filtered, washed, and then left for two hours in one litre of water, with frequent shaking. After filtering the water was evaporated at 100° C., a little ammonia having been added to retain all transformation products. The solubility was thus found to be approximately 1:50,000 at 13° C.

Even in solution TNA does not react with water as readily as appears to be commonly supposed[19]:

No. 33. 20 g. of TNA was dissolved in 225 c.c. of acetone at about 30° C., filtered, and stirred into 400 c.c. of water at ordinary temperature. About 90% of the TNA was thus recovered; the rest remained in the mixed solvent, also unchanged, since, even after an hour, the solution gave no nitrous acid reaction with potassium iodide test paper.

No. 34. *Hygroscopicity.* This has been given[20] as 0·12% for a material made on a small scale. This figure approximately holds good for the standard ("green") commercial material. A sample which had been plant-dried to 0·49% of moisture was completely laboratory-dried at 95° C., and then exposed to moist air until its weight became constant, when it was found to contain 0·13% of moisture. A more finely divided ("yellow") TNA became constant after 32 days, with 0·19% of moisture.

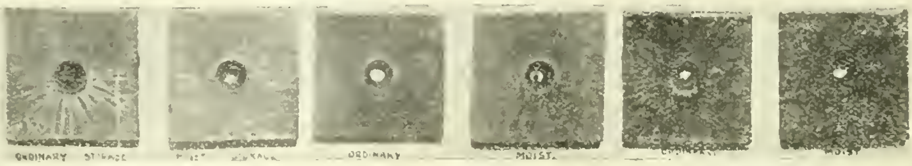
No. 35. *Storage of TNA in detonators.* The detonators were manufactured with 0·3 g. of 80% fulminate and 0·4 g. of TNA per detonator, at a pressure of 176 lb.

Ten weeks' ordinary moist storage (80% saturation):—

(Gain in weight calculated on original weight.)

Week.	Gain in wt. (g.).	Lead block. c.c.	Week.	Gain in wt. (g.).	Lead block. c.c.
1st	0·0015	13·0	6th	0·0030	12·8
2nd	0·0019	12·9	7th	0·0030	12·6
3rd	0·0021	12·85	8th	0·0030	12·6
4th	0·0035	13·0	9th	0·0030	12·6
5th	0·0025	12·9	10th	0·0030	12·6

The keeping qualities of TNA detonators when exposed to moisture at ordinary temperature are thus quite satisfactory. This was confirmed by lead-plate tests carried out on No. 6 detonators, after a year's ordinary and a year's hot-moist storage at 40° C., as shown by the accompanying illustrations.



Fulminate alone. Fulminate-TNA. Lead azide-TNA.

J.—Consideration of tests Nos. 1 *to* 35 *in relation to each other and to the behaviour of other nitro-explosives with a mobile nitro-group [tetryl, nitroglycerin (nitroglycol), nitrocellulose (nitrostarch)].*

According to the bulk of expert opinion (*cf.* Guttmann,[21] Nathan,[21] Thomson,[21], Reid,[21] Cullen,[21] Aspinwall,[22] Spica,[23] Barthelemy,[24] Sy,[25] Lenze,[26] Escales,[27] Will[28]), the Abel heat test records, in the first place, not the degree of stability, but the degree of purity of an explosive. When a given impurity is known to lower the heat test of a given explosive and at the same time to cause its progressive decomposition, then the Abel test becomes indirectly a measure of the stability of a particular explosive as affected by a particular impurity. It therefore does not necessarily indicate the relative stability of samples of the same explosive contaminated by different impurities; still less does the Abel test claim, to quote Cullen,[29] to measure the relative stability of different explosives.

Nevertheless, if it is often impossible to draw definite conclusions from a bad Abel test, a good test, provided that no foreign substance which would mask oxides of nitrogen is present, necessarily indicates a corresponding degree of stability; moreover, the Abel tests usually obtainable from good commercial grades of various explosives enable certain conclusions to be drawn as to their relative stability if the effect of impurities normally present on both the test and the stability is taken into consideration.

According to test No. 1, Van Duin and Van Lennep obtained a TNA which would evolve rather less than 0·01% of NO_2 in 115 years at 32° C. (89° F.) and in 37 years at 50° C. (122° F.).[30] In the preparation of this sample potassium nitrate and

---

[19] Test No. 33 proves that Van Duin (Rec. Trav. Chim., 1917, **37**, 117; 1920, **39**, 150) is mistaken when he makes water responsible for the instantaneous reaction of TNA with sodium acetate in aqueous acetone at ordinary temperature which had been previously described by the present author. Besides, numerous other basic reagents react similarly in the total absence of water.

[28] Z. angew. Chem., 1901, **14**, 775.

[29] *Loc. cit.*,

[30] These authors (see also Van Duin and Van Lennep, Rec. Trav. Chim., 1917, **37**, 114; Van Duin and Brackmann, Chem. Weekbl., 1919, **16**, 501) and also Stettbacher, base on these results, and on these alone, their allegation that TNA shows "rapid decomposition." Obviously they failed to realise the quantitative meaning of their tests.

acetic acid had been used, both of which lower the heat test of TNA and are never employed in its manufacture. It is therefore not surprising that, on a commercial scale and without any purification other than water-washing, a TNA is obtained which, when properly dried on a plant scale, gives still better results, such as the official tests No. 2.

Nos. 2 and 3 show the effect of moisture on the Abel test. Attention had already been called[31] to the fact that TNA—which, as evidenced by Nos. 21, 25, 30, and 31 and the official tests No. 26 to 29 and 22 is not affected by moisture under any conditions arising during its manufacture, storage, and use—at more elevated temperatures slowly reacts with water[32] according to the equation:

$$C_6H(NO_2)_4(NH_2)+H_2O=C_6H(NO_2)_3(OH)(NH_2)+HNO_2,$$

producing the trace of nitrous acid required to colour the test paper. If at the ordinary temperature the action of even large amounts of water becomes immeasurably small, this must be ascribed not alone to the temperature coefficient of this reaction itself, but to its product with the temperature coefficient of the solubility of TNA in water, which solubility, at the ordinary temperature, is practically nil (see No. 32).

That the quality of TNA does not suffer by the action of moisture during the heat test (No. 2) is due to the fact that the permanent product of the reaction, aminopicric acid, does not affect the stability of TNA (Nos. 12 and 13).

The gas evolution tests at 120° C. are in good agreement with the loss of weight at 130° C., for a gas composition of equal volumes of water vapour, carbon monoxide and dioxide (see below), weighing about 1⅓ mg. per c.c. at 0° C. and 760 mm., a temperature coefficient of approximately 2 per 5° C., and corresponding stages of the evolution. The same temperature coefficient is obtained when gas evolution tests Nos. 4 and 7 are compared with each other (*i.e.*, practically the same evolution at 100° C. in first 32 hours as at 120° C. in first 2 hours). There is always a relatively substantial initial evolution or loss of weight, indicating the removal of traces of an impurity, followed by a smaller evolution at a decreasing rate. The impurity is very probably oxalic acid, for the following reasons: The quantitative course of TNA nitrations indicates the formation of substantial amounts of oxalic acid, which is only sparingly soluble in strong sulphuric acid. When nitration is carried out increasingly under conditions (which are well known) causing decomposition of oxalic acid, catalysed by sulphuric acid, the apparent colour of TNA (before drying) changes from yellow to greenish, the occlusion (see under II.) in the crystals decreases, and their gas evolution and loss of weight decrease. Oxalic acid, catalysed by traces of sulphuric acid, is known to decompose into carbon monoxide and dioxide and water at the temperatures of the tests, and with the above temperature coefficient[33] of about 2 for 5° C. Tests No. 3 prove that the gas contains only traces of nitrogen oxides (initially about ¼%). These include nitrous and nitric acids occluded in the crystals and NO_2 produced by the action of water vapour derived from the decomposition of oxalic acid, and their gradual elimination causes the rate of evolution of NO_2 to fall off (*cf.* No. 3, *f* and *g*, and, for elimination of occluded NO_2 by storage, No. 2, *c* and *d*), until it finally reaches a figure—exceedingly small even at 130° C., and too small for observation at 65·5° C.—representing the actual decomposition of TNA.[34]

Where even traces of occluded impurities, such as certain acids, lower the stability, as with tetryl,[35] the gas evolution increases with the size of the crystals[36]; conversely, actual decomposition of a pure material appears to decrease with increasing size of crystals.[36] Tests Nos. 5 and 6, and 12 and 13, prove that the initial gas evolution of commercial TNA remains unaffected by the size of the crystals. On the other hand, the evolution of NO_2 is higher for ground than for ordinary TNA, even after the effect of steam from oxalic acid decomposition has been practically eliminated by 22 hours' pre-heating at 130° C. Both these facts, again, are explained when the bulk of the initial evolution of total gas is ascribed to removal of an impurity—oxalic acid—which, like aminopicric (*cf.* Nos. 12 and 13) or sulphuric acid, does not affect the stability of TNA. In the following table, the gas evolution from TNA and other explosives containing a mobile nitro or nitrate group is compared:—

	Total gas at 120° C. (c.c. per g. per hr.).			NO_2 at 120° C. (mg. per g. per hr.) 1st 8 hrs.	Effect of product of hydrolysis on gas evolution.
	First 2 hrs.	First 40 hrs.	100th to 200th hour.		
TNA (unrecryst., commercial)	0·425	0·089	0·005[37]	about 0·0007	5% aminopicric acid no effect.
Tetryl (unrecryst., comm.)	0·07	>0·135	—	—	—
„ (recryst., British Service)	0·020[38]	0·022[38]	0·75[35]	about 0·01[39]	10% picric acid causes. 14% initial increase.[35]
Guncotton (good quality, Brit. Service)	—	0·366[40]	—	about 0·04 aver.[40]	—
Nitroglycerin[41]	—	3·65[42]	—	5[42]	—
Amatol (50% crude TNT, 50% pure ammonium nitrate)	—	0·015[43]	—	—	—

The NO_2 figures explain the difficulty in obtaining a commercial tetryl which will give as good an Abel test as TNA, even after recrystallisation; also the fact that TNA does not evolve brown fumes at 135° C. in 60 hours, whereas good American tetryl was found to do so in 40—60 minutes—thus indicating inferior stability even after allowing for the fifty-fold increase caused by the liquid state[44]

---

[32] Whether the same is mixed with the TNA, or derived from the wet test paper.

[33] *Cf.* Bredig, Z. Elektrochem., 1906, **12**, 459.

[34] The approximate accuracy of calculations, by Robertson and Smart's formula, of very low NO_2 concentrations from Abel tests is evidenced, for instance, by the good agreement of figures thus calculated for guncotton at 71° C. with Robertson and Napper's actual determinations of NO_2 at 135° C. (J. Chem. Soc., 1907, **91**, 769), taking Robertson's temperature coefficient of 1·9 for 5°.

[35] Farmer, J. Chem. Soc., 1920, **117**, 1603.

[36] Hinshelwood and Bowen, Phil. Mag., 1920, **40**, 569.

[37] Calculated from gas evolution at 140° C., as loss of weight tests at 130° C. include traces of volatile solid matter which count where decrease is small.

[38] Figures obtained by different observers with different regular Service samples.

[39] Calculated from Farmer's test at 125° C. (*loc. cit.*).

[40] From figures by Robertson (*loc. cit.*); Robertson and Napper, J. Chem. Soc., 1907, **91**, 783.

[41] The NO_2 evolution of NG can be calculated for ordinary temperature by Robertson's temperature coefficient (2·2 for 5° C.). In view of this and the comparatively enormous decomposition of NG at 120° C., Stettbacher's remark (Schweiz. Chem.-Zeit., 1919, **1**, 95) that NG, while less stable than TNA at 70° C., was more stable at ordinary temperature, is absurd. Van Duin's (Rec., 1919, **39**, 163) corresponding reference to the absence of acidity in Sobrero's preserved sample of NG overlooks the precautions taken to remove acidity.

[44] Farmer, J. Chem. Soc., 1920, **117**, 1603.

of tetryl at 135° C. The above tests, moreover, afford support for the proposals of the International Commission on Unification of Explosives, Barthelemy, Lenze, and others, to use a storage-fume test at more or less elevated temperatures as the standard stability test, since loss of weight, gas evolution, and trace tests alone are seen to be misleading unless the nature of the change is taken into consideration. Taken in conjunction with a fume test, however, the other stability tests bring out the following crucial fact concerning the relative stability of TNA, with its mobile nitro-group attached to an aromatic ring carbon atom, compared with explosives containing a mobile nitro-group attached to oxygen—such as nitrocellulose, nitroglycerin, or nitrostarch—or to nitrogen, *e.g.*, tetryl:—*Whereas with TNA traces of certain impurities, which are either normally present or else produced in some conditions by the mobile nitro-group, may affect the Abel test, but do not affect the stability, with nitrocellulose, nitroglycerin, tetryl,*[45] *etc., they generally affect both the test and the stability.* TNA is accordingly intrinsically more stable than any of these materials, and this becomes particularly obvious when old industrial products, and not specially purified samples,[46] are compared.

"Instability" (*i.e.*, tendency to intramolecular, spontaneous decomposition) must not be confounded with "reactivity" (*i.e.*, tendency to inter-molecular reaction with other substances). Thus the reactivity of a nitro-group contiguous to two other nitro-groups—which obtains in TNA—is also to be found in 2.3.4-trinitrotoluene, but less in 3.4.6-, and still less in 2.4.6-trinitrotoluene. Notwithstanding this, Farmer [47] found the gas evolution to be no greater for the 2.3.4- than for the 2.4.6-, and less than for the 3.4.6-compound.

Even reactivity depends essentially on solubility, and the practical insolubility of TNA in water at usual temperatures, together with the lack of autocatalysis by impurities, no doubt largely accounts for the fact that, during periods of storage of TNA, with its own moisture,[48] ranging from 7 to 17 years, no change either in appearance, composition, or melting point has been observed, even with the first samples—some of which were acid or otherwise impure.

K.—Resistance to light.

No. 36. Samples of TNA of varying preparation and purity have been exposed to daylight in ordinary glass bottles on open shelves for periods ranging from 7 to 17 years. In no case has there been any change in appearance or otherwise. Certain other explosives, *e.g.*, nitroglycerin,[49] hexanitrodiphenylamine,[50] and TNT,[51] are, on the other hand, affected by daylight.

L.—Resistance to fire.

The flash point of TNA had been found[52] by a British firm of explosives manufacturers to be 220° C., compared with 186° C. for tetryl. The temperatures of explosion of 247°—237° C. (corr.) for TNA and 196°—187° C. (corr.) for tetryl have since been given by Van Duin and Van Lennep.[53]

No. 37. Some experience is now available on the effect of fire on large quantities of TNA. Once a fire, caused by a diphenylamine autoclave, extended to large vats in which about 16,000 lb. (dry weight) of TNA containing 20 to 25% of moisture was stored. Though the terrific heat of the burning TNA twisted the steel girders of the building into almost unrecognisable shapes, the TNA merely flashed, but did not explode.

No. 38. Later, a TNA packing room was, in the absence of the workers, set on fire by a time fuse; several thousand pounds of dry TNA, nailed down in cases ready for shipment, again flashed without explosion.

M.—Resistance to shock.

Comparative drop-weight tests are not always reliable,[54] and the results previously given[55] have not been confirmed. Later experience proves that TNA is slightly more sensitive than picric acid, and slightly less sensitive than tetryl. Thus, under strictly comparable conditions, the relative insensitiveness to mechanical shock is expressed by the figures:—

	TNT.	Picric acid.	TNA.	Tetryl.
No. 39 (Van Duin and Van Lennep)[56]:				
2 kg., maximum height in cm. for no detonation out of 6	–	.. <60	..<60	..<60
Minimum height in cm. for 6 detonations out of 6 ..	–	.. <60	.. 54·5	.. 52
No. 40 (R. Robertson)[57]: Relative figures	115	.. 100	.. 86	.. 70

In view of these results, which agree with general experience, the impression conveyed by J. Marshall[58] (of the Du Pont Powder Company) that TNA was slightly more sensitive to shock than tetryl is obviously incorrect.

No. 41. A. P. Howell's[59] pendulum friction tests afford a comparison with some other explosives:—

Steel shoe (with 44 lb. added.) 1·5 m. swing.		Steel shoe (with 44 lb. added.)	TNA.		NG-dynamite 40%	
			Tested.	Passed.	Tested.	Passed.
Passed TNT, etc.	Failed Tetryl. TNA. 50/50 Amato .	1·0 m. Swing.	1	0	1	0
		0·5 m. Swing	1	1	1	0
		2 m. Swing (with aloxite cloth)	1	1		

No. 42. Admixture of very little paraffin reduces the sensitiveness of TNA to mechanical shock below that of TNT; *e.g.*, with 5% of paraffin uniformly distributed throughout the material, with 2 kg.,[60] the maximum height for no detonation in 5 out of 5 for TNA was 7 in., TNT 11 in., and TNA 95%, paraffin 5%, 28 in.

---

[45] Farmer, *loc. cit.*

[46] Farmer (*loc. cit.*) states: "On account of the instability of the nitro-amino group, this compound (tetryl) . . . may undergo deterioration on storage if not completely purified."

[47] J. Chem. Soc., 1920, **117**, 1442.

[48] In actual practice, whether used in blasting cartridges, fuses, shells, bombs, torpedo heads, or elsewhere, the material will necessarily be stored in the dark and in a compressed or cast form. As shown by the tests on exposure to water, moist behaviour to metals, etc., there is in such conditions no change, even with loose material offering a large surface of reaction, and with moisture in excess of the 0·12–0·2% normally present.

[49] Compare Gody, "Matières Explosives" (1907).

[50] Carter, Z. ges. Schiess- u. Spreng., 1913, **8**, 251.

[51] *Cf.*, *e.g.*, Molinari and Quartieri, Z. ges. Schiess- u. Spreng., 1913, **8**, 405, 432. Even the purest TNT is turned green by daylight, a change which is, no doubt, analogous to the photochemical transformation of *o*-nitrotoluene to *o*-nitrosobenzoic acid. This reaction as well as the condensations of *o*- and *p*-nitrotoluenes to stilbenes, etc., and some new observations to be published later, may be attributed to tautomerism (in analogy with the author's bridge formula for primary and secondary nitro-groups; J. prakt. Chem., 1902, **66**, 161, 329):

$$C_6H_4<\begin{matrix}NO_2\rightarrow\\ CH_3\leftarrow\end{matrix}C_6H_4<\begin{matrix}N\\ CH_2\end{matrix}\begin{matrix}<OH\\ >O\end{matrix}$$

[57] J. Chem. Soc., 1921, **119**, 18.

[58] J. Ind. Eng. Chem., 1920, **12**, 336.

[59] U.S. Bureau of Mines, Tech. Paper 234, 1919.

No. 43. The Trauzl block "strength" of TNA is not much reduced by such mixtures with 5% or less of paraffin, but is materially affected by 10% of paraffin; *e.g.*, the Trauzl block net expansion (c.c. per 10 g.) of pure TNT was 216, TNA 315, TNA with 5% paraffin 285 and 295, and with 10% paraffin 205 and 225.

No. 44. Six-pdr. projectiles loaded with a mixture of 95% TNA, 5% paraffin (Mixture "B"), were fired through a 2½ in. steel plate: the respective weights were 6·05 and 5·94 lb., and the striking velocities 2381 and 2382 f.s. In each case the impact was normal and the projectile penetrated the plate. In the first case the projectile was recovered whole and undeformed, the burster charge remaining entirely inert. In the second case the projectile was recovered broken transversely, in two pieces just forward of the band score. Here again the bursting charge remained entirely inert.

No. 45. Shell fragmentation obtained with above mixture. The report says:—"4-in. Common projectile 1. Weight empty, with base and fuze 28·82 lb. Bursting charge, 2·03 lb. Mixture "B" (tamped) plus 63 g. loose TNA as a booster. Standard 8 dynamite cap and Bickford fuze fitted through fuze plug. Recovered 276 fragments weighing 11·66 lb. Weight of largest fragment 2·9 lb. (base plug); smallest fragment less than 2 grains. Average weight of fragment 0·042 lb. Calculated number of fragments 663." In these tests the material was only hand-tamped, otherwise a substantially higher loading density would be obtained.

No. 46. *Behaviour of TNA towards concussion by an explosive wave.* 5000 lb. of TNA, packed in open cases, was stored in a magazine of galvanised iron, protected by an earth barricade. A packing room a few yards beyond the barricade was blown up, leading to an explosion of about 800 lb. of dry TNA, which precipitated a rock on a railroad cutting about five miles away, partially demolished the barricade, warped the magazine, and threw about the TNA cases, but the 5000 lb. of TNA remained intact. It may be added that, as far as the author is aware, this is the only explosion of TNA which has so far occurred in a TNA plant. It was attributed by the authorities to sabotage.

IV.—PHYSIOLOGICAL PROPERTIES.

TNA shares with nitrocellulose (nitrostarch etc.) the distinction of having no injurious effect on the health of operators or users. It is well known that other nitro-explosives[61] either affect the internal organs, notably TNT[62] before it is completely purified, NG,[63] picric acid,[64] tetryl[65]; or else the skin, *e.g.*, hexanitrodiphenylamine,[66] trinitroanisol.[67]

V.—POWER AND SENSITISING PROPERTIES.

The outstanding feature of TNA is its enormous shattering power or brisance (B), which results from its combining a high velocity of detonation (v) with great density (d) and great energy (E), as expressed by Herlin's[68] formula:—$B = E.d^{1+K}.v^K$, wherein K is a constant. The energy E or "strength," measured by the pressure of the explosion gases, is proportional[69] to the volume of the explosion gases, per gram of explosive, at the temperature of explosion and at atmospheric pressure.

No. 47. In the following table, column V gives the relative Trauzl block expansions of a number of explosives. They have been referred to tetryl = 375 c.c. by means of Kast's[70] graphical reducing method for elimination of the excess of expansion due to progressive weakening of the block, the reduced figures being given in col. IV; col. VII contains the corresponding reduced Trauzl block figures calculated for equal volumes (6 c.c.) at maximum densities.

Solid high explosives (other than mixtures).	I. Temperature t of explosion. ° C.	II. Gas vol. at t° in litres per gram.	III. Relative "strength" calculated.	IV. [72] Temperature for tetryl calculated by Kast should lead to the higher of the two temperatures given for TNA.

[73] Kast, *loc. cit.*

[74] G.P. 260,571.

[75] This relative figure for TNT is, according to the author's experience, generally obtained with a No. 8 detonator, and about 0·255 with a No. 6. TNA and tetryl are little affected by the size of the primer.

[76] According to pressure gauge results obtained by Crawshaw (J. Franklin Inst., 1919, **189**, 607) the "strength" of hexanitrodiphenylamine would exceed that of tetryl by 4·5%. This is not only contrary to general experience, but theoretically impossible.

[77] Bichel, "Testing Explosives," Table III.; value referred to TNT.

[78] Escales, "Schiessbaumwolle."

As to the relative "strength" of nitroglycerin as such, the available data are contradictory. According to the calculations of Waller,[79] by Mallard and Le Chatelier's formula, the "strength" of NG, with an explosion temperature of 3158° C., would be only 332, compared with 395 for TNA; the same proportion would follow from Hofwimmer and Haeckel's[80] calculations for blasting gelatin. The specific heat of gases above 2000° C. is, however, uncertain; accordingly, Kast[81] calculates an explosion temperature of 4250° C. for NG, and 3370° C. for tetryl, which would give relative "strengths" of NG and TNA of about 447 and 427. Comey and Holmes[82] found the ballistic pendulum recoil for 6·15 g. of blasting gelatin and 10 g. of TNT to be identical (=1·62:1), corresponding to a ratio of "strength" for NG and TNT of about 1·53:1; Kast's Trauzl block figures, reduced by his graphical method,[83] give the—incorrect (see note [84]) —ratio 1·58:1 for NG:TNT, and Bichel's[85] "Druckmesser" pressures for blasting gelatin and TNT (1·46:1) about 1·4:1 for NG:TNT. On the other hand, the ratio of TNA:TNT, according to Waller's theoretical figures, would be 1·55:1; according to average Trauzl block effects, reduced by Kast's method,[86] 1·4:1; and by comparative pendulum swings[87] 1·46:1. The ratio of the "strength" of NG to that of TNA therefore lies between the limits 0·95:1 and 1·1:1.

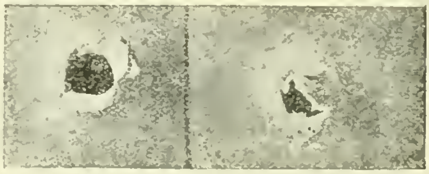
Concerning the relative "strength" of the amatols, Crawshaw[88] gave the maximum theoretical pressures, when detonated in their own volume, at 1·6 density, as 10,978 kg. per sq. cm. for an 85/15 amatol, 9851 for TNA, and 9486 for tetryl. Quite apart from the general inaccuracy of "Druckmesser" determinations,[89] Crawshaw had to use a "booster" of 24 g. of tetryl to detonate the amatol, deducting from the result the pressure given by the "booster" alone. He overlooked the fact that the mixture of an amatol with excess of oxygen, and tetryl with a deficit, must give a pressure substantially in excess of the added pressures of the ingredients. Crawshaw's figures are, moreover, theoretically impossible. Not even the gas volume of an 80/20 amatol,[90] with its almost ideal oxygen balance, could produce Crawshaw's relative pressures, even if its temperature of explosion were not very much lower than that of TNA due to its somewhat lower heat of explosion and the composition of its gases (about 60% of which, as compared with about 20% for TNA, are water vapour and carbon dioxide with a high average specific heat). Thus Waller[91] gives for an 78·73/21·27 amatol the temperature of explosion as 2310° C. (TNA=3238°), and its pressure ("strength") as 8·2622 (TNA=10·55).[92]

Not only is an 85/15 amatol substantially weaker than TNA at equal pressures, but there is also little to be gained by comparing relative theoretical pressures, up to 1·6 density, of an amatol which Crawshaw could only detonate with a booster, even at a density of 1·02 (with a theoretical pressure, even based on his figures, of only 7000 kg. per sq. cm.), with an explosive like TNA which can be detonated by an ordinary cap up to its maximum density (with a theoretical pressure, again according to Crawshaw, of about 11,500 kg. per sq. cm.).

As to the relative "strength" of tetryl, its inferiority to TNA by about 10%, as measured in the ballistic pendulum,[93] agrees with Waller's theoretical and experimental figures and with innumerable —partly official—Trauzl block tests. It is therefore obvious that the pendulum results of Cope,[94] recording for NG : TNA : tetryl : TNT the pressure ratios 14 : 12·1 : 12·1 : 10, cannot be correct.

Thus taking equal weights, the energy (E) of TNA approaches that of NG, and exceeds the energy of other explosives. For equal volumes[95] at maximum densities it exceeds all explosives. For its maximum density (*d*) (see under 11) surpasses that of NG (1·6) by about 18%.

For its velocity of detonation (*v* in the brisance formula) no accurate comparative figure at equal densities are at the moment available, but it has been definitely established that it would exceed those of tetryl or nitroglycerin[96] by several hundred metres per second at equal densities, and exceeds them still more at maximum densities. *In consequence the "brisance" of TNA is not reached by an equal weight, and still less by an equal volume at high density, of any other explosive.*



TNA. **Tetryl.**

No. 48. The following photographs, obtained by Stettbacher,[97] illustrate the superiority as regards brisance of TNA over tetryl when 3 g. of each were detonated on iron plates 3 mm. thick. Elsewhere[98] Stettbacher states that TNA in respect of its velocity of detonation far surpasses all other nitrocompounds, that the difference between its brisance and that of TNT is perhaps as great as between TNT and dinitronaphthalene; the difference between its brisance and that of tetryl at least as great as between tetryl and TNT; and that its explosive properties undoubtedly surpass those of all other explosives.

No. 49. An idea of the comparative brisance of TNA and TNT is conveyed by the following test:—A bar of wrought iron 5 in. wide, ¼ in. thick, was laid on steel supports 15¾ in. apart. A paper cartridge containing 100 g. of TNA, or TNT, was

[80] Z. ges. Schiess- u. Spreng., 1918, **13**, 175.

[81] *loc. cit.*

[82] Comm. 8th Int. Cong. Appl. Chem., 1912, **25**, 217.

[83] *loc. cit.* His reduced figures for NG and TNT (485 and 280) are erroneous and should, by his own diagram, read "435" and "275."

[84] The ratio of the "strength" of NG, blasting gelatin, etc., to that of solid explosives, as found in the Trauzl block, is invariably too high. For solid explosives are tested as loose powders, with a low rate of detonation (about 5000 m. per sec. for aromatic high explosives at a density of 1·0) corresponding to the low density of loading; the results are comparable with each other, but not with nitroglycerin, which is tested at a density of 1·6, with a rate of detonation of above 7000 m. per sec.; such a large difference in the rate of detonation results in an additional enlargement of the cavity.

[85] "Testing Explosives" (1905) tables.

[86] See above.

[87] Z. ges. Schiess- u. Spreng., 1013, **8**, 185.

[88] J. Franklin Inst., 1919, **189**, 607.

[89] Comey and Holmes, *loc. cit.*; this is further confirmed by Crawshaw's exceedingly inaccurate value for hexanitrodiphenylamine (see above).

[90] *Cf.* Robertson, J. Chem. Soc., 1921, **119**, 25.

[91] *loc. cit.*

[92] An American 80% ammonium nitrate explosive, tested in the ballistic mortar by Comey and Holmes (*loc. cit.*), was found to possess 73% of the strength of blasting gelatin; it is therefore about equal to 75% guhr dynamite.

[93] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[94] J. Ind. Eng. Chem., 1020, 12, 870.

[95] Waller (*loc. cit.*) says: "The volume of the charge chamber in which explosives are compared in the field is practically a constant, whether it is a borehole or a war head. It would therefore seem more rational to compare explosives in the laboratory by volume." To do this, the above relative "strength" figures must be multiplied by 1·86 to 1·90 for TNA, by 1·5 to about 1·75 for the other explosives, and from the "efficiency" values thus calculated, the "brisance" maxima are obtained by taking velocities of detonation at these maximum densities.

[96] This refers to the higher rate of detonation of NG (>7000 m./sec.). It has also a lower rate (<2500 m./sec.) (*cf.* Comey, 7th Int. Cong. Appl Chem., **3**, B, 28).

[97] Schweiz. Chem.-Zeit., 1919, **1**, 06.

[98] Z. ges. Scheiss- u. Spreng., 1916, **11**, 112; 1918, **13**, 225.

laid crosswise on the bar, midway between the supports, and detonated by a No. 8 cap. TNA tore the iron over a width of 4¾ in. out of 5 in. and folded it completely together. TNT merely bent it to the extent of 7¼ in. in the centre without tearing it.

No. 50. *Comparative brisance of TNA and TNT transmitted through water.* Cartridges composed of varying quantities of TNA and TNT were suspended under water at varying distances from submerged drums made of 1/10 in. steel strengthened by two ribs. In one series of tests, with 1 oz. at 1 ft. distance from a drum 42¾ in. long and 28¾ in. diam., with TNT the indentation produced was 20 in. wide, 13 in. high, and 3 in. greatest depth, but no rib was crushed and a hole was blown on the near side only. With TNA the indentation was 26×21½×5½ in., one rib was crushed, and holes were blown on both near and far sides.

No. 51. *Comparative brisance in bombs and grenades.* Mills grenades containing 1 oz. each of TNA and other service explosives (tetryl, TNT, etc.) were placed in a wooden box filled with sawdust and suspended from the ceiling of a wooden shed, and detonated to obtain comparative fragmentation. With TNA alone the experiment miscarried, as the floor of the shed was blown through.

No. 52. Brisance tested on steel plates 7×120×120 mm., with paper cartridges containing 100 g. of TNA. With the cartridge standing upright a hole was cut clean through. With the cartridge lying lengthwise across the steel plate (which was supported at both ends), the plate was folded completely together. With the steel plate half protruding over the edge of a steel table, with the cartridge lying on the plate parallel to edge of table, just balanced so that a slight touch would cause it to fall to the ground, the plate was cut completely in two.

Tests such as No. 50 have a direct bearing on the efficiency of charges for depth bombs, mines, and especially torpedoes.[99] In torpedo heads the density is of additional importance,[100] as the volume can only be increased at great expense, also because for equal weights the centre of explosion is brought closer to the object to be destroyed.[101] Wet guncotton is in this respect even inferior to TNT.[102] The amatols under water are also stated to be inferior to TNT, no doubt owing to their low rate of detonation.[103]

Brisance as evidenced by tests Nos. 48, 49, 51, and 52 is all-important for surface demolition, and particularly again when weight or volume is limited, *e.g.*, by the carrying capacity of bombing aircraft,[104] by the calibre of guns used against fortifications, or by the feasible weight of grenades thrown against tanks.

The brisance of TNA, combined with its sensitiveness to detonation by primers, can also be utilised to explode other materials, by employing it either as an intermediate detonator, or else as a sensitiser admixed to such materials.

No. 53. Sensitiveness to detonation by fulminate. Tests by Storm and Cope,[105] 0·4 g. of each nitro-compound per test:—

	Priming charge.		Minimum wt. of primary charge for complete detonation.	
	Fulminate %	Chlorate %	Slightly hand-tamped partially confined.	Compressed at 200 atm., entirely confined.

0·4g.	90	10	0·3750	0·2300
	80	20	0·3750	0·2200
TNT	100	0	>1·0	0·2600
0·4g.	90	10	>1·0	0·2500
	80	20	>1·0	0·2400

It is the last column (compression and confinement) which corresponds to practical conditions in detonators and fuses. J. Marshall[106] (of the Du Pont Co.) misquotes the results (for fulminate-chlorate) as tetryl = 0·2000, TNT = 0·2500, and TNA = 0·2000 (which latter should be 0·1700 as actually recorded).

No. 54. The Dynamit-A.-G. Nobel, of Hamburg, record[107] that tetryl and TNA both "when they are compressed to their highest density, retain their property of facility to detonate by means of the initial impulse of fulminate of mercury," and point out that friction under firing strain, which may lead to detonation of the primer in a shell fuse containing an incompletely compressed intermediate charge, is thereby avoided.

No. 55. Sensitiveness of larger quantities of compressed and confined TNA to fulminate.

Paper cartridges containing 100 g. of TNA and 1 g. or ½ g. of fulminate each gave two complete detonations in two tests, while with ¼ g. of fulminate three tests gave one complete detonation and two ignitions.

No. 56. Sensitiveness of wet TNA to an initial impulse. Using a No. 6 detonator, 50 g. of TNA with 0·55% moisture gave compression of lead block 16·32 mm.; with 5·79% moisture 16·06 mm.; no compression was observed with 10·06% and 15·06% moisture, the TNA failing to detonate.

The following results were obtained using No. 6 detonator and primer of dry TNA:—

Wt. of dry primer.	TNA.	Moisture. %	Comp. of lead block, mm.
5·0	45	15·06	17·38
1·0	49	15·06	16·44
0·75	49·29	15·06	None
1·0	49	15·90	15·14
1·0	49	16·42	None
5·0	45	16·42	None

No. 57. Comparative power developed by different explosives when detonated by fulminate alone, and by TNA primed with fulminate:—

Explosive.	Detonator.	Lead block test. (c.c. enlargement/g.)			Ballistic pendulum test. (Net ft. lb./10g.)

[103] For rate of detonation *cf.* Robertson, J. Chem. Soc., 1921, **119**, 27.

[104] TNA bombs used in the war have been described in *Illus. London News* (Dec. 26, 1914) (charge of TNA alone), and by Colver ("High Explosives," 1918) (charge of 2 parts of TNT and 1 part of TNA). In either case the violence of the explosion is emphasised

[105] U.S. Bureau of Mines, Tech. Paper 125, 1916.

[106] J. Ind. Eng. Chem., 1920, **12**, 336.

[107] E.P. 2407/1912.

The fulminate detonator contained 1·0 g. of fulminate charge, and the TNA detonator 0·3 g. of fulminate charge, the remainder having been replaced by about half its weight of TNA. Similar results were obtained when No. 7 or No. 8 detonators were used. Thus fulminate, acting through TNA, has a higher initiating effect than a fulminate charge heavier than both of these together when employed alone.

No. 58. Relative power developed by TNT shell charges exploded by TNA- and tetryl-intermediate detonators. The conclusion was reached by the officer in charge that "the action of TNA was not inferior and was even superior to the action of commercial tetryl, which is the regular explosive for detonators of the type mentioned."

As to the sensitising properties of TNA when used as an ingredient in explosive compositions, several tests have already been recorded.[108] Substantial progress has since been made, and a few further tests will now be described.

No. 59. Sensitising and pressure effects of TNA when mixed with TNT.

(*a*) TNT-TNA composition, cast, then ground (TNT solidif. p. 77° C.). With TNT alone the enlargement with a No. 6 cap in Trauzl block (average of 4 tests) was 228·75 c.c.; TNT with 9% TNA 239·25 c.c.; TNT with 20% TNA 264·75 c.c.

(*b*) TNT-TNA mixtures, not cast (TNT=m.p. 77° C.). With No. 6 cap (5 tests each), TNT alone gave average 235·0 c.c.; with 10% TNA 246·8 c.c. Using No. 8 cap (3 tests each) TNT 275·0 c.c.; TNT with 10% TNA 290·7 c.c.

(*c*) TNT-TNA mixtures, not cast (standard pure TNT). Using No. 6 cap TNT alone gave 228 and 190 c.c.; TNT with 5% TNA 208 and 217 c.c. Using No. 8 cap TNT alone gave 237, 250, and 174(?) c.c.; TNT with 5% TNA gave 256, 255, 245 c.c.

No. 60. Sensitising and pressure effects of TNA when cast with dinitrobenzol (DNB), then ground:—Pure TNT gave an enlagement (Trauzl block) 230 c.c.; TNA 25%, DNB 75%, 221 c.c.; TNA 33%, DNB 67%, 240 c.c.; TNA 40%, DNB 60%, 255 c.c.; TNA 50%, DNB 50%, 277 c.c.

No. 61. Sensitising and brisance effect of TNA when cast with dinitrobenzol in shells.

6-pdr. shells, loaded with a cast composition of 3 parts of dinitrobenzol and 1 part of TNA, were fired against steel plate in same conditions and with identical results as given under No. 44. The following fragmentation was obtained in a 4-inch common projectile:—Weight empty with base and fuze plugs 28·80 lb. Bursting charge 2·7 lb. Mixture "A" (cast) plus 63 g. loose TNA as a booster. Standard 8 dynamite cap and Bickford fuze fitted through fuze plug. Recovered 400 fragments weighing 9·65 lb. Weight of largest fragment 2·16 lb. (base plug), smallest less than 2 grains. Average weight of fragments 0·024 lb. Calculated number of fragments 1161.

No. 62. Sensitising effect of TNA on TNT in detonating fuses. It has already been recorded[109] that, in equal conditions, an admixture of 20% of TNA increases the velocity of detonation of a 2·6-mm. TNT detonating fuse by 12%.

Nitroglycerin (or dinitroglycol) and TNA appear to be the only materials with which it is commercially[110] possible to sensitise cheap ingredients so as to obtain powerful explosives of high density, good oxygen balance, and a high rate of detonation.

No. 63. *Types of industrial TNA explosives.*

(1) Dry. (*a*) Substituting TNA for TNT etc. to obtain higher density without loss of sensitiveness and thereby reduced hygroscopicity and higher power. Examples: TNA 35%,[111] ammonium nitrate 65% (compressed to 1·6 sp. gr.); TNA 50%,[111] barium nitrate 40%, potassium nitrate 10% (compressed to 1·8 sp. gr., no packing required). (*b*) Substituting TNA plus cheap and comparatively inert ingredients for TNT etc. Example: TNA:Dinitrobenzol (1:3) 12%[111]; ammonium nitrate 88%. (*c*) Adding TNA to black powder.

(2) Plastic. (*a*) Substituting TNA plus a liquid or semi-liquid material for NG in dynamites to increase power by reducing amount of inert material necessary for oxygen balance; to achieve greater safety in manufacture, transportation, and use, avoid risks from exudation,[112] volatility,[113] or freezing, and prevent deterioration on storage[114] or through warm climates. Example: TNA 35%, liquid nitrated solvent naphtha (about 14% N) 5%, nitrocellulose 0·2%, combustible matter 2·2%, sodium nitrate 57·6%. The pressure, velocity of detonation, and sensitiveness of this explosive were found to be close to those of a corresponding 40% NG-dynamite. (*b*) Sensitising cheap plastic compositions by means of TNA, to obtain increased power and reliable detonation[115] at increased densities. Examples: TNA 20%, liquid nitrated solvent naphtha (14% N) 9·7%, nitrocellulose 0·3%, barium nitrate 70%. This gave good detonation with No. 8; it was not tested with No. 6 detonator.

Small block compression (No. 7 detonators) (75 g. explosive)	13·18 mm.	not taken	not taken	12·0 mm.	13·12 mm.

Mixtures of TNA, liquid nitrated toluols, and a chlorate or perchlorate in varying proportions may be used according to nature of chlorate selected and degree of nitration of the toluol.

It appears remarkable that the enormous brisance of TNA can be reduced to such an extent as to

---

[108] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[109] *loc. cit.*

[110] Tetryl has also been proposed for this purpose, for instance in "Fortex" with ammonium nitrate (Mem. Poudres et Salp., 1913-14, 128), but its brisance is not such as to compensate for its high cost of manufacture.

[111] Some comparative tests carried out with these explosives have been described in Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[112] To which sodium and ammonium nitrate dynamites are particularly liable (*cf.* Marshall, "Explosives," 2nd ed., p. 363).

[113] Which leads to "the severe and nauseating headaches and other disagreeable and dangerous maladies which result from the handling of explosives containing nitroglycerin" mentioned in U.S.P. 1,309,553 by Swint (du Pont Powder Co.).

[114] Thus gelatinised dynamites suffer on storage in warm climates, blasting gelatin quickly becomes difficult to detonate and loses in power, sodium nitrate gelignite cartridges are particularly liable to remain unexploded after storage, and NG has a tendency to revert to its lower rate of detonation, and large consignments of such explosives have to be condemned from time to time (*cf* Marshall, "Explosives," 2nd ed., p. 368; Kast, Z. ges. Schiess- u. Spreng., 1913, **8**, 89, 175; Stettbacher, *ibid.*, 1918, **13**, 405; Hargreaves, J., 1914, 337; Mann and Kirton, Report to Govt of West Australia, J., 1919, 848A).

[115] Thus potassium and still more sodium chlorate explosives are generally difficult to detonate even at moderate densities; sodium and ammonium nitrate and sodium chlorate explosives give the more trouble through insensitiveness due to hygroscopicity, the less compressed they are; plastic nitrostarch (*cf.* Swint, *loc. cit.*) and nitrated solvent naphtha explosives and other plastic non-NG explosives (*cf.* Schweizer, Z. ges. Schiess- u. Spreng., 1919, **14**, 25) generally tend to be too insensitive, and TNT as a sensitiser is insufficiently active and cannot be used in sufficient proportions on account of its great oxygen deficiency (*cf.* U.S.P. 1,357,764, Cook and Harris, Atlas Powder C.).

permit of large proportions of the same being embodied in propellants for fire-arms.

No. 64. The following is an example of a composition which gave the required velocity *within the permissible pressure*, when fired with a 150-g. bullet in a 0·3 Service rifle:—

60 parts of finely ground TNA was embodied with 40 parts of soluble nitrocellulose by means of 92 parts (by weight) of pure ethyl acetate,[116] and worked into powder of 0·0602 in. diam. by 0·2185 in. length.

Charge.	Initial velocity. ft. per sec.	Pressure. lb. per sq. in.
42 grains	2523	46,750
43·5 ,,	2593	47,400
44 ,,	2647	52,100

The weight, and still more the volume, of such a charge are substantially less than for a corresponding nitrocellulose powder charge. These tests have only been preliminary, and it is not yet possible to state either the maximum velocity obtainable within the permissible pressure, by further changes of composition and dimensions of the powder, or the nature of stabilisers, if any, which may possibly be required.

VI.—Notes on the Manufacture of TNA.

Experience has shown the nitration of *m*-nitraniline to TNA to be an exceedingly safe operation, and it has all along been carried out as an ordinary chemical—not an explosive—manufacture. This is due to the great solubility of *m*-nitraniline in sulphuric acid, which excludes any formation of separate layers, such as may occur with mixed acid and toluene or nitrotoluenes; also to the high melting point of TNA, which causes it to be obtained as a finely divided, crystalline suspension in the spent acid (which cannot be detonated even after filtration), and thus prevents—unlike TNT—the formation of separate layers of explosive and spent acid; perhaps also to the relatively low temperature of nitration, though according to tests on an experimental plant scale the temperature may be allowed to rise uncontrolled without danger of explosion; and, lastly, to the fact that the nitration is a single-stage operation, and can therefore easily be made fool-proof.

The nitration has hitherto been carried out in units up to about 2500 American gallons capacity. The control has been found so easy that there is no objection to the use of even larger units. The time occupied by a nitration has been reduced to about 6 hours. After separation from the undiluted spent acid by filtration the TNA is water-washed and again filtered. It is then ready for drying. With 20% of water content it cannot be detonated by any method (*cf.* No. 56), and is admitted on the U.S. railroads as a non-explosive.

The drying of TNA corresponds to the drying of picric acid, *i.e.*, it is relatively safe. Several methods have been employed, but drying on shelves, by means of hot air fans, has given the best results.

The latest operating results indicate the following net consumption of materials, per lb. of TNA produced, including all intermediate stages (dinitrobenzol and *m*-nitraniline): Benzene 0·6 lb., sulphuric acid (100% basis, including 5% reconcentration loss) 2·3, nitric acid (100%) 1·0, sodium sulphide (60%) 1·0, sulphur (lumps) 0·4 to 0·5 lb. About 1·7 lb. of sodium thiosulphate can be recovered, but has hitherto been run to waste. The above sulphuric acid consumption can be substantially reduced where the high—and superfluous—heat test requirements for military TNA are waived, also where the reconcentration loss of the relatively large amounts of sulphuric acid used is avoided by mixing the spent acid directly with fresh acid for nitric stills. This has been found possible in actual practice, since the spent acid retains neither explosive nor volatile organic matter, and since it is recovered undiluted.

Starting from a reasonably pure *m*-nitraniline, the yield previously given for the final stage (130—140 parts of TNA per 100 parts of *m*-nitraniline)[117] has been confirmed on plant scale.[118]

Conclusions.

In 1913, on the basis of results obtained on an experimental scale, it was stated[119] that TNA possesses valuable properties in a high degree; that it is a well-characterised crystalline chemical compound, neutral, without action on metals; that it is the strongest solid explosive,[120] has a higher density than any other purely organic explosive, is non-hygroscopic, does not change on storage, is specially resistant to heat and friction, not over-sensitive to mechanical shock, can be easily detonated by an ordinary detonator even when highly compressed, has a smaller oxygen deficiency than other aromatic explosives, that it is a very suitable ingredient of explosive mixtures, and can be made at a competitive price.

All of these conclusions have been confirmed by later developments on an industrial scale. In addition, it has been proved that TNA is not injurious to health, and that it does not change through moisture, during manufacture, storage, or use—such change requiring more or less prolonged exposure to a combination of moisture and temperature which both substantially exceed the normal, whereas in practice, where temperature may exceed the normal (in shells, bombs, etc.), moisture does not, and where moisture may be high (in submarine mines etc.), the temperature is not.

The successful development of the industrial production of TNA has been achieved largely by the skill and perseverance of American technical men and operators.

Fleet, Hampshire.

THE DETERMINATION OF ZINC BY THE POTASSIUM FERROCYANIDE METHOD.

BY E. OLIVIER.

The determination of the zinc content of Australian concentrates is usually carried out volumetrically, either by the so-called American method (the potassium ferrocyanide method) or by the Schaffner method (titration of the ammoniacal

---

[116] This solvent was selected as it does not react with TNA, whereas alcohol does.

[117] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[118] Van Duin and Van Lennep (Rec. Trav. Chim., 1917, **37**, 114) on the basis of a few laboratory nitrations of aniline and of *m*-nitraniline with potassium nitrate—which are but two of the numerous methods of obtaining TNA described in the author's patents—record somewhat lower yields. In view of the definite examples previously given of nitration temperatures of 100° C. down to below the ordinary (*e.g.*, E.P. 3224 (1910); Z. ges. Schiess- u. Spreng., 1913, **8**, 185). Van Duin and Van Lennep's remark (*loc. cit.*, *cf.* Rintoul, Soc. Chem. Ind. Ann. Repts., 1919, 530) that the author's nitration temperature of 70° C. was too high, is irrelevant; whereas Stettbacher's converse allegation (Z. ges. Schiess- u. Spreng., 1916, **11**, 112) that no nitration occurs below 100° C., is entirely incorrect. Subsequently Stettbacher himself (Schiess- und Sprengstoffe, 1919, 201-2) quotes "Van Duin's (*sic*) method" of nitration at 50° C. as the best. As to the nitration of *m*-nitroacetanilide, attention had already been called (Flürescheim, G.P. 243,079) to an intermediate compound characterised by its pale yellow needles which had been obtained by Witt and Witte (Ber., 1908, **41**, 3091) when using two equivalents of potassium nitrate and operating in certain conditions, which they found on analysis to be a new isomeride of picramide. Van Duin and Van Lennep (Rec. Trav. Chim., 1920, **39**, 145), departing in material respects from the indications given by Witt and Witte, were thereby misled into erroneous suppositions which will be dealt with elsewhere, in connexion with a discussion of the purely scientific aspect of the mechanism of these nitrations.

[119] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[120] It can now be added that it has a higher shattering power than *any* other explosive

solution with sodium sulphide); this last method is also sometimes termed the Vieille Montagne method (*cf.* Fiévet, Bull. Soc. Chim. Belg., 1919, 28, 351).

In the American method, as usually carried out, the ore or concentrate is decomposed by means of nitric acid and potassium chlorate, the mixture evaporated to dryness, the residue boiled with ammonia and ammonium chloride solution, and the filtrate acidified; the copper is removed by means of lead foil, the liquid is neutralised with ammonia, a solution of potassium hydrogen tartate and ferric chloride is added, the solution heated to about 75° C., and titrated with standard potassium ferrocyanide solution in presence of ammonia until a spot test with acetic acid shows a blue coloration.

The method used for preparing the solution for analysis results in the extraction of the zinc together with the copper, cadmium, calcium, and magnesium, and part of the lead, iron, and manganese. Of these elements only the zinc, copper, cadmium, and manganese are precipitated by the ferrocyanide, and only the copper is removed prior to the titration, so that the cadmium and manganese present are returned as zinc. Whilst the amount of cadmium present in the concentrates is usually so small as to be negligible (it averages about 0·1%), this is not so in the case of manganese, which may be present to the extent of considerably more than 1% and so result in a high figure being returned for zinc. In one case, for example, the author found 1·16% of manganese (as Mn_3O_4) in the zinc solution before titration.

That amounts of manganese such as are found in concentrates vitiate the titration is shown by experiments in which manganese corresponding to 2% and 4% respectively of Mn_3O_4 was added to solutions of known zinc content; on titration of these solutions 0·8% and 2·3% or zinc in excess of the quantity present was indicated.

To separate the manganese completely from the solution, a few c.c. of hydrogen peroxide are added to the mixture of ammonium chloride solution and ammonia used to treat the residue resulting from the decomposition of the ore; this renders the manganese insoluble, and the results obtained agree closely with those found by the Schaffner method.

When the percentage of manganese present is small (*e.g.*, 0·25%) the results obtained by the two methods (without the use of hydrogen peroxide) agree within about 0·1%, but in most cases manganese will be present in amounts sufficiently great to necessitate the use of hydrogen peroxide.

The American method has another disadvantage, especially where a large number of titrations have to be made daily—viz., the titration is carried out in hot solutions; this is necessary in order to obtain complete precipitation of the zinc ferrocyanide in a dense, gelatinous form. Further, the blue coloration produced in the spot test is not entirely satisfactory, since although the reaction is very sensitive the colour is not always very distinct in presence of coloured ferrocyanides and the intensity of the colour is not appreciably increased with increasing amounts of potassium ferrocyanide.

In the author's opinion, the Schaffner method is preferable to the American method in view of the above facts, and also having in mind the fact that the zinc is precipitated as colourless sulphide, which affords a ready indication of its freedom from other metallic sulphides. The only other colourless insoluble sulphide known is the double sulphide of zinc and cadmium, discovered by the author in 1886, but the error arising from this source is negligible since, as already pointed out, zinc ores contain very little cadmium, and moreover the greater part of the cadmium is separated as sulphide together with the lead and copper.

Central Laboratory of the Vieille Montagne.

Meeting held at Glasgow on April 22, 1921.

MR. J. H. YOUNG IN THE CHAIR.

THE PREPARATION OF GUANIDINE SALTS AND OF NITROGUANIDINE.

BY THOMAS EWAN, M.SC., PH.D., F.I.C., AND
JOHN H. YOUNG, M.SC., F.I.C.

The methods described in this paper for the preparation of guanidine salts and nitroguanidine easily and economically were worked out between 1903 and 1905. At that time the authors thought they saw a possibility of utilising guanidine nitrate and nitroguanidine industrially.

The possibility of preparing guanidine salts from cyanamide was first investigated. Erlenmeyer (Annalen, 1868, **146**, 253) obtained guanidine from cyanamide and ammonium chloride in alcoholic solution at 100° C. Volhard (J. prakt. Chem., 1874, [2], **9**, 15) heated aqueous cyanamide and ammonium thiocyanate at 100° C. (10 hrs.) and obtained some guanidine thiocyanate. In these papers no mention of yield is made.

The authors first investigated the formation of guanidine nitrate from sodium cyanamide (Na_2CN_2), a sample containing 72·8% Na_2CN_2 being used; 5 g. of this was dissolved in 200 c.c. of cold water and concentrated nitric acid added drop by drop as the cyanamide was dissolving so as to keep the solution as nearly neutral as possible, and finally made just acid to methyl orange with one drop of *N*/1 nitric acid. The solution, containing cyanamide and sodium nitrate, was evaporated on the water-bath to a small bulk and transferred to a large test tube; 5 g. of solid ammonium nitrate was added and the whole heated in a sulphuric acid bath to 145°—150° C., and kept at this temperature for about one hour, during which time the liquid evaporated considerably and became pasty, but there was no appreciable disappearance of cyanamide. The temperature was then slightly raised and a little more (1 g.) ammonium nitrate added. At 155° C. the mass began to froth considerably and cyanamide slowly disappeared, and after a further ½ hr. none was left. The product was dissolved in hot water, filtered from a little insoluble matter, and the guanidine determined as picrate. The yield was 43·1% of theory.

Vozarik's method (Z. angew Chem., 1902, **15**, 670; J., 1902, 1041) was employed to determine guanidine quantitatively. A quantity of the substance containing about 0·25 g. of guanidine compound is dissolved in 25 c.c. of water (filtered if necessary), precipitated with 75—125 c.c. of 0·8% ammonium picrate solution (made by dissolving 3·75 g. of picric acid in water, adding ammonia till alkaline and making up to 500 c.c.), and after standing for 1—2 hrs., filtered through a known weight of asbestos in a Gooch crucible, washed twice each time with 12 c.c. of ammonium picrate solution, drained well on the pump and dried at 100° C. to constant weight; 1% of the weight of the precipitate and 2·5% of the weight of asbestos is allowed for ammonium picrate retained, and the solubility of guanidine picrate in ammonium picrate solution is taken as 1 in 4000.

A number of preparations of guanidine nitrate, starting with sodium cyanamide, were made with yields usually near 50% theory. The operation may be divided into the following stages:—(1) Dissolving the sodium cyanamide in dilute nitric acid to form a solution neutral to methyl orange and containing cyanamide and sodium nitrate. (2) Evaporation of this solution to dryness in the water-bath under reduced pressure (50 mm.). (3) Extracting the cyanamide from the residue by digesting with ether. (4) Evaporation of the ethereal solution. (5) Heating the residue with excess of solid ammonium nitrate to 150°—180° C. to form guanidine nitrate.

In one experiment the amount of cyanamide at the end of stages (1) to (4) was determined and the quantity of guanidine nitrate at the end of (5). The following were the yields at the respective stages expressed as percentages of the theoretical yield: (1), 100; (2) and (3), 97·9; (4), 95·2; (5), 57·3%. From the above results it appears that the loss of yield takes place in stage (5), so it was decided to polymerise the cyanamide at the end of stage (4) by adding a few drops of ammonia and warming; when this was done the subsequent stage (5) gave an almost theoretical conversion of dicyanodiamide into guanidine nitrate according to the equation $H_4C_2N_4+2NH_4NO_3=2CN_3H_5.HNO_3$.

This led the authors to investigate more fully the formation of guanidine salts from dicyanodiamide.

B. Rathke (Ber., 1885, **18**, 3102) found that dicyanodiamide heated with ammonium chloride and water at 150° C. gives considerable quantities of guanidine hydrochloride; ammonia and carbon dioxide are also produced and react with dicyanodiamide to form biguanide and melanurenic acid respectively.

$$NH_2.C(:NH)NH.CN+NH_3=NH_2.C(:NH).NH.C(:NH).NH_2$$

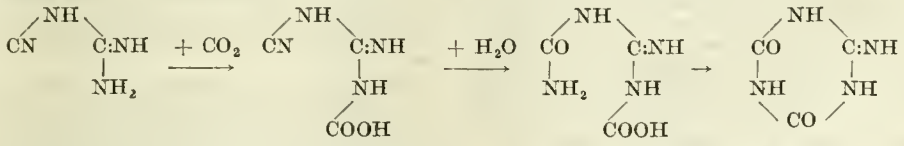
Biguanide

$$NH_2.C(:NH).NH.CN+CO_2=NH_2.C(:NH).NH.CO.N:CO$$

$$= NH{<}\begin{matrix}C(:NH).NH\\CO\text{——}NH\end{matrix}{>}CO$$

Melanurenic acid

G. Bamberger (Ber., 1883, **16**, 1074) observed the formation of melanurenic acid from dicyanodiamide and water at 160°—170° C. and later (Ber., 1890, **23**, 1856) he formulated the change as follows:—



Smolka and Friedreich (Monatsh., 1888, **9**, 1227) obtained biguanide from the product of the interaction of alcoholic dicyanodiamide and ammonium chloride at 105° C. (8 hrs.), and have also (Monatsh., 1889, **10**, 86) described experiments in which small quantities of dicyanodiamide and ammonium chloride (1 mol.) or sulphate (½ mol.) were heated together in the dry state at 160°—170° C. The products of the reactions were biguanide salts. The melt, when dissolved in water and treated with copper sulphate and sodium hydroxide, gave a rose-red precipitate of biguanide copper sulphate $(C_2N_5H_6)_2Cu,H_2SO_4$.

Bamberger and Dieckmann (Ber., 1892, **25**, 543) say that the formation of biguanide by this method is a very delicate operation, temperature, proportion of reactants, and time affecting the result. They recommend that an intimate mixture, quite dry, of 5 g. of dicyanodiamide and 8 g. of ammonium chloride be heated in an oil bath, with constant stirring, until the temperature reaches 195° C., at which point it is kept for 5—10 mins. and then cooled, extracted with water, filtered from a little insoluble matter (ammelin), and the copper salt precipitated; the yield of copper salt was 45—50% of theory.

Bamberger and Dieckmann also state that Smolka and Friedreich's temperature (160°—170° C.) is too low, and that at 195° C. biguanide decomposes into ammelin. The authors examined Bamberger and Dieckmann's method and concluded that the proportions given (5:8) were due to a printers' error (5:3 is more nearly correct). The following results were obtained:—

Dicyanodiamide. g.	NH_4Cl. g.	Final temp. ° C.	Time to heat up, mins.	Time at top temp., mins.	Copper biguanide sulphate dried at 100° C., g.	Yield % theory.
5	8	190-200	—	6	0·08	0·7
5	3	190-200	—	6½	0·8	7·3
5	3·2	195	—	5½	0·8	7·3
5	3·2	195	—	10	0·42	3·8
5	3·2	185	5	5	1·57	14·3
5	3·2	175	5	5	1·88	17·1
5	3·2	165	2	5	2·00	18·2

It will thus be seen that most of the investigators mentioned above considered a biguanide salt to be the principal product resulting from heating a mixture of dicyanodiamide and an ammonium salt. Where the formation of a guanidine salt was stated no mention of yield was made, and the fact that very high yields can be obtained seems to have been quite overlooked. The authors prepared the following guanidine salts, viz., nitrate, thiocyanate, sulphate, and chloride, by heating mixtures of dicyanodiamide with the respective ammonium salts in the manner described below. In the case of the nitrate and thiocyanate almost theoretical yields were obtained, whilst in the case of the less fusible sulphate and chloride the yields were not quite so high, but nevertheless satisfactory. One of these salts (thiocyanate) was made later in the same way, and a very satisfactory yield obtained by Werner and Bell (Chem. Soc. Trans., 1920, **117**, 1133), who found that by heating an intimate mixture of 43·5 g. of dicyanodiamide (95·5%) and 76 g. of ammonium thiocyanate to 120° C. for 3½—4½ hrs. guanidine thiocyanate is formed, and a yield of 90·8% of theory was obtained.

Guanidine nitrate.—The following method was found to be satisfactory. The proportions used were according to the equation

$$H_4C_2N_4+2NH_4NO_3=2CN_3H_5,HNO_3.$$

A mixture of 300 g. of dicyanodiamide and 576 g. of ammonium nitrate was heated in an enamelled iron pan, 10 in. diameter and 6 in. deep, by means of a Bunsen flame, and stirred with a thermometer. The mass was all fused at 110° C. and was heated to 150° C., at which point the burner was removed as the heat of the reaction kept the temperature up for some time. The mass became more viscous as guanidine formed. As soon as the temperature began to fall the burner was replaced till the temperature reached 160° C., when the reaction usually gives out sufficient heat to increase the temperature of the mass to 180°—190° C., at which point the reaction is soon completed. Finally it was heated to 200° C. for about 10 minutes and poured into iron moulds. 90—95% of guanidine nitrate was obtained in this way. The time of the complete operation was about 1½ hrs.

Larger batches were made in the following way:—3 kg. of ordinary commercial ammonium nitrate was melted in an enamelled iron pan 12 in. diam. and 6 in. deep over a Bunsen flame and some 20—30% of the dicyanodiamide theoretically required (say 1·5 kg.) added during the fusion in order to lower the melting point; the remainder was added gradually at 160° C. at such a rate that no external heat was required to keep the temperature steady at this point. When all the dicyanodiamide had been added the mass began to crystallise, so the temperature was raised to 170° C. The mass became liquid again but soon solidified, so the temperature was raised to 180° and finally to 190° C., waiting each time till the mass was pasty. Finally it was heated to 200° C. and poured into moulds. The product contained 91% of guanidine nitrate and the loss of weight was about 3%. 3 hrs. was required for an operation. About 170 lb. of guanidine nitrate was made in this way.

Guanidine thiocyanate, $CN_3H_5,HSCN$, was made in a similar way to the nitrate by heating an intimate mixture of 55 parts of dicyanodiamide and 100 parts of ammonium thiocyanate. Yields of over 90% were easily obtained.

Guanidine sulphate, $(CN_3H_5)_2,H_2SO_4$. When the ammonium salt is not readily fusible it is more intimately mixed with the whole or a considerable part of the dicyanodiamide before being heated. For example, 100 parts of dry ammonium sulphate is ground together with 60—62 parts of dicyanodiamide (or a considerable part of it) and the mixture fused in an open vessel. The fused mass (to which any dicyanodiamide remaining unmixed is added gradually) is then maintained at a temperature preferably between 150° and 180° C. until it has solidified to a cake of guanidine sulphate. In one experiment 125 g. of an intimate mixture of equal molecules of dicyanodiamide and ammonium sulphate was heated. At 140°—145° C. the product caked together and gave off ammonia; at 157° C. it was semi-fused, and became at 165° C. a thick paste, considerable heat being evolved. At 177° C. it was quite fluid and frothed a good deal, and the temperature was maintained without external heat. The mass was kept at 170°—180° for ½ hour. 111 g. of product was obtained containing 5·67% insoluble in water (ammelin), 1·16% of biguanide sulphate, 93·7% of guanidine sulphate, and a trace of melamine. This represents a yield of guanidine sulphate of 83% of theory.

Guanidine hydrochloride, CN_3H_5HCl, was made in a similar way to the sulphate from 100 parts of ammonium chloride and 80 parts of dicyanodiamide.

Nitroguanidine, $CN_3H_4.NO_2$, was prepared by J. Thiele (Annalen, 1892, **270**, 1) by treating 100 g. of guanidine nitrate with a cold mixture of 100 c.c. of concentrated sulphuric acid, 50 c.c. of sulphuric acid containing 10% of SO_3, and 40—50 c.c. of nitric acid (sp. gr. 1·5) and pouring into 2 litres of water after a few minutes. The yield does not seem to be mentioned.

The authors prepared nitroguanidine from guanidine nitrate in three ways, viz., by the action of: (*a*) sulphuric acid alone, (*b*) nitric acid alone, (*c*) a mixture of sulphuric and nitric acids.

Method (*a*).—The solubility of nitroguanidine in dilute sulphuric acid was first determined; 1 g. of powdered nitroguanidine was mixed with a definite quantity of water and concentrated sulphuric acid (sp. gr 1·84, 82%, 1 c.c. contains 1·69 g. H_2SO_4 and 0·15 g. water) added, drop by drop, till the nitroguanidine had just dissolved. The temperature of the saturated solution was 13° C. The following results were obtained:—

% H_2SO_4 in final acid.	Solubility of nitroguanidine, g. in 100 g. acid.	g. Nitroguanidine dissolved for each g. H_2SO_4 in the acid.
33·2	2·55	0·077
28·2	1·37	0·049
25·2	0·95	0·038
22·7	0·87	0·038
20·0	0·72	0·036
17·2	0·65	0·037
5·8	0·37	0·064

The sulphuric acid should therefore be diluted so as to make the final acid 20%; 4% of the nitroguanidine should remain in solution for each g. of H_2SO_4 used per g. of nitroguanidine.

To examine the action of sulphuric acid on guanidine nitrate the materials used were 92% acid as above, and Nordhausen acid (1 c.c. weighs 1·9 g. and contains 62·23% H_2SO_4 and 33·77% SO_3). The guanidine nitrate used was crystallised from dilute nitric acid and was colourless and practically pure. Nordhausen acid acts too violently on guanidine nitrate; it also appears to decompose nitroguanidine. In one experiment the nitroguanidine dissolved in concentrated sulphuric acid decomposed suddenly, with evolution of much heat and gas, on adding a little sulphuric anhydride to it.

In the following experiments the temperature never exceeded 30°—40° C.; a little gas is evolved in the warm mixtures—none if the temperature is kept at 12° or 13° C.—but the yield appears to be hardly affected. The mixture was always poured (after standing for a definite time) into sufficient water to dilute the sulphuric acid to 20%. The nitroguanidine which separated was filtered on the pump, washed once with a little cold water, drained well, dried, and weighed.

The action of different quantities and strengths of sulphuric acid on guanidine nitrate, also different times were considered systematically. In experiments using 5 g. of guanidine nitrate and 16·9 g. of acid the highest yields (79·1% in 30 mins., 79·6% in 18 hrs.) were obtained with acid containing 92% of H_2SO_4, although almost equally good yields (77·7—78%) were obtained for both times with 87% or 95% acid. Using 5 g. of guanidine nitrate and 25·4 g. of acid for 48 hrs., the highest yield (75·1%) was found with 87·1% acid; with a smaller quantity of acid (8·45 g.) the best yield (84·5% in 48 hrs.) was obtained with 95·5% acid, but yields of over 80% resulted when 92% or 100% acid was used. With 10 g. of guanidine nitrate and 8·45 g. of acid the yields were low in all cases, the best results (36·8% in 22 hrs. and 40·5% in 72 hrs.) being obtained with acid of 102·4% H_2SO_4.

To ascertain the effect of temperature on the reaction, 5 g. of guanidine nitrate was dissolved in 10 c.c. of 92% sulphuric acid, without cooling, and placed in a water-bath at 81° C. rising to 84° C. 7 mins. after mixing much gas was being evolved from the acid liquor. The product was poured into water and let stand overnight before filtering etc. Yield 3·03 g.=71·1% theory.

To try whether the nitroguanidine separated completely in a few minutes when poured into water, 5 g. of guanidine nitrate was mixed with 10 c.c. of 92% sulphuric acid, allowed to stand for 25 mins., poured into 65 c.c. of water, allowed to stand for 18 hrs., filtered, washed, dried, etc.; yield 3·35 g.=78·7% theory, which is practically identical with the yield got by filtering at once after pouring into water.

The time allowed for reaction of 5 g. of guanidine nitrate in 5 c.c. of 92% acid appears to influence the yield considerably; *e.g.*, after 10 mins. the yield was 64·5%; 17½ hrs., 76·5%; 48 hrs., 83·1%. When 5 g. of guanidine nitrate is dissolved in 10 c.c. of 92% acid the time of reaction has little effect; thus after 12 mins. the yield is 78·2%; 25 mins. 78·7%; 30 mins., 79·1%; 3 hrs. 23 mins., 78·2%; 17 hrs. 40 mins., 79·6%.

Method (*b*).—The solubility of nitroguanidine in nitric acid was determined by dissolving 0·5 g. of nitroguanidine in hot water, cooling to get it finely divided, and adding nitric acid, drop by drop, till the whole was just dissolved in the cold. Results:—

c.c. water.	c.c. conc. HNO_3.	% HNO_3 in final acid.	g. nitroguanidine dissolved by 1 g. HNO_3.
15	4·5	27	0·085
25	6·0	23	0·064
40	7·5	19	0·051
50	7·2	15·5	0·053
100	5·3	6·4	0·073

The minimum solubility thus lies at 19% HNO_3. The concentrated nitric acid used contained 87·6% HNO_3 (1 c.c.=1·3 g. HNO_3 and 0·18 g. H_2O), and was reddish coloured. 10 c.c. weighed 14·814 g. The following results were obtained using 5 g. of nitroguanidine and nitric acid alone for nitration:—18 hrs.: 3 c.c. of acid, yield=0%; 5 c.c., 11·3%; 10 c.c., 15%; 15 c.c., 46·5%. 96 hrs.: 3 c.c., 0%; 5 c.c., 24·4%; 10 c.c., 53·8%; 15 c.c., 64·5%. The mixtures stood at the ordinary temperature. The 5 g. of guanidine nitrate dissolved completely in 15 c.c., almost completely in 10 c.c., very little in 5 c.c., whilst the 3 c.c. was soaked up completely, leaving a solid mass. The 5 c.c. mixture solidified to a mass of prismatic crystals on standing, and several crystals of the same shape came out of the 10 c.c. lot. Apparently guanidine nitrate is capable of combining with another molecule of nitric acid.

Method (*c*).—Action of mixture of H_2SO_4 and HNO_3 on guanidine nitrate. The following results were obtained, using 5 g. of guanidine nitrate and allowing to stand for 68 hrs:—

HNO_3. %	H_2SO_4. %	H_2O. %	Acid mixture, g.	Yield. %
35·1	50·8	14·1	7·4	11·5
50·0	36·1	13·9	10·4	44·4
38·3	60·6	1·1	6·8	65·7
38·3	60·6	1·1	13·6	76·0

The above results show that method (*a*) is the most satisfactory and that the best yields are obtained by using 5 g. of guanidine nitrate to 5 c.c. of 92%—98% sulphuric acid and standing for 48 hrs., but if time is a consideration very satisfactory yields can be obtained by using 5 g. of guanidine nitrate to 10 c.c. of 87%—95% acid and standing for 30 mins. A batch of about 60 lb. of nitroguanidine was made as follows:—80 lb. of crude guanidine nitrate (90—94%) was dissolved in 147 lb. of 95% sulphuric acid and stirred by hand with an iron rod in a steel ladle, 21 in. diameter and 15 in. deep, set in a wooden tub with cold water flowing. The temperature was kept at 25°—33° C. Six hours was required to get the guanidine nitrate dissolved (this could be reduced by more efficient cooling). The mass was allowed to stand overnight, when it had half solidified; it was diluted with 514 lb. of water in stoneware vessels and the nitroguanidine was filtered on a stoneware vacuum filter. The cake was washed with a little water and then stirred with 100 lb. of water in a stoneware vessel and a portion tested by titrating with $N/1$ sodium carbonate and methyl orange; 2 lb. of sodium carbonate was added, which made the liquor slightly alkaline. It was filtered off and drained again, then stirred with a further 100 lb. of water, filtered, pressed well down, and finished with a small wash on the filter. The damp product weighed 94 lb. and contained 43% of water. It was dried in an evaporator till a final product was obtained which weighed 55 lb. and contained 6·57% of water and 0·17% of sodium sulphate. Assuming the guanidine nitrate used to be all 94% (which is too high as it was slightly damp), the yield works out at 80·2% of theory.

This work was done in the laboratories of the Cassel Cyanide Co., Ltd., Glasgow, and our thanks are due to the directors for permission to publish the results.

Meeting held at Burlington House on April 4, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE SCIENTIFIC PRINCIPLES OF COLD STORAGE.

BY PROF. WALTER STILES.

(*Abstract.*)

From the physico-chemical point of view all foods consist of very complex systems. With the exception of butter, the chief constituent of each system is water in which are dissolved various inorganic salts, while organic substances, particularly proteins and fats, are dispersed through the aqueous phase in the form of an emulsion, or in the colloidal condition.

Most foods are capable of preservation in cold storage, and many systems of classification of such substances are possible according to the point of view adopted. When we have to consider the scientific principles involved, the most satisfactory classification is one based on the temperature of storage. From this point of view we can divide all food materials into two classes. In the first class the food material during storage has to be maintained at a temperature above the freezing point of the food on account of serious deterioration which takes place if the water in the food is allowed to separate out as ice. Fruits are very typical of this group of foods. Many other plant organs, such as tubers and roots, behave similarly. Unless it be in very exceptional circumstances, freezing has so far not been applied with success to the preservation of these, and when kept in cold storage care has to be taken that the temperature does not fall below the freezing point. In the second class much lower temperatures are employed, so that it is ensured that the greater part of the water is frozen. As typical of this group of foods may be cited mutton and rabbits.

These two methods differ greatly with regard to the scientific problems involved. In the first case, the physical condition of the food remains unaltered, but various chemical processes, including enzyme actions, take place, which lead to changes in the composition of the food, which are known as maturing or deterioration according as the changes improve the quality of the food or the reverse. At these temperatures of storage also many foods are liable to be attacked by micro-organisms, which in practically all cases lead to unpleasant changes in the food substance. The changes taking place in foods during cold storage at temperatures above the freezing point are thus chemical changes that are to be investigated by the methods of organic chemistry, including biochemistry. In the second case, however, in which the food is preserved in the solid frozen condition, we are faced with an entirely different set of problems. The chemical actions which bring about changes in the composition of the food must proceed with extreme slowness, both on account of the low temperature and because the liquid medium in which such reactions take place is now replaced by a solid one. From the freezing point downwards the quantity of liquid becomes less and less until at the eutectic point the whole mass is completely solid. For the same reasons the growth of micro-organisms is either greatly retarded or completely inhibited. On the other hand, freezing involves a change of state of one of the substances of the food, that is, there is a change in physical structure. Cold storage in the frozen state will only be successful if this change in physical structure which takes place on freezing is reversed on thawing, so that in its final state preparatory to use the system comprising the food is nearly identical with the fresh produce. The problems involved here are problems of physical chemistry; the biochemical problems which figure largely in the storage of food above the freezing point take here only a secondary place, but they are not necessarily negligible, especially if storage is continued over a long time.

There are several advantages in keeping food in the frozen rather than in the physically unchanged state. As the result of the much slower rate of the chemical reactions which produce deterioration, material can be preserved for a considerably longer time frozen than unfrozen. Produce can be packed more closely when frozen and, not being nearly so liable to the attacks of micro-organisms, does not require nearly so much attention and inspection.

One of the main objects of scientific research in cold storage should therefore be to transfer as many substances as possible from the class of substances which cannot be preserved frozen to the class of those which can.

As an example of the first class of foods fruit may be selected. The conditions which allow of variation are the temperature and humidity of the air in the storage chamber, illumination, movement and composition of the air in the store, and the possible protection of the fruit by a wrapper of some sort. The stage of development at which it is best to commence the storage of fruit is obviously a matter of importance, and so is the determination of the length of time which the fruit can be kept in store. For the solution of these problems it is clear that a careful study of the changes taking place during the ripening of fruit is necessary. Moreover, there is no reason to suppose that different species of fruit, or even different varieties of the same fruit, go through the same series of changes, so that it appears probable that every species of fruit will have to form the subject of a separate biochemical examination. Such investigations are now being made, and the results should be of the greatest interest for the student of cold storage. The need for such separate investigations is emphasised when it is remembered that the value of each particular species or variety of fruit depends upon something very characteristic in the flavour or aroma.

Since the rate of the reactions involved in ripening of fruit increases with rise of temperature, it may be concluded that, in general, the nearer the temperature is to freezing point, so long as it is above it, the longer can the fruit be stored, and there has been in practice a continuous tendency to use lower and lower temperatures until at the present time temperatures about 0° C. are often employed. As to other conditions in the store, the degree of movement of the air and the relative humidity are generally determined by the liability of the fruit to lose water by evaporation, or to be attacked by moulds or bacteria. In the latter case air movement with a comparatively dry atmosphere is indicated; in the former, moist still air is more suitable.

What has been said so far will give some idea of the principles involved in the cold storage of fruit; similar considerations will hold for other food substances stored above the freezing point; even a material such as beef, which is usually preserved in this way, is to be considered as subjected to the same scientific principles. It will not be necessary therefore to consider further instances of food maintained above the freezing point, and we may pass on at once to the principles concerned in the preservation of food in the frozen condition.

It has already been noted that the chief difficulties here arise from the change of state from liquid to solid not being reversed on thawing with sufficient completeness. In substances such as rabbits and mutton, which are generally stored in the frozen condition, this reversal is practically complete; in other cases, as in some fish and in beef, with the ordinary methods of freezing the reversal is anything but complete, and such frozen material on thawing yields material inferior in quality both to fresh produce and to that stored for short periods above the freezing point.

We are at once faced with the question of how systems such as meat and fish behave on freezing. Many observations have been made on somewhat similar systems, such as sols and gels of gelatin. If a gelatin gel with a concentration of, say, 2 to 5% is allowed to freeze in a cold room, ice separates out at a number of centres leaving a more concentrated solution of gelatin. As the ice crystals grow there will thus be left a network of gelatin getting more and more concentrated, enclosing in the network solid ice crystals. On thawing the mass, the water resulting is not re-absorbed by the gelatin to any greater extent than gelatin will normally absorb water at a low temperature. A certain proportion of the water will be re-absorbed, but not by any means the whole of it, and so the original system will not be regained after the freezing and thawing processes. If the block of gelatin is squeezed in the hand, water can be squeezed out of the gelatin as readily as it can be squeezed out of a wet sponge.

The same sort of thing happens when vegetable tissues—at any rate, such things as apples and potatoes—are frozen and thawed, while a similar phenomenon is to be noted in the case of beef. When a quarter of beef frozen in air is cut, there is generally a noticeable separation of liquid from the beef ("drip") whereby valuable nutrient substances may be lost from the meat; it is also possible that the alleged toughness of some frozen beef is connected with this. On the other hand, no such difficulty arises with mutton.

Our main problem is, therefore, can we by any means so alter the method of freezing that the separation out of comparatively large crystals of ice can be prevented? Can we so freeze the tissues that the space relations of the water and other constituents are maintained the same in the frozen as in the unfrozen condition? If this be done, we may then hope that on thawing the original system will be renewed.

As a guide in this matter we have the researches of Tammann on supercooled liquids. By varying the degree and rate of cooling it was shown to be possible to vary within wide limits the texture of the resulting solid. By cooling a liquid slowly to a temperature not far below the freezing point there is a high crystallisation velocity but only a few centres of crystallisation form; hence crystals grow rapidly from a few centres, and so a very coarsely crystalline mass results. Further below the freezing point the number of crystallisation centres increases, so that a finer-grained mass results. Further still below the freezing point the number of crystallisation centres reaches a maximum and at lower temperatures diminishes again until at a certain low temperature the number of crystallisation centres which form in unit time is practically zero. If then the substance is cooled so quickly that it passes rapidly through the temperature interval over which crystallisation centres form at an appreciable rate, the substance should set in a form approximating to an amorphous or glass-like condition as the number of crystallisation centres which form is small, and so is the crystallisation velocity. Working on these principles, Tammann was able to obtain 59 substances out of 153 examined, in the form of a glass, and he expresses the opinion that with sufficiently rapid cooling the majority of substances should be obtainable in this condition.

In the case of a gel or a viscous substance such as the content of the muscle of fish and meat, there is another point of view. The formation of large crystals at a few centres leaving a more concentrated gel forming a network, involves the movement of water molecules through the viscous or jellified mass. This movement requires time. For this reason also rapid cooling of such systems as animal juices should prevent the separation of large ice crystals from the general mass.

These considerations suggest that rapid freezing may solve the difficulty of the separation of the constituents of frozen tissues. A number of experiments carried out on the freezing of complex sol and gel systems at different rates supported this conclusion, while there are a number of records in the literature indicating clearly the efficacy of rapid freezing in preserving the relations of the constituents of complex colloidal and organic systems after freezing and subsequent thawing.

The evidence thus seems clearly to indicate the solution of the problem of storing food in the frozen condition. The next step is to discover means for carrying out the freezing sufficiently rapidly. When only small objects are in question this is not as a rule a difficult matter; lowering the temperature may be sufficient, and for small experiments the low temperature of liquid air can be used without much trouble. But the matter is not so simple when we have to deal with large objects, such as large fish and quarters of beef, since the rate of cooling and freezing at any point in the body depends on its nearness to the surface and on the specific heat and thermal conductivity of the body, as well as on the temperature of the cooling medium.

With differences in these respects we need not be concerned here, as most of the food materials with which we have to deal do not differ much in their specific heat and thermal conductivity from water, 75% or upwards of their substance consisting of that compound. But it is of some importance that the thermal conductivity of ice is about four times as great as that of water, while its specific heat is only about one half. On these accounts ice will cool much more quickly than water, other things being equal. Consequently, the passing over of the outer layers of a cooled mass of meat or fish into the frozen state, so far from hindering the further withdrawal of heat from the inner regions, materially assists it.

In order to bring about rapid freezing various devices are possible. The most obvious is to use a lower temperature. But here the cost of maintaining very low temperatures will probably limit the downward extension of the temperature of the cooling medium beyond a certain limit. Strong agitation of the cooling medium will also aid in the more rapid cooling of objects, owing to the breaking down of temperature gradients. This means can, however, not effect a very great increase in the freezing velocity. A third variable which influences the rate of cooling is the thermal conductivity of the cooling medium. Cooling curves of pieces of beef and other food substances of the same dimensions frozen in a variety of substances have shown without question how greatly the rate of cooling is influenced by the thermal conductivity. We are in practice limited by two considerations, namely, cost and any injurious action of the cooling medium on the food material. Thus mercury, in spite of its high conductivity, is ruled out altogether as a possibility. Of practicable substances water has a fairly high thermal conductivity, but as it freezes at a higher temperature than the food, it is of no use for the purpose. But salt solutions have much the same thermal conductivity as water, and these can be obtained in liquid form right down to their eutectic points. Thus sodium chloride can be obtained in solution down to a temperature of −21° C., magnesium chloride down to −33·6° C., and calcium chloride down to −55° C. These temperatures are considerably lower than those generally employed for freezing materials in air—the ordinary method—whereas the thermal conductivity is about 28 times as great as that of air.

By the use, then, of lower temperatures or of a salt solution instead of air as the cooling medium, the rate of freezing can be much increased, and by applying these facts it should probably be possible to achieve the cold storage of any food material in the frozen condition. The use of a cooling medium of high conductivity is, however, more effective in the case of smaller objects than with larger ones. For instance, cylinders of 5% gelatin 1 cm. in diameter in brine at −10° C. freeze 13 times as quickly as in air at the same temperature, whereas when the diameter is 25 cm. they only freeze 2½ times as fast. For this reason freezing in brine should be more efficient in the case of fish than of large bodies such as hind-quarters of beef. Many experiments with fish on both a small and large scale, in this country and in Holland and Germany, indicate that freezing fish in sodium chloride brine is highly satisfactory with most species of fish, and the method is probably capable of extension to all species of fish. Penetration of salt into the fish is in most cases negligible and on cooking there is no evident salty flavour; in any case the entrance of salt can be prevented by the use of a protective covering if it is thought necessary.

With beef the problem is not yet completely solved. Small pieces of beef, up to about 6 lb. or so, can be frozen in brine so that there is no sign of separation of liquid after thawing. The elimination of "drip" is then only a question of using a suitable freezing velocity. It may be necessary to use a lower temperature than −21° C., in which case some solution other than sodium chloride brine would have to be employed. The objection to calcium chloride or magnesium chloride is the unpleasant taste of these salts, but some mutton frozen in calcium chloride brine had not the slightest trace of unpleasant flavour on cooking, and some hindquarters of beef frozen in sodium chloride brine at −20° C. showed no sign of "drip" after they were thawed, nor of salty taste when cooked. But here a secondary difficulty presents itself. A large body, such as a hind-quarter of beef, has to remain in brine at −20° C. for from 12 to 24 hours for freezing to be complete to the middle. During this time a considerable quantity of salt enters the surface layers of the tissue, and on thawing the quarter the surface appears to have a dull colour. The meat itself appeared excellent in flavour in the trials made with whole quarters, but the appearance was against it. But the solution of this difficulty should only be a matter of biochemical research, and one may conclude with confidence that to obtain frozen beef of a quality indistinguishable from that of fresh meat is only a matter of time. Whether it will be economically worth while so to preserve this or any other food material is another matter, which does not concern the scientific investigator as such.

DISCUSSION.

The **CHAIRMAN** said that some 25 years ago considerable interest had been shown in the storage of hops in evacuated metal cylinders. The results were satisfactory and comparable with cold storage; it seemed unfortunate that more had not been done in this apparently promising direction.

Dr. G. **SCHACK-SOMMER** said that some experiments had been made by Charles Tellier, the pioneer of refrigeration, in which meat and fish were subjected to a vacuum to remove the oxygen from the tissue, before placing them in cold storage. Successful results had also been obtained in preserving soft fruit in cold storage by the use of an atmosphere of carbon dioxide to prevent respiration.

Dr. R. T. **COLGATE** asked for information as to the best methods of thawing frozen food. It was stated that frozen eggs should be thawed at quite a low temperature.

Mr. E. **HATSCHEK** said that the freezing and thawing of gelatin gels was not a completely reversible process, and he could not see that the rate of freezing or thawing could ever make it so. The swelling of a gel was also materially affected by the electrolytes present in the water, and particularly by hydrogen and hydroxyl ions. If a gel containing an electrolyte was frozen, the water froze out a good deal of the electrolyte also, and that, it seemed to him, was an additional difficulty in getting the process reversible with animal tissues, which contained electrolytes isotonic with 0·7—0·9% NaCl.

Dr. S. **MIALL** asked if the author had had occasion to study the conditions under which minute animals could live through freezing.

Mr. C. J. **TABOR** said that rabbits could not be kept in cold storage for ten months at a temperature of 8° or 10° F. without damage. Meat could be kept for 6 or 8 months, and chickens about 6 months. One difficulty in the refrigerated produce trade was the elimination of moulds. His own tests had shown that they were harmless, but it was customary to condemn produce carrying mould growths. A rise of about 10° F. in the temperature of the refrigerating apparatus (say from 15° to 25°) was sufficient to start mould growth, although it would not occur if the temperature were kept constant. Once started, a reduction of the temperature did not prevent the growth. The reason for this was that the rise of temperature produced a surface dampness to which the moulds (*Mucor mucedo* and *Penicillium glaucum*) adhered. Another trouble with frozen meats was the yellow discoloration caused by bursting of the fat cells on thawing, whereupon the fat became discoloured and rancid. The freezing of fish always involved loss of flavour; the tissues were more delicate and more readily disrupted by the expansion of their watery contents than in the case of meat. Another form of damage, quite distinct from mould, was "must"; it exhibited no signs of fungoid growth and could not be removed by wiping. Its cause was obscure; beyond a slimy dampness on the goods, and a very disagreeable odour, nothing could be traced; meat so damaged was dangerous to health.

Prof. **STILES**, replying to a question by the Chairman, said that butter which had been kept in cold storage at −10° C. for nine months showed no alteration in the fat-soluble vitamins. He was not aware that any experiments had been carried out on the other vitamins. In reply to Dr. Colgate, he said that German investigators had concluded that if the meat were frozen rapidly enough, so that the space relations were maintained in the frozen condition, it did not matter whether the thawing was rapid or slow. On the other hand, the American, Richardson, advocated slow thawing if freezing had taken place in air, because apparently some of the water that was otherwise lost in the "drip" was re-absorbed if the meat were thawed slowly. All his own experiments had been conducted with the view of trying to get the freezing so rapid that a reversible change on thawing was obtained. He had tried to freeze eggs in brine, but they had always burst. Referring to the freezing of small animals, he said there were references in literature to fish that had been frozen in Lake Superior and lived afterwards, but he did not believe that that fish had ever really been frozen, and he often wondered whether small animals like worms were really frozen. Frogs' muscles, when frozen very rapidly, had been found alive after thawing. Micro-organisms were not always destroyed by freezing; some probably were, but the majority of spores were not, and directly the conditions were suitable for their growth, especially when water condensed on the surface, they would germinate and grow. Fish that had been frozen rapidly in brine was indistinguishable from fresh fish when cooked. Although water expanded on freezing by 10%, this did not burst the tissues. Plant tissue could be frozen, but that did not burst the cells, and the reason why frozen salmon turned rancid was probably connected with the fact that it had been slowly frozen. He doubted if it would turn rancid so soon if it were rapidly frozen.

Meeting held at Burlington House on May 2, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

FRACTIONAL DISTILLATION WITH CONTACT RING STILL-HEADS.

BY R. LESSING, PH.D.

In the discussion following the paper on gas scrubbing towers by Donnan and Masson (J., 1920, 239 T) I drew attention to the advantages of packing absorption towers and distilling columns with contact rings of the type described in my British Patent No. 139,880 (J., 1920, 321 A). These rings, as shown in fig. 1, consist of cylinders of approximately equal height and diameter, having a gap in the circumference and a more or less diametrical partition connected on one side with the cylinder, but out of touch on the opposite side. They are disposed indiscriminately in the tower or column at the angles which they find when dropped promiscuously into the vessel. Packing material of a similar kind but consisting of plain cylinders was devised by Raschig (E.P. 6288 of 1914; J., 1914, 907), and has found extensive application for works purposes of various kinds. The provision of the central partition and openings, however, has been found to increase the efficiency of the packing very considerably by adding to the contact surface available in a given tower space, and by enhancing the drainage capacity of the packing.

The further advantage of greater ease in manufacturing these rings in large numbers has made it possible to provide them also for laboratory purposes in smaller sizes than the standard one used in large scale plants, which is usually 1 in. diameter by 1 in. height.

The 1-in. rings are used in a great variety of plants of the chemical and gas industries, amongst which may be cited ammonia scrubbers, oil scrubbers, absorbers, washers, tar extractors, carbolate decomposers, carbonating and decarbonating towers, debenzolising stills, distilling columns, and still-heads for many substances such as tar and petroleum products, alcohols and essential oils, also condensers, coolers, and heat exchangers. Indeed they are applicable wherever large interfacial surface for liquid and gas or vapour, combined with a minimum of back pressure, is essential.

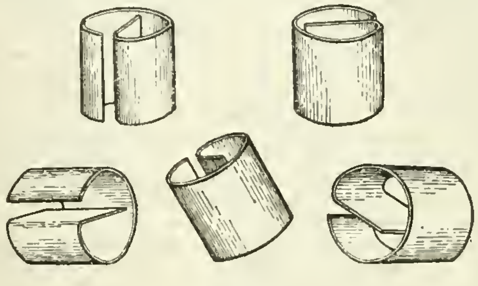

Fig. 1.

The inferiority of laboratory methods to works practice of fractional distillation has been frequently pointed out (*e.g.* Kreis, Annalen, 1884, 224, 259; Silvester, J., 1920, 188 T), and is mainly due to the impossibility of reproducing the factors of time, contact, and distance on the small scale. Since the small rings have been put on the market it has become possible to remedy this deficiency and to use them for the construction of laboratory still-heads on the lines on which the larger ones are applied in manufacturing operations. The early experiments were made mainly with the intention of reproducing as far as possible works conditions in the laboratory, and for this purpose plain tube still-heads as proposed by Hempel were used in which the glass beads were replaced by contact rings ¼ in. × ¼ in. This made it possible to do away with the principal drawback attaching to the Hempel still-head, viz., choking and consequent "puking" caused by the very considerable resistance offered by the glass beads, which usually take up 80% or more of the still-head space. The resistance of a ring-packed column is so small that still-heads of very considerable height can be used. Incidentally the surface offered by this ring packing is a very large one. It amounts to 8250 sq. cm. per litre (251·5 sq. ft. per cb. ft.), whilst the volume occupied is only about 13% of the total space, leaving 87% of the space free for vapour and condensate.

The advantages of such an arrangement are:—Extreme simplicity—the rings are dropped into plain glass tubes and the use of complicated and fragile products of the glass blower's art is avoided; the same charge of rings can be transferred from one still-head to another whatever its dimensions, or can be used for other purposes in absorption towers or reaction vessels, and are therefore of general applicability; they are not lost if the vessel containing them should get broken.

Apart from these advantages, still-heads packed with these rings have been found to possess a fractionating efficiency which is superior to any known laboratory still-heads or dephlegmators of comparable dimensions. The reason for this must be sought firstly in the large surface per unit of volume which affords ample opportunity for condensation of the vapours and re-evaporation of the condensate; secondly, the turbulence created by the frequent deflection of the currents of vapour and condensate, which can only flow in any one direction for a distance of ¼ in. or less. Thus, formation of "cores" and "channelling" is avoided, and the release of vapour trapped in the condensate is promoted by the continual exposure of fresh surfaces.

A not inconsiderable portion of the action is due to surface tension effects of liquid forming films along the points or lines of contact between adjoining rings. These films or pockets are more or less effective seals, to be broken by the ascending vapour current and thus ensuring intimate contact and interchange between liquid and vapour phase. This amounts to a very considerable bubbling effect which is increased or decreased with the rate of drip of condensate. In order to enhance this bubbling effect and also to keep all surfaces well irrigated, it is desirable to induce as much return-flow as is compatible with the drainage capacity of the column and the avoidance of excessive back-pressure. If the still-head is used unlagged, as is done with the majority of "dephlegmators," it acts largely as a reflux condenser with a rapidly decreasing quantity of condensate towards the top. The bubbling therefore diminishes from bottom to top, and the surface effect of the upper portion of the still-head is not utilised to the full extent. For this reason it is preferable to lag the still-head with asbestos, cotton wool, or corrugated cardboard, thereby avoiding premature condensation, and to provide a reflux condenser which allows the required portion of vapour to pass uncondensed and to distil over, whilst the bulk is condensed and returned, copiously wetting the whole length of the still-head.

This reflux condenser need not be worked as a "regulated temperature" still-head (see F. D. Brown, Trans. Chem. Soc., 1880, 37, 49), but merely serves to re-condense that portion of the vapours which it is desired to use for the irrigation of the still-head and not to send over into the receiver. In this connexion it may not be generally known that the ratio of vapour collected as distillate to that returned into the still can be determined calorimetrically by connecting the water outlet of the final condenser with the inlet of the reflux condenser. The ratio of the rise of temperature in the reflux condenser to that in the final condenser indicates directly the proportion of return flow to distillate. By this mode of working the adjustment of the degree of fractionation for a given height of still-head can be effected, at any rate on the large scale, and may also be occasionally of use in the laboratory.

Where long still-heads are used, a water- or oil-cooled reflux condenser can be dispensed with by leaving a short length of the upper end of the tube unlagged, relying on atmospheric cooling.

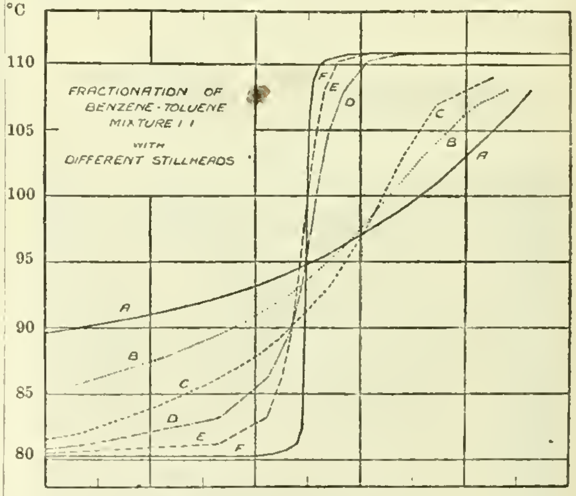
A still-head packed with rings may, then, be regarded as a scrubber in which the ascending vapours are scrubbed with the descending condensate. All considerations applied to the theory and practice of scrubbing or absorption towers are therefore applicable to still-heads, and their study should yield valuable results if carried out from the scrubbing point of view.

However well a still-head is lagged there is bound to be a certain amount of radiation and gradual drop of temperature from bottom to top. If a sufficiency of scrubbing liquid is to flush the whole length of the column, radiation must be compensated by the sensible and latent heat of the vapours. In cases where the heating of the still would become excessive, or the quantity of material is insufficient, the loss by radiation may be made up by external heating of the still-head—say by means of electric resistance wires. It is also important to pay attention to the specific heat and conductivity of the packing material.

Whilst the drainage capacity of the packing is very high, the rings of necessity retain a thin film of the liquid after draining. On account of the large surface involved this is more than, for instance, in Young's evaporator still-head, which is specially designed to retain a minimum of condensate. This point acquires importance only in cases where very small quantities are fractionated and the distillation of the last fraction is desired. In preparative work or in analysis where large enough quantities are available, this drawback disappears entirely as the error becomes negligible, or may be corrected in many cases by steaming the column and recovering the distillate. The amount retained varies according to the viscosity of the substance, its wetting power for various metals, the physical condition of the rings, and the height of column. For instance, aluminium rings retain after 30 minutes' draining 1—2 c.c. of toluene per 100 c.c. of column space, whilst a retention as low as 0·06 c.c. by the same volume was found for a petroleum spirit after some hours' draining.

The construction of these still-heads is exceedingly simple. Tubes from 2·5 to 4·0 cm. wide and from 40 to 150 cm. long will cover the range of most ordinary requirements. The usual constriction at the bottom for connecting through a cork stopper should be as wide as possible to avoid choking with condensate. The tubes may be fitted with a side-tube at the top when no separate reflux condenser is used, or may have an outlet fixed through the top stopper with or without the interposition of a reflux condenser. In glass tubes as a rule no support for the rings is required. They are merely dropped into the tube in a slanting position; on turning it up the rings will arrange themselves and bridge over the bottom shoulder.

If metal tubes are used, as is the case on a semi-manufacturing scale, wire gauze of as large a mesh as will support the rings should be fixed at the base, and practically the whole cross-section of the tube is then available for the discharge of condensate into the still and the upward current of vapours.



A. Ordinary distilling flask with side tube.
B. Glinsky still-head with three bulbs (3 cm. diam.).
C. Hempel still-head with glass beads (3 cm. diam. × 35 cm. high).
D. Young evaporator still-head. 5 sections. (75 cm. high.)
E. Young and Thomas dephlegmator. 18 sections. (130 cm. high.)
F Lessing contact rings in plain tube (4 cm. diam. × 140 cm. high).

Fig. 2.

In fig. 2 the separating efficiency of a contact ring still-head is compared with that of a number of other still-heads, the classical example of a 1:1 mixture of benzene and toluene being selected. Curves A, B, and C are plotted from values given by Friedrichs (Z. angew. Chem., 1919, 32, 340); D and E are taken from Young's work (Trans. Chem. Soc., 1899, 75, 708). Curve F represents a distillation with a plain tube still-head 4 cm. wide and 140 cm. high filled with ¼-in. aluminium contact rings, at a rate of 60 drops per minute.

The dimensions of the various still-heads are stated on the graph, and although they are not directly comparable, the almost complete separation is very striking. Benzene and toluene distilled over to the extent of 47% and 48% respectively, each within 1°, leaving only 5% of the total mixture in the middle fraction.

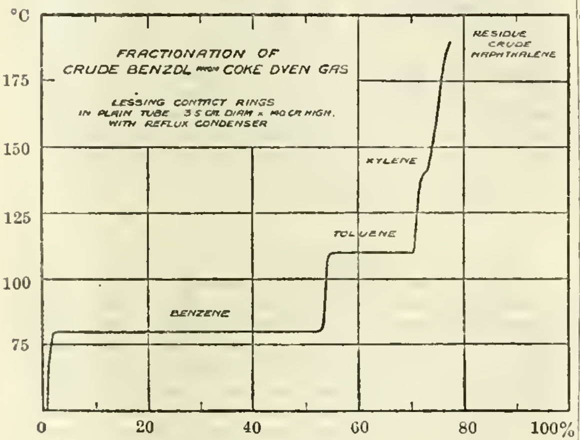


Fig. 3.

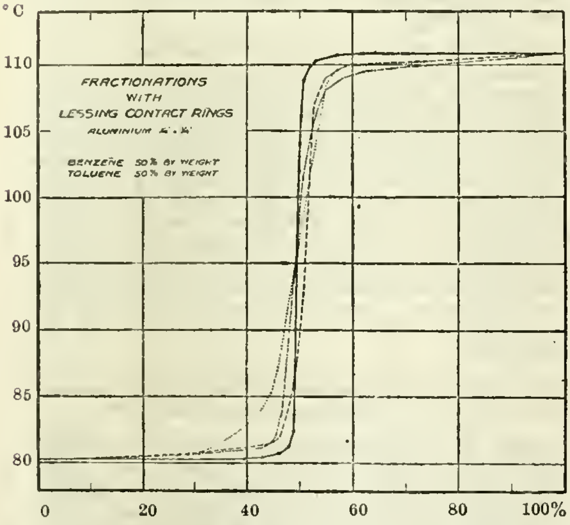
Fig. 3 shows the fractionation of a commercial sample of crude benzol obtained from the washing of coke-oven gas with creosote oil. In this case 2000 c.c. was distilled from a metal still in an oil bath with a ring-filled still-head 3·5 cm. diameter by 140 cm. high. A short reflux condenser was employed. These conditions explain the extreme sharpness of the curve, which even indicates the presence of a small quantity of xylene. The sample contained over 20% of naphthalene and wash-oil, and the residue solidified on cooling.

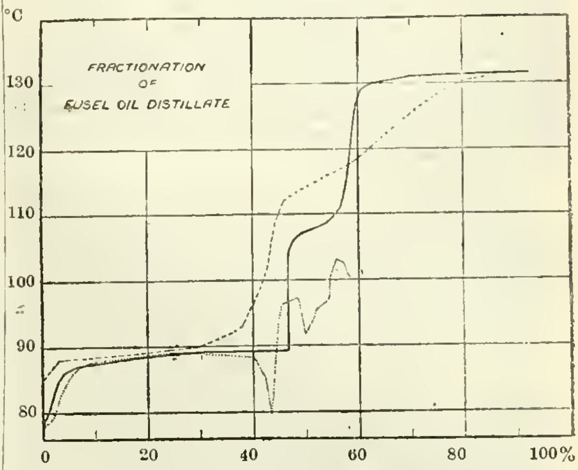


...... A. 11. 2·5 cm. diam. × 40 cm. high, lagged with cardboard. Reflux condenser.
- - - B. 7. 3 cm. diam. × 75 cm. high, unlagged.
-·-·- B. 5. 3 cm. diam. × 75 cm. high, lagged with cardboard except 10 cm. from top.
——— C. 8. 4 cm. diam. × 140 c.m. high, lagged with asbestos card except 10 cm. from top.

Fig. 4.

In fig. 4 four distillations are plotted in order to show the influence of the still-head dimensions, heat insulation, and reflux condensing. This graph proves clearly that a certain minimum of scrubbing surface is required in order to obtain the best results. Curve C8 is identical with Curve F in fig. 2.

Very interesting results were obtained in the fractional distillation of a commercial fusel oil distillate of sp. gr. 0·840 at 15°/15° C. The results of a preliminary distillation of this sample with a Young 12-pear still-head (fig. 5) show the type of curve obtained by the test customarily employed in many works laboratories.



- - - - - Young 12-pear-bulb column.
——— Lessing copper contact rings in plain tube 4 cm. diam. × 140 cm. high.
.... Lessing aluminium contact rings in same tube.

Fig. 5.

The following results were obtained on fractionating 1000 c.c. from a glass flask with a glass tube still-head 140 cm. high by 4 cm. wide, filled with ¼-in. copper contact rings and lagged with asbestos cord to within 10 cm. of the top. The exposed portion was covered with corrugated paper during the distillation of the fractions above 100° C. Rate of distillation 5 c.c. per minute. At 130·0° the still-head was replaced by a smaller one 40 cm. high by 2·4 cm. wide, and distillation continued at a rate of 7 c.c. per minute. This change accounts for the loss of 1·4%. Volume of distillate was noted for every rise of 0·2° and plotted in fig. 5.

Fractionation of fusel oil distillate with Lessing contact-ring still-head.

	Loss ..	—	1·4	—	—

In the preceding table the percentages of fractions as taken off, together with their specific gravities and refractive indices, are recorded.

Fraction I. contains a mixture of aqueous ethyl and *n*-propyl alcohols. The bulk of fractions II. and III. is propyl alcohol. The first drop of free water came over in repeated experiments at 89·1°, and sharply indicates the beginning of the isobutyl alcohol. Fraction IV. was collected in two layers, showing that the mixture of constant boiling-point contains more water than the alcohol is capable of dissolving at room temperature. The rise of temperature, after the last drop of water contained in the sample had distilled over, was so sudden that the curve shows an almost perfect right-angle at this point. The remainder of the isobutyl alcohol came over in anhydrous condition in fraction V., after which amyl alcohol was collected in the remaining fractions.

The distillation of the same sample, carried out under identical conditions except that aluminium rings were used in the place of copper ones, gave somewhat curious results, which seem worth recording. They are plotted in the dotted curve (fig. 5). This curve is, for the first 40% of distillate, practically identical with the copper ring curve, except for a slightly sharper separation in fraction I., probably due to the difference in the specific heat, and therefore rate of warming up of the two metals. The appearance of the first drop of free water at the same point has already been noted. After 40% of the distillate had come over, the temperature being constant at 89·1°, it suddenly dropped. At the lowest point reached, 79·6°, the escape of gas carrying white fumes with acrid smell was noticed. The thermometer then rose again repeatedly, when at 97·2° a similar drop and subsequent rise occurred, which was once more repeated at 103·0°. The distillation was then stopped, as a solid deposit was noticed in the distilling flask. The residue in the flask set solid on cooling, and after steam-distilling the alcohol from flask and column, the solid was found to be voluminous aluminium hydroxide, of which more than 200 g., equivalent to 35 g. of Al_2O_3, was collected.

The aluminium rings were found to be attacked very considerably, those in the lower layer being pitted and pierced with holes, and a good deal of metal was dissolved away. This observation confirms the results of previous workers (Gladstone and Tribe, J. Chem. Soc., 1876, **29**, 158; Seligman and Williams, J., 1918, 160 T), who found that the higher alcohols when anhydrous attacked aluminium violently, and that such action is inhibited by traces of moisture.

As an explanation for the abnormal distillation curve it is suggested that at the time when the temperature drop occurred the alcohol in the flask and lower part of the still-head was anhydrous. In reacting with the aluminium, alcohol was used up by the formation of aluminium butoxide to such an extent that the amount of vapour reaching the thermometer was insufficient to keep it heated. The failure of vapours to pass through the still-head caused air to diffuse back, and as the condenser was at that time wetted with a mixture of butyl alcohol and water, traces of the latter on reaching the rings stopped the reaction. Hence, the sudden rise and second drop of temperature when the water was again cleared out from the still-head and when this phenomenon was repeated. The most interesting feature in this connexion from the point of view of fractionation is the fact that when the action occurred, and judging from the experiment with copper rings, the column must have still contained 69 c.c. of the mixture of butyl alcohol and water of constant boiling point, partly in the form of vapour and partly in the form of condensate. The division between the moist and anhydrous portions of the column was therefore an extremely sharp one, and the rings acted as a perfect seal against moisture. Whilst this experience shows a drawback of aluminium, which in many cases is preferred to other metals, it indicates possibilities of usefulness of ring-packed still-heads which have not yet been exploited.

In conclusion, I wish to express my indebtedness to Professor Sydney Young, F.R.S., for his helpful criticism, to Mr. H. E. Burgess for permission to publish the graph and data of the fusel oil distillation, to Messrs. Barnsley Main Colliery Co., Ltd., for their permission in regard to the crude benzol curve, and to Messrs. C. H. Butcher, A. H. Raine, and F. S. Shadbolt for carrying out the experimental work and preparing the drawings.

DISCUSSION.

The **CHAIRMAN** asked Dr. Lessing if it would be possible by using the apparatus described to increase the strength of the ordinary 93½% industrial spirit. Those who in the course of their work used alcohol as a precipitant for dextrins, gums, etc., obtained large volumes of low strength alcohol (80%). It was tedious to use lime for dehydrating such spirit, and it would be a great convenience if the column was applicable in such a case.

Dr. M. W. **TRAVERS** said that the probability that any particular ring would be so placed that the opening at the side would be exactly at the bottom, which was the only condition under which it would facilitate drainage, appeared to be very small. The same remark applied to the opening between the edge of the feather and the inner wall. Would it not be better to make the rings of perforated metal?

Dr. R. C. **FARMER** asked if any definite comparisons had been made with the original plain rings and the present ones, which were split. In his experience the split rings tended to link together, and this would presumably interfere with their efficiency.

Dr. F. M. **PERKIN** said that channeling was very tiresome in most cases, and even in this case surely there was a chance of it taking place. In distillations in reference to benzol and toluol, he had used shell turnings, which was the only material available at the time, and to prevent channeling wooden rings were placed between the turnings, so that the vapour was diverted into the centre again. He found that extremely useful, and it was also useful in scrubbing. Working on the laboratory scale, he had prevented radiation by using a silica tube with pear-shaped condenser and an evacuated outer casing; this on a small scale worked very well, but on a commercial scale it would probably be too expensive.

Mr. **CHRISTENSEN** asked if rings of non-conducting metal would be preferable to aluminium.

Capt. C. J. **GOODWIN** said he was not satisfied that it was always necessary to have such a long tube as suggested by Dr. Lessing. He also thought it would be a good plan to decrease the size of the rings from the bottom upwards; that would lessen the surface and reduce the quantity that had to drain back, and the quantity of liquid that was retained on the filling. The size of the rings was really of very great importance, and experience showed that the greatest scrubbing surface was necessary at the top of the column.

Mr. P. **Parrish** said that Dr. Lessing had failed to deal with the practical aspect of the question, and there shauld have been some comparisons between the laboratory experiments and actual practical working. The author appreciated the importance of surface area and local pools as important factors affecting efficient fractionation, but he would find that columns of the character described when applied on the practical scale would be infinitely better if arranged in such a way as to afford actual and positive bubbling. The fractionation of alcohol was still effected on the large scale in Coffey stills, where bubbling was the salient principle.

Dr. H. P. **Stevens** asked for information as to the time taken to fractionate the liquid when comparing different distillation heads.

Dr. **Lessing**, in reply, said that so far the dimensioning of still-heads or scrubbers had been entirely empirical. The graduation of the rings, as suggested by Capt. Goodwin, had already been applied on the large scale. Dilute ethyl alcohol (80—93%) could easily be fractionated to a concentration of 95%; beyond that it became theoretically impossible. With regard to Dr. Travers' point, the majority of rings did get into a position where drainage was facilitated, even if some were lying with the gap on top. The liability of the rings to nest in each other was dependent on efficiency in manufacture, because, according to the thickness of the material, he thought it would be possible to make the slit of such a size that this would not happen. The trouble so far had been that they had not had sufficient control over the raw material; there was sometimes a spring in the material if it were not annealed to the correct hardness, and the rings then opened out more than they were intended to. He had tried the effect of dehydrating agents on alcohol fractions, but they were not of very great use. With any alcohol higher than propyl alcohol, with repeated distillations it was possible to get out practically 50% of the water each time, so that with two or three distillations it was possible to get 70 or 80% more of the alcohol in the anhydrous form without the aid of a dehydrating agent. With regard to the channeling, mentioned by Dr. Perkin, with shell turnings there would be the very difficulty which was avoided with rings, namely, a corkscrew action, which carried the condensate down and allowed the vapour to rise, whilst in the case of the rings it was broken and deflected. Vitreous rings could not be made on the small scale in the thin sections in which they would be required, and on the whole, he was inclined to the opinion that metal rings were preferable on account of their conductivity and quicker exchange of heat between the two phases. He did not agree with Mr. Parrish's remarks; a set of experiments had been carried out during the war on the debenzolisation of benzolised oil in which an ordinary distilling column of the bubbling type had been displaced by a plain gas pipe which had exactly half the cubic capacity of the other still, and was filled with rings; the debenzolisation efficiency rose from 60% to 92 or 93%, and inversely the purity of the mixture of benzol and toluol was increased to a similar degree, so that the benzol-extracting capacity of the return oil was about 90% as against 60—70% in the other case. He had found that channeling was very much more likely to happen with perforated rings than with solid rings; there was a straight run up the tube and dripping right down without the deflection which was obtained with the solid ring. The rate of distillation was very important and was recorded in every case. Generally a higher rate of distillation could be employed when contact rings were used without impairing the efficiency.

Meeting held at Textile Institute on March 4, 1921.

MR. JOHN ALLAN IN THE CHAIR.

NORMAL AMYLBENZENE AND SOME OF ITS DERIVATIVES.

BY L. GUY RADCLIFFE, M.SC.TECH., F.I.C., AND N. SIMPKIN, M.SC.TECH., A.I.C.

The present investigation refers only to normal amylbenzene and its derivatives, as considerable difficulty is experienced in preparing pure iso-amyl compounds, and the ordinary iso-compound is easily converted into a tertiary compound, whilst on the other hand straight-chain compounds can be readily obtained pure.

Normal amylbenzene, $C_6H_5.CH_2.CH_2.CH_2.CH_2.CH_3$, was discovered by Schramm (Annalen, 1883, 218, 388); its preparation by the action of sodium on a mixture of benzyl bromide and normal butyl bromide has been described in considerable detail. The hydrocarbon is a colourless liquid with an agreeable odour and boils at 200·5°—201·5° C. under 743 mm. pressure.

In the research to be detailed, Schramm's method of preparation was used with certain modifications, for example, benzyl chloride was used in place of the exceedingly unpleasant benzyl bromide, with good results. The adoption of this method was further influenced by the following considerations:—(1) Normal butyl alcohol can be readily obtained almost pure, whereas amyl compounds from which the required hydrocarbon could be made are extremely difficult to obtain pure. (2) The mechanism of the reaction is fairly simple. (3) It is possible that important derivatives of *n*-amylbenzene may be discovered and thus afford a means of utilising the considerable stocks of *n*-butyl alcohol which are available. In reality the reaction does not correspond exactly to the equation:—

$$C_6H_5.CH_2Br+2Na+Br.C_4H_9=C_6H_5.C_5H_{11}+2NaBr.$$

Subsidiary reactions occur in which, *e.g.*, two benzyl radicals unite to give the well-known dibenzyl and further, two butyl radicals couple to form *n*-octane; and it is clear that other reactions must take place, as there is always formed a large quantity of thick oil having a very high boiling point. The effect of these secondary reactions is to reduce the yield of *n*-amylbenzene to about 25% of the theoretical yield.

Experimental.

The first preparations of *n*-amylbenzene were made by treating a mixture of benzyl bromide and normal butyl bromide with sodium, the conditions being modified in various ways with a view to increase the yield of amylbenzene and decrease the amount of by-products; with this same object in view benzyl chloride was substituted for the benzyl bromide. The effect produced by diluting the reacting mixture with benzene was also exhaustively studied.

The investigation of the *n*-amylbenzene itself was, after determining its physical properties, mainly confined to a partial study of its sulphonation, in which was included the preparation and properties of a monosulphonic acid and its barium salt, also the corresponding sulphonic chloride and sulphonamide and a phenol. The constitution of the sulphonic acid has been determined, whilst the mononitro compound has been prepared and its properties investigated.

In order to establish the constitution of *n*-amylbenzene with certainty, *n*-amyl bromide was synthesised from *n*-butyl alcohol and coupled with bromobenzene in order to produce amylbenzene by a very different method. A comparison of this amylbenzene with that made by Schramm's method showed that they were identical. The *n*-butyl bromide used in the experiments was made by treating a mixture of commercial butyl alcohol (sp. gr. 0·8133 at 15·5° C., b.p. 115°—118° C.) and red phosphorus with bromine. Using 212 g. of the alcohol, 36 g. of phosphorus, and 255 g. of bromine, a yield of 87·7% was obtained. Many experiments were carried out in order to ascertain the conditions under which the best yield could be obtained.

The benzyl bromide was made by the direct bromination of boiling toluene, and the yield of pure product was about 60%, obtained in the form of a colourless liquid, b.p. 198°—202° C. This product kept well and did not appear to undergo decomposition even after standing for several months.

The benzyl chloride used in the experiments was obtained by the fractionation of the commercial product, the portion boiling from 176° to 179° C. being used for the experiments. It appears worth recording that much uncertainty exists as to the true boiling point of benzyl chloride.

The *n*-amylbenzene was prepared as follows, using 128 g. of benzyl bromide, 103 g. of *n*-butyl bromide, and 34·5 g. of metallic sodium. Sodium in the form of wire was added gradually to the mixed benzyl and butyl bromides; the temperature of the mixture soon rose to 35° C., whereupon it was cooled by immersing the vessel in water. After about one-fourth of the sodium had been added, the temperature being kept below 50° C., the action appeared to slacken and the mixture was heated to about 80° C. Fresh quantities of the sodium wire were added, and when about half the sodium had been added the mixture was allowed to stand overnight. The contents of the vessel now consisted of a solid layer (sodium bromide) surmounted by a pale yellow liquid. As the large amount of sodium bromide present apparently hindered the reaction, the mixture was diluted by the addition of 100 c.c. of dry benzene and gently boiled on the water-bath. The remainder of the sodium was gradually added, and the boiling continued for a further 25 hours to complete the reaction. At this stage the liquid was dark yellow in colour and possessed a pleasant odour, while the whole of the sodium had been converted into the bromide. The mixture was heated by means of an oil-bath, and about 60 c.c. distilled off. The residue was then steam-distilled to obtain the amylbenzene, which collected on the surface of the water as a bright, colourless liquid. Soon crystals began to appear in the distillate, whereupon the receiver was changed and steam distillation continued for another hour, making in all a total of 9 hours. The residue in the distillation flask consisted of the sodium bromide solution, upon the surface of which floated a thick, dark yellow oil. The white, needle-like crystals melted at 52° C. and were dibenzyl. The thick oil has not yet been investigated.

The colourless oil resulting from the steam distillation was carefully fractionated, and gave a 27·6% yield of crude *n*-amylbenzene, b.p. 195°—205° C. Further quantities of dibenzyl were also obtained. The yield is not good, and the secondary reactions resulting in the formation of dibenzyl, octane, and the high-boiling thick oil, are not at present clear.

It was found not to be advisable to dilute the reacting mixture with benzene at the beginning of the experiment. In the other preparations of amylbenzene, benzyl chloride was used with butyl bromide both with and without dilution with benzene, and it was found that the benzyl chloride gave just as good a yield as the benzyl bromide. As a result of many experiments, in which the conditions were slightly varied, it was concluded that the following conditions tend to give the best yield of amylbenzene:—

1. The sodium wire (sodium cut into slices was also used, but was slower in its action, especially towards the end of the reaction, unless the shavings were very thin) should be added slowly to the mixture of benzyl chloride and butyl bromide, the latter being in slight excess of the theoretical amount required, and the mixture shaken or frequently stirred.

2. The reacting mixture should not be diluted with benzene, and should be kept as cool as possible, *i.e.*, compatible with the continuance of the reaction.

3. To complete the reaction, it is advisable to let the whole mixture stand for a few days with an occasional shaking, since the application of heat, or the development of heat during the reaction, lowers the yield of amylbenzene and increases the amount of the higher boiling hydrocarbons. A diluent with a boiling point lower than that of benzene, such as pure dry ether (free from any alcohol), might give better results, as the mixture would boil at a considerably lower temperature.

Purification of crude amylbenzene.

The fraction boiling at 195°—205° invariably contained traces of the benzyl halide, and to remove this, the crude hydrocarbon was mixed with alcoholic potash and gently boiled in an oil-bath for 9 hours, after which the excess of alcohol was distilled off and the residue distilled with superheated steam. The upper layer of distillate was heated to 105° in contact with thin shavings of metallic sodium for 7 hours. The product was free from halogen. The still impure amylbenzene was then fractionated, using a 4-bulb column, and the product boiling between 200·5° and 202° C., under 761·2 mm. pressure, collected as pure amylbenzene. From careful observation the boiling point would appear to lie between 201° and 202° C. at 761·2 mm., agreeing with the figures given by Schramm, viz., 200·5°—201·5° C. under 743 mm.

Properties of n-amylbenzene.

Normal amylbenzene is a colourless liquid possessing a rather pleasant odour. It is readily soluble in alcohol, benzene, ether, carbon bisulphide, methylal, chloroform, carbon tetrachloride, and glacial acetic acid. If sulphuric acid is added to the hydrocarbon, drop by drop, a slight brownish sediment forms upon the addition of each drop, and with an excess of acid, or on warming, the amylbenzene dissolves (*cf. infra*). The hydrocarbon does not dissolve in cold 70% nitric acid, but does so on warming the mixture; on cooling, however, the amylbenzene comes out of solution. Further details of the nitration are given later.

The density was found to be:—at 15·5°/15·5° = 0·8664; at 15·5°/4° = 0·8651; at 22°/22° = 0·8624, and at 22°/4° = 0·8602. Schramm gave the density of his amylbenzene as 0·8602 at 22° C., but does not state whether this is compared with water at the same or some other temperature (*loc. cit.*). A quantity of amylbenzene was distilled, and the refractive index of each 5 c.c. of distillate determined by means of the Pulfrich instrument; the index in each case was $n_D^{15} = 1{\cdot}4751$.

Sulphonation of n-amylbenzene.

After a number of preliminary experiments had been performed, 10 g. of the hydrocarbon was sulphonated by the gradual addition of an equal volume of concentrated sulphuric acid, with frequent shaking. A brownish-white substance was produced with the addition of each drop of acid, and a slight development of heat occurred. After all the acid had been added the resulting mixture was a brownish-white liquid containing globules in suspension, presumably of unchanged amylbenzene, as the characteristic odour still persisted. To complete the reaction the contents of the flask were heated on the water-bath with frequent shaking for 2 hours, and finally for ½ hour over a small flame. The liquid, now dark brown in colour, was poured into about 250 c.c. of distilled water and neutralised with barium carbonate, followed by boiling for ½ hour and filtering. The filtrate rapidly deposited fine white, shining, needle-like crystals which appeared flaky when dry, and were very soft in texture; the residue, consisting of barium sulphate and carbonate, was repeatedly extracted with boiling water, and from each extract small crops of crystals were obtained upon evaporation. Each crop was analysed to determine whether mixtures of the mono- and disulphonic acids were formed under the above conditions. The theoretical percentage of barium in barium amylbenzenemonosulphonate, $(C_{11}H_{15}SO_3)_2Ba$, is 23·21%; by analysis, 23·26% was found. Further experiments led to a 54% yield of the monosulphonic acid being obtained; the barium salt crystallised without water of crystallisation.

Preparation of the sulphonic chloride and sulphonamide of n-amylbenzene.

To determine whether the barium amylbenzenemonosulphonate was a single isomer or a mixture of two isomers, a portion of each crop of crystals of the barium salt was converted into the sulphonic chloride and thence to the corresponding sulphonamide.

The sulphonic chloride was prepared by heating a mixture of the finely-powdered barium amylbenzenesulphonate with powdered phosphorus pentachloride on a water-bath for two hours, with occasional shaking, adding the mixture to water, and extracting the oil with ether. On evaporation the ethereal solution yielded a pale brown oil which solidified to flat, needle-shaped crystals of the sulphonic chloride; this melts at 38°—39° C., it has a peculiar unpleasant odour, and has the property of remaining liquid at the ordinary temperature for a considerable time. It is readily soluble in ether, petroleum spirit, chloroform, benzene, carbon tetrachloride, and carbon bisulphide, but is only sparingly soluble in cold alcohol.

The sulphonamide was prepared from each batch of sulphonic chloride by heating with powdered ammonium carbonate for about 2 hours, grinding the product with several quantities of cold water, and crystallising the pale brown substance thus obtained from dilute alcohol, from which the sulphonamide separated in white, hair-like, glistening crystals somewhat resembling glass wool. Every batch of crystals melted at the same temperature viz., 86°—87° C. It would thus appear that only one isomer was present in the barium salt, as obtained by the above method.

The sulphonamide was analysed by a modification of the Kjeldahl method, and was found to contain 6·18% of nitrogen. Calculated for $C_6H_4.(C_5H_{11}).SO_2.NH_2$, N=6·17%.

In order to determine the orientation of the sulphonic acid and its derivatives, the amylbenzenesulphonamide was oxidised by boiling with an alkaline solution of potassium permanganate (Pinner, Ber., 1888, 21, 243), and the sulphaminebenzoic acid isolated in the usual way and recrystallised from boiling water; it was obtained in small, flat, needle-shaped crystals, almost colourless, and melting at 278°—280° C. with decomposition. This observed melting point agrees with that of *p*-sulphamine-benzoic acid, whence it may be concluded that the acid formed by the sulphonation of *n*-amylbenzene as described above is *n*-amylbenzene-*p*-sulphonic acid, and further, that no appreciable quantity of any other isomer is formed.

The free sulphonic acid itself was obtained from the barium salt in the form of very hygroscopic, needle-shaped crystals, which were exceedingly soluble in water, and further, the potassium, silver, and calcium salts have been prepared.

n-Amylphenol.

About 5 g. of potassium amylbenzene-*p*-sulphonate was mixed with 14 g. of powdered caustic potash and transferred to an iron tube, sealed at one end. The powder was washed down with 2 c.c. of water and the mixture stirred. The temperature was gradually raised to 330°—340° C. and kept thereat for 1 hour, whilst a slow stream of hydrogen was passed into the top of the tube throughout the experiment to prevent oxidation of the phenol. After cooling, the dirty, greenish mass obtained was dissolved in about 40 c.c. of water and the solution acidified, whereupon a thick, pale brown oil separated on the surface. This oil was extracted with ether and distilled, yielding a colourless fraction, boiling at 262° C. and giving reactions corresponding to a phenol; it is very sparingly soluble in boiling water, readily soluble in caustic soda, ether, acetic acid, or alcohol; the alcoholic solution gave an olive-green coloration on the addition of ferric chloride, which was discharged by hydrochloric acid. When chilled in a freezing mixture, the amylphenol formed white crystals which melted at the ordinary temperature. It is not considered that this compound was obtained in a chemically pure condition. The benzoylamylphenol, made in the usual manner, crystallised from alcohol in white needles, m.p. 52° C. A bromo-derivative was also prepared by adding bromine to the amylphenol dissolved in glacial acetic acid and pouring into water; the product, after repeated crystallisations from dilute alcohol, was obtained in colourless crystals, m.p. 88°—89° C.

Nitration of the amylbenzene.

Attempts to nitrate amylbenzene with a mixed acid composed of sulphuric acid (sp. gr. 1·84) and nitric acid (sp. gr. 1·42) did not give very satisfactory results, as it appeared that nitration was not, in any experiment, complete. Mononitroamylbenzene was, however, obtained by the following method:—40 g. of fuming nitric acid (sp. gr. 1·508) mixed with 20 g. of glacial acetic acid was added slowly to 20 g. of amylbenzene dissolved in a further 20 g. of glacial acetic acid, the temperature being kept below 20° C. by external cooling; the mixture gradually turned brown in colour, and, after the addition of all the nitric acid, which occupied about 1 hour, was allowed to stand, when it separated into two layers. When the whole was heated for ½ hr. in a bath of water at 50° C., brown fumes were evolved and a homogeneous liquid was produced. After standing for 12 hours, the heating was resumed for a further hour, the mixture cooled and poured into water containing lumps of ice, whereupon a yellow, oily liquid was thrown down. The mixture was made alkaline with caustic soda solution and extracted with ether. The ether solution, after drying over anhydrous sodium sulphate, was distilled, leaving a yellow liquid having a characteristic odour, the bulk of which distilled under 14 mm. pressure at 158°—159° C. A determination of nitrogen gave a slightly high result, indicating possible contamination with a small amount of the dinitro-compound. Thus prepared, mononitro-*n*-amylbenzene is a pale yellow oil of sp. gr. 1·0650 at 15° C. and miscible with the usual organic solvents. When oxidised by the process used for the sulphonamide, *p*-nitrobenzoic acid, m.p. 236°—237° C., was obtained; it was concluded that the nitro-compound was *p*-nitroamylbenzene.

At this stage the preparation of *n*-amylbenzene by a quite different method was undertaken in order to be certain that the compound hitherto studied was in reality *n*-amylbenzene. The process chosen was to treat a mixture of monobromobenzene and synthetically prepared *n*-amyl bromide with metallic sodium, when the following reaction would take place:—$C_6H_5Br+2Na+BrC_5H_{11}=2NaBr+C_6H_5.C_5H_{11}$. For this reaction *n*-amyl alcohol was synthesised from *n*-butyl alcohol according to the method of Adams and Marvel (J. Amer. Chem. Soc., 1920, 42, 311—315). This, briefly described, entails the conversion of *n*-butyl alcohol to the nitrile *viâ* the intermediate stage of the butyl bromide, then the hydrolysis and esterification of the nitrile by means of 95% ethyl alcohol and strong sulphuric acid to give ethyl valerate, and finally the reduction of the latter by means of sodium and absolute ethyl alcohol to *n*-amyl alcohol. This synthetically prepared *n*-amyl alcohol was then converted into its bromide by means of the phosphorus halide method, and the resulting *n*-amyl bromide coupled with bromobenzene, using metallic sodium as usual. It is necessary to use absolute alcohol when reducing the ester with sodium, as otherwise the reaction fails. All the materials were highly purified at every stage. The final coupling of bromobenzene and *n*-amyl bromide with metallic sodium gave a product which was identical with that originally prepared by the interaction of benzyl chloride and butyl bromide. The outstanding feature of this last method of preparation is the fact that the yield of *n*-amylbenzene is between two and three times as great as in the previous experiments; it would thus appear easier to introduce an aliphatic side chain into a benzene ring than to add another group to an already existing side chain.

In concluding this paper, it may be mentioned that a highly-odourous aldehyde has also been obtained, but the work has been interrupted, and a description of this product cannot be given at present.

DISCUSSION.

Captain F. S. **SINNATT** said that *n*-amylbenzene would probably be converted into an α-methyl derivative of tetrahydronaphthalene with considerable ease; such a compound would have a very high boiling point and a considerable percentage might be present in the residual oil obtained by the authors, which might yield on examination some interesting compounds.

Mr. H. G. **SHATWELL** said if the ring were chlorinated and the end of the chain were also chlorinated, and the resulting compound treated with sodium, it might be possible to cause that ring to close as suggested. Had any attempt been made to reduce the nitro-compound described?

Mr. N. **SIMPKIN**, in reply, said that a large amount of work had already been done in America on the utilisation of butyl alcohol. Apparently the oil might contain such a substance as benzylamylbenzene. In reply to Mr. Shatwell, certain chlorine derivatives of this hydrocarbon had been prepared, but it had been found that instead of the end of the chain being chlorinated, a mixture of compounds resulted. Furthermore, in order to produce a naphthalene ring as Mr. Shatwell suggested, the side chain would require to be chlorinated at the δ-carbon atom, not the ε- or end carbon atom, in order to couple up with the benzene ring. The compound had been brominated, and several distinct compounds with 1, 2, and 3 atoms of bromine obtained, but not in the pure state. The nitro-compound had not been reduced owing to lack of time.

PROF. P. PHILLIPS BEDSON IN THE CHAIR.

THE EFFECT OF SOME PHYSICAL CONDITIONS ON CALCIUM SULPHATE CEMENTS.

BY C. L. HADDON.

Anhydrous calcium sulphate cement bears a number of different names, such as flooring plaster, "Estrich gips," and dead-burnt plaster. A slightly modified form is called Keene's cement.

The actual setting time of flooring plaster depends on the temperature and duration of heating used in its manufacture, but subsequent conditions have the same comparative effect on different samples of plaster.

It was long ago shown that the setting of flooring plaster is due to the anhydrous salt dissolving and being precipitated as crystals of the less soluble dihydrate. These crystals in dilute solutions form radiating bundles of needles, and it was assumed that this occurred in its use as a cement, and that fracture of the cement was caused by the breaking of the interlocking crystals. It was also shown by using a dilatometer that in setting there was first a contraction followed by an expansion. This was explained by Davies as being due to the formation of orthorhombic crystals spontaneously changing to monoclinic crystals. Data as to its superficial expansion—the more important from the practical point of view—are lacking. According to Lunge's "Technical Methods of Chemical Analysis," "increase in volume is not a property of dead-burnt plaster." On the other hand, other authorities state that it expands on setting, but no figures are given. The apparatus used for measuring expansion was Le Chatelier's, as laid down in the Engineering Standards' specification for Portland cement. The dimensions of this instrument are so designed that for relatively small expansions (less than 1%) the measured expansion in centimetres is approximately equal to the percentage linear expansion. It is not a suitable instrument for measuring expansion during the plasticity stage of setting.

The same flooring plaster was used throughout these experiments. Three parts by weight of plaster was mixed with one part of water or solution and placed in the cylinder, and the expansion was measured at different times. The subjoined table shows that:—

(1) The expansion was least when accelerating solutions were used, and greatest when retarders were used.

(2) Wet set plaster, using a 5% solution of a sulphate as accelerator, although reaching its maximum strength within 24 hours, yet continued to expand during recrystallisation.

(3) Wetness has a great effect on tensile strength. With plaster kept weakened in this way, a very much greater expansion resulted. The degree of wetness affects expansion.

(4) The expansion under normal conditions is very small—about 0·1%—and ceases within seven days, *i.e.*, the time for complete setting or drying.

In the case of calcium chloride the expansion was measured after the first day; a further expansion of 0·7% took place when thoroughly re-wetted due to drying before complete hydration.

No attempt was made to measure expansion while the cement was still plastic.

The cause of the expansion is obvious—it is due to the pushing apart of the mass by crystals as they are formed. An expansion of 5% can easily be produced by using a retarder, and keeping the cement wet.

In dry room.	% Expansion from time of loss of plasticity.			
	1 day.	4 days.	7 days.	14 days.
Mixed with water..	0·08	0·12	0·17	—
„ 5% soln. $CaCl_2$	—	0·40	0·75	0·97
„ 5% soln. K_2SO_4	0·06	0·07	0·08	No further increase.
„ 5% soln. $FeSO_4$	0·06	0·07	0·08	
Mixed with water placed in water after 1½ hrs.	1·0	1·5	1·85	—

The amount of expansion has an effect on the tensile strength. Briquettes which have expanded 5% have less than a quarter of the strength of similarly made briquettes allowed to dry in air, when the expansion is very much less. Similarly, in test-pieces where the plaster was placed in water six hours after making the briquette, and the briquette broken after seven days when still wet, the tensile strength averaged 200 lb. per sq. in., while when the briquette was allowed to dry in air and placed in water only for the seventh day, the average tensile strength was 250 lb. per sq. in.

In a recent paper (J., 1920, 165—168 T) the author mentioned the weakening of flooring plaster by wetness, and it was suggested that it was due to the lubricating action of water. In order to investigate this, test-pieces were placed in water after six hours, taken out after 14 days, and then left in a warm, dry room till they ceased to lose weight. Briquettes were immersed in different liquids for 24 hours and then broken.

The average tensile strength of the dry briquettes was 470 lb. per sq. in.; after immersion in paraffin it was 470 lb.; in thin lubricating oil, 470 lb.; in methylated spirit, 470 lb.; in a mixture of 2 pts. of spirit to 1 of water, 320 lb.; in a mixture of 1 part of spirit to 2 of water, 250 lb.; in water, 200 lb.; and in concentrated calcium sulphate solution, 200 lb. The test with thin lubricating oil gave the same result at the end of 10 days; figures identical with those of the 24-hr. tests were also obtained with water (10 mins.) and concentrated calcium sulphate solution (1 hour).

Thus mineral oils have no effect on strength, while with mixtures of alcohol and water the loss in strength is dependent on their proportions. Water reduces the tensile strength by one half, as does a concentrated solution of calcium sulphate. Leaving in water for ten minutes, provided that the whole cross-section of the cement is wetted by capillary action, has the same effect, showing that it is not due to solubility of the set cement in water. The small amount of water necessary is shown by the fact that if one end of the test-piece is placed in water, the same weakening effect is produced by the water creeping up through capillarity. In the same way crushing strengths are reduced from about 2 tons per square inch to half that amount.

There is no accepted explanation of lubrication. It seems curious that oil should not act as a lubricant, while water does. Oil certainly acts as a lubricant when one slab of set flooring plaster is rubbed over another. In metals, the crystals are supposed to be covered with some amorphous intercrystalline cement which is stronger than the crystals, which break in cases of fracture. It is possible that some such amorphous calcium sulphate dihydrate exists, and this is affected by free water. Our present knowledge of physical phenomena is not sufficient to justify a full explanation.

The cementing power of calcium sulphate cement may be described as follows:—Crystals of the dihydrate grow in the form of needles, until there is great frictional resistance to disruption and also interlocking. Breaking is due largely to this frictional resistance being overcome, and not to the breaking of the crystals themselves, as is the case with metals.

The value of all published data on the mechanical strength of flooring plaster is impaired by the fact that no standard has been laid down as to the condition of the briquette on breaking. The popular method seems to be to keep the briquettes in a more or less damp room during setting. The effect of different amounts of free water would considerably vitiate the results. The fairest way is to do precisely as is done with Portland cement—leave the briquettes in the moulds for 24 hours, take them out and place them in water, and then break the wet briquettes after a week; this would give comparable results as regards the effect of expansion, and eliminate error as regards wetness. The proportion of flooring plaster to water by weight should be 3 to 1, as this gives a plastic mass of uniform composition, while deviations from these proportions give cements of different strengths.

Communications.

A MODIFICATION IN THE COMPOSITION OF IODINE SOLUTION FOR THE REICH TEST.

BY H. M. LOWE, M.SC.

Standard iodine solution used for testing gases for sulphur dioxide may be conveniently made by substituting for the potassium iodide in which the iodine is dissolved a proportion of caustic soda, insufficient to react with the whole of the iodine, but sufficient to form enough sodium iodide to dissolve the remaining iodine. The formula recommended is: Iodine, 127 g.; caustic soda, 30 g.; water, to 10 litres. Thus the 30 g. of caustic soda replaces 150—180 g. of potassium iodide. The iodine reacts with this to give a solution of iodide and iodate and is quantitatively released as free iodine on acidification with a large or small excess of acid. The sulphur dioxide in the gas it is desired to analyse acts in this way in $N/10$ solution without further addition of free acid. When the solution is used in great dilution, *e.g.*, $N/100$ to $N/1000$, as in treating exit gases, it is necessary to add some acid previous to use.

Experiments with this solution showed that the theoretical amount of iodine is always liberated on acidification, whether with a large or small excess of acid. Titration with standard thiosulphate of the iodine thus liberated forms a convenient method of standardising the solution for use. It is immaterial whether the acid is added all at once to the iodine or in small portions as the titration proceeds, but the latter method avoids the iodine being thrown out of solution at any time.

If desired the solution may be titrated with free SO_2 without addition of acid.

Comparison tests on the inlet gases to a Grillo oleum plant showed identical results with the ordinary solution or with the modified solution.

When the solution is diluted to 10 times its bulk it forms a reagent for testing the exit gases from the converter. In this case it is necessary to add to the solution to be tested a small amount of sulphuric or hydrochloric acid together with the starch indicator, as at the dilution used (about $N/1000$) a very appreciable concentration of acid is required before the iodide and iodate react instantaneously. At a dilution of $N/2000$ and a bulk of 200 c.c., on the addition of 6 c.c. of $N/10$ H_2SO_4 to a neutral mixture of iodide and iodate, a blue colour develops slowly; with 7 c.c., however, the colour is obtained instantaneously. In the test, therefore, the addition of 1 c.c. of 10% H_2SO_4 is ample to ensure the instantaneous working of the indicator.

The sulphur trioxide present, together with the dioxide at the exit of the converter, would be thought to provide the necessary acidity, and, indeed, usually does so; but on one or two occasions the test failed, and the blue colour was discharged prematurely; it was found, however, that the addition of a little acid caused the blue colour to be reformed. It is therefore advisable always to add a little acid to the test solution before commencing.

The $N/100$ solution may be standardised against thiosulphate in the same way as the $N/10$ solution and titrated with sulphur dioxide solution after acidification. Tested on exit gas from a Grillo converter the $N/100$ solution gave results identical with those using the ordinary potassium iodide solution.

The $N/10$ solution is sufficiently stable for ordinary purposes. Thus, a 10-litre bottle kept full showed no change in strength after a month, and one half full showed no change in strength after eight days.

H.M. Factory, Gretna.

THE ESTIMATION OF RESIN ACIDS IN FATTY MIXTURES.

BY DAVID MCNICOLL, M.A., B.SC.

Twitchell's method for the estimation of resin acids in fatty mixtures (J., 1891, 1804), though it was a distinct advance on the methods then known, has many faults, as pointed out by Lewkowitsch (J., 1893, 502). Since that time no improvement has been made as regards accuracy accompanied by simplicity. The method detailed in this paper not only eliminates the faults of Twitchell's method but simplifies it by the substitution of methyl for ethyl alcohol and of naphthalene-β-sulphonic acid for gaseous hydrogen chloride.

It is well known that with Twitchell's method, resin acids undergo decomposition with the production of water-soluble acids of lower molecular weight, and it is the formation of these in varying amount which causes the irregular results. Lewkowitsch has also shown that esterification of the fatty acids is far from being complete.

Volumetric method.—About 2 g. of the mixture is dissolved in 20 c.c. of a 4% solution of naphthalene-β-sulphonic acid in dry methyl alcohol and heated under a reflux condenser for 30 mins. with the addition of several pieces of porous plate to ensure regular ebullition. A blank experiment with 20 c.c. of the sulphonic acid solution is also carried out for the same time, as the titration value increases slightly during the process. The best results are obtained by heating the flasks on an electric plate or asbestos wire gauze or in an oil-bath; esterification is not so complete when a water-bath is used. The contents of both flasks are then cooled and titrated with $N/2$ methyl alcoholic potassium hydroxide solution. For unknown mixtures the resin acids are calculated on the combining weight of 346, as suggested by Lewkowitsch.

Gravimetric method.—The neutralised solution obtained above is employed. The contents of the flask are transferred to a separating funnel—the volume being noted—and the flask washed out with an equal volume of water made slightly alkaline with potassium hydroxide. After shaking, the mixture is extracted with an equal volume of a mixture of ether and petroleum spirit, the flask having again been washed with the solvent. Separation is instantaneous. The small amount of insoluble soap that usually separates is drawn off with the soap solution, which is extracted twice in similar fashion. The united extracts are washed with a little 50% aqueous alcohol and the washings added to the resin soap solution, which is then acidified and extracted twice with ether.

Esterification of fatty acids.—Pure fatty acids are completely esterified by the method described, as shown by the following figures:—

	c.c. N/2 KOH used.	
	Experimental.	Blank.
Cotton oil fatty acids, 2 g. ..	8·50	8·50
Oleine, 2 g...	8·52	8·50
Palm kernel acid oil, 2 g.	8·57	8·50

The distilled olein, ruby red in colour, showed by titration after treatment the presence of 0·14% of free fatty acids calculated as oleic acid. With the palm kernel "acid oil" an acidity of 0·51% as oleic acid was found. The residual acidity in these two cases is doubtless due to colouring matter which, while being of an acid nature, is not esterified.*

Lewkowitsch has shown (*loc. cit.*) that Twitchell's method leaves 2—6% of fatty acids uncombined.

Treatment of resin.—On submitting resin to the process, partial esterification takes place amounting to 1—3% of the resin acids present; the amount varies for different qualities of resin.

A number of mixtures of known composition were examined by the methods described; the errors in the volumetric method varied between −0·22 and −0·56% and in the gravimetric method between −0·38 and +0·35%. The results obtained by Twitchell's method (as quoted by Lewkowitsch) show errors varying between −9·73 and +5·26%.

The following results were obtained from three different samples. In each experimental figure the value of the blank test has been deducted:—

Resin, g.	Before treatment. c.c. N/2 KOH.	After treatment. c.c. N/2 KOH.	Resin found. %
1·0473	6·00	5·93	98·8
2·4295	14·32	14·02	97·9
1·2159	7·08	6·90	97·4

That esterification had occurred was confirmed by saponification, 1·2 c.c. of $N/2$ potash being absorbed in the first experiment. The difference from the esterification value can be accounted for by oxidation of the alcohol.

That there is no appreciable production of water-soluble-decomposition products was proved in the first experiment by the recovery of 1·0375 g. of resin, which absorbed 5·88 c.c. of $N/2$ potash after evaporating the resin soap solution, dissolving in water, and extraction with ether after acidification.

Examination of mixtures of known composition.

Details of the examination of three mixtures by volumetric and gravimetric analysis are recorded below; in the experimental figures the value for the blank has been deducted.

Mixture.		Volumetric method.				Gravimetric. Resin. % Found.*
		Titration. c.c. N/2 KOH.		Resin. %		
Fatty acid.	Resin.	Calc.	Found.	Calc.	Found.	
2·0391	0·2652	1·53	1·57	11·51	11·84	11 73
1·4320	0·6091	3·46	3·52	29·84	30·28	30·23
1·0624	1·0080	5·73	5·70	48·69	48·45	48·88

* The amounts of resin found are corrected for the 5% unsaponifiable matter present.

Research Laboratory,
British Oil and Cake Mills, Ltd., Hull.

* Further experiment has substantiated this assumption. The estimation of true fatty matter in the by-products from the refining of cotton oil will be dealt with in a later paper.

A DIRECT METHOD FOR THE DETERMINATION OF DICYANODIAMIDE.

BY ERLING B. JOHNSON.

R. N. Harger (J. Ind. Eng. Chem., 1920, 12, 1107; J., 1921, 92 A) has recently described a gravimetric process for the determination of dicyanodiamide (cyanoguanidine) in cyanamide and mixed fertilisers, based on the precipitation of a compound of silver picrate and 1 mol. of dicyanodiamide, $C_6H_2(NO_2)_3OAg,C_2H_4N_4$.

Some years ago the present author, working with Mr. Berbom, isolated the same complexes as those described by Harger in the attempt to obtain a method for the determination of dicyanodiamide, but as it was important to have as rapid a method as possible, a volumetric process was worked out.

It is practically impossible to determine dicyanodiamide volumetrically by means of the above compound on account of the large excess of silver solution which must be used. On the other hand, it was found that under certain conditions the compound of silver picrate with 2 mols. of dicyanodiamide was so insoluble and changed so slowly into the mono-compound, thus:—

$$C_6H_2(NO_2)_3OAg,2C_2N_4H_4+C_6H_2(NO_2)_3OAg= 2C_6H_2(NO_2)_3OAg,C_2N_4H_4$$

that a volumetric method could be based on the determination of the amount of standard silver solution used to effect the precipitation. It is necessary to use weak solutions, a low temperature, and excess of picric acid.

The method is carried out as follows: When the sample being analysed contains 5—15% of dicyanodiamide nitrogen 5 g. is used, or a correspondingly larger amount if less nitrogen is present. The sample is transferred to a 500 c.c. flask and 450 c.c. of cold water added. If the sample is calcium cyanamide or other product containing lime, glacial acetic acid is added to bring all the lime into solution as acetate. By this means the nitrogenous compounds present are dissolved much more rapidly and completely than without any acid. A small excess of acetic acid does not matter. Stronger mineral acids isomeriso the nitrogen compounds. The solution obtained with acetic acid is suitable for a Kjeldahl determination of the total water-soluble nitrogen, but this is not possible if nitric acid has been used, as has been suggested, to shorten the period of shaking.

The flask is shaken in a machine for 3 hours, the solution is made up to 500 c.c. and filtered; 5 c.c. of 20% nitric acid is added to 100 c.c. of the filtrate, followed by 20 c.c. of sodium picrate solution heated to 40° C. (7·5 g. of picric acid neutralised with caustic soda and diluted to 100 c.c.), and the solution is cooled to about 5° C., and titrated with $N/22·4$ silver nitrate solution, which is added drop by drop with constant shaking. About 2 c.c. more silver solution is used than is required by the amount of dicyanodiamide believed to be present. The dicyanodiamide compound is precipitated in a more or less gelatinous form according to the amount of dicyanodiamide present. After vigorous shaking the mixture is stood aside for fifteen minutes at 5° C., during which time it is agitated two or three times, then diluted to 200 c.c. with cold water, shaken and filtered. The excess of silver solution used is estimated by titration with $N/22·4$ sodium thiocyanate in 100 c.c. of the filtrate after adding a further 5 c.c. of 20% nitric acid and about 2 c.c. of 5% ferric sulphate solution as indicator.

If 5 g. of the sample has been treated according to the method described, every c.c. of silver solution used corresponds to 1% of nitrogen as dicyanodiamide.

To obtain good results some corrections must be applied, but each observer should work these out for himself, as they will depend largely on the personal equation.

The corrections as worked out by the author are shown in the following tables.

Influence of the excess of silver solution.—As the compound of silver picrate with 2 mols. of dicyanodiamide changes into the compound with 1 mol. in presence of excess of silver salt, it is possible that such excess may influence the results. This is shown in the following table. Pure dicyanodiamide was used with the addition of 1 c.c. of 20% nitric acid.

Dicyanodiamide-N.	Excess of silver solution.				
	2 c.c.	3 c.c.	4 c.c.	5 c.c.	6 c.c.
0·05 g.=5%	98	103·6	103	105·3	108
0·10 g.=10%	99·5	99·7	100	100·9	101·5
0·15 g.=15%	97	97	97·5	98	98·7

Note.—In this and the succeeding tables the figures given are the percentages of the amount actually present.

Influence of increasing addition of nitric acid.

Dicyanodiamide-N.	Excess of 20% nitric acid.		
	1 c.c.	5 c.c.	10 c.c.
0·05 g.=5%	98	94·8	90
0·10 g.=10%	99·5	97·4	95
0·15 g.=15%	97	96·4	95·5

Influence of nitric acid and different amounts of calcium acetate (the latter would he present in analysing samples of calcium cyanamide or other products containing lime).

Dicyanodiamide nitrogen.	Additions.						
	Nitric acid.	1 c.c.	1 c.c.	1 c.c.	5 c.c.	5 c.c.	10 c.c.
	Calcium acetate.		1 g.	5 g.	1 g.	5 g.	5 g.
0·05 g.=5%	—	98	90	80	102	82·4	84
0·10 g.=10%	—	99·5	98	89	99·8	92·4	95
0·15 g.=15%	—	97	98·7	94·7	97·5	95·3	96

Influence of temperature on the precipitation.—2 c.c. excess of silver solution was used in each case.

Dicy. N present.	5° C.	10° C.	15° C.	20° C.	25° C.
0·10 g.=10%	99·6	98	96·4	90·5	85·1
0·05 g.=5%	98	95·5	92	85·5	70

It will be obvious that when working with calcium cyanamide the use of 5 c.c. of 20% nitric acid per 1 g. of calcium acetate present and the addition of 2 c.c. excess of silver solution will give good results without any corrections.

A characteristic feature of the precipitation of dicyanodiamide with a greater excess of silver solution and picric acid is the change of the gelatinous di-compound first precipitated into the small crystals of mono-compound; this occurs more or less rapidly according to the excess of silver and the concentration.

The method has been tested in the presence of urea and dicyanodiamidine (guanylurea), but neither of these compounds was found to influence the results.

The following table shows the reliability of the method and gives the results of the analyses of very old samples of calcium cyanamide.

When chlorides and soluble sulphides are present a blank test must be carried out by titrating the silver solution without addition of picric acid.

Sample.	New method (picrate).				Old method (modified Caro).			
	Cyanamide nitrogen.	Dicyano-diamide nitrogen.	Urea nitrogen.	Total.	Cyanamide nitrogen.	Dicyano-diamide nitrogen.	Urea nitrogen.	Total.
1	1·11	10·67	1·14	12·92	1·11	10·62	1·21	12·94
2	0·86	10·16	1·96	12·98	0·86	9·94	1·89	12·69
3	0·86	10·31	1·27	12·44	0·86	10·22	1·29	12·37
4	0·77	10·49	1·59	12·85	0·77	10·51	1·62	12·90
5	1·12	10·44	0·96	12·52	1·12	10·46	1·00	12·58
6	13·25	1·76	0·45	15·46	13·25	1·80	0·4	15·45

Further research showed that the formation of dicyanodiamide-silver complexes is not limited to picric acid. The reaction is typical of all nitrophenols which are soluble in water. Compounds of the silver salts of dinitrophenol, trinitroresorcinol, and trinitrocresol with one and two mols. of dicyanodiamide have been isolated; of these, trinitroresorcinol (styphnic acid) seems to give a more nearly quantitative precipitation and better results than picric acid.

Odda, Norway.

NOTE ON THE DETERMINATION OF UREA IN FERTILISERS.

BY ERLING B. JOHNSON.

The method used in this laboratory for the determination of urea in fertilisers and fertiliser mixtures depends on the well-known fact that urea forms a characteristic, slightly soluble salt with oxalic acid. By using the necessary precautions the solubility of the oxalate can be made so small that a quantitative determination is possible. The following method was developed: 2—5 g. of the dried sample containing urea is extracted with 100 c.c. of anhydrous amyl alcohol, 25—50 c.c. of the filtrate is treated with an equal volume of ether, and the urea precipitated as oxalate by the addition of 25 c.c. of a freshly prepared 10% solution of anhydrous oxalic acid in amyl alcohol. The vessel is stirred and allowed to stand in cold water for half an hour and the precipitate collected on a Gooch crucible, washed first with a mixture of equal volumes of amyl alcohol and ether, and then with ether alone, the volume used in each case being about one and a half times the capacity of the crucible. The precipitate is dried in a vacuum desiccator and weighed. It contains 26·67% of nitrogen and 57·01% of urea according to the formula $H_2C_2O_4,2CO(NH_2)_2$.

The appended table shows the necessary corrections as regards solubility:—

Urea found. g.	Percentage of actual amount present.
0·005	90
0·01	92·8
0·02	95·2
0·04	97·5
0·05	98
0·08	98·8

In some cases the urea is present as a salt or in complexes such as $Ca(NO_3)_2,4CO(NH_2)_2$, in which form it does not dissolve completely in amyl alcohol. In such cases the urea must be liberated.

It is important that the reagents and samples used should be as free from water as possible.

Odda, Norway.

NOTE ON THE ESSENTIAL OIL FROM THE LEAVES OF SKIMMIA LAUREOLA.

BY JOHN LIONEL SIMONSEN.

Skimmia laureola, Hook. f., is an extremely aromatic evergreen shrub which grows throughout the temperate Himalayas from Murree to Mishmi and Khasia Hills. It is also a common undershrub in the Dun Hills. The oil obtained by the steam distillation of the leaves was found to consist mainly of *l*-linalyl acetate, whilst in addition a hydrocarbon, *l*-linalool, and a complex mixture of sesquiterpene alcohols and esters were isolated.

Experimental.

The oil used in these experiments was obtained by the distillation in steam of the shade-dried leaves, a steam pressure of 25 lb. being maintained during the distillation. The yield of oil averaged about 0·5% on the dry leaves.* The oil, which was pale emerald green in colour, had the following constants:—Sp. gr. at 30°/30° 0·9041, n_D^{30}=1·4648, acid value 3·63, saponification value 197·96, saponification value after acetylation 238·6.†

After washing with dilute alkali to remove the traces of free acid present, the oil was fractionated under diminished pressure (200 mm.), when the following fractions were obtained:—145°—160°, 18·5%; 160°—165°, 5·7%; 165°—175°, 38·6%; 175°—180°, 7·3%; 180°—190°, 9·4%; 190°—240°, 13·8%; loss and residue (by difference), 6·7%. The fractions distilling above 175° C. were all more or less deeply coloured, the colour varying from emerald-green to deep indigo-blue. The higher boiling fractions also showed a beautiful blue fluorescence, but careful tests indicated the absence of methyl anthranilate.

On further prolonged fractional distillation under diminished pressure (200 mm.) the following fractions were ultimately isolated:—(I) 130°—140°, 0·46%; (II) 140°—145°, 4·6%; (III) 145°—150°, 0·61%; (IV) 150°—155°, 8·4%; (V) 155°—160°, 2·3%; (VI) 160°—167°, 2·0; (VII) 167°——173°, 50%; (VIII) 173°—177°, 0·61%; (IX) 177°—182°, 1·05%; (X) 182°—190°, 1·2%; (XI) above 190°, 18·2%.

Fractions I, II, and III appeared to consist essentially of a hydrocarbon. On redistillation a

---

* The yield of oil and also the ester content varied considerably with the time of collection. Leaves collected in the Chakrata Division during June and early July gave the above mentioned yield of oil, whilst those collected at the end of July and early August contained a much lower percentage of oil. On the other hand, a sample of leaves collected in the middle of August gave a yield of 1% of oil.

† Prior to acetylation the oil was mixed with turpentine as recommended by Boulez (Bull. Soc. Chim., 1907, 4, I., 117).

considerable fraction was obtained boiling at 130°—135° (200 mm.) and at 176°—182° (695 mm.). Analysis gave C=85·5, H=11·6%, whilst the following constants were observed:—Sp. gr. (30°/30°) 0·859, $n_D^{30}=1{\cdot}471$, $[\alpha]_D^{30}=-4{\cdot}11$. The boiling point suggested that the hydrocarbon consisted largely of terpinene, but attempts to confirm this were unsuccessful. Treatment with sodium nitrite and acetic acid in petroleum solution resulted in the production of only the merest trace of a nitrosite, which separated in fine needles melting indefinitely at about 130°; too little was, however, obtained for recrystallisation and analysis. When oxidised with potassium permanganate in ice-cold solution in the usual manner no trace of erythritol or αα′-dihydroxy-α-methyl-α′-isopropyladipic acid was isolated. The nature of the hydrocarbon present in the oil must therefore for the present remain undecided.

Fraction IV consisted of nearly pure *l*-linalool, since on treatment with phenyl isocyanate in the usual manner an excellent yield of linalyl phenylurethane, m.p. 65° C., was obtained.

Fractions V and VI were found to be a mixture of *l*-linalool and *l*-linalyl acetate. After hydrolysis with alcoholic potassium hydroxide an oil was obtained which boiled constantly at 150°—152° (200 mm.) and showed all the properties of linalool. Acetic acid was isolated from the alkaline solution.

Fraction VII, which comprised the bulk of the oil, distilled mainly at 112° (20 mm.), and had the following constants:—Sp. gr. (30°/30°) 0·892, $n_D^{30}=1{\cdot}4537$, $[\alpha]_D^{30}=-7{\cdot}25°$. (Found C=73·9, H=10·1; calc. C=73·5, H=10·2%.) This fraction was pure *l*-linalyl acetate, as shown by hydrolysis, when *l*-linalool and acetic acid were obtained.

Fraction VIII gave on analysis C=74·4, H=10·0%, and was evidently nearly pure linalyl acetate. This was confirmed by hydrolysis when linalool and acetic acid were obtained.

Fraction IX, like fraction VIII, also consisted essentially of linalyl acetate. On hydrolysis linalool contaminated with a trace of a high-boiling alcohol and acetic acid were obtained.

Fraction X was not analysed. On hydrolysis it yielded acetic acid and a mixture of linalool and a high-boiling alcohol. The latter was not obtained in sufficient quantity for examination.

Fraction XI, boiling above 190° (200 mm.), was repeatedly distilled at 43 mm., but no constant boiling fraction could be isolated. Analyses of the various fractions, which were all deeply coloured, showed a carbon content varying from 76·1 to 81·0% and a hydrogen content varying from 10·3 to 11·2%. No more satisfactory results were obtained after hydrolysis of the various fractions, and further investigation of the somewhat unpleasant smelling oils was abandoned.

In conclusion the author wishes to thank Mr. Puran Singh for placing the results of the preliminary experiments at his disposal, and his assistant, Mr. T. P. Ghose, for making most of the analyses.

Dehra Dun, India.

NOTE ON THE PRODUCTION AND TESTING OF ZIRCONIA.

BY W. R. SCHOELLER, PH.D.

Several of the processes which have been proposed for extracting zirconia from Brazilian ore are based on the precipitation of zirconium as a basic sulphate (*cf.* Rossiter and Sanders; J., 1921, 70 T). The chief aim of these processes is the elimination of iron, generally without regard to the simultaneous removal of any titanium present. Thus, Rossiter and Sanders' method, though shown to effect a quantitative precipitation of zirconia free from iron, admittedly fails to eliminate titania. This is not surprising, considering the readiness with which titanium sulphate is hydrolysed in a hot, feebly acid solution. It is remarkable, however, that the Brazilian ore experimented upon by Rossiter and Sanders was found to contain only "traces of titanium," and this statement may convey an erroneous impression that the ore from the Brazilian deposits is almost free from titania. Analyses of samples representing large shipments proved titanium to be a regular constituent of the Brazilian ore in quantities varying from 0·6 to 1·2%. The principal constituents of six samples are given in Table 1; the analyses were carried out according to the method of Powell and Schoeller (Analyst, 1919, 44, 397; J., 1920, 67 A). Small amounts of lime and magnesia were also present.

TABLE 1.

	A.	B.	C.	D.	E.	F.
ZrO_2	79·68	77·47	76·18	68·82	56·56	63·50
SiO_2	14·70	10·32	15·68	21·30	28·11	28·04
TiO_2	0·68	0·98	1·29	1·12	0·65	1·04
Al_2O_3	1·78	1·68	1·45	2·52	3·61	6·06
Fe_2O_3	2·48	6·60	4·61	3·48	7·76	6·22
MnO	0·12	n.d.	0·39	0·19	0·25	n.d.
Ign. loss	n.d.	n.d.	n.d.	2·14	2·34	1·96
	99·34	95·95	99·60	99·57	99·28	96·82

n.d.=not determined.

Titanium and all other impurities found in the ore are, however, completely removed in the process based on the preparation of crystallised zirconium oxychloride. This process is seldom mentioned in English technical literature, probably because it is more expensive than a precipitation process; further, the oxychloride mother-liquor is fairly rich in zirconium, part of which is not recoverable in the pure state, because a solution heavily charged with impurities will not crystallise; but the operation is a simple one, and can be made to yield chemically pure zirconia.

It occurred to the author that the economics of a combined oxychloride-basic sulphate process might repay investigation, and the following suggestions for a process embodying Rossiter and Sanders' work are put forward tentatively. The finely ground ore is fused with sodium carbonate (*cf.* U.S. Pat. 1,261,948; J., 1918, 339 A), which the author considers superior to caustic soda because a better decomposition of the zircon in the ore is effected at the higher temperature required to melt the charge. The melt is leached 2 or 3 times with hot water, the volume of the first leach liquor being adjusted so as to deposit sodium carbonate crystals on cooling; the recovered alkali is available partly for neutralisation, and partly for opening up a fresh charge of ore. The insoluble residue is treated with the zirconium oxychloride wash-liquors and part of its mother-liquor, the solution evaporated to dryness, and the mass extracted with hot water. The filtered liquid is concentrated somewhat, mixed with hydrochloric acid, and left to crystallise; the crystals are filtered off by suction and washed with cold hydrochloric acid (1:1) till the washings are colourless. Instead of converting the oxychloride into zirconia by precipitation with ammonia and ignition of the hydroxide, the crystals may be heated in porcelain or silica vessels until the water and acid are expelled; the dry residue is powdered, boiled with dilute ammonia, filtered off and strongly ignited, giving pure zirconia. The acid used in washing the oxychloride is mixed with a certain proportion of the oxychloride mother-liquor and used for dissolving the next batch of leached fusion residue; the balance of the mother-liquid—sufficient to prevent undue accumulation of impurities—is withdrawn from the circuit, neutralised with recovered sodium carbonate, and precipitated with sulphurous and sulphuric acids according to Rossiter and Sanders' process. The last operation yields the remainder of the zirconia practically free from iron and alumina, but contaminated with titania; this oxide is probably quite pure enough for certain industrial purposes (*e.g.*, as a pigment). Further experimental work based on fractional solution or precipitation will probably indicate a method for eliminating the titania.

Examination of commercial zirconia.

To judge from the results of analyses of zirconia made by the author, the efforts of British manufacturers to produce a pure oxide have not so far been attended with success. The composition of the samples indicated that the ore had been opened up by fusion with nitre cake: the material was found to be strongly contaminated with arsenic pentoxide, no doubt derived from nitre cake obtained from impure sulphuric acid. The presence of arsenic is highly objectionable, especially where the zirconia is intended for use in X-ray work or as an opacifier in enamelling cooking utensils; it is liable to be overlooked unless a special test is made. For its detection and determination, 2 g. of zirconia is fused with 15—20 g. of sodium carbonate in a platinum crucible, the melt is leached with hot water, the solution filtered, acidified with hydrochloric acid, and saturated with hydrogen sulphide. To expedite the precipitation of the arsenic sulphide, the acidified filtrate may be first digested on a water-bath with potassium iodide, which reduces the arsenic acid. The sulphide is filtered off, evaporated with sulphuric acid until fumes are evolved, the liquid made alkaline with bicarbonate, and titrated with iodine solution.

Table 2 shows the impurities found in three samples of zirconia of British manufacture.

TABLE 2.

	(1).	(2).	(3).
SiO_2	1·28	0·76	0·64
TiO_2	1·45	0·98	1·70
Al_2O_3	0·16	0·30	0·13
Fe_2O_3	0·36	0·34	0·28
As_2O_5	1·03	1·37	1·30
SO_3	0·16	1·85	1·94

In addition to the above constituents, the author has detected other impurities or added ingredients in specimens of zirconia obtained from abroad; viz., lime, soda, fluorine, chlorine, carbon dioxide, and boron trioxide. The analysis of zirconia must be made on the unignited sample, as the loss on ignition represents sulphur trioxide, carbon dioxide, fluorine, and chlorine, if present, as well as moisture or combined water.

London Section.

Meeting held at Burlington House on May 2, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THERMAL LOSSES IN THE GAS PRODUCER PROCESS.

BY N. E. RAMBUSH.

The object of the present paper is to elucidate the principles by means of which it is possible to determine with a reasonable degree of accuracy the thermal efficiency of the gasification of a given fuel without large-scale tests, and generally to emphasise the relative importance of the various causes of thermal losses to engineers and chemists concerned with the working and design of gas-producer plants.

There are many types of gas-producers on the market, and within limits, it would be more or less right to say that producer-gas can be made in practically any apparatus. The object of this paper is not to discuss the advantages or disadvantages of any of the many producer types available, but it will be assumed that a gas-producer is employed which is suitable for dealing with the particular fuel and purpose under consideration.

Gas-producers and plants may be divided into two main groups:—

(1) *The hot gas-producer* in which the gas made is consumed in the same hot crude state in which it leaves the producer.

(2) *The cold gas-producer*, to which gas cooling and cleaning plant is attached to enable the gas to be supplied cold and of a degree of cleanliness that corresponds to the application in question. This group may again be divided into two subsections according to whether by-products are recovered or not.

The points having a bearing upon the thermal efficiency of the gas-producer process are:—(1) Moisture content in fuel, (2) nature of volatile matter in fuel, (3) grading of fuel, (4) soot formation, (5) ash content of fuel, (6) the radiation and convection heat losses from the producer proper to the atmosphere, (7) gas leakage losses, (8) losses in washing liquors, (9) moisture content in gas, (10) the temperature of and sensible heat contained in the hot gas leaving the producer.

Before dealing with these various points I should like to make clear the basis upon which I have determined the thermal efficiencies and losses. I have come to the conclusion that the best standard from the point of view of the gas-producer technologist is the ratio between the net heating value and volume at N.T.P. of the gas evolved per unit weight of theoretically dry fuel and the net heating value of the said unit weight of theoretically dry fuel. For plants in which the tar and oils are recovered as a valuable by-product and not considered a nuisance in the gas-making process, it might be argued that the heating value of the tar obtained (which can be utilised as fuel) should be added to that of the gas. Since the tar (especially on a by-product plant) may have a larger value to the industry than that corresponding to its heating value, I have refrained from doing so. On the other hand, it appears undesirable to complicate still further the matter of calculating the thermal efficiency of the gas-producer process by making allowances for the fuel required to raise the steam for the air blast, and create the power required for driving the auxiliary machinery, since this involves factors entirely outside the proper process of gas making.

1. *Effect of moisture content in fuel.*—Most good-class bituminous fuels have such a low moisture content that the evaporation of this small amount of moisture has very little effect upon the thermal efficiency of the gas-producer process; but for such high-moisture fuel as wet coke breeze, and especially some peats or lignites, the moisture content will have a very great effect.

This may be demonstrated by the example of the gasification of a peat having a moisture content of 50% and a net heating value of 4000 Cals. per kg. (7200 B.Th.U. per lb.) of theoretically dry substance. For each kg. of dry substance of such peat introduced into the producer 1 kg. of water would have to be evaporated and heated to the gas outlet temperature of, say, 150° C.

Supposing now the peat instead of being introduced in a wet state were introduced in a moisture-free state into a by-product recovery producer, and the gas volume (at N.T.P.) and average specific heat of the gas evolved be approximately 2·5 cb. m. per kg. and 0·3 Cal. per cb. m., respectively, also that the gas outlet temperature be about 500° C., then the sensible heat in or the thermal capacity of the gas from 1 kg. of dry peat between 150° and 500° C. would be $2·5 \times 0·3 \times (500-150) = 262$ Cals.

Now the heat required to raise 1 kg. of water to 100° C., evaporate it and superheat the steam to 150° C. will be 652 Cals., so that there is a deficit of $652-262$ Cals. (=390 Cals.) per kg. of dry fuel, which must be supplied by burning a part of the fuel itself (roughly 10%) in the lower part of the producer, with a consequent reduction in the heating value of the gas and the thermal efficiency.

If the fuel bed is not deep enough to enable the sensible heat of the gas generated in the lower part to be utilised for the evaporation of the moisture, the thermal loss will of course be still higher, but the above remarks will indicate quite clearly why wet peat gasifications in the past have often met with so little success.

Returning now to the effect of the moisture content upon the thermal efficiency of the gas-producer process, it is obvious that before being able to estimate accurately the effect of evaporating the moisture it would be necessary to determine the difference in the gas outlet temperatures theoretically when using a dry and a moist fuel. Such determination could only be made by those practically experienced in this work, and even then may be liable to considerable error if the particular gas-producer design is not borne in mind.

As the object is to find what may reasonably be expected as to thermal efficiency, it is suggested that the heat required for bringing the moisture content to 100° C. and evaporating it be taken as having to be supplied from the heating value of the dry fuel only, while the heat required for superheating the steam thus raised is assumed to come from the sensible heat of the gas. Under this assumption the decrease in thermal efficiency obtainable in practice due to moisture will always be smaller than the thus estimated figures.

The curves in Fig. 1 show the reduction in the percentage of the thermal efficiency for fuels of varying heating value and different moisture content, estimated in this manner.

2. *Effect of volatile matter in fuel.*—Since the percentage of volatile constituents in fuels used for gas production varies from, say, 1% (on coke and anthracite) to above 80% (for woods), it is difficult to predict from the ordinary methods of ultimate gas analysis how much of this volatile matter will be obtained as gas or tar, unless of course the same material had been treated in a gas-producer before.

For the above reasons I decided about 12 months ago to alter the method of fuel investigation in our laboratory at Stockton-on-Tees. The method I instituted is, generally speaking, to subject a small quantity of the fuel to a retorting test under temperature conditions approaching those obtained when treating the fuel in a by-product producer.

Heat loss due to moisture in fuel.

1. 8000 Cals. per kg. (14,400 B.Th.U. per lb.).

4. 5000 „ „ (9000 „ „).
5. 4000 „ „ (7200 „ „).

Fig. 1.

So far a reasonably close agreement has been found between the quality and quantity of the volatile matter obtained as tar in our special distillation test apparatus and that obtained in practice, excepting that the tar obtained in practice seems to have a higher average boiling point and is always obtained in a slightly smaller quantity. Probably some decomposition of the lighter oil constituents of the tar takes place in the producer. Our fuel testing method and its bearing upon the results to be obtained in practice is not yet completely established, but in another six months or so it is hoped to publish laboratory results, and also to show comparisons between these and the results obtained in practical operation with the same fuel.

As certain fuels in properly designed by-product producers may yield a very large quantity of tar, and as this tar per unit weight may have double the heating value of the fuel treated, a retorting test is, in my opinion, the best method by which to determine the "tar value" of a producer. Even if this should yield a slightly higher quantity of tar than is obtainable in practice, the laboratory results will indicate a slightly lower thermal gasification efficiency than actual operation, and incidentally is far cheaper to carry out than a large-scale commercial test.

To arrive at the net heating value of a fuel from its ultimate analysis,, all the oxygen is commonly assumed to be combined with the hydrogen. This is not so, since in practice substances like acetic acid, phenols, etc., are often obtained in the tar and liquors on a gas-producer plant, thus indicating the presence of carbon-oxygen links as well as hydroxyl groups in the fuel. For this reason, and since heat may be required inside the fuel itself to liberate its various particles, it is clear that a calorimeter determination, deducting the latent heat of the steam formed by the combustion of all the hydrogen of the fuel, be used as the measure for the net heating value instead of a net heating value arrived at from the ultimate fuel analysis.

3. *Effect of fuel grading.*—The grading of the fuel is a most important factor, not only from the point of view of the solid fuel particles that may be carried away by the gas (as dust), but also from the point of view of the output of the producer and the gas quality.

With fuels containing an excessive quantity of fines the dust loss may be serious unless preventive provision is made in the design. With the same grading of the fuel the loss is obviously a function of the gas velocity in the outlet pipe. Since the dust-carrying power of a gas alters with the sixth power of the velocity it is obvious that the best means to prevent thermal loss on this account is to have the crude gas as it leaves the producer as cold as practicable, or to provide large dust settling spaces (say a roomy space above the top level of the fuel bed).

To obtain the same gas analysis and output from fuels of various grading in a producer of the same diameter it is necessary to alter the fuel depth, or alternatively to provide that depth of fuel bed which is the most economical for the worst conditions of grading.

I have had communicated to me privately the following results of tests made in reference to this matter.

Fuel.	Grading.	Economical depth.
Coke	¾ in.—1¼ in. cubes	2 ft. 6 in.
	1¼ in.—2 in. cubes	3 ft. 9 in.
	2 in.—3 in. cubes	5 ft. 10 in.
Coal	1 in. nuts	1 ft. 10 in.
Coal	Run of mine	4 ft. 10 in.—6 ft. 6 in.

Analyses of the fuel and of the gas are not given. It is, however, not surprising to find that the more uneven the grading and the larger the biggest pieces of fuel, the greater must be the fuel depth for efficient gasification.

It should be borne in mind that certain fuels (in particular some lignites) break up and crumble shortly after introduction into the producer, so that a larger dust loss will be obtained in practice than might be expected from the grading test carried out on the fuel in its natural state.

Other aspects to be considered, quite apart from the gas-producer process in itself, are the losses such as may be incurred (due to wind) by storing a slack fuel containing a large quantity of fines in the open or handling it in an unprotected fuel-conveying plant. Gas producer users will be well advised to have their fuel and storage plant protected against atmospheric effects, not only from the point of view of dust loss, but also on account of the moisture added to the fuel on rainy days.

4. *Soot formation.*—This varies with the type of fuel used, but it is caused by the tarry matters evolved from the coal being exposed to such a high

temperature inside the producer that they are decomposed into gas and carbon (soot). Soot formation is practically absent in some by-product producers where the only decomposition of tar which takes place is into gas and oils of a higher boiling point; but even with hot gas producers soot formation can be reduced considerably by feeding or distributing the fuel evenly over the top of the fuel bed, especially if the latter be not too shallow.

Thermal loss by dust and soot formation.—As is obvious this will vary considerably, but tests carried out several years ago on some large by-product producer plants working with rough slack as fuel indicate that this loss may be as high as 3% of the heating value of the fuel. With the latest designs of by-product producer plant it is reduced to a very much lower figure.

5. *Effect of ash.*—The three main factors in connexion with the ash which have a bearing upon the gasification process are:—(*a*) the composition of the mineral matter in the fuel; (*b*) the sensible heat lost in the hot ashes; (*c*) the loss due to unburnt carbon in the ash.

(*a*) Except for the work by J. T. Dunn (J., 1918, 15 T) I am not aware that any considerable work has been done in reference to the fusing temperatures of ash from various English coals, although a large amount of work has been done both by the U.S. Bureau of Mines on American fuels and by the University of Zürich on Continental fuels. Until more extensive research has been carried out it will not be possible to point out in advance what quantities of steam would be the most advantageous to use or whether the producer should be water-jacketed or not, etc., in gasifying fuels of various qualities of ash. I shall therefore not go into the details of the extensive subject of ash fusibility, but only point out one or two other points of interest to the gas-producer technologist.

If the mineral matter in the fuel is not completely oxidised, extra oxygen is required from the air blast to complete the oxidation, with a consequent dilution of the resulting producer gas by nitrogen.

On the other hand, the ash may contain compounds which partly volatilise on heating up (say carbonates), also with dilution of the gas as a consequent result. Discrepancies in some fuel analyses are often due to similar causes.

(*b*) The sensible heat contained in the hot ashes leaving the producer varies with the ash content of the fuel, but is not of any consequence in a water-luted producer, because the heat is utilised practically completely to raise steam (by diffusion) and to preheat the air blast, but even with a "dry bottom" producer this heat loss is very small. Assuming the temperature of the ashes leaving the producer to be 100° C. and 400° C. for wet and dry bottom producers respectively, and assuming that 20% of the coal is removed as ash (sp. heat 0·3) the total sensible heat in the ash per kg. of fuel will be 6 Cals. and 24 Cals. and the loss of heating value of fuel (6700 Cals. per kg.) will be 0·09% and 0·36% respectively.

(*c*) The thermal loss due to incompletely burnt fuel varies, apart from the skill of the operator, with the heating value and the ash content of the fuel.

The figures in the following table give the approximate thermal loss due to this cause for several assumed conditions.

It is generally found in practice that the higher the ash content in the fuel, the higher will be the carbon content in the ashes; hence the ash loss is of the cumulative order in regard to the ash content.

It will probably be agreed that with bituminous coals containing up to 15% of ash it is possible to maintain the carbon content in the ash at or below 10%, which means that the thermal loss will not be more than 2·05% of the heating value of the fuel.

The carbon loss in % on the fuel used is calculated by the formula $X = ac/(100 - c)$, where X is the carbon lost in percentage on fuel used, a the ash content of the fuel, and c the carbon content of the ash.

	Carbon content of ash. %	Lb. of carbon lost per 100 lb. of fuel gasified, *i.e.*, % carbon loss.	Thermal loss on heating value. %
Fuel, 10% ash, 12,000 B.T.U./lb. or 6700 Cals./kg.	10	1·1	1·33
	15	1·8	2·17
	20	2·5	3·02
Fuel, 20% ash, 10,700 B.T.U./lb. 5950 Cals./kg. ..	12	2·7	3·66
	18	4·4	5·92
	25	6·7	9·08
Fuel 30% ash, 9500 B.T.U./lb. 5280 Cals./kg. ..	15	5·3	8·08
	22	8·4	12·85
	30	12·0	19·70

Fig. 2 has been prepared to cover the possible conditions met with in practice. Given a fuel of a certain ash content, and knowing the carbon content in the ashes, the thermal loss in terms of percentage on the net heating value of the fuel is at once obtainable.

6. *Radiation and convection loss.*—To obtain a more definite idea as to the order of the radiation and convection loss from the outside shell of a producer, I measured in 1918 the "skin" temperature of a 10-ft. by-product recovery gas-producer under full load conditions and found that the temperature 4 ft. from ground level was 69° C.; 6 ft., 85°; 8 ft., 101°; 10 ft., 109°; 12 ft., 92°; 14 ft., 79°; 16 ft., 76° C. The producer was 20 ft. high and the grate level was at 5 ft. 6 in. and fuel level 13 ft. from ground level. Thus the producer in question had an average skin temperature of about 80° C., while the total exposed surface was about 84 sq. m. Assuming for exposure to average atmospheric conditions a total radiation and convection loss of 760 Cals. per sq. m. per hour, we get a total loss of 63,000 Cals. per hour. The producer in question gasified about 850 kg. of coal per hour at 6700 Cals. net heating value per kg., hence the loss was equivalent to 1·1% of the heating value of the fuel. The producer in question had an exposed surface unnecessarily large in reference to its diameter, the exposed surface of many producers of the same or larger throughput, especially where no by-product recovery is aimed at, being only about 45—50 sq. m., with a corresponding decrease in the radiation etc. loss.

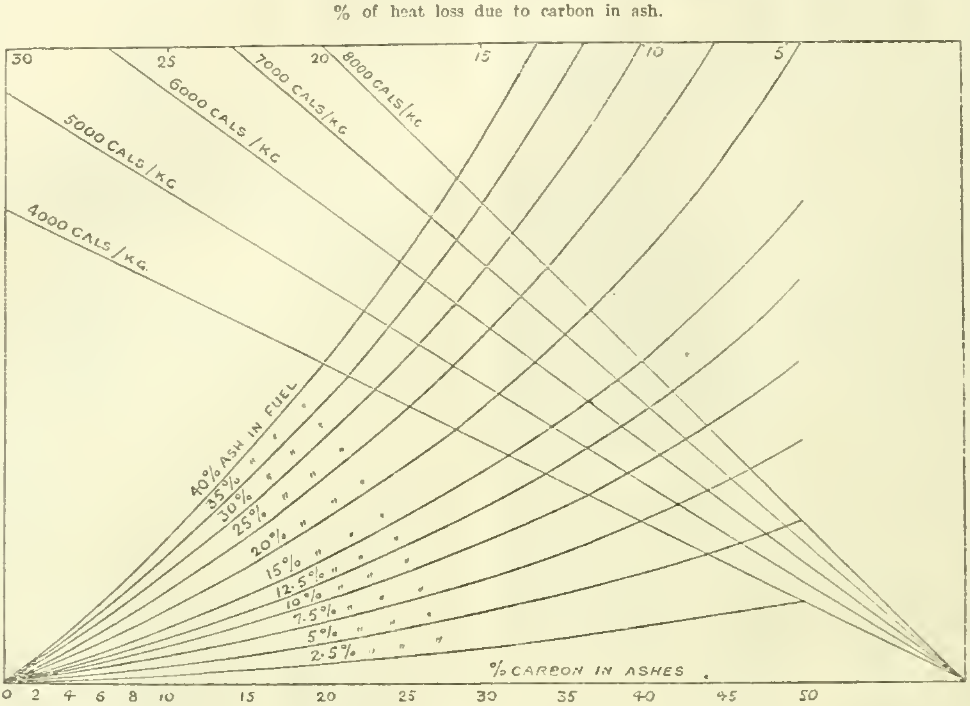
The radiation and convection loss from the outside casing of most gas producers to the atmosphere will be independent of the rate of gasification and represents a practically constant hourly loss proportionate to the total exposed surface.

Judging from the above practical observations as to the "skin" temperature and when using good class bituminous fuel, I consider that for the larger producer capacities (working at not less than $\frac{3}{4}$ load) the radiation and convection loss should not exceed 1% of the heating value of the fuel gasified per unit of time.

7. *Losses due to leakage* may be subdivided into (*a*) periodical loss due to poking and cleaning, (*b*) continuous loss due to leaky joints.

(*a*) Assuming a 2-in. hole be open on the top of a producer having a gas outlet temperature of 500° C., then the corresponding hourly loss will be 3000 cb. ft. when the gas pressure is 2 in. and 10,000 cb. ft. when the pressure is 20 in. These gas volumes correspond to cold and clean gas. Many poking and cleaning holes are larger than 2 in. On many static producers a man will occupy on an average about one-tenth of his time poking the fuel bed of a producer, hence the thermal loss may easily be 0·5% of the fuel gasified. Of course, on producers having mechanical stirring and ashing means this loss is practically eliminated. Cleaning of mains during operation should be avoided as far as possible, and mains should be arranged vertically or inclined so that they are as "self-cleaning" as possible.

(*b*) Leaky joints such as are caused by faulty manufacture or vibration (due to wind, machinery, etc.) exist even on the best plants. Even on such carefully laid pipe lines as for town gas supply it has been proved that leakages may be 1% of the gas supplied. Of course, the loss will depend on the surface of the plant exposed to the atmosphere, and is obviously largest on cold gas producer plants. This type of loss becomes larger with cleaner gas, but smaller with lower pressure difference between the gas and the atmosphere.



C in ashes. ↑ Ash in fuel. → Cals./kg. ↑ Heat loss.

FIG. 2.

It is obvious that the plant which works with the lowest possible pressure difference between the gas and the atmosphere will have the smallest leakage loss; thus if the whole plant were under suction this loss would disappear. For obvious reasons it is always advisable to have the gas under pressure at any points where poking or cleaning is required during operation. This pressure difference, however, should be maintained, automatically if possible, at the lowest limit.

Assuming average conditions I do not think that the leakage loss on a cold gas producer plant should be assessed at less than 1% of the heating value of the fuel gasified.

8. *Loss in gas cleaning and cooling plants.*—The losses on this account may be divided into two subheadings, viz., (*a*) substances mechanically carried away by and (*b*) matters dissolved in the washing liquid.

(*a*) An appreciable quantity of gas is carried away mechanically with the washing liquors leaving the cooling, cleaning, absorbing, etc. towers and thus escapes to the atmosphere. The loss can be reduced, but its existence can be observed on any gas-washing plant by watching the behaviour of the washing liquid leaving a tower. If an inverted bottle filled with water is placed below the water level and close to the water outlet pipe in the tank, gas will soon rise in the bottle, replacing the liquid. From a test made by me on one of the early types of combined air saturator and gas cooler on a Lymn plant (by estimating the CO_2 content in the air entering and leaving) the gas loss due to this cause was estimated at over 0·5%.

(*b*) All gases dissolve in water, and also some of the tar oil compounds are soluble, particularly the tar acids or phenols. The loss occurring in this respect, so far as the gaseous substances are concerned, is not very large and cannot be avoided; but by carefully controlling the waste liquors of the plant and the cooling water system, the phenols can be recovered. It is not impossible to obtain an effluent containing up to 0·5% of these phenols, which effluent can be economically treated. There are, however, many gas-producer plants in existence, where by exercising a little care and slightly modifying the working cycle of the plant the phenols can be recovered, instead of being run into the sewers.

Summarising the matter of the thermal losses due to gas carried away by the washing liquors, I do not think that even with a well-designed plant this should be considered less than 1% of the heating value of the fuel treated.

9. *Content of water vapour in hot crude gas.*—This originates from three sources: (*a*) That amount of the steam admitted with the air-blast which is not decomposed in the producer; (*b*) the amount due to "moisture content" of fuel; (*c*) the amount due to "water of decomposition" of fuel.

As to (*a*), the following figures, given partly in the two papers by Bone and Wheeler (Proc. Iron and Steel Inst., 1907 and 1908) and partly arrived at in my own experience, will give a general guide as to the amount of steam decomposed in the gas-producing process when using bituminous fuels:—

Depth of fuel bed ..	3 ft. 6 in.			7 ft.					7 ft. 6 in.	12 ft.
Temp. of air blast, °C.	50	55	60	60	65	70	75	80	85	78
Lb. of steam per lb. of coal	0·21	0·33	0·45	0·45	0·56	0·80	1·1	1·55	2·5	1·45
% steam decomposed	95	100	76	87·4	80	61·4	52	40	30	62
Lb. of steam decomposed per lb. of fuel	0·2	0·33	0·34	0·39	0·45	0·49	0·57	0·62	0·75	0·90

It will be obvious that the deeper the fuel-bed the more complete is the steam dissociation. So far as the steam-carbon reaction is concerned it is obvious that the time factor plays a rôle.

I have further come to the conclusion that if by suitable modifications it is possible to increase the gasification capacity of a producer for the same fuel (such as by introducing mechanical stirring means), it is advisable at the same time to increase the fuel depth if a good quality gas is to be maintained.

Speaking broadly, and quite apart from the softening effect of the steam upon the clinker formation, the most economical blast temperature, from a thermal point of view, is that which corresponds to a practically complete dissociation of all the steam supplied with the air-blast. It has been calculated (see Richards, "Metallurgical Calculations") that the decomposition of about ½ lb. of steam per lb. of bituminous coal will counterbalance the exothermal reactions caused by the formation of the carbon dioxide usually present in gas obtained in ordinary hot gas producer work. It will be noticed that the calculated figure practically agrees with those quoted as results of ordinary practice.

From the point of view of the thermal efficiency of the gas-producer only (quite apart from the heat required to raise steam), it is obvious that the more undecomposed steam remaining in the crude gas, the larger will be the thermal loss due to the sensible heat in such undecomposed steam, which leaves at the same temperature as the gas. This rule holds good in spite of the fact that the gas temperature will be lower, the higher the percentage of undecomposed steam.

In connexion with the use of steam as the endothermal agent in the gas-producer process, reference may be made to a suggestion put forward many times in the past thirty years or more—namely, to introduce products of combustion instead of steam with the air-blast for the purpose of saving in the steam consumption. From the calculation below, showing the steam saving that can be effected at a certain reduction in the heating value of the gas, it will be clear why the experiments in this respect have been fruitless, and the gas in many cases useless for industrial work.

Assume that with the addition of steam *only* to the air-blast the following operating conditions are obtained:—Steam per kg. coal, 1·5 kg. (78° blast temp.); gas per kg. coal, 3·5 cb. m. (N.T.P.); heating value of gas, 1370 cals. per cb. m. (154 B.Th.U. per cb. ft.) net. Then steam per cb. m. of gas = 0·43 kg.

When adding products of combustion, assume that they have the composition: 18% CO_2, 82% inerts. Now assume that it is permissible to reduce the heating value of the gas by 20% (from 155 to 124 B.Th.U. per cb. ft.), due to the introduction into the gas of nitrogen from the products of combustion. This means that if all the CO_2 is decomposed we can add per cb. m. cold gas: $20 \times 100/82 = 24·4\%$ or 0·244 cb. m. of products of combustion.

The weight of carbon dioxide of this volume is: $0·244 \times 18 \div 100 \times 1·964 = 0·086$ kg.

The relative endothermal effects of steam or carbon dioxide on hot carbon are as follows:—

$$C + CO_2 \rightarrow 2\,CO - 38{,}800 \text{ Cals.}$$
$$C + H_2O \rightarrow CO + H_2 - 28{,}800 \text{ Cals.}$$

—*i.e.*, the endothermal effect of 1 kg. of carbon dioxide is equivalent to that from $3·88 \times 18 \div (2·88 \times 44) = 0·55$ kg. of steam. Therefore the addition of 0·244 cb. m. of products of combustion to the air-blast will replace $0·086 \times 0·55 = 0·0473$ kg. of steam.

In other words, the above rough calculation shows that by reducing the heating value by 20% the saving in steam is only 11% when using 1·5 lb. of steam per lb. of coal.

The calculation takes no account of the fact that the sensible heat loss incurred by cooling the hot gas is practically proportional to the volume of the hot gas, hence when adding products of combustion with a consequent larger gas production per unit of fuel the thermal gasification efficiency will certainly be less than with steam as the endothermal agent.

When the trouble involved in handling products of combustion is borne in mind, it is obvious that only disadvantages are to be looked for, unless perhaps the future enables us to use a gas richer in carbon dioxide.

As to the moisture content in the hot gas due to moisture in fuel and water of decomposition, both of these can be judged from the laboratory examination of the fuel, it being practically certain that none of the "moisture" in the fuel will be decomposed by the reaction with the carbon in an updraught type of gas producer.

10. *Effect of gas outlet temperatures and sensible heat loss.*—If a good class bituminous coal is used the following gas composition and outlet temperatures may be reasonably expected:—

	Hot gas producer.	Cold gas producer.	
		Without recovery.	With ammonia recovery.
Gas analysis:			
CO_2	5	9	10

N_2	52	46	44
Moisture, g. per cb. m. of dry gas at N.T.P. ..	30	110	430
Equiv. saturation temp. of gas, ° C.	28	50	73
Temp. of hot gas ..	950° C.	700° C.	550° C.
Net latent heat of gas at N.T.P.			
B.Th.U. per cb. ft.	165·9	156·7	142·3
Cals. per cb. m. ..	1476·6	1394·5	1266·5
Thermal capacity per cb. m. gas N.T.P. in Cals.	329	264	290

In calculating the thermal capacity of the gas (total sensible heat) I have used the figures given by Holborn and Henning for diatomic gases, steam, and carbon dioxide, and by Langen for methane. Fig. 3 has been drawn (completed early in 1918) upon which thermal capacity per cb. m. (N.T.P.) of each gas has been plotted against the temperature. In the above figures for sensible heat in gas any sensible heat contained in tar, dust, and soot has been eliminated, as the thermal loss due to these will be very small in comparison with the heat loss in the gas. The carbon and hydrogen losses from these three sources are of another order and have been dealt with under their separate headings.

Thermal capacity in Cals. per metre³ (N.T.P.) between 0° and T° C. at constant atmospheric pressure.

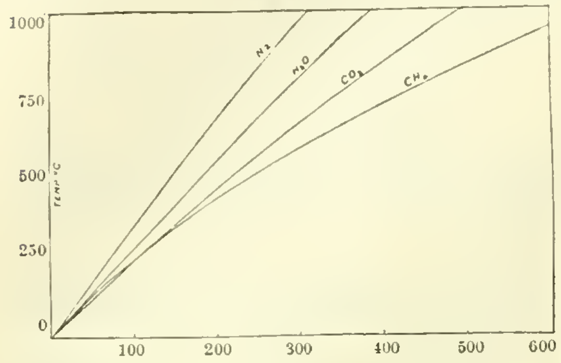

FIG. 3.

Sensible heat in hot gases.

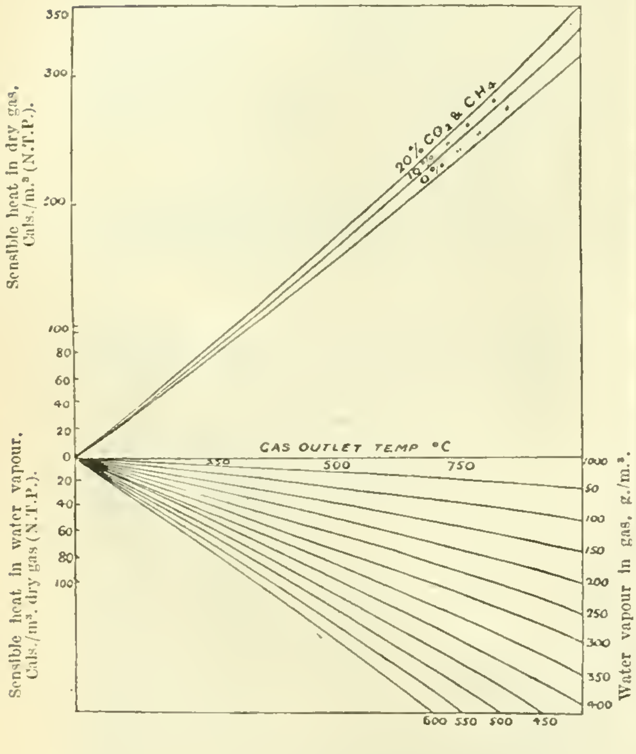

FIG. 4.

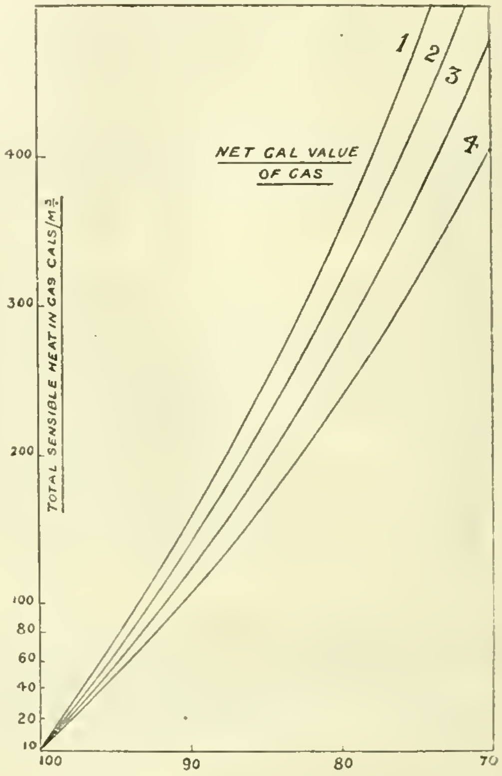
It will be seen from the summary table at the conclusion of this paper that in the three cases the thermal loss due to the sensible heat in the hot gases leaving the producer represent:—(1) 17%; (2a) 14%; (2b) 16% of the calorific value of the fuel; therefore the sensible heat loss is the chief among all the losses of the cold gas producers. The only means available for utilising such heat is either to obtain a lower gas outlet temperature with a gas richer in heating value, or to utilise the heat for other purposes, *e.g.*, to raise the steam required in the process by cooling the gas, either (1) directly by washing the air blast for the producers with the hot water from the gas cooling plant, or (2) indirectly by raising steam or heating water in boilers or vaporisers.

Loss due to sensible heat in gas.



% latent heat.

2. 1250 „ „ (140·4 „ „).
3. 1100 „ „ (123·5 „ „).
4. 950 „ „ (106·7 „ „).

FIG. 5.

But even for the hot gas producers the loss of sensible heat in the gas may be of consequence if the furnaces are not placed close to the producers, and although it may be an advantage to have a high carbon monoxide content from a heating process point of view, it is often more economical from a thermal point of view to increase the hydrogen content somewhat at the expense of the carbon monoxide content, thus decreasing the outlet temperature and thereby radiation losses, while the difference in sensible heat for the two outlet temperatures will be present as the latent heat of the hydrogen in the gas.

It should therefore be emphasised that the gas composition is not always a measure of a thermally efficient hot gas producer plant unless the loss in gas temperature between gas producer and furnace is borne in mind.

All the above remarks are only generally applicable to an average English bituminous producer coal, but the gas composition, gas outlet temperatures, and moisture content in gas will vary considerably with the various kinds of fuel gasified (from wood waste, wet peat, and town refuse to anthracite).

For this reason I have prepared Fig. 4 on which the sensible heat (thermal capacity) per cb. m. (N.T.P.) of gas of varying composition and of the accompanying moisture content can be directly determined for various gas outlet temperatures. Seeing that the methane content is generally less than the carbon dioxide content, and its specific heat not very different from that of this gas and the rest of the components of producer gas (all diatomic gases), the diagram should prove of practical utility even if a small error is caused by assuming the specific heat of methane to be the same as that of carbon dioxide. I have also assumed that the relative specific heats of the various gases do not alter if the gases are mixed together.

---

* This calculation is made only for comparison, and the loss only exists in practice in a degree corresponding to the difference in the gas temperature at furnace and leaving producer.

It may have been noted that all the losses in the gasification process, except the sensible heat loss, can be expressed in terms of the net heating value of the fuel. As, however, it is easier to express the sensible heat loss in terms of that contained per unit volume (at N.T.P.) of cold gas, it will be necessary when determining the expected thermal efficiency first to assess all the other losses, thus giving as a deficit that heat which must exist as sensible heat in the hot gas and as latent heat in the cold gas. When the ratio between the net available latent heat in the cold gas and the total sensible and latent heat in the hot gas is calculated, the sensible heat loss in terms of the calorific value of the fuel, and therefore the net gasification efficiency, can be obtained (see Fig. 5).

General use of above statement.—Following are some examples of how the above statements may be applied for calculating the thermal gasification efficiency of various types of fuel and plant. The figures and assumptions are given in the serial order in which they are best determined.

As regards cases 3, 4, and 5 the actual thermal efficiencies obtained in practice were:—(3) 70·2; (4) 74·5; (5) 76·5. The figure in case 3 represents a yearly average of data on coals used and gas metered, while case 4 represents a 288 hours' continuous test and case 5 a one-month test.

The discrepancies between theory and practice of the three cases are of so small an order that the method of calculation put forward is in my opinion sufficiently reliable for general adoption—perhaps in certain cases with an additional factor of safety.

In conclusion I wish to express by thanks to the Directors of The Power-Gas Corporation, Stockton-on-Tees, for their kindness in permitting me to publish results obtained by my firm, and also to Mr. A. T. Grisenthwaite, B.Sc., for help given in working out the curves and table appended hereto.

DISCUSSION.

Captain C. J. **GOODWIN** asked as to the possibility of utilising a small quantity of oxygen for enriching the air supply to producers. It would increase the temperature considerably and tend to fuse the ash, but he thought there was the possibility of obtaining improved results.

Dr. M. W. **TRAVERS** said that he had been working at the heat balance of the steam-blown gas-producer (*cf.* J. Soc. Glass Tech. 1921). From experience in connexion with the glass industry with modern gas-producers, from which the gas issued at a temperature of not over 700° C., it did not appear that soot was actually formed in the producer. The gas as it issued from the producer was loaded with tar fog, but the actual formation of soot appear to be, at least in some measure, due to the reversal of the CO_2—C—CO reaction in contact with the dust. In speaking of the velocity of the gas issuing from the producer he presumed that the author referred to the velocity of the gas in the top layer of the fuel bed. Some interesting work on the nature of the fuel bed, the resistance to the flow of the gas, and the nature and grading of the fuel had been carried out by the U.S. Bureau of Mines (Tech. Paper 137, p. 57). He had been unable to find any information in technical literature which would enable him to connect the chemical and thermal properties of tar, which was certainly endothermic. In one of the latest publications on the subject, the Report of the Research Committee of the Institution of Gas Engineers, it was assumed that the heat of formation of the tar could be calculated from the composition of the tar, on the assumption that the heat of formation was equivalent to that of naphthalene. Mr. Rambush had determined the heat of combustion of the tar, and a few analyses of his material would provide the necessary information.

Mr. P. **PARRISH** said that the author gave the thermal efficiency of a coke breeze gas-producer plant as 66·3% where cold gas had to be utilised; did he regard it as more advantageous to adopt the gasification of coke breeze in conjunction with a Bonecourt boiler for the production of steam in lieu of ordinary steam production in a Lancashire boiler using a forced draught furnace for coke breeze? In the latter case an efficiency of 58—60% was certainly possible. The cost of the plant, *i.e.*, the producer for gasifying coke breeze and the provision of a Bonecourt boiler for an installation capable of dealing with 750 gallons per hour, would be something of the order of £6000, whereas a Lancashire boiler with a chimney shaft to deal with 750 gallons per hour would cost £3000. The theoretical efficiency which the author would lead one to expect was 66·3%, and that higher efficiency entailed an extra expenditure of £3000 for 750 gallons per hour. Did he consider that to be a commercial proposition which would justify embarking on the gasification of coke breeze in a producer in conjunction with a Bonecourt boiler, in comparison with the forced draught type of Lancashire boiler, which was in operation to such a large extent to-day? Again, he doubted whether it was possible economically to gasify coke breeze by itself. It had been tried at the Birmingham gas works for a long period, but it had been found necessary to mix 50% of producer coal to get satisfactory results. Moreover, in view of the flame temperature of the cold producer gas, it was found that some form of regeneration was necessary to get the best effect.

Mr. ARTHUR H. **LYMN** said that he had carried out a large number of large-scale tests during the last twenty years, and had seldom known them to come nearer the actual regular figures of later works practice than did the figures which the author had given. Consequently the author's anticipated results seemed so near the actual results of works practice that they not merely anticipated the figures of large-scale tests, but practically eliminated the necessity for them. The efficiency of the producer should include the steam that went into it, although in those cases where other apparatus was included with the producer, such as washing plant, it was always possible to recover that steam from the waste heat of the gases. Nevertheless he would like to see the figures in the paper also shown on the basis of including the steam. In dealing with the heat contained in the gas from hot gas-producers as compared with the recovery gas, the author had taken certain temperatures of the outgoing gases from the producer. His own opinion, from a wide experience, was that 900° C. was scarcely a fair figure for hot gas-producers; it should not be more than 700°, and where the author spoke of 17% in comparison with 14% losses for different types of plant, that would probably change this to 12 or 13%, but it would be well if they could have the calculations for an outgoing temperature of 700° also, because a well-conducted hot gas-producer should not have a higher temperature than that. The author had drawn attention to the determination of the fusibility of ashes. He (the speaker) suggested that some institution in this country should undertake a systematic investigation of the fusibility of fuel ashes, as had been done by Constam for German fuels some years ago.

Dr. R. **LESSING** agreed that the fusibility of ashes was one of the most important points in running gas-producers. The fusibility of the ash in a coal sample need not be exactly the same as that obtained when working on a large scale, because in the latter case they were not dealing with a finely powdered and homogeneous sample. In some samples of ashes of mixed fuels consisting of cannels and coals there was a large lump of refractory cannel ash enveloped in fused coal ash which had held up the whole fuel charge and led to trouble. In that case a properly prepared sample would have shown a very high degree of refractoriness, but not fusibility. He had adopted a plan of carrying out ash analyses on an extensive scale by which it was possible to predict the clinker formation in a particular fuel charge with a high degree of accuracy.

Professor J. W. **Cobb** wrote that any reliable process which enabled the individual losses incurred in producer-gas practice to be gauged with an approximation to truth from a laboratory examination of the fuel would serve a useful purpose. The loss due to sensible heat in gases leaving the producer was due to the carriage of heat upwards by the products of gasification of the fixed carbon in the bottom of the producer, and its incomplete extraction in the distillation process at the top; if, as now seemed likely, it became possible to replace air in many cases by oxygen in gasification owing to the cheapening of oxygen which was being brought about, the absence of nitrogen in large volume would tend to lessen that loss. Other accompanying economies would also increase efficiencies so far that some items of loss inevitably remaining would assume a greater importance relative to the total loss than had been the case in the past. One of these was the loss by radiation and convection, which had usually found a place in an omnibus item, termed "radiation, convection, etc.," and was made responsible for leakage, unknown losses, and the avoidable and unavoidable errors of experiment. He was interested therefore in the author's observations and calculations under this head. His figure of 1% for a large producer under at least three-quarters load confirmed the one which Mr. Hodsman and himself had felt justified (from the substantial agreement of three methods of calculation) in using when estimating the probable losses of an oxygen gasification process.

Dr. J. H. **Paterson** wrote that from a theoretical point of view the losses which took place during the artificial cooling of the gas produced had little interest. On the other hand, data showing the relationship between gas outlet temperature and rate of combustion and thickness of fuel bed would add very considerably to our somewhat scanty knowledge of these subjects. Of great value also would be curves showing the effect of fuel bed thickness and rate of working on the unaltered water content of the gas, and also on the hydrogen content.

Mr. **Rambush**, in reply, said that it was possible to design a gas-producer to use oxygen or air enriched with oxygen; probably it might mean a producer in which the ash was tapped out as molten slag, because (unless endothermal agents were added to a large extent) the heat would be far more intense in the lower zones. Investigations on the relative effect of steam and oxygen in the gasfication process were still in hand. He had not been able to determine the heat required for liberating the tarry matter from the fuel, but considered it to be of a small order, since the fall in temperature of the gases between the lower and upper part of the producer would account for this splitting up; in other words, if there were no volatile matters to be driven off, the gas outlet temperatures would be still higher than those used in the tables in his paper. The amount of dust removed depended upon the velocity in the gas outlet pipe; if the velocity in the gas outlet pipe became lower due to the removal of a smaller volume of gas per unit of time, it would become lower in the upper parts of the fuel bed as well as in the gas space above. With regard to the efficiency calculated for the gasification of coke breeze, he had chosen as typical a coke breeze containing 30% of ash although he had gasified successfully coke ballast containing up to 45% ash. By careful working the ash loss might be made less than the 10% assumed as an illustration, but whether such a coke breeze could be burnt more efficiently on a boiler grate he could not say. The coke breeze gas producer plant at the Birmingham Gas Works was designed for using coal, but as there was a superproduction of coke breeze to be burned somewhere, it was burnt with the coal in the gas producers. Dr. Lessing had mentioned the clinker formation when using mixed fuels. His experience was that the use of mixed fuels often caused such difficulties and his advice was not to mix different fuels if the best efficiency were aimed at. In his opinion there was still more work to be done on the relative fusing temperatures of ashes from various coals, such as had been commenced by Dr. Dunn. The temperature of the outgoing gases was very important and depended upon many factors especially upon the depth of fuel bed and the quantity of steam that was being added to the air blast. He had seen gas producers with temperatures as high as 900° and others of 700° C.

In reply to Dr. Paterson's remarks, the losses that took place by artificial cooling were of great importance as they emphasized that a thermally economical cold gas producer must be so designed as to give a crude gas leaving the producer, which retained as sensible heat as little as possible of the heat of the solid fuel. The further data required in reference to depth of fuel bed in reference to all factors to be considered in the working of a gas producer plant were very difficult to put down in definite figures, unless given in reference to a given fuel of constant quality and grading.

Regarding Prof. Cobb's remarks there was a limit to the completeness of the extraction of heat from the hot gases leaving the producer and that limit depended either upon what one could afford to spend in the construction of the gas producer, or upon the possibility of gasifying the particular coal at very low temperatures. The present state of the industry did not enable one to lay down any definite rule in this respect.

Glasgow Section.

Meeting held on February 22, 1921.

MR. J. H. YOUNG IN THE CHAIR.

LEAD CORROSION WITH RELATION TO SULPHURIC ACID MANUFACTURE.

BY WM. G. McKELLAR.

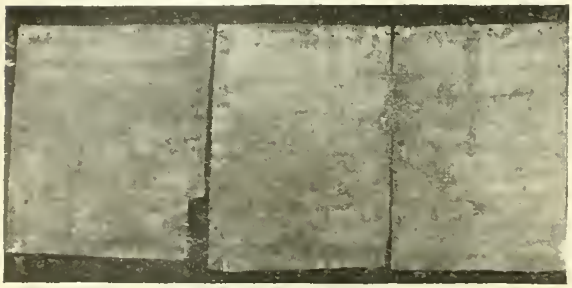
In the manufacture of sulphuric acid by the chamber process, frequent troubles are encountered owing to the failure of the lead sheets used in constructing the chambers, and an attempt has been made to ascertain the most suitable quality of lead for the purpose. Two types of desilverised lead are in general use for building chambers, namely, Pattinsonian and Parkes; each brand is advocated by the various refiners, and every maker guarantees that his lead is at least of 99·9% purity.

In the past Parkes's lead has often been regarded with suspicion, and generally for chamber building it has been blamed, I believe, by most chamber constructors, who prefer to use Pattinsonian lead; but in spite of preferences for one brand of lead or another, the results obtained, measured by years of service, out of any particular chamber or set of chambers are very unsatisfactory, and the reasons for failure most obscure.

It should be noted that while the problems relating to lead in chambers seem to be ever-recurring, trouble seldom occurs with lead used in Glover towers, cisterns, gas flues, and pumping pipes. Lead used in these situations usually appears to be immune from the troubles which beset chamber lead.

When the conditions of chamber working are surveyed, the following points are seen to deserve attention.

Method of supporting the leaden sheet.—Some builders prefer to hang the sheets from the top rail of the chamber frame and have no cross rails in the structure; the leaden sheets are secured to the vertical posts simply by clinching or folding over the end of the strap round the section of the post. Now while this form of construction has the merit that it provides very efficiently for expansion and contraction due to changes of temperature, it creates a difficulty which does not seem to have been sufficiently appreciated, arising from the fact that the sheet at the point of suspension is in a state of stress due to the weight so carried, which stress is a maximum at the point of suspension, reaching zero at the bottom of the sheet; a sheet so hung (when the chamber is at work) has its interior surface attacked by a corrosive atmosphere, accompanied by a relatively high temperature, 100°—180° F. (38°—82° C.), and these three sets of conditions, namely, stress and corrosion with high temperature, acting at the same time, appear capable of producing disastrous results in a very short time. Fig. 1 shows a strip cut from a sheet in a chamber, the entire lead work of which failed or gave way after a much shorter time than it should have done; the sheet is badly pitted, the pits being deepest and more marked at the top and disappearing towards the bottom. Analysis in such a case is useless, and even micrographical examination failed to disclose any difference in structure likely to cause this failure. The immunity from attack by sulphuric acid enjoyed by lead is probably due to the formation of an insoluble lead sulphate, and it can easily be conceived that if a protecting skin on lead once formed is subject to a continuous stretching action the skin will never be allowed to adhere, but will become detached as quickly as formed; further, the continuous stretching action exposes fresh lead surfaces to the action of the gases, and these surfaces are probably very susceptible to the action of the acid gases. There is therefore some reason in favour of modifying our views regarding this form of chamber construction. The alternative system of cross rails raises difficulties due to timber being an excellent non-conductor and not allowing sufficient heat radiation from the lead skin, and notwithstanding all the devices which have been proposed for helping to get the heat away, much yet remains to be done to perfect the cross-rail system. Further, the cross-rails prevent the free circulation of air around the chamber sheets, which is most desirable, and there is a lack of flexibility in the provisions for expansion. In any system in which timber is in contact with lead work, the life of a leaden chamber is greatly lessened at these points of contact.



Lead sheet, showing aggravated corrosion at top of sheet.

FIG. 1.

Chamber ventilation.—In any chamber plant working under normal conditions, there is always a large amount of energy in the form of heat due to the reaction between the sulphur dioxide and oxygen, which must be dissipated either by natural ventilation or by artificial cooling by water sprays on the outside of the lead work. Water cooling can be and is carried out satisfactorily, although this method involves an extra charge; but where there is no such arrangement, it is necessary to depend on the access of a free circulation of air round about the lead work. In the past this problem has not had adequate attention. In too many cases the passages are unduly restricted, due no doubt to the desire on the part of the builder to get as large an internal capacity as possible; in the west of Scotland the very wet climate is also a contributory cause. The passages are roofed in, thus imprisoning much heat that could easily be spared and tending to shorten the life of an acid chamber. In the years when lead cost £12 or less per ton, I believe it would have paid manufacturers to floor the chamber passages with lead, allowing free ventilation for the chamber sides and ends by dispensing with passage roofs.

Efficiency of nitre recovery.—With no system of nitre recovery, the quantity of sodium nitrate used would amount to 11% on the sulphur charged, but by the introduction of the Gay-Lussac tower this figure was reduced, till to-day over the United Kingdom it might average 3½%; on certain plants figures as low as 1¾% are claimed, and with close supervision and adequate gas scrubbing plant there is no doubt this low figure can be obtained over a continuous period of months. A low nitre consumption or loss leads to an increased life in a chamber plant, and the reason is not difficult to find. If sodium nitrate is "potted" or ammonia oxidised, nitric acid is formed, and this enters the chambers and attacks the lead work, whereas if the nitrosulphonic acid is decomposed by mixing with weak acid, and the mixture run down the Glover tower, either N_2O_4 or N_2O_3 is formed, both of which are excellent carriers of oxygen without the vicious properties of nitric acid.

Supply of water vapour.—The regular and well-distributed supply of water vapour, either in the shape of water sprays or steam, is essential. If the supply is insufficient, the strength of the acid mist in a chamber may rise dangerously, and a set of conditions exist which cause serious destruction of the lead work. On the other hand, if the supply is in excess, equally serious damage may be done to the lead work, accompanied by a greatly increased loss of nitrous compounds.

For all the four factors dealt with above as having an influence on the life of a sulphuric acid chamber, the chamber management alone is responsible; factors which merit the attention of the lead maker will now be considered.

Speed of sheet lead rolling.—The work of the Corrosion Committee of the Institute of Metals has shown that the cracking of brass condenser tubes is due to the state of internal stress produced in drawing them out; in fact any form of stamped or cold-drawn brass work is unreliable because of the abuse it has received in the process of manufacture, and in the light of a failure of lead, to be described, it is evident that lead also can receive such abuse on rolling that it never recovers. It may be said that lead anneals at ordinary temperatures; but while this may be generally taken as correct, it would seem that there are cases in which the lead has been so severely treated that it did not recover, even after the lapse of years. The particular failure to which reference is made happened both at our St. Rollox factory and in that of one of our neighbours. A large number of leaden boxes were made for the purpose of sending sulphuric acid abroad; the lead was $\frac{1}{16}$ inch thick and weighed 5 lb. per sq. ft. Each box carried 198 lb. of acid, and there was 7% clearance space to allow for any gas that might be given off after filling. The boxes were protected by an outside casing of wood, and all the joints were autogenously welded by means of the air and hydrogen flame. A small filling hole was cut out of the roofs of the boxes, and after filling the boxes were finally sealed by welding as before, a period of two days elapsing between the filling and final sealing, so as to allow of any gas generated to escape. The boxes lay in the warehouse for seven days preparatory to shipping, and about 3% developed leaks in a most alarming fashion. On examination of the defective cases it was found that numerous cracks had been formed in the lead, through which the acid flowed. The lead was exceedingly brittle, and a moderate blow with the fist on a defective side of a box caused the lead to give way with an irregular fracture, and left a hole which resembled the hole left in a glass pane when broken with a stone. There was no swelling of the lead work, so that it was evident that the lead had not been stressed by internal pressure. The lead was brittle and broke off short when bent in any direction. Exhaustive analyses showed that the lead was 99·9%.

It was evident that some means other than analysis was required to assist in clearing up lead problems, and accordingly I have endeavoured to inaugurate micrographic work for this purpose.

Naturally a lead maker wants to run his mill at the highest possible speed so as to get the highest output per unit of power and other charges involved, but care should be taken that the sheet of metal so produced has not received serious injury in the rolling process. Where cost is immaterial, certain architects insist on cast lead for roof work, and it is alleged that such cast lead is very superior to any form of rolled lead.

The presence of lead oxide inclusions in the mass of the metal is another source of failure, and these account, I believe, for the failures which take place in new leaden sheets in a chamber when first put to work. The failure takes the form of minute circular perforations which soon develop into large holes, and sheets having this defect never have a satisfactory life.

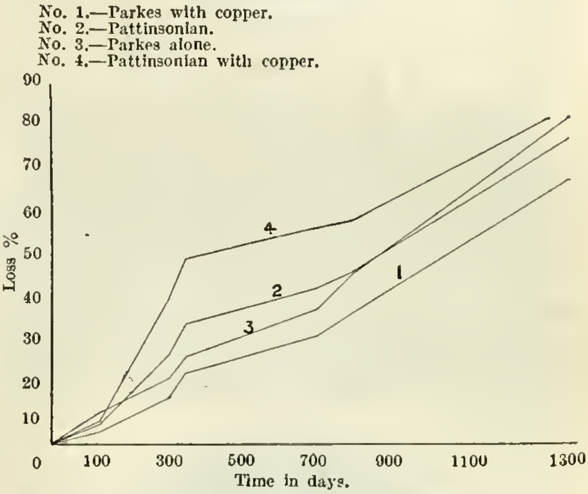
Attempt to solve the problem of lead corrosion.—Some fifteen years ago it was stated that lead containing about 0·1% of copper, either resulting from the presence of copper in the ores or introduced into the molten lead, resisted the action of the gases in a sulphuric acid chamber excellently. I regarded this very much as a quack remedy, and microscopical examination confirmed this, but in order to test the question along other lines four sample strips were prepared as follows:—

	No. 1. Zinc-treated lead with copper.	No. 2. Pure Pattinsonian.	No. 3. Zinc-treated lead.	No. 4. Pattinsonian with copper.
	%	%	%	%
Pb (diff.)	99·9029	99·9897	99·9719	99·9142
Cu ..	0·0790	0·0005	0·0017	0·0780
Bi ..	0·0120	0·0004	0·0170	0·0006
Sb ..	0·0005	0·0017	0·0008	0·0012
As ..	0·0009	0·0009	0·0017	0·0008
Sn ..	0·0022	0·0028	0·0030	0·0025
Fe ..	0·0003	0·0017	0·0003	0·0007
Mn ..	Nil	Nil	Nil	Nil
Ni ..	Nil	Ft. trace	Nil	0·0004
Zn ..	0·0020	0·0020	0·0034	0·0015
Ag ..	0·0002	0·0003	0·0002	0·0001

The strips measured 10¼″×3″, and were hung facing the travel of the gases by leaden hooks in the centre of a second chamber in a set for varying periods of time, and the losses in weight noted. The experiment lasted in all 1270 working days; at the conclusion the pieces had the following composition:—

	1.	2.	3.	4.
	%	%	%	%
Pb (diff.)	99·8966	99·9796	99·9647	99·9021
Cu ..	0·0550	0·0010	0·0004	0·0660
Bi ..	0·0400	0·0110	0·0260	0·0255
Sb ..	0·0030	0·0018	0·0024	0·0019
As ..	0·0009	0·0004	0·0008	Trace.
Sn ..	0·0020	0·0031	0·0036	0·0025
Fe ..	0·0003	0·0012	0·0003	0·0006
Mn ..	Nil	Nil	Nil	Nil
Ni ..	Nil	Nil	Nil	Ft. trace.
Zn ..	0·0020	0·0017	0·0016	0·0013
Ag ..	0·0002	0·0002	0·0002	0·0001

Unfortunately the analysis failed to throw any light on the problem, and the appearance of the pieces did not produce any evidence of value in determining the factors which regulated corrosion. The losses which occurred are shown in the following table and graph. The curves show to some extent the value of the clean, polished surface of the new lead in resisting attack, and also illustrate the protective value of the lead sulphate formed on the lead as indicated by the increased rise in the curve after cleansing at short intervals.

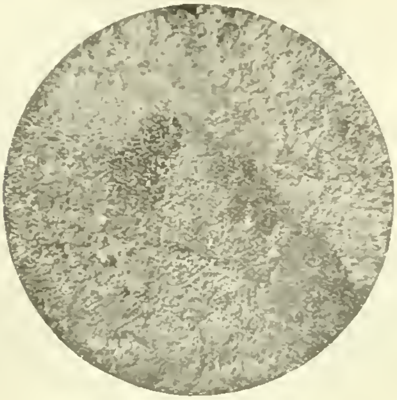


Time, days.	% Loss.			
	1.	2.	3.	4.
121	2·92	4·82	7·80	5·63
288	11·30	21·7	16·2	35·4
328	17·34	29·34	21·44	45·24
649	26·28	37·99	32·87	53·10
734	31·63	41·66	41·34	54·61
1270	64·69	74·72	79·86	82·21

These curves also raise the query "if the addition of copper was of value in the case of lead No. 1, why was it not equally valuable in the case of No. 4?"

Some time after the test had been running it was evident that it would have been of great advantage if there had been four parallel samples under test, which were only weighed at the conclusion of the experiment, and the disturbing effect of washing eliminated, but the test had reached such a stage that this could not be done for want of sufficient sample material to work on.

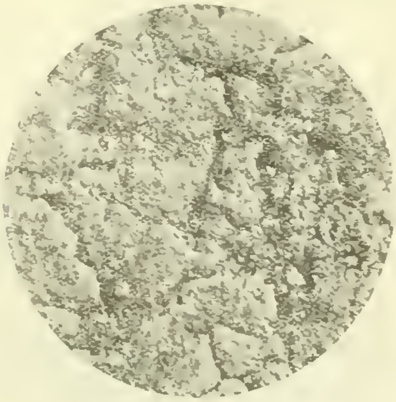
Micrographs were made of all four samples. The samples were cut with a sharp joiner's chisel, washed with methylated spirit to remove grease and dirt, immersed in cold 10% nitric acid, and the lead nitrate removed at frequent intervals by means of a camel-hair swab brush. The etching occupied about 3—4 days.



Parkes lead (copper-treated).
× 12.

FIG. 2.

It was found later on that the samples cleaned by spirit were often twisted and uneven, and as it was not desirable to flatten them out with a blow, they were planed true with a Stanley plane and then etched. A sample of copper-treated lead shows no outward indication of the presence of copper, but if it is etched the copper speedily appears as large segregates, which are apparently capable of causing a good deal of harm. Fig. 2 shows a sample of Parkes lead (copper-treated, ×12) etched by 1/1 nitric acid vapour, and reveals a deep pit with a large copper segregate, the deep black stain being due to a very dense segregate and the lighter shaded marks to less dense segregates.



Pattinsonian lead, copper-treated.
× 80.

FIG. 3.

Fig. 3 shows a sample of Pattinsonian copper-treated lead (×80) etched with 10% nitric acid; the black network showing all through is due to streaks and prills of copper. When 10% nitric acid is used for etching it is very difficult to keep the copper from disappearing, but by etching with the vapour from 50% nitric acid the copper is not nearly so severely attacked; unfortunately lead recrystallises at about 90° C., so that the vapour method of etching is of no use in examining the general lead structure.

From Figs. 4—7, showing the four sample pieces etched with 10% nitric acid, it is evident that the addition of copper to lead causes a very marked reduction in the size of the crystals. This may, however, be due to the violent plunging the lead receives after the copper is added, and not to the presence of copper at all.

Zinc-treated lead, with copper.
× 26.

FIG. 4.

Conclusions.—Summing up what has been said, the following points emerge:—

Wastage and destruction of lead in chamber work arise from faults which may readily creep in during the course of acid production, and it is for the makers of sulphuric acid to reduce these chances to the minimum.

Equally, trouble will arise with lead owing to the treatment it may have received at the rolling mills, and it falls on the lead makers to consider carefully this, and to disabuse their minds of the belief that notwithstanding the treatment lead may receive it will always anneal and recover at ordinary temperatures.

Pure Pattinsonian lead.
× 26.

FIG. 5.

Analysis alone is of no value in disclosing the source of trouble in lead, but if used in conjunction with micrographic work progress would be made.

I am satisfied that there is no alloy of copper with lead at the end of the scale where lead predominates, or in other words, it is not possible to produce a solid solution of copper in lead.

The vagaries as between the results obtained with Parkes and Pattinsonian lead which have been treated with copper lead to the conclusion that the protective value of the copper is mythical. There might be some value in treating the lead at the last stage of refining with a proportion of liquid copper, which, after thorough stirring through the molten charge, should be allowed to settle off. It should not be poured along with the lead. In this case the copper might act beneficially as a scour by alloying itself with certain prejudicial metals which are likely to be present with the lead, but great care would be required to see that all the copper was actually settled out, otherwise in the atmosphere of an acid chamber there is every probability that destructive galvanic action would be set up by the presence of the copper.

Zinc-treated lead.
× 26.

FIG. 6.

Pattinsonian lead, with copper.
× 26.

FIG. 7.

Experience with plant actually built with copper-treated lead has so far shown it to have a shorter lifetime than a similar quality of untreated lead.

All our experiments and observations, so far, still incline us to favour the use of Pattinsonian lead against Parkes, and as zinc is insoluble in lead, the presence of any zinc accidentally left in after separation of silver would be quite as detrimental as that observed in the case of copper, with this difference, that, owing to the copper being readily seen, it is much easier to see when mischief has been caused by that metal than it would be in the case of zinc, which cannot be so readily detected by micro-examination.

Communications.

THE RELATION BETWEEN THE DENSITY AND COMPOSITION OF GLASSES.

BY W. L. BAILLIE.

Prior to the researches of Winkelmann and Schott (Winkelmann, Ann. Phys. Chem., 1893, **49**, 401; 1897, **67**, 105; Winkelmann and Schott, *loc. cit.*, 1894, **51**, 697, 731) little appears to have been definitely known regarding the relations existing between the composition of glasses and their physical properties. It was shown (*loc. cit.*) from the study of a large number of glasses that many physical constants admit of computation with tolerable accuracy by means of appropriate numerical factors and that, in particular, density may be so calculated. For the majority of the silicate and borosilicate glasses studied, the calculated and observed densities agreed to within 2% or thereby. Larger discrepancies, however, were encountered in the case of zinc borate and lead borate glasses, the greatest being just over 10%.[*]

The relation between density and composition was investigated later by Tillotson (J. Ind. Eng. Chem., 1911, **3**, 897; 1912, **4**, 820), who proposed considerable modifications in certain of Winkelmann's factors. It was shown from experimental meltings and from data collated from Larsen (Amer. J. Sci., 1909, **28**, 163), Wallace (Z. anorg. Chem., 1909, **63**, 1), Day and Allen (Bull. 31, Carnegie Inst. of Washington) and others, that the new factors so obtained led to distinctly better agreement between calculated and observed values than did the old. Unfortunately, however, Tillotson did not derive factors for PbO (†) and K_2O, two important constituents of many varieties of optical glass. In this respect, therefore, his results are incomplete, and full comparison with other systems of density moduli is not directly possible.

In connexion with the work of the Directorate of Chemical Inspection it became necessary to ascertain the applicability of published moduli to certain types of glassware. Winkelmann's values being found to lead to greater discrepancies between calculated and observed densities than was desirable, an endeavour was made initially to complete Tillotson's series of factors. Consideration of his data, however, led to a distinctly lower value for the density of combined SiO_2, and it became apparent that it would be necessary to evaluate new factors on this basis. Conditions rendered it impossible to prepare suitable series of glasses of known and simple composition. The problem had therefore to be attacked by consideration of published data and determination of the densities of available glasses already analysed.

Subsequent to the completion of this work, English and Turner published two papers on the density of lime-soda and magnesia-soda glasses respectively (J. Soc. Glass Tech., 1920, **4**, 153, 126). They showed that the original factors of Winkelmann and Schott are inadequate, and that Tillotson's factors, although superior, do not satisfactorily reproduce their experimental results. A few factors are tentatively proposed by them, but final pronouncement is delayed pending further work. It is shown, however, that certain results are at variance with Tillotson's deductions from Larsen's data (*loc. cit.*). This anomaly is discussed below.

It is customary to express the composition of glasses in terms of constituent oxides. The calculation and application of density moduli is based on the assumption that to each of these oxides, in

---

[*] Adequate summaries of these researches are given, with numerical data, in Hovestadt's "Jena Glass" (Macmillan), 1902, pp. 144 *et seq.*

[†] See note to Table 11.

its combined state, may be assigned a constant, though empirical "density."

Let the analytical results for a glass be $a\%$, $b\%$, $c\%$, ...$n\%$ of the n oxides composing it, and let the sum of the determined constituents be S—a quantity which should differ only slightly from 100. If, now, these oxides have, in their combined states, densities A, B, C ....N, and if the density of the glass, as determined by experiment, be X, then, equating the sum of the partial volumes to the total volume, we have:—

$$\frac{a}{A}+\frac{b}{B}+\frac{c}{C}+\ldots\ldots\ldots+\frac{n}{N}=\frac{S}{X} \quad \ldots\ldots\ldots\ldots \quad (1)$$

Given a suitable series of n glasses of identical qualitative composition, numerical values may be obtained for the n density moduli, A, B, C............N from the n simultaneous equations which are derived. Satisfactory values having been obtained for the commoner constituents, it is comparatively simple to extend the series to include other oxides. The concordance shown below between calculated and observed results is substantial indication of the validity of the basic assumption, but the anomaly mentioned above would appear to indicate that the nature of the remaining oxides may not on occasion be without effect on the density moduli of certain constituents.

Generally, by analogy with liquid mixtures, it is to be expected that the densities calculated for the combined oxides will exceed those observed for the same oxides in the free state. This was stated to hold without exception by Winkelmann and Schott (*loc. cit.*). Tillotson, however, found that Al_2O_3 appears to expand in combination with resulting diminution in density. This observation has been confirmed, and it is shown below that Sb_2O_4 behaves similarly. At this stage it is not possible to express a definite opinion on the significance of these conclusions, but it is suggested that combination of these oxides with silica and bases to form vitreous bodies may be attended with fission of their molecules. The following table shows the difference between the densities of the free and combined oxides, as found by the observers named. In the last column are given the moduli now proposed.

TABLE I.

Densities of glass-forming oxides in free and combined states.

Oxide.	Density in free state.		Density in combined state.		
	Determined.	Remarks.	Winkelmann.	Tillotson.	Proposed.
SiO_2	2·22	Deville 1855	2·3	2·3	2·24
Al_2O_3	3·85	Rammelsberg	4·1	2·75	2·75
Sb_2O_4	6·69	—	—	—	3·00
B_2O_3	1·79	Clarke	1·9	2·24	2·90
As_2O_3	3·74	—	4·1	(4·1)	3·33[1]
ZnO	5·65	Schröder	5·9	5·9	5·94
BaO	5·00	Clarke	7·0	7·0	7·20
CaO	3·30	Moissan	3·3	4·1	4·30
MgO	3·60	Clarke & Moissan	3·8	4·0	3·25[2]
PbO	9·30	Clarke	9·6	9·6	10·30
K_2O	2·66	—	2·8	(2·8)	3·20
Na_2O	2·55	—	2·6	2·8	3·20

[1] Provisional only.

[2] In absence of alkali oxides, the value 4·30 is to be taken.

The analogy with liquid mixtures, which is not invalidated by the behaviour of Al_2O_3 and Sb_2O_4, explains simply the considerable discrepancies recorded by Winkelmann and Schott in the case of the borate glasses, and also the differences now found in the case of the two exceedingly dense flint glasses (Nos. 8 and 9, Table 9). It will be seen that all the markedly exceptional glasses are substantially of the nature of simple borates or silicates. The glasses which show close agreement are invariably of the more usual double silicate, borosilicate, or aluminosilicate types. It would therefore appear that this treatment is, in general, inapplicable to glasses of the simplest composition. Fortunately this reservation is generally of little moment since, in practice, such glasses are only very rarely encountered.

It will be clear from the manner of their derivation that all these moduli are interdependent, so that errors in the values of the moduli for the commonest oxides will be reflected in all deductions based thereon. Since silica is the major component by weight in the majority of glasses, and since its modulus is the smallest, it follows that the partial volume of combined silica is generally the largest in a glass. For these reasons attention was primarily directed to the determination of the density of combined silica, employing data from Tillotson (*loc. cit.*). For reasons discussed below, Winkelmann's data were disregarded.

The method of obtaining these moduli renders it possible to achieve absolute concordance between calculated and observed value for any small series of glasses all containing the same oxides and to the same number as there are glasses in the series—*e.g.*, four glasses containing SiO_2, CaO, Na_2O, and Al_2O_3 in different proportions. This misleading appearance of accuracy must be sacrificed if good general agreement is to be obtained with glasses of widely different compositions. The moduli now proposed have been derived for this more general purpose. Certain causes are considered below which may impair the degree of correlation which may be obtained when many glasses are in question.

It is known that the thermal history of a glass exercises a profound influence upon its physical and mechanical properties. "Rupert's drops" represent a familiar laboratory example, while the "tempered"—more accurately, case-hardened—glass of de la Bastie represents an attempted commercial utilisation of the resistance to impact and sudden changes in temperature shown by glass which has been subjected to appropriate heat treatment. The presence of strains, due to inefficient annealing, has been shown to augment expansibility, to reduce thermal endurance, and to diminish density. In the case of certain MgO—Na_2O—SiO_2 glasses, English and Turner (J. Soc. Glass Tech., 1920, 4, 153) found that careful annealing of air-cooled rods caused increases in density of as much as 0·01. Similar figures have been recorded for window glass (Chevandier de Valdrôme and Wertheim, Comptes rend., 1845). Zulkowski has made the suggestion that "plaining" yields a homogeneous glass primarily because it allows of the attainment of chemical equilibrium in the mass (Chem. Ind., 1900, 23, 108). If this be accepted it follows that faulty heat-treatment during founding may occasion discrepancies between observed and calculated densities which annealing cannot eliminate.

Tillotson has rightly insisted that the densities attributed to the (combined) constituent oxides of glasses must be regarded as controlled by more than the density of the uncombined oxides alone. The general order of the moduli would appear to indicate that the density of the free oxide is a controlling factor. On the other hand, it is yet to be proved that mode of combination is without effect. Indeed, the anomalous behaviour of MgO, described later, suggests that this factor is occasionally of considerable importance.

The duplex character of the "plaining" process premised by Zulkowski (*loc. cit.*) leads to the conclusion that during the process some at least of the oxides must alter their state of combination till equilibrium is reached. Up to this point no constant modulus may be applicable. It is conceivable, indeed, that "plaining" may not entirely correct this, so that, depending on the qualitative and quantitative composition of the glass, application of any rigid modulus may lead to imperfect concordance between calculated and observed results. On the other hand, it appears hardly likely that considerable differences can exist between the moduli appropriate to the various states of combination, so that the differences between calculated and observed results should be, in all probability, of the order of 1—2%. This conclusion is borne out in the case of MgO, the only oxide which, so far, has been found to show any variation in modulus with mode of combination. In the case of experimental melts it is comparatively simple to carry "plaining" to the required degree, and in such cases agreement between calculated and observed results should be close. Optical glasses, on the other hand, do not always admit of such prolonged heating, and for this reason less rigorous agreement may not unreasonably be expected. It is noteworthy, in this connexion, that not only is this state of affairs realised in the data below, but that marked divergencies between calculated and observed densities in the case of glasses of extreme composition are generally negative, *i.e.*, the calculated densities are high.

The effect of permissible analytical errors upon the calculated densities may be shown generally as under:—

Let the true composition of a glass be $a\%$, $b\%$, $c\%$.........$n\%$ respectively of its n constituents. Then—

$$\frac{a}{A}+\frac{b}{B}+\frac{c}{C}+\dots\dots\dots+\frac{n}{N}=\frac{100}{X}\quad\dots\dots\dots\dots\quad(2)$$

If, now, the analytical results be in error by amounts α, β, γ.........ν, then the calculated density, X_1, is given by

$$\frac{a+\alpha}{A}+\frac{b+\beta}{B}+\frac{c+\gamma}{C}+\dots+\frac{n+\nu}{N}=\frac{100+\alpha+\beta+\dots+\nu}{X_1}\dots(3)$$

Rewriting and substituting from (2), we have

$$\frac{100}{X}+\Sigma\left(\frac{\alpha}{A}\right)=\frac{100+\Sigma(\alpha)}{X_1}\dots\dots\dots\dots\dots\dots\dots\dots\quad(4)$$

Whence:—

$$X_1=X\left\{\frac{100+\Sigma(\alpha)}{100+X\Sigma\left(\frac{\alpha}{A}\right)}\right\}\dots\dots\dots\dots\dots\dots\dots\dots\quad(5)$$

In general the differences between $\Sigma(\alpha)$ and $X\Sigma\left(\frac{\alpha}{A}\right)$ are slight, so that discrepancies due to allowable analytical variations are much less considerable than those mentioned above.

It would therefore appear that experimental results may not be reproduced if the glasses tested be not free from strain or have been insufficiently plained during manufacture. The effect of other ingredients on the moduli of particular oxides is discussed, in the case of MgO, after Table 7. Slight inaccuracies are also possible in the moduli themselves, depending on the operation of the foregoing sources of error upon the glasses examined. Fuller discussion on this point is not at the moment possible, sufficient data being lacking.

It was initially hoped that the wide range of glasses studied by Winkelmann might be employed with advantage in calculating density factors. (Seventy-two glasses in all are described, including silicates, borosilicates, aluminosilicates, borates, phosphates, etc.; *vide* Hovestadt, "Jena Glass," pp. 146—147.) Consideration of the compositions given, however, led to the conclusion that they were not based upon analysis. The fact that the sum of the constituent oxides always lay between 99·9 and 100·1 was taken as at least an indication of recalculation of results to the 100% basis—if not, indeed, calculation from the batch. The absence of traces of impurity normally found even in optical glasses, due to impurities in the raw materials or to solution of the pot substance, appeared to confirm the latter supposition unless all the melts had been made in platinum, a fact which surely would have been recorded. Confirmation of the final conclusion that the results were calculated from the batch was found in a paper by Zschimmer (Z. Elektrochem., 1905, 11, 629). This finally invalidates Winkelmann's data for the purpose in question, and some of his glasses, selected at random, have shown that even poorer agreement may now be found than with his original moduli,

TABLE 2.

Composition and densities of Na_2O—BaO—SiO_2 glasses.

	Algebraical sum of errors..							0·522	0·005	0·114

the discrepancies being occasionally many times greater than in the case of the analysed glasses discussed below. On all grounds, therefore, Winkelmann's series of factors may be discarded as inherently inadequate to reproduce experimental results with any reasonable degree of accuracy.

Examination of the available data indicated that Tillotson had already discussed the most serviceable observations. Comparison of his tables led to the choice of his 21 melts in the Na_2O—BaO—SiO_2 series from which to derive the factor for combined SiO_2. By selection of three sets of three melts, three slightly different values for SiO_2 were obtained, and from these values for Na_2O and BaO were calculated. The densities of the twenty-one glasses were then computed, using each series of factors in turn, and the results led to the adoption of the following mean values:—SiO_2 2·24; Na_2O 3·20; BaO 7·20. Employing these moduli, Table 2 has been constructed.

It will be clear that, however judged, Winkelmann's factors give the poorest results. There is less difference between the remaining systems and correspondingly closer agreement between calculated and observed results. The slight diminution in the mean square error, however, is regarded as indicating that the factors now proposed are slightly superior.

Larsen's data for CaO—MgO—SiO_2 melts were employed for evaluating the moduli for these bases, the above value for SiO_2 being utilised. As before, several pairs of factors were deduced and applied to the glasses in turn, when the greatest degree of concordance between calculated and observed densities was found to be obtained using the values MgO 4·30; CaO 4·30.

By means of certain of the foregoing values the density of combined Al_2O_3 was deduced from the results of Day and Allen for albite-anorthite mixtures (*loc. cit.*). In agreement with Tillotson, the mean value best representing their results is 2·75. It therefore appears that Winkelmann's value, 4·1, is definitely much too high. The factors have been applied also to English and Turner's CaO—Na_2O—SiO_2 glasses, with results as given.

It will be seen that Winkelmann's factors again fail to reproduce experimental results, and that the factors now proposed show a slight but definite advantage over those published by Tillotson.

Scrutiny of the densities of MgO—Na_2O—SiO_2 glasses recorded by English and Turner (*loc. cit.*) showed that the modulus for combined MgO obtained from Larsen's data was quite unsuitable, since its adoption would necessitate an increase in density on successive replacement of Na_2O by MgO, and not a slight fall as was found experimentally. It was found, however, on consideration of the figures, that the value 3·25 for MgO, in conjunction with the figures previously adopted, expressed the experimental results very closely (Table 7). The compositions and densities of the glasses are shown in Table 6.

* From English and Turner, *loc. cit.*
† Including 0·5% CaO.

Details of minor ingredients are not given in the original. A mean modulus 3·0 has been assigned for use with the factors now proposed, and 3·5 for use with Winkelmann's factors.

The factors tentatively proposed by English and Turner are as follows:—

	Series 1.	Series 2.
SiO_2	2·20 ..	2·30
Na_2O	3·47 ..	2·9
MgO	3·38 ..	2·0

Comparison of Tables 3 and 7 shows that the experimental results are adequately reproduced by the systems of factors proposed, subject to the adoption of the smaller factor for MgO in the latter case. The density of combined MgO therefore appears to exceed that of the free MgO in the $CaO—MgO—SiO_2$ glasses and to be less in the $Na_2O—MgO—SiO_2$ glasses. In the former series of melts it is reasonable to suppose that $CaSiO_2$ and $MgSiO_3$ are formed and that the metasilicates are mutually soluble. Indeed, it may simply be demonstrated graphically or by calculation that this assumption meets the facts. On the other hand, it is established from the properties of $Na_2O—MgO—SiO_2$ melts that they could not have resulted simply in mutual solution of silicates of sodium and magnesium, but that further reactions occurred with the formation of more stable compounds possessing in increasing degrees those qualities of chemical durability usually associated with the term "glass" as the magnesia content increased. The conclusion appears to be indicated that, in alkali-containing melts, the density of combined MgO is less than that of the free oxide, thus making it comparable with Al_2O_3 and Sb_2O_4, but that an increase in density occurs in melts of such composition that no chemical action is probable beyond the formation of a simple magnesium silicate. For this reason, therefore, the value 3·25 has been adopted for the density of combined MgO in ordinary glasses, and the results tabulated below have been recalculated

(from the value 4·30 previously adopted) on this basis.

None of the remaining constituents of optical glasses being included in the available published data, the list of moduli was extended from 34 glasses of known composition. Density determinations were made by means of a specific gravity bottle. This was chosen primarily for convenience and immediate availability and the fact that, besides involving neither unusual nor elaborate accessories, it admits of the attainment of a sufficient degree of accuracy without unduly laborious supervision. It is unnecessary in this work to carry results beyond the fourth decimal place to secure accuracy in the third, and the method adopted was found, by the concordance between duplicate determinations, to be sufficiently delicate. This degree of accuracy corresponds to an error rarely exceeding 0·04% and further refinement is needless. Densities were determined on clean, freshly-broken fragments which were brushed free from dust, thus almost wholly eliminating trouble from adherent air-bells. Water was employed throughout, none of the glasses exhibiting sufficient solubility to negative its use. The succeeding tables show the compositions and densities of the glasses employed, and the degree of correlation between the observed values and those calculated by the various systems of factors.

Density factors for PbO and K_2O were calculated to be 10·30 and 3·20 respectively. After making correction for the small amounts of Sb_2O_4, ZnO, and B_2O_3 by means of factors subsequently deduced, the following densities were calculated.

The factor 5·94 was deduced for ZnO from No. 1 of Table 10 and the small corrections for minor con-

Algebraical sum of errors ..	4·109	0·729	0·118

Summary.

(1) The relation between the density and the composition of glasses has been re-investigated.

(2) The moduli proposed by Winkelmann and Schott have been found to lead to discrepancies exceeding 2% in the case of glasses of normal types. The more satisfactory moduli proposed by Tillotson have been shown to be susceptible of certain improvements.

(3) New moduli are proposed whereby glasses of extreme composition may be included with as high a degree of accuracy as was formerly possible for glasses of normal composition.

(4) Applied to 91 glasses, the new moduli have been found to lead to the smallest average error, the smallest mean-square error, and the lowest algebraical sum of errors.

(5) The theory has been discussed and the reasons for certain discrepancies are indicated.

I wish to acknowledge the assistance of my former colleague, Mr. W. T. Lockett, in the experimental work and the calculations involved. Thanks are due also to Mr. G. H. Perry, O.B.E., Director of Chemical Inspection, for the interest he has shown in this work, and to the Director of Artillery, War Office, for permission to embody in the paper analytical and other results obtained in the work of this laboratory.

THE BACTERIAL PURIFICATION OF TRADE WASTES.

BY DR. G. McGOWAN.

The Ninth Report of the Royal Commission on Sewage Disposal[*] deals with the disposal of liquid wastes from manufacturing processes. The outbreak of the war, however, cut short the study of the subject, and various points requiring investigation were of necessity left untouched or unfinished. One of these was to acquire accurate experimental data with regard to the amenability of different trade wastes to bacterial purification or, in other words, to ascertain the respective volumes which could be treated on a cubic yard of contact bed or percolating filter. Since that time the activated sludge process of sewage purification has gained increasing prominence, and as this process largely conserves the nitrogen of sewage, it may be expected to become more widely applied as time goes on. Still, the data to be given in the present paper will apply so long as the purification of sewage on contact beds and percolating filters continues; and, besides, the relative rates at which different trade effluents undergo oxidation affect the activated sludge process also.

The bacterial treatment of domestic sewage is now fairly well systematised, the volume which can be dealt with on unit of filter depending on the strength of the sewage or tank liquor. This "strength" is measured in terms of the oxygen required to oxidise fully the organic matter and ammonia present. 100,000 parts by weight of a sewage of average strength require about 100 parts by weight of oxygen for this purpose.[†]

To estimate the strength of a sewage or other polluting organic liquor, a small measured volume is mixed with a large measured volume of good tap water, *i.e.*, with excess of dissolved oxygen, and the oxygen in solution is determined (*a*) at the time of mixing and (*b*) after all the oxidisable matter present has been oxidised. The difference between the two figures found gives the amount of oxygen taken up by the sewage or other liquor.

The procedure followed in this determination of dissolved oxygen absorption is to be found in the Eighth Report of the Royal Commission, Vol. II., Appendix, p. 93 *et seq.* [Cd. 6943 (1913)], but a short outline of it may be given here. The requisite dilution having been made with water at a temperature of about 18° C., the liquid is poured quietly, in alternate sections, into two bottles, (*a*) a smaller one of about 350 c.c. capacity, in which the determination of the initial oxygen is immediately made, and (*b*) a quarter-Winchester of 600—700 c.c. capacity, with a well-fitting stopper. Both bottles are of course filled full to overflowing. After the stopper of the quarter-Winchester has been firmly inserted and tied down with tape, a small piece of wide rubber tubing of about 20 mm. internal diameter and 50 mm. long is slipped over it, the top of the rubber remaining about 15 mm. above the head of the stopper. The rubber joint is then nearly filled with mercury and the bottle set aside until the oxidation has completed itself. Unless the glass stopper should have been a bad fit, which rarely happens, this forms a satisfactory joint for the purpose.

At the end of the period allowed for this "long aeration," the small quantity of gas which has collected at the top of the bottle is transferred and analysed, the figure for the oxygen which it contains being added to that for the oxygen in the residual liquid. The method of the transference is described in the Eight Report, Vol. II., Appendix, p. 149. It should, however, be added that bottles which have been jointed for a number of years, like those referred to in this paper, may have the stopper so firmly cemented in that this treatment is at first insufficient to loosen it. In that case, after pouring a drop or two of water on to the stopper, the rubber and mercury (not the tape) should be replaced and another trial at opening made next day. I have in the most persistent cases had to try three or four times in this way before succeeding in getting the stopper loosened. The precautions necessary for the estimation of the residual oxygen in the liquid are detailed in the Eight Report, p. 149; I might add here that, instead of liberating the iodine in the water in the presence of some mercury and immediately pouring off, an alternative method is to siphon the liquid into a smaller bottle, previously filled with carbon dioxide, rejecting the first and last portions.

The various samples of trade effluent dealt with in this paper were typical ones drawn by the Officers of the Commission between 1907 and 1914, together with a few drawn later. They were fully analysed at the time by Messrs. A. C. Carter, F.I.C., A. F. Girvan, B.Sc., A.I.C., and the late W. G. Winterson, B.Sc., these analyses including

the determination of dissolved oxygen absorption for the shorter periods up to five days or so, and of the initial oxygen of the "long aerations." The residual oxygen of the latter and of the separated gases have been estimated recently by myself (in 1920). The actual quantities of these gases (reduced to N.T.P.) in 58 estimations were:—

	Extremes.	Average.
Carbon dioxide	0 to 0·07 c.c.	0·02 to 0·03 c.c.
Oxygen	0 to 0·65 c.c.	0·27 c.c.
Nitrogen	0·46 to 3·15 c.c.	1·76 c.c.

As it may be useful, for purposes of future reference, that the general character of the samples examined should be known, the reference is given to the pages of the Ninth and Sixth[§] Reports of the Commission where, with a few exceptions, the detailed analyses are to be found. The two samples from the jam factories were examined after the publication of these reports, and are therefore not included in them; nor are some of the malt distillery samples. The general character of the latter can, however, be deduced from the other similar samples. Meantime, it will suffice to give here the figure for dissolved oxygen taken up in five days and that required for complete oxidation.

The ratio of the figure for dissolved oxygen absorption in five days at 18° C. to that for complete oxidation is in the case of domestic sewage something like 1:3. A higher ratio—say, 1:6—means that the oxidation as a whole proceeds more slowly, *i.e.*, that the liquor in question is more difficult of oxidation than sewage. Failing, therefore, a full series of estimations for each sample, giving the figures for dissolved oxygen absorption in 2, 5,......x days, the ratio between the figures obtained for five days and for complete oxidation may in the meantime be taken as a guide for getting at the amenability of the trade liquor to bacterial treatment.

The length of time which should be allowed for the "long aeration" of trade effluents, *i.e.*, for their (practically) complete oxidation in the laboratory, is difficult to state precisely. Probably three months at a temperature of about 18° C. would be sufficient in nearly all cases, but it would be safer to allow six months, either at 18° C. or at laboratory temperature.

[§] "Disposal of Liquid Refuse from Distilleries" (1909), Cd. 4511.

Cotton dyeing and printing.—In the case of the seven samples examined the ratio of A:B varied from 1:3·4 to 1:4·6, the average being 1:4·1—say, 1:4. A waste liquor or partially purified effluent from cotton dyeing and printing, therefore, which takes up about 25 parts of dissolved oxygen from water in five days at 18° C., may be regarded for purposes of bacterial purification as approximately equivalent to a sewage of strength 100.

It is to be noted here that the two lowest ratios, 1:3·4 and 1:3·6, are given by a crude waste and a tank liquor which contained respectively 11·6 and 6·6 parts of suspended organic solids. The foregoing tentative conclusion, therefore, to look upon such waste giving a five days' figure of 25 as equivalent to sewage with a corresponding figure of 33 receives from this some corroboration.

It has also to be borne in mind that here, as in the case of other types of trade effluent, bacterial oxidation will proceed more rapidly the larger the proportion of domestic sewage there is in the mixture.

Cotton bleaching.—The data here are too meagre for any conclusions to be drawn, but the probabilities are that effluents of this class would not differ materially from cotton dyeing and printing effluents, provided that no large excess of hypochlorite was left in them. Any large excess of the latter would of course retard bacterial oxidation.

Paper mills.—Here, again, the data are very few, but the ratio of the five days' figure to that for complete oxidation may with some degree of probability be taken in the meantime as 1:4·5. This would make a paper mill liquor or effluent with a five days' figure of about 22 equivalent to a sewage with a figure of 33.

Tanning and fellmongering.—The ratio here may also be taken tentatively at 1:4·5.

Jam factories.—With almost no data to go upon, nothing can be said here excepting that such liquors are organically very strong and that they are also slow of oxidation. Possibly the proportion of nitrogen to carbon may be too small for the best rate; in these two samples the combined nitrogen would amount to only about 2 and 3 parts per 100,000, respectively. Pending further results, I think that the ratio A:B might be taken at about 1:10.

Malting and brewing liquors.—Although there are only two results here, they indicate that these liquors are readily oxidisable, the ratio A:B being much the same as that for domestic sewage.

Distillery waste.—The purification of waste distillery liquors is gone into in detail in the Sixth Report of the Commission. The samples cited in the tables were drawn for the purposes of that report in 1908–9 (one in 1907).

Grain distilleries.—Here we have four samples altogether of steep water, spent waste, and spent wash (apart from the paper-filtered samples), and three of them were aerated in duplicate. The four gave a ratio of A:B=1:2·5 to 1:3·5, average 1:3·0. Such liquors, therefore, with a five days' figure of about 33 and a strength of 100 would be equivalent to a sewage of strength 100. The actual strength of the undiluted liquors is of course excessive—in the above samples reaching as high as 50 to 60 times the strength of an average sewage. Considering the very high dilutions (up to 1 in 10,000) that had to be made here, the agreement between the figures for dissolved oxygen absorption by the duplicate samples was fairly good. In the second sample of spent waste, which was examined both before and after filtration through paper, 1 part of the suspended solids present required 1·6 parts of oxygen for oxidation, while 1 part of the soluble solids required 4·0 parts oxygen.

Malt distilleries.—The results (leaving spent lees for the moment out of account) are similar to those given by grain distillery liquors. The ratio A:B in the first seven samples varies from 1:2·3 to 1:4·2, average 1:2·8. As modifying this, however, it must be noted that the figures taken for the five days' dissolved oxygen absorption are not quite the true figures; the true figure would probably be more than that for five-sevenths of seven days, while it might be less than that for five-fourths of four days. On the whole, therefore, the ratio may safely be taken as about 1:3—the same as for domestic sewage. The actual strength of the liquors is great, notably that of the pot ale; the others were less strong than those from the grain distillery. With the exception of the pot ale sample, where the very high dilution of 1 in 15,000 had to be made for the long aeration, the other duplicates showed very fair agreement.

Spent lees.—The volume of spent lees in a malt distillery, as compared with that of the pot ale and steep liquor, is so small, and its organic strength so much less, that it hardly requires detailed consideration here. The results obtained with the two samples tabulated above are, however, interesting as showing the slow rate at which oxidation went on. Mixed with the other distillery liquors, therefore, the spent lees will tend to retard the bacterial oxidation of the whole, though its relatively small volume renders this of little moment. I cannot account for the discrepancy between the two figures obtained for the oxidation of the distillation residue from the first sample (83·5 and 58·5).

Summary.—Excepting in the case of the distillery and, inferentially, the brewery waste liquors, the results given in this paper require to be materially supplemented. Pending, however, detailed figures giving the rate of bacterial oxidation of the various kinds of trade waste, this oxidation being carried to its limit, the following wastes may in the meantime be roughly classified as follows:—

	Dissolved oxygen taken up from water in 5 days at 18° C. Parts per 100,000, by weight. About
"Standard" domestic sewage ...	33
Waste liquor from—	
Grain distilleries	33
Malt distilleries	33
Maltings and breweries	33
Calico printing and dyeing ...	25
Calico bleaching ... (probably)	25
Paper mills	22
Tanneries	22
Jam factories	(?)10

In other words, unit section of bacterial filter will purify one volume of "standard" domestic sewage, or one volume of waste distillery liquor, or 25/33 volume of waste liquor from calico printing and dyeing, and so on, all the liquors being assumed as diluted to the same "strength" as the sewage.

Chemical Laboratory,

EXAMINATION OF SOME METHODS OF ASCERTAINING THE PURITY OF SACCHARIN.

BY PHYLLIS VIOLET McKIE.

The saccharin prepared from toluene by the usual methods contains, before purification, small quantities of other sulphonic derivatives of toluene. The most common of these impurities are:—

(1) *p-Sulphamidobenzoic acid.*

(2) *Ortho- and para-toluenesulphonamides.*

(3) *o-Sulphamidobenzoic acid.*—Statements in the literature regarding the isolation of this acid are misleading. It is described by Fahlberg (Ber., 1888, 21, 243) as being very easily soluble in water, and for that reason only isolated by ethereal extraction. I

have, however, prepared this acid, and find that subsequent strong acidification of the mother liquor, which had been three times extracted with ether and gave by this means 61·5% of the theoretical yield of *o*-sulphamidobenzoic acid, deposited crystals of the same acid on standing representing a further 14%. It is therefore possible to "salt out" this acid with strong mineral acid. As saccharin is isolated by a similar "salting out," it is probable that the *o*-sulphamidobenzoic acid will, if present, be precipitated, to a certain extent with the saccharin.

(4) *Toluene*-2.4-*disulphonamide.*

(5) *Toluene*-2.4-*disulphonic acid.*

The presence of any of the above substances in commercial saccharin is variously indicated. Three criteria are of value in estimating the purity of saccharin:—

(a) *Depression of the melting point.*—The presence in saccharin of small amounts of impurity causes in several cases considerable depression (10°—15°) of the melting point.

(b) *Incomplete solubility in sodium bicarbonate.*—The presence of certain impurities is also indicated by incomplete solubility in aqueous sodium bicarbonate. Ortho and para-toluenesulphonamide and toluene-2.4-disulphonamide, in that they are extremely weak acids, are insoluble in this reagent. This property, moreover, as well as specifically indicating the presence of one or other of these substances, affords a means of eliminating them from the saccharin mixture.

(c) *Hydrolysis.*—Saccharin is hydrolysed in acid solution to *o*-sulphobenzoic acid and ammonia. Determination of the quantity of ammonia thus evolved from a known weight of commercial saccharin is, under certain conditions, a criterion of its purity.

(a) *Depression of melting point.*

The effect of each of the most common impurities, *p*-sulphamidobenzoic acid, *o*-toluenesulphonamide, and *o*-sulphamidobenzoic acid, on the melting point of saccharin has been examined.

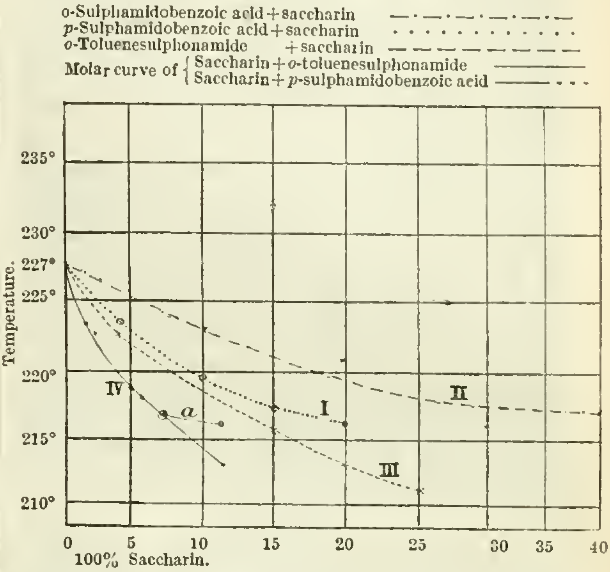
The melting point of saccharin formerly given in the literature is 220° C. with partial decomposition (Mosso, Jahresb., 1887, 2585), but completely pure saccharin melts at 227°—227·5° C. (corr.) and shows no sign of decomposition; it re-solidifies and melts again at the same temperature. Richmond and Hill (J., 1919, 8 T) give m.p. 229° C.

p-Sulphamidobenzoic acid.—Mixtures of pure saccharin and *p*-sulphamidobenzoic acid of varying composition have been examined, and a diagram of the curve of the depression of the melting point of saccharin by successive additions of *p*-sulphamidobenzoic acid is given (*cf.* curve I.).

Melting point of p-sulphamidobenzoic acid.—Palmer (Amer. Chem. J., 4, 164) describes this acid as decomposing at 280° C. without melting, but this statement is erroneous. Even with markedly impure specimens such behaviour was never observed. Perfectly pure *p*-sulphamidobenzoic acid, prepared by repeated recrystallisation from water, has a sharp m.p. of 288°—289° C. (corr.), with no obvious sign of decomposition. On cooling, the substance partially re-solidified and melted again at 250°, showing that some decomposition had in actual fact occurred. This mixture again solidified, and a third melting point, showing marked decomposition, was observed at 300°.

It will be seen from the figure that the melting point is a fairly safe guide as to composition for mixtures containing from 0 to 10% of *p*-sulphamidobenzoic acid, the depression for which is normal, but the melting points of mixtures with a higher content of *p*-sulphamidobenzoic acid than 10% seem to indicate abnormality, as is shown by the marked flattening of the curve in the region of 15% *p*-sulphamidobenzoic acid. Hence, in the case of mixtures of a lower melting point than 219·5° C. (the melting point of a 10% mixture) melting point is not a safe guide as to the content of *p*-sulphamidobenzoic acid.

o-Sulphamidobenzoic acid.—As before, the upper region of the curve of the depression of the melting point of saccharin by *o*-sulphamidobenzoic acid has been examined. The curve appears to be a straight line (curve II.), but in view of the fact that *o*-sulphamidobenzoic acid at a temperature of 180° changes into saccharin and *o*-benzoic ammonium sulphonate (Fahlberg, *loc. cit.*), the melting points of mixtures of this substance and saccharin cannot be taken as trustworthy evidence of the composition.



Melting points of mixtures of saccharin with allied substances.

p-Sulphamidobenzoic acid.			*o*-Toluenesulphonamide.			*o*-Sulphamidobenzoic acid	
%	Mols.*	M.p.	%	Mols.*	m.p.	%	m.p.
10	0·04975	219·5°	5	0·02907	221·5°	10	223·0°
15	0·07463	217·5°	10	0·05815	218·5°	25	221·0°
20	0·09949	216·0°	20	0·11620	213·5°	35	216·5°
						40	214·0°

* On the graph these numbers are shown multiplied by 100.

o-Toluenesulphonamide.—The depression of the melting point of saccharin produced by the presence of *o*-toluenesulphonamide is uniformly normal. Hence the melting point curve (curve III.) of these two substances is parallel to that of *p*-sulphamidobenzoic acid and saccharin up to the point at which the latter becomes abnormal, and since the molecular weights of *p*-sulphamidobenzoic acid (201) and *o*-toluenesulphonamide (171) are not appreciably different, is only separated from it by a difference of melting point of 1°—1·5° C.

The divergence of these two curves produced by the abnormality indicated in the melting point curve of *p*-sulphamidobenzoic acid and saccharin is clearly shown by consideration of the "equimolar" curves for these two pairs of substances (curve

IV.). The weight of each substance taken, divided by their molecular weight, gives the number of mols. which produce a depression corresponding to the observed melting point. Since equimolecular quantities of different substances produce equal lowering of melting point, the two curves should be congruent. But, as will be seen from the figure (IVa) that representing the melting point curve of *p*-sulphamidobenzoic acid and saccharin diverges sharply when 15% of *p*-sulphamidobenzoic acid is reached.

(b) *Solubility in sodium bicarbonate.*

Dilute, 6—8% sodium bicarbonate is added, drop by drop, to the powdered saccharin mixture until effervescence ceases, and solid ceases to be dissolved. After standing for some hours the mixture is filtered. Any toluenesulphonamide initially present in the crude saccharin is thus eliminated in this residual solid. The bicarbonate liquor contains the saccharin, plus any *o*- or *p*-sulphamidobenzoic acid present. Addition of moderately strong acid causes all these substances to be precipitated together. Saccharin comes down more slowly than does *p*-sulphamidobenzoic acid, but no separation by this means is practical.

On the other hand, when the bulk of the impurities has been removed by one of the standard procedures, this method can be conveniently used to obtain completely pure saccharin. The purified saccharin, m.p. not lower than 224° C., is dissolved in an equivalent quantity of aqueous sodium bicarbonate. The solution, filtered if necessary, is diluted with boiling water to twenty parts by volume for every one part of saccharin. The mixture, kept at a temperature of about 80° C., is very slowly precipitated with aqueous 5% hydrochloric acid in 30—50% excess. The addition of hydrochloric acid equivalent to 10 g. of saccharin took, under these conditions, six hours. In this way, and by slow cooling in a hot bath, large lustrous crystals with a sharp melting point of 227°—227·5° C. can be obtained.

(c) *Hydrolysis.*

The hydrolysis of saccharin to *o*-sulphobenzoic acid and ammonia by acids of certain strengths is well known, and a method for the estimation of saccharin is based on this reaction (Emmet Reid, Amer. Chem, J., 1899, 21, 461; Proctor, Chem. Soc. Trans., 1905, 87, 242). The method consists in boiling a known quantity of saccharin (0·3—0·5 g.) with $N/1$ hydrochloric acid (50 c.c.) for 2½ hrs. The ammonia is then estimated by the usual method. Experimental examination of this method showed an error of (1) −0·5%; (2) +0·2%; (3) −0·05%; (4) +0·3%, in four different estimations.

Of the sulphonic derivatives of toluene described above as common impurities of crude saccharin, all contain the group $-NH_2$ and are therefore potentially capable of yielding ammonia on hydrolysis. That the validity of this method of estimation of saccharin might be fully tested, it was essential to ascertain whether the conditions favourable to the hydrolysis of saccharin led also to the elimination of the $-NH_2$ group from these substances.

Proctor (*ibid.*) definitely states that the reliability of the process is not affected by the presence of any of the substances which are likely to occur as impurities in unpurified saccharin. This conclusion he bases on an examination of only *p*-sulphamidobenzoic acid and *o*-toluenesulphonamide, which two substances he shows remain entirely unchanged under the conditions of the estimation. He did not, however, examine the behaviour of the three substances *p*-toluenesulphonamide, *o*-sulphamidobenzoic acid, and toluene-2.4-disulphonamide, all of which are possible impurities of saccharin. Proctor's results for *p*-sulphamidobenzoic acid and *o*-toluenesulphonamide have been confirmed

p-Toluenesulphonamide.—Treatment of the pure amide with $N/1$ hydrochloric acid for 2½ hrs. led to no hydrolysis. In one case the acid liquor was made alkaline and distilled as in the usual Kjeldahl process; no ammonia was detected. In a second experiment the acid liquor after boiling was allowed to crystallise, when a solid with a melting point corresponding to that of pure *p*-toluenesulphonamide was recovered with no appreciable loss of weight.

Toluene-2.4-disulphonamide.—Again no hydrolysis was detected under the standard conditions. The amide does not crystallise out from the mother liquor on cooling, but extraction with ether gives a quantitative recovery of pure toluene-2.4-disulphonamide.

o-Sulphamidobenzoic acid.—This acid stands alone, in that it is hydrolysed to a very large extent —80%—under the standard conditions.

Of these substances, the most common impurity in unpurified saccharin is *p*-sulphamidobenzoic acid. This, as shown above, is not attacked by $N/1$ hydrochloric acid, and hence the recognised method of estimating saccharin holds, in general, fairly accurately. The presence of *o*- and *p*-toluenesulphonamide, and of toluene-2.4-disulphonamide also in no way affects the validity of the process. But the method is not capable of universal application since in the presence of *o*-sulphaminobenzoic acid (a not very uncommon impurity of saccharin) considerable inaccuracy may be introduced. Moreover, the specific detection of this acid is not easy.

In a modification of Proctor's method for the estimation of saccharin (Richmond and Hill, J., 1918, 246 T) the presence of this acid also invalidates the estimation. But in a later paper (*ibid.*, 1919, 8 T) the authors suggest a means of detecting and estimating this acid in mixtures with saccharin.

The above investigation was undertaken at the suggestion of Professor Orton, to whom I am indebted for direction and criticism.

ECONOMIES IN THE HANDLING OF LIQUID COAL-TAR CHEMICALS.

BY S. P. MILLER.

This paper contains an account of some of the ways in which economies in the handling of liquid coal-tar products have been effected by the Chemical Department of The Barrett Company.

The manufacturer of coal-tar products is called upon to deal with a large variety of materials which, while quite similar, must nevertheless usually be kept entirely separate. It is necessary to employ in addition to the coal-tar compounds the ordinary inorganic materials, such as sulphuric acid of various concentrations, hydrochloric acid, nitric acid, solutions of nitre cake, sodium nitrate, salt, caustic soda, caustic potash, milk of lime, and sodium carbonate, each of which presents its special problem. A great number of tanks and a labyrinth of pipe lines are required. Unless continual care is exercised, new lines and equipment creep in where those already in place might have served. An exact knowledge of the inter-relation of products is required to handle the situation economically. The problem appears less simple if it is realised that some 200 crudes, intermediates, and finished products are involved.

The constantly fluctuating business conditions of to-day require a large amount of apparatus, such as agitators, washers, filters, fusion kettles, nitrators, sulphonators, stills, etc., to be maintained in readiness to produce at odd intervals products which have previously been manufactured steadily. The economic handling of materials becomes a matter of prime importance at this time when the exceedingly small amount of purchasing incites keenest competition on the part of manufacturers.

The crude oils usually arrive in tank cars. Notable exceptions are anthracene and naphthalene, which are shipped in burlap bags; large amounts of the latter, however, are also received in tank cars. A few materials arrive in steel drums; these are emptied at once if possible, as all such packages are regarded as an enormous hazard in case of fire. Coke oven light oil, drip oil, carbolic oil, and crude tar acids constitute, in addition to naphthalene, the great bulk of the crudes. Immediately after arrival the cars containing them are sampled and placed on a track devoted to unloading and loading. The contents of eight to twelve cars per day can be handled through a central pumping station which delivers the material into storage tanks or directly into stills. Empty cars are either pulled out at once or are moved forward to a cleaning and loading station for refilling with finished products. Steam-driven duplex pumps are employed; they require less attention than either rotary or centrifugal types, may be worked over a wide range of pumping rates, and can be used safely all over the works; whereas motor-driven equipment can only be used in the absence of inflammable vapours. Crude naphthalene of m.p. 66°—76° C. is pumped with no difficulty into tanks in some cases nearly ½ mile away; the system is thoroughly heated before pumping and the material maintained at 15°—20° above its melting point and moved rapidly.

The only material not handled as indicated is sulphuric acid of 66° B. This is blown by means of air directly to storage; this system will in the future be replaced by centrifugal pumps.

For storage our practice favours the use of vertical, cylindrical tanks, rather than of the horizontal type. With vertical tanks ground space is economised and also the separation of water may be accomplished more readily than in the horizontal type. Vertical tanks may be equipped with try cocks on the side and the draw-off line fixed at a point about eight inches from the bottom of the tank; small quantities of water then collect and are drawn off periodically. This feature is of great importance if the oils are to be distilled, since it minimises trouble due to priming and effects a great economy of fuel and of distillation capacity.

The importance of removal of water is evident when it is remembered that water requires about 7 times as much heat to evaporate as oil, and that water produces 4—8 times as much vapour per unit volume as the ordinary coal-tar products. Thus the presence of a large percentage of water will give rise to great trouble due to building up of pressure if any considerable rate of distillation is attempted, and condenser troubles will also follow. We have not yet employed centrifugals for removing water, as their capacities are low, their first cost is high, and the specific gravities of the oils are, in general, sufficiently far from unity to give good separation normally. Thus representative oils, as charged to stills, contain water as follows:—Carbolic oil 5·5%, drip oil 1%, coke oven light oil 1%. A small amount of water is added to the oils in handling, as all lines are blown with steam prior to use; this amount is minimised, however, by blowing into a "slop tank" until the line is warm; the oil then sent through picks up only a very small amount of condensed water.

Each of the tanks of 2000 gallons or more capacity is equipped with a man-hole on the side near the bottom to provide easy access for cleaning. One or more man-holes in the roof provide means for sampling, inspection, introduction of temporary coils, etc. Tanks of 30,000 gals. capacity and above are usually equipped with inside steel ladders. All are either fitted with individual outside ladders or arranged in groups served by a common platform. Portable ladders are avoided when possible. Storage vessels containing the more volatile oils, such as benzol, toluol, etc., if located inside buildings, are vented to the outside. Those containing naphthalene are vented by means of a small hole drilled in the tank roof. Relief lines on naphthalene tanks are not safe as they may become clogged with sublimed product; the presence of water in the tank may then cause a pressure sufficient to give trouble. We have seen several hundred gallons of molten naphthalene blown from a tank the vent of which had become clogged and had caused accumulated pressure. The draw-off lines from tanks are supplied with two control valves, one within the tank; in case of accident to the outside valve the inside one may be closed.

Certain oils, such as carbolic oil and naphthalene, require to be stored in heated tanks; such tanks should be insulated, since in nearly all cases the cost of insulation is more than off-set by the saving over a year. Storage should not be heated until required.

For pipe lines wrought iron pipe and cast iron fittings are generally used. Those carrying the sodium salts of tar acids and solutions of sodium carbonate and caustic soda should be of steel. Lead lines are required for handling pyridine sulphate, dilute sulphuric acid, and the various acid sludges resulting from washing of oils with sulphuric acid. Piping practice varies so slightly from plant to plant that it requires no further consideration.

The stills are of two types, simple or fractionation. They are either fire- or steam-heated, and only in rare cases is live steam blown into the still to assist distillation. They are operated either under 1—2 lb. pressure or under vacuum. The fire-heated stills are either of the direct-fired or of the return-arch type. The Dutch oven setting is not used. In some cases anthracite coal is employed, but most of the fuel consists of tar residues from oils distilled.

Practice varies widely as to the use of return-arches under fire-heated stills. At present direct fires are being used in most cases because a large amount of expensive fire-brick is eliminated, changes in the intensity of the fire are felt at once in the rate of distillation, more sensitive control is possible, and distillation stops immediately if the fire is checked. Residues may be removed immediately the distillation is complete and the still may be at once re-charged without danger from priming. This is accounted for by the fact that the setting cools rapidly in the absence of the arch, which always acts as a reservoir for an enormous amount of heat. The open type setting is more economical of fuel. Thus a much higher rate of distillation is safely possible than with the arch type still. No trouble due to burned out still bottoms should be experienced; this depends almost entirely upon design.

Fire-heated stills operated under reduced pressures should be equipped with a positive-acting vacuum breaker. This is of prime importance when distilling high-boiling tar acids, as the bottom sheets frequently become red-hot during the latter part of the distillation. A common type of breaker consists of a vertical rod, one end of which rests on the still bottom, and the upper end touches a relief valve; if the sheets start to pull in the rod opens the relief valve and prevents further damage by breaking the vacuum.

The greatest economy in the operation of steam-heated stills lies in the saving of steam. Stills should be thoroughly insulated and the heating units should be of sufficient capacity to maintain a maximum rate of distillation, which should depend only on the condensing capacity in the case of simple stills and upon best fractionation in the case of the column stills.

If alterations to existing distillation units are made, or if new units are designed, the greatest care should be given to the determination of proper pipe-line sizes. Abnormally high vapour velocities are not desirable, especially in the case of fractionating stills. Rectifying stills operated under vacuum should receive very careful attention along this line if close-cut fractions are to be made. Care must be exercised to ensure a free flow through the fractionating column of the liquor returned by the dephlegmator. The best results are not possible if flooding within the column occurs.

The agitators used in treating the oils with caustic soda or sulphuric acid are of five types:—(1) Vertical type in which mixing is accomplished by means of a shaft carrying two sets of propellers. (2) Vertical type in which agitation is secured by means of a slow-moving scraper. This apparatus is particularly useful in operations in which the material tends to stick to the sides or the bottom. (3) Horizontal type, in which slow-moving paddles accomplish the result by a tumbling action. This is an excellent machine for use with suspensions of solids. (4) Vertical type, with agitation by means of air introduced at the bottom. This type is of value for use with materials which tend to emulsify if beaten violently, as in the others mentioned. (5) Vertical or horizontal, with the means of agitation outside the vessel. A centrifugal pump is employed to circulate the liquids out of the bottom and into the top of the agitator. The pump should be of ample size. We are using a vessel of 3200 gallons capacity in conjunction with a centrifugal pump of 3500 gallons per minute capacity. A slow-speed, low-head pump is satisfactory. Where extremely efficient agitation is required, this equipment is difficult to equal.

Where large volumes of materials are handled through agitators, the question as to the most economical size of equipment arises. Apparatus of large volume, *i.e.*, 7500—12,000 galls., in general, has the great disadvantage of not allowing the highly efficient contact between reagents required for greatest economy of time and materials. The use of the centrifugal pump mentioned above appears to offer most opportunity for mixing efficiently large volumes of liquids. This is of first importance in the washing of benzols and solvent naphthas with sulphuric acid, the extraction of tar acids from oils with caustic soda, and similar operations.

We have practically discarded the idea of building large agitators of the batch type. These will gradually be replaced by apparatus for continuous operation, since much smaller units are required for a given output; violent agitation is more easily accomplished in small than in large agitators; a comparatively small volume of product is present and if cooling or heating is necessary, temperature control is far easier than in large equipment; the greater ultimate capacity of the continuous equipment allows a reduction in labour; ease of temperature control tends towards an improved quality of product, as almost all operations require regulated temperatures; repair costs on continuous equipment are lower, as the apparatus is much smaller and more easily handled. In many cases complete spare machines may be kept in stock for replacement in emergency.

It is, of course, true that the amount of material to be handled determines absolutely whether continuous operation is desirable. Rather small productions are satisfactorily dealt with in batch type equipment. If, however, several thousand galls. of material are handled daily, the continuous apparatus deserves serious attention.

An example of a continuous process which avoids the use of batch agitators is the Dennis-Bull process (U.S.P. 1,247,999) for continuous sulphonation of benzol. This was operated on a works scale at our plant during the war.

Lead-lined apparatus which must be heated deserves attention. The best practice seems to be to install coils on vertical supports; these are set at least 6 in. from the sheet lead, which in the absence of local over-heating will not sag and split. Many costly and irritating repairs are thus avoided.

The removal of naphthalene and other solids from refrigerated oils is accomplished in open centrifugals. With a 52-in. machine, the oil may be run through at a rate of roughly 1000 galls. per hour. A good cake forms and the removal of solids is complete. The operation is practically continuous. Only oils having very low vapour pressures are handled in this equipment.

Filter-presses of the plate and frame or clam shell types are used for filtration of oils of relatively high vapour pressure. Although not continuous, they have an advantage over the rotary filter in that losses of volatile oils are minimised. Centrifugal pumps are used for charging practically all the filters; in addition to giving excellent service, they have the advantage of a limited pressure capacity. No danger of excessive pressures in presses is possible if proper pumps are chosen initially.

Centrifugals are employed on all those solid products which, for purification, require the elimination of relatively small quantities of oil. Hydraulic pressing does not improve the quality of the materials. The centrifugal has much in its favour, not only from the mechanical standpoint, but also from that of ease of operation. Phenol and naphthalene are purified in centrifugal machines.

Liquid products leave the works in tank cars, steel drums, tight barrels, and in various types of tin cans. Naphthalene, phenanthrene, α-naphthylamine, and *p*-coumarone resin are all shipped in the solid condition. We endeavour, however, to handle these materials as liquids up to the last operation. Common practice in the case of some of these is to allow them to solidify in shallow pans, from which they are subsequently removed, crushed, and packed in barrels. Others are run molten into light-weight metal destructible drums and are allowed to solidify prior to shipment. Some of these products are now finished in machines similar to those used for flaking caustic soda, sodium sulphite, nitre-cake, shellac, etc. Many advantages are gained; less labour is required; less floor space is occupied by equipment; smaller quantities of inflammable materials are held in storage at any time, as, being continuous, the flaking machine handles the refined product as fast as it is manufactured. Expensive machines such as these are probably not warranted unless production is large.

Fire and health hazards must be given continual attention in a works handling materials which are at once inflammable and injurious to health of workmen. Benzol is the worst offender from all standpoints; it has a flash-point well below 0° C. and forms with air explosive mixtures, as also do toluol, xylol, and solvent naphtha. The entire system of tanks, lines, agitators, and stills should be tightly closed and no open connexions of any kind tolerated. All storage tanks should be vented to the outside atmosphere and preferably into a large line the exit end of which is thoroughly protected from fire and is at a considerable distance from the plant. Buildings should be maintained absolutely free from fumes. Puddles of oil on floors are dangerous. All apparatus should be thoroughly grounded by means of copper wires securely fastened to the apparatus and to a ground wire. Serious fires have resulted from static discharges. Precautions taken to avoid them are of the utmost importance.

Naphthalene is not regarded as poisonous. It does, however, comprise a real fire hazard. It is usually purified by distillation in fire-heated stills. Its tendency to sublime causes blocked lines, safety valves, and condensers unless extreme care is exercised. Sudden pressures in fire-heated stills are sources of trouble. All safety valves should be steam-heated, and should blow into heated lines which will deliver the discharged materials to a point well isolated from the fires. Disaster has resulted from lack of realisation on the part of operators of the suddenness with which naphthalene will block lines.

Frankford, Pa.

Meeting held at New York on May 27, 1921.

THE MANUFACTURE OF CONSTRUCTIONAL GLASS IN THE UNITED STATES.

BY E. WARD TILLOTSON, JUN.

Constructional glass embraces window glass, plate glass, wire glass, and the miscellaneous types of rolled glass referred to as fancy figured, cathedral, opalescent ribbed, etc. Of all the branches of the American glass industry the manufacture of constructional glass is second in magnitude only to the production of bottle glass.

There are at present nearly 400 glass factories of all types in the United States, capitalised as about $200,000,000 and producing 1,500,000 tons of products, valued normally at $200,000,000. The constructional glass industry *per se* comprises 125 factories, with a capitalisation of about $100,000,000, and a production of 500,000 tons, valued normally at $60,000,000. Of the 600,000,000 sq. ft. of constructional glass produced annually about 450,000,000 is window glass, 80,000,000 is plate, 20,000,000 is wire glass, and 50,000,000 includes cathedral glass and miscellaneous types of sheet glass.

The success of the constructional glass industry is, without question, the result of the remarkable machinery which has been developed for producing glass in quantity. In the modern glass factory, especially where glassware is being produced in large quantities with the aid of automatic glass-forming machinery, all operations are carried out with the minimum of manual labour. The incoming raw materials are unloaded by mechanical devices and transported by conveyors to the storage-bins; while beneath the batch storage-bins there is a railway track carrying a motor-driven car with a rotary mixer mounted on scales which delivers the mixed batch to another conveyor which, in turn, carries it to the batch storage-bins above the charging-end of the melting furnaces. The manual labour of charging the furnaces consists largely in the opening and closing of valves at suitable intervals.

In several of the glass-making processes mechanical appliances have been developed which take the place of skilled artisans and which perform their work more easily and more efficiently and produce a far superior product. As in the cases of certain other industries, the manufacture of glass has tended to develop more and more along engineering lines, and its progress has been noteworthy from the viewpoint of the mechanical technologist. An increasing amount of attention is being accorded to the chemical aspects of the industry, but this advancement has in the past proceeded with a halting step and accordingly is overshadowed by the mechanical progress.

The window glass industry.

The successful production of window glass in the United States commenced about 1800. Previous to that time the attempts in glass manufacture had been unsuccessful, but about 1800 the manufacture of window glass and bottles (commonly made in the same factory) became a permanent American industry.

For many years the methods of producing window glass were essentially the procedures of history, but during the past forty years innovations have gradually been introduced which have brought the industry to its present status. The early 80's witnessed the introduction of natural gas as a fuel, the use of the continuous tank for melting glass, and, not the least of the improvements, a continuous annealing lehr. However, the great advance which has made possible the present window glass industry resulted from the experiments of J. H. Lubbers, which were commenced about 1894 and which first became commercially successful in 1905. Lubbers was a "flattener" in the employ of James A. Chambers, a glass manufacturer of Pittsburgh, Pa., who succeeded in making window glass by drawing cylinders from a pool of molten glass instead of blowing them by the laborious hand process. While Lubbers did not live to see the highest commercial development of this process, he did define the fundamental conditions necessary for its successful operation, and his invention is to be considered as one of the most important advances in glass technology. The practical difficulties to be overcome in the application of this process were numerous and have required the help of several inventors; as it is in use to-day, the process is particularly remarkable in that the mechanical operations are adjusted so to counterbalance the changing properties of the cooling glass that cylinders over 40 feet in length and of substantially uniform diameter and with a uniform wall thickness are produced consistently.

The operations involved in producing these cylinders of glass are briefly as follows:—The glass is taken from the furnace in large iron ladles and is poured into a shallow clay "pot" from which the cylinder is drawn. All the glass for a cylinder must be gathered at one time and the ladles, therefore, have a capacity up to about 1000 lb. of glass. The drawing pots are about 40 inches in diameter and are reversible on a horizontal axis, so that, while a cylinder is being drawn, the glass left from the previous drawing is draining from the underside. The glass is allowed to remain for a few minutes in the pot, so that it may cool to the correct temperature and acquire a uniform temperature distribution. An iron "bait" is then introduced and the drawing operation commenced. This bait is about 12 inches in diameter and is hollow, with an inwardly projecting ledge at the lower end. When this is lowered into the pot the glass flows over the ledge and solidifies there, forming a lip which supports the cylinder during the drawing operation. The bait is raised by a hoisting motor-driven mechanism controlled by an attendant who commonly operates three machines. At first the bait is raised slowly and the compressed air which is introduced through the bait is supplied at a low pressure. Then the air pressure and the speed of draw are increased, and the diameter of the cylinder is thereby increased to the required extent.

In the drawing operation the air must be supplied to the interior of the cylinder at constant pressure and in gradually increasing amounts. The drawing of a 40-foot cylinder requires about 15 minutes and during this time the glass in the drawing pot is constantly cooling; as a result, the viscosity and the surface tension of the glass are increasing, and, therefore, the speed of draw must be increased steadily to produce a constant thickness of the cylinder wall. Moreover, since the temperature of the glass in the drawing pot is rarely symmetrical, and since such a lack of symmetry produces an unevenness in the cylinder and also causes the cylinder to wander to one side of the pot, it is necessary to adjust the apparatus so that the cylinder is drawn as nearly as possible from an isothermal zone. The cylinder finally is detached from the pot by "cracking" it off with a cold rod or by rapidly increasing the speed of draw, which thins out the cylinder wall so that it may be broken loose easily.

The "taking down" of these cylinders, which may weigh as much as 1000 lb., was by no means a simple problem to work out, but the present process, which consists in swinging out the bottom of the cylinder which is supported by a rope and trolley system while the hoisting mechanism is rapidly lowered, is carried out almost automatically and the cylinder is delivered in a horizontal position beside the rack on which it is "capped off." This operation, by which the cylinder is cut into (usually) 5-foot lengths or rollers, is accomplished by an electrically heated wire wrapped around the cylinder, but the splitting of these rollers and the flattening operation are still carried out by hand methods.

Within the past three years a new machine, differing radically from that already described, has become a commercial success and promises to be a keen competitor of the cylinder machines. This invention is the result of the work of I. W. Colburn, an electrical and mechanical engineer who commenced his experiments about 1900. The technical success of the process dates from 1918.

In the Colburn process a continuous sheet of glass is drawn from a pool of molten glass in a compartment of the melting furnace, and, after rising about 30 inches, the plastic sheet passes over a roller and is thereupon carried in a horizontal direction through the annealing lehr. This process is continuous and obviously requires no separate flattening operation. The sheets, which are about 72 inches in width, are drawn at a rate of from 2 feet to 6 feet per minute, depending on the thickness; each unit, therefore, is capable of a yearly production of 10,000,000 sq. ft. on the basis of single-strength glass. In this process not only single- and double-strength glass may be drawn, but also sheets ¼ inch in thickness. It becomes, therefore, a competitor of the present plate glass industry, for the product is suitable for many purposes, such as automobile glass, for which polished plate glass is largely employed. Although the bulk of this product is satisfactory for purposes not requiring the highest grade of glass, selected sheets of a quality suitable for silvering are produced to a limited extent and the development of the processes to give a larger percentage of this quality of glass is not unexpected. In general, it may be said that in its present state of development the Colburn process is particularly adaptable for the heavier grades of glass and that the cylinder process is better adapted for producing the lighter weights.

The successful industrial operation of Colburn's process has required the solution of a large number of difficult problems. The maintenance of a uniform temperature in the pool of molten glass and on both sides of the sheet has been one of the serious problems. Furthermore, the roller over which the sheet is turned from the vertical to the horizontal position must possess a well-nigh perfect surface to avoid producing defects in the surface of the glass and must maintain this for long periods at the necessarily high temperature to which it is exposed. The temperature of the sheet must also be sufficiently high to avoid cracking or other defects in bending over the roller and the apparatus must be so ordered that the plastic sheet must not be distorted after it leaves the roller during the time of cooling previous to entering the lehr.

The Colburn machine has not as yet been installed extensively and is, therefore, producing only a fraction—about 25%—of the total window glass requirements. It is noteworthy particularly because of its fundamental simplicity, and it may not be unreasonable to expect that a process by which sheet glass is drawn continuously will eventually displace the intermittent and rather cumbersome cylinder process.

The success of machine-made window glass has been the cause of much improvement in the design of the melting furnaces. Continuous tanks are used exclusively and the possibility of supplying 8 to 12 cylinder machines from one tank has made possible and almost necessary the use of larger furnaces. The preferred size of these tanks has increased steadily during the past several years and at present tanks are being built about 140 feet long and 38 feet wide, inside dimensions, and with a depth of about 5 feet of glass. These tanks contain 2000 tons of molten glass and possess a daily melting capacity of 400 tons. The economy and advantage of a large tank are more or less obvious; since its surface area is less per unit of capacity, there is a relatively smaller loss of heat, and the melting of larger quantities of materials offers a better opportunity for the production of a more homogeneous and a better glass.

The composition of window glass varies somewhat in the several plants, but the average is represented fairly by the following batch formula and percentage composition.

Batch formula.		*Percentage composition.*	
Sand ..	.. 1000 lb.	SiO_2 ..	.. 73%
Limestone	.. 350 lb.	CaO ..	.. 14%
Soda ash	.. 250 lb.	Na_2O ..	.. 13%
Salt cake	.. 75 lb.		

At all times a portion of the soda content of the glass is derived from salt cake. On occasions, as the economics of the situation may warrant, the salt cake may entirely replace the soda ash. In this case a small amount (about 5% of the weight of the salt cake) of powdered coal is added to assist in the decomposition of the sulphate. The necessity for using salt cake in addition to soda ash is not entirely apparent. It has been learned that a good glass may be made from sand, lime, and soda ash without salt cake if the molecular ratio of lime to soda is less than 0·5; but that, if the ratio exceeds that figure, there is formed on the surface of the molten glass a white scum which renders the production of good glass impossible. It has been found by experience that the use of a small amount of salt cake in the batch prevents the formation of this scum, and this is the practical reason given for its employment.

At present about one-third of the total window glass made in the United States is manufactured by the well-known hand process while the balance is the product of machines. The hand-operated factories have existed for the past ten years in the face of certain destruction. When the importation of window glass from Belgium was discontinued in 1914, these plants benefited by the increased market which was created thereby, but now window glass is again being imported, and it is a question whether the hand-operated factories can long survive.

Before the period of the war most of the glass for photographic plates, lantern slides, etc., was imported from Belgium, but for the past several years American manufacturers have been producing these glasses at least equal in quality to those formerly imported. Strictly speaking, this type of glass is not constructional glass, but its successful production in the United States illustrates the adaptability of the cylinder machines.

The manufacture of plate glass.

The plate glass industry was established successfully in the United States about 1879, after many years of fruitless effort; and while it is now in a fairly prosperous condition, it has not experienced recently such a spectacular advance as has the window glass industry. The principal innovations in practice have consisted in the introduction of labour-saving machinery.

Plate glass is melted in open pots, the size of which is determined by the size of the casting table. The average capacity is about 2000 lb. of glass, which is sufficient for a casting table 14 feet by 24 feet, or for a 300-foot sheet of glass, but plates of glass are being rolled which contain 400 sq. ft. The melting furnaces are rectangular, regenerative furnaces containing 16 to 20 pots, arranged in two rows on opposite sides of the furnace.

The composition of plate glass, as it is commonly made, is similar to that of window glass and is on the average represented by the following data:—

Batch formula.		*Percentage composition.*	
Sand	1000 lb.	SiO_2	72%
Limestone	320 lb.	CaO	13%
Soda ash	310 lb.	Na_2O	15%
Salt cake	65 lb.		
Charcoal	3 lb.		

In the modern plate glass plant nearly every operation is carried out with the help of mechanical appliances. The batch is introduced into the already heated pot with the assistance of a large iron ladle, into which the batch is shovelled and which is commonly operated by hand. Recently, however, a mechanically-operated semi-automatic charging ladle has been developed which is operating successfully in several plants. The pot is charged in three fillings, in order to secure as full a pot as possible; and after the melting and refining period, which requires about 20 hrs., the furnace is allowed to cool to bring the glass to the correct casting temperature, which is about 1000° C. The entire cycle of operations requires about 25 hrs. When the glass is ready for casting, the pot is taken from the furnace and any impurities on the surface of the glass are removed. The pot then is grasped by a clamp suspended from a motor-driven travelling crane and is brought to a position over the casting table. The casting operation consists in tipping the pot and at the same time moving it across the table so that the glass is distributed more or less uniformly just in front of the roller. The roller, which is about 30 inches in diameter, is then drawn over the glass, an operation which requires about one minute. By this time the plate is cooled sufficiently to be transferred to the lehr. The sheet is, however, too soft to be supported on lehr rods, and, until it has cooled further, it rests on the floor of the lehr and is pushed mechanically from one compartment to the next. These compartments are usually five in number and are so arranged that the plate follows a zig-zag course, for easier mechanical operation. The plate then advances into a straight, mechanically-operated rod lehr, which is some 280 feet long and in which the annealing operation is completed. This type of annealing lehr was introduced about 1900 and marked a considerable advance in plate-glass making. Formerly it had been the custom to anneal the plates in kilns. After passing through the lehr, the plates are placed on cutting tables and cut into the required sizes. These tables are arranged to tilt, to provide for the easy handling of the larger sheets, which are transported by overhead travelling cranes to the storage or to the grinding room.

The grinding and polishing operations now employed in the United States represent the principal advances in plate glass technology. Previously plates were placed on a rectangular table which moved from side to side and the grinding was accomplished by the rubbing action of the grinding tool which had a reciprocal motion at right angles to that of the table. At present the sheets are set with plaster of Paris in a circular table which may be as large as 35 feet in diameter, the various sized sheets being fitted together so that the table is filled completely. The table rotates and the grinding tools, which are blocks of cast iron set in the under surface of two smaller circular tables, revolve slowly by reason of friction with the glass surface. Water is supplied to the table, and at first coarse sand, then continually finer sand, and finally emery. After the grinding has been completed, the table with the glass is moved to the polishing room, where the polishing operation is carried out in a similar way, but with a modified mechanical arrangement, and, of course, with the use of felt blocks and of rouge for finishing. The glass then is removed from the tables and reversed, and the operation is repeated.

Recently an improvement in the grinding operation has been made which has not only eliminated much manual labour but has also effected a saving in the time required for grinding. This consists of automatic devices by which the sand from the grinding tables is classified into several sizes and the required grade is returned at once to the table. The importance of this is indicated by the fact that 10 lb. of sand is required in the grinding of 1 sq. ft. of surface. This innovation has perhaps halved the time of grinding, which at present is about 1½ hrs. for each surface. This is to be compared with 5 or 6 hrs. required in the original method of grinding and polishing. The use of the circular table for this purpose is referred to as the "Belgian system" and was introduced into the American industry about the year 1890.

The plate glass industry therefore owes its present status to the introduction of machinery which supplants a large part of the manual labour, but which is not to any degree automatic. The manufacture of plate glass has never required the same kind of skill that is characteristic of the making of other types of glassware and accordingly the present processes represent essentially the adaptation of machinery to operations for which unskilled labour was formerly employed.

The wire glass industry.

Although wire glass constitutes only a small fraction of the total production of constructional glasses, it serves a most useful purpose in constructional work and constitutes one of the most interesting members of this group. It was made successfully first in 1892 and its development into an article of commerce is attributed to American genius. To Frank Shuman, of Philadelphia, is due the credit for the beginning of this industry, which has furnished an unique and valuable material for building purposes.

Since wire glass is formed by rolling, its technology is similar to that of plate glass, with the exception that the glass is melted in continuous tanks and is transferred to the casting table by ladles. There are two different methods of manufacture, known as the "sandwich process" and the "solid process," respectively. In the "sandwich process" a plate of glass of one-half thickness is rolled first. The wire netting passes under the roller and is, therefore, rolled into the surface of the sheet, and then another one-half thickness of glass is rolled over the netting. The success of this operation depends upon the rolling of the second sheet before the first sheet has had an opportunity to cool materially, so that a complete welding of the two sheets of glass is effected.

The "solid" process was carried out originally by rolling a plate of full thickness, applying the wire netting, which was forced into the glass by a corrugated roller, and then finishing with a smooth roller. At present the method of operation is somewhat simpler. The wire netting is held at the correct height above the table, either by crimping it at intervals or by holding it in position by suitable guides, and the glass is cast and the roller is passed over it. A single operation, therefore, is sufficient for the formation of this complex product.

A certain amount of wire glass is made with an obscuring design rolled into one surface, and some is ground and polished. One of the latest wire glass products is a corrugated sheet for skylights, which is designed to be used with the standard corrugated roofing sheets.

There have been no recent technical developments of note in the making of wire glass. However, with the development of sheet window glass machines, it would not be surprising if a similar principle should be applied to the production of wire glass.

The manufacture of miscellaneous sheet glass.

There are several miscellaneous types of sheet glass, such as, for example, pressed prism plate glass, cathedral glass, and several kinds of figured glass.

Pressed prism plate is characterised usually by a single unit of obscuring design on each sheet. It is made by first rolling a sheet of glass and then pressing it against a plate engraved with the desired design. Several units may be pressed on a single sheet, which later is cut to the required size. By this method of manufacture a much sharper and more perfect design is secured, but it has the disadvantage that a separate engraved plate is required for each size of window to be fitted.*

Cathedral glass and the other rolled obscured glasses are commonly made on small tables in sheets about 4 feet by 10 feet in dimensions. The table is mounted on a small truck which runs on a railway track so that it may be easily moved about the factory. In figured glass the design is engraved in the table; a number of tables are therefore required, and, like figured moulds, they must be cleaned at frequent intervals. Since glasses of several colours are required for cathedral glass, they are commonly melted in pots and transferred by ladles to the casting table where they are mixed. The plate is then transferred to a hand car, which is wheeled to the lehr, and the glass is pushed into the first compartment. The lehrs are of the zig-zag type used for plate glass.

It has been mentioned that, in figured glass, the design is engraved in the table. The sheets are removed by passing a "sword" between the sheet and the table, an operation which tends to deface the sharp corners of the design and which is eliminated in the pressed prism plate glass mentioned above.

This industry, in which a large number of special figured designs are produced, is not a promising field for mechanical development. Although the total quantity of product manufactured is rather large, the quantity of any one type is rather small and the industry is one which is necessarily of small unit production.

The future of the constructional glass industry.

The constructional glass industry is at present located for the most part in Western Pennsylvania, West Virginia, and Indiana. At first sites for glass factories were chosen with regard to sources of raw materials and of fuel. When natural gas became available for fuel because the paramount factor in the choice of localities, and accordingly glass factories became concentrated in the gas belt. At present the supply of natural gas is diminishing rapidly, and producer gas is being introduced generally in the industry. The geographical expansion of the constructional glass industry may, therefore, be expected to be with reference to the deposits of coal and, to a lesser extent, of petroleum. It is thought, therefore, that a considerable expansion may take place on the Pacific coast, since the Eastern manufacturers cannot compete with the imported glassware because of the overland transportation charges. Some development in the matter of locating more suitable deposits of sand and the establishment of the manufacture of sodium carbonate will be necessary before the glass industry attains its greatest development on the Pacific coast.

Developments in the technology of constructional glass promise to continue along strictly mechanical lines. It has already been indicated that the process of drawing glass in the sheet form offers advantages over the cylinder process. Several new sheet glass processes are now in the experimental stage, and important developments in this field are to be expected in the near future. Important advances in the technology of wire glass are also in prospect. One of these is the combination of a sheet of wire glass and a sheet of plate glass with a bonding sheet of celluloid or other organic material which will combine the properties of an unbreakable and fire-resistant product.

It is possible, too, that the general use of producer gas may have a considerable influence in developing chemical technology in the glass industry. Since the most efficient operation of the gas producer requires the supervision of technically trained men, it seems probable that the glass manufacturer in the future will require the services of the chemical technologist. There is certainly a large opportunity for chemical development in this great branch of the glass industry. It is evident, therefore, that a need exists for more adequate instruction in glass technology in our universities,

---

* Pressed prism plate glass is now being manufactured at Morgantown, West Virginia, according to the process devised by F. L. O. Wadsworth.

but there is also the requirement that the value of the chemist be brought impressively to the attention of the glass manufacturer.

The organisation of a Society of Glass Technology in England and the inauguration of a department of glass technology at Sheffield University are notable examples of leadership in this field, and the formation of a glass research association of British manufacturers under the auspices of the Department of Scientific and Industrial Research is an accomplishment to which American manufacturers well may give serious attention. It is not to be inferred, however, that these activities have been entirely neglected, for one of our universities recently has established courses in glass technology and a strong technical organisation, the Glass Division of the American Ceramic Society, is adequate for the purpose which it serves, but concerted chemical research on the part of the manufacturers has not yet become a reality.

It seems obvious that the industry will not attain its highest advancement until the chemical aspects of the technology of glass have received consideration and development equal to that accorded to the mechanical phases of the industry.

DR. H. W. BROWNSDON IN THE CHAIR.

COLOUR IN WATER: ITS NATURE AND REMOVAL.

BY JOSEPH RACE, F.I.C.

Many colours are to be found in natural waters, but the only one that is common and of commercial importance is brown, which occurs in various shades. Brown waters may be divided into two categories according to the nature of the colour-producing substances: (A) those in which the colour is mainly organic, and (B) which includes such ferruginous waters as produce the typical ochre streams of mining districts. The latter are of relatively minor importance and will not be considered in this paper.

The colour of the waters in the first category is generally regarded as due to the presence of the products of putrefactive processes in vegetable matter, and wherever such decomposition is taking place in large masses of material the run-off from such areas will contain more or less colour. In England typical waters of this class are found on the uplands between Lancashire and Yorkshire and constitute the chief source of water supply for the adjacent towns. In these cases the colour is derived from the peaty soil and is not so high as in surface waters derived from districts where decomposition of vegetable matter is more active or where the products of decomposition are more concentrated. Bogs, locally knowns as muskeg, are quite common in some parts of North America, and some of the largest rivers are so highly coloured that they appear to be almost black when deep layers are observed. Similar conditions obtain in Siberia. In the southern part of the United States the drainage from cypress and other swamps is very dark and colours of 300 to 400 (platinum cobalt scale) are not uncommon.

The decomposition products found in peat etc. include humic, ulmic, crenic, apocrenic, and other acids. Adeney and S. Rideal have shown that such acids combine in the colloidal state with ammonia, lime, and magnesia and impart a brown colour to the liquid. In some cases the amount of bases present is insufficient to neutralise the products of decomposition and the waters are acid in character. Iron also appears to play an important rôle in coloured waters, for in many instances the colour bears a direct relation to the iron content. For a résumé of the chemistry and physics of the humic acids a recent paper by Odén should be consulted (Kolloid-Chem. Beihefte, 1921, 11, 75—260).

Important though the nature of the colour-producing substances may be, the properties are still more so because the chemical and physical ones determine the most suitable method by which the colour can be removed from potable supplies.

The substances producing colour in water are not usually regarded as physiologically objectionable, although in some cases the mild purgative effect of such waters has led to their association with "paludism." The Nile water is said to have this effect, but in America, where highly coloured supplies are not uncommon, there is no general evidence of a laxative action. The author has noted several cases in which a coloured supply has produced temporary diarrhœal symptoms in troops previously accustomed to hard colourless waters, but it was impossible to determine whether the symptoms were caused by the organic matter in solution or to the change in mineral content. Waters which are both coloured and turbid are often slightly purgative, but the action is due to the irritating effect of the mineral matter in suspension and not to the colour-producing substances.

Although there is no general evidence of an adverse physiological effect of colour, there is no doubt as to its psychological effect. A yellow or brown water appears dirty to the consumer and is regarded with suspicion until experience teaches him that it is quite harmless. Domestic bathing in coloured waters is distasteful, whilst in a swimming pool the colour is often sufficient to obscure objects on the bottom and so becomes a potential source of danger.

Colloidal nature of colour.

Until the beginning of the present century the presence of colloids in water was not generally recognised, but in 1904 Blitz and Krohnke (Ber., 1904, 35, 1745) showed that part of the organic matter in water was colloidal in character and, as it migrated to the anode under the influence of the electric current, was negatively charged. S. and E. K. Rideal ("Water Supplies," London, 1915, p. 100) described the general properties of colloids in relation to water, but it was not until 1916 that the practical importance of this relationship was established (Catlett, Eng. Rec., 1916, 73, June 3rd, and Amer. Pub. Health Assoc. meeting, 1916). Saville (J. New Eng. Waterworks Assoc., 1917, 31, 78) further explored this field of investigation and contributed several new facts concerning the colloidal nature of colour in water.

Briefly summarised, the evidence that colour acts as a colloid is as follows:

(1) The particles are visible in the Tyndall ray.

(2) The colour migrates under the influence of an electric current. Colour colloids that migrate to the anode can be made to wander to the cathode by the addition of an excess of positively-charged ions; in the same way positive colour colloids, which are exceptional, migrate to the anode on the addition of a base.

(3) Colour colloids are precipitated on the addition of an electrolyte containing ions of the opposite electrical charge. This property is of great practical importance because it is the basis of colour

removal. Long before the chemistry of colloids was established it had been recognised that aluminium and iron salts, usually alum and alumina-ferric, were the most efficient precipitating and flocculating agents that could be employed. It is now recognised that the efficiency of the salts of aluminium and iron is due to the fact that the coagulating power of an ion is proportional to the valency. Thus Al will have three times the coagulating power of the Na-ion. The anion in the electrolyte would have a stabilising effect on the negative colour colloid, so it is desirable to reduce the proportion of this ion to a minimum. This explains the desire for basic material in filter alum specifications. Hale (J. Ind. Eng. Chem., 1914, 6, 632) gives the following analyses of commercial aluminium sulphate as used at the Brooklyn filters; the comparative figures for the neutral salt are added.

Samples.	Al_2O_3. %	SO_3. %	Ratio.
Average	18·2	39·3	2·16
Maximum	20·6	41·4	—
Minimum	16·6	35·9	—
$Al_2(SO_4)_3.18H_2O$ ..	15·3	36·0	2·35

The average deficiency in SO_3 on the amount required to form a neutral salt is about 8%.

Basic aluminium sulphate is sometimes regarded as being difficult to dissolve, but this is not correct. The porosity of the material, which determines the rapidity of solution, is influenced by the method of manufacture, the temperature of the acid being the chief factor.

The filter plants in the United Kingdom are not large enough to warrant the manufacture of filter alum individually, but in America several of the large plants now make their own alum by the Hoover process.

(4) In some cases there is a critical concentration of the electrolyte. This is well exemplified by the results obtained by Hale with the Great Swamp water (*loc. cit.*). With this water there was a definite critical concentration of alum at about 1·75 grains per U.S. gall. (2·10 grains per Imp. gall.) below which no precipitation occurred. The colour colloid in this water was probably more homogeneous than that in the majority of waters, for the amount of colour removed is usually a function of the concentration of the added electrolyte. The effect of various concentrations of filter alum on the Ottawa River water is shown in Fig. 1. The original alkalinity of the water was 22 p.p.m. to methyl red and the alkalinities shown were obtained by the addition of sulphuric acid or sodium carbonate.

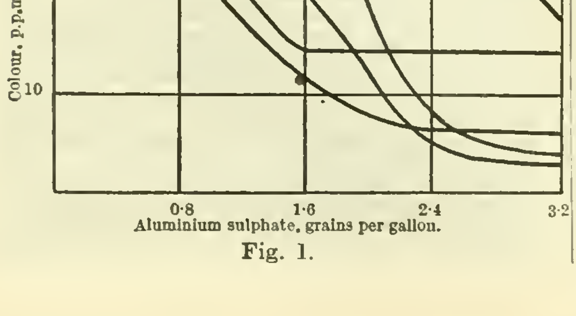

Fig. 1.

This diagram shows several interesting features. The curve for alkalinity 32 illustrates the stabilising effect of hydroxyl ions on the colour colloid; when the alkalinity was reduced to zero ($p_H = 5$) the addition of alum produced very little effect, the potential being very quickly reduced and the colloid taking up a positive charge from the electrolyte, remains dispersed. The other curves apparently show that precipitation occurs with each reduction of the potential and that precipitation ceases when there is an excess of positive ions. It will be seen that the removal of colour ceases soon after the alkalinity to methyl red has been reduced to zero, and if the iso-electric point is approximately identical with this hydrogen-ion concentration the maximum colour removal can be obtained by the maximum concentration of electrolyte that can be added without changing the polarity of the disperse phase. The slight colour removal effected after the alkalinity has been reduced to zero can be explained by the enmeshing of the dispersed colloids by the "floc." It is of course obvious that the relation of the electrolyte to the alkalinity is not the only factor in the process: the amount of original colour and its nature must also be considered.

The curves could also be explained by the hypothesis that the precipitation was not due to the action of $Al^{\cdot\cdot\cdot}$ but to aluminium hydroxide sol formed by hydrolysis, and that the stability of the colloid was increased by the addition of alkali. The work of Whipple and others has shown, however, that the precipitating effect of aluminium hydroxide is much less than that of the sulphate.

The curves show many facts that are of practical importance in water decolorisation, viz., (1) That negative ions (alkalis) should not be added before or with the alum unless there is a serious deficiency of alkalinity in the water. If the addition of a base is necessary for the reduction of acidity it should be added after coagulation or after filtration. At one plant (capacity 200,000 galls. per day) treating the Ottawa River water, alum and soda ash were added at the same point. No precipitation occurred and there was no reduction of colour after mechanical filtration. At another plant the same water was treated with 2·0 to 2·5 grains of alum per gall. without the addition of alkali and the colour was reduced from 40 p.p.m. to 4 p.p.m. (2) That colour reduction is not a linear function of the concentration of the electrolyte. The greatest efficiency is shown by the last fraction of electrolyte that reduces the electrical potential to zero. When the potential is considerable the first effect of an electrolyte is to reduce the dispersity, but the reduction may be insufficient to produce visible precipitation. If 0·8 grain of alum per gall. is added to the Ottawa River water no visible action takes place for several hours, but aggregation of the colloids is shown by the fact that they can no longer pass through fine filter paper. Aggregation of colour colloids, on the addition of alum, appears to be practically instantaneous, but visible flocculation may not occur until some time afterwards, the period depending upon various conditions. These two aspects of the same phenomenon have led to the difference between English and American practice in filter design. In the former the water is filtered before visible flocculation occurs and the colloids are removed by a filmed filter; in the latter a sedimentation basin is provided which permits and promotes precipitation and has a period of retention long enough for the majority of the "floc" to settle out. The water passing to the filters carries less sediment, *cæteris paribus*, under American practice with the consequence that filter runs are longer and wash water is proportionately less. Some English rapid filters, operated without a sedimentation basin, give runs as long as the average of many filters in America and use as little wash water, but this is due to the smaller amount of impurities in the raw water.

Each system is adapted to the water it is usually called upon to treat, and, under favourable conditions, there is relatively little difference between the results obtained. In America, however, where coagulation is such an important part of the process, this phase has been studied intensively, and it might justly be stated that alum is used more scientifically there than in Great Britain. As the most efficient fraction of alum is that which reduces the charge to approximately the iso-electric point, it is preferable to reduce one volume to zero potential and to mix this with an equal volume of raw water than to treat two volumes with the same amount of alum. The former method may be applied by the constant addition of alum to a fraction of the supply or by intermittent addition to the whole supply. The latter variety of the excess alum method, as it is usually known, has been used by Lochridge at Springfield, Mass., for several years, and has resulted in considerable economies in the alum used.

Aluminium hydroxide in filtered waters.

When aluminium sulphate is added to a water containing bicarbonates of calcium and magnesium there is a reduction of alkalinity somewhat in accordance with the equation

$$Al_2(SO_4)_3+3CaCO_3+3H_2O= Al_2(OH)_6+3CO_2+3CaSO_4.$$

If neutral sulphate were used, the alkalinity, calculated as $CaCO_3$, should be reduced by 6·43 p.p.m. for each grain per gallon, but the daily analyses made at many American plants show that the loss of alkalinity is rarely in accordance with the theoretical as calculated from the sulphate (SO_3) content of the added alum. The deficiency varies and at some plants it is as high as 30%. The cause has not been definitely established, but it may be explained either by adsorption of the added electrolyte by the colloid or floc or by assuming that the intermediate product $Al_2(CO_3)_3$ is not entirely hydrolysed to the hydroxide.

The aluminium hydroxide formed by hydrolysis is highly dispersed, and in some cases an appreciable amount passes the filters and coagulates subsequently. When the coagulant is used in a proper manner no visible hydroxide appears in the clear water basin, but according to Howard and Hannan (Can. Eng., 1920, May 13), the presence of alumina can be detected in all filtered alum-treated waters by the logwood, hæmatoxylin, and acetic acid tests. The samples they examined included waters from gravity filters, pressure filters, drifting sand filters, and special laboratory filters. Heap (Pub. Health, 1916, 29, 95) has apparently found aluminium hydroxide in the sediment from the mechanical filters dealing with the Ashton supply. Although the presence of alumina in alum-treated filtered waters seems to be universal, there is no evidence that the amount passed has any hygienic significance.

Electrical methods for colour removal.

Various electrical methods for producing a coagulant have been tried in the past, but these have usually involved the use of iron electrodes, and comparatively few reliable results have been published as to the efficiency obtained as regards colour removal. In 1916 the author deemed it desirable to experiment with electrical methods for the purpose of obtaining further information as to the nature of the colour colloids in the Ottawa River water. The first experiments were made with laboratory apparatus having a capacity of 2 galls. per hour. The data obtained were utilised in the design of a larger plant having a capacity of 200—300 galls. per hour. An isometric drawing of this plant is shown in Fig. 2. The raw water entered at A through a ball valve which ensured a constant water elevation throughout the whole plant. At this point the conductivity of the water was increased by the addition of about 2·5 grains per gall. of salt in the form of a 20% solution, from B. This increased the conductance from 40 reciprocal megohms to 100 units. The water with the salt solution then passed over a weir, extending the whole width of the tank, into the electrode section, C. This section contained 28 aluminium plates about 2 ft. square and ⅛-inch gauge, which were slotted into the sides of the tank and suitably insulated. The plates were set 1 inch apart and were staggered vertically so that the water would flow over one and under the next throughout the whole series. With a flow of 200 galls. per hour the average vertical velocity of the water up and down the plates was about 3 ft. per minute. This more than sufficed to prevent the deposition of the floc on the floor of the electrode section and so eliminated short circuits. The electrodes were connected in parallel and charged with a low density (4—6 volts) direct current. The effluent from the electrode section was allowed to settle for 3 hours in a sedimentation tank, D, provided with suitable baffles, and then filtered through sand in a rapid gravity filter, F. The underdrains, G, of this filter consisted of perforated galvanised wrought-iron pipe, which was covered with 1 inch of stone. Above the stone were thin layers of gravel of decreasing diameter which supported the sand bed 18 inches in depth. The sand was washed free from fine particles and had an effective size of 0·28 mm. with a uniformity coefficient of 2·2. The filter was back-washed by placing a stop board in the weir between the filter and the sedimentation tank, closing the outlet valve, H, and back-washing with water from the city supply, E, until the overflowing water was free from suspended matter. The filtered water was measured through a meter and the flow regulated with the aid of a small pitometer. The manometer connected with the pitot tubes was filled with petroleum ether to increase the sensitiveness and was calibrated against the meter. A loss of head gauge and a white concrete box for observing the colour of the filtrate completed the installation.

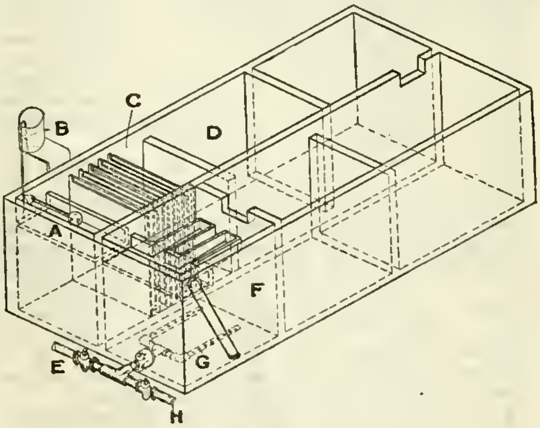

Fig. 2.

The operation of the plant was quite simple. After the maximum rate of flow that would give a practically colourless effluent had been determined, all that was necessary was to open the outlet valve until the manometer indicated this rate (200—220 galls. per hour), switch on the current, and open the pinch-cock on the brine discharge pipe. For controlling the operations routine tests of the conductivity were made and samples examined for colour at the outlet of the electrode section. The usual length of filter run was 8—10 hours, this being the period required to produce negative head in the filter.

The following results were obtained with aluminium electrodes:—The amount of water purified was 20,000 galls.; loss of weight of plates, 0·25 lb.; current used, average 11 amps. at 5 volts = 55 watts; salt used, 2·45 grains per gall. Before treatment the water had a colour of 40 p.p.m. and alkalinity 22 p.p.m.; after treatment the respective figures were 3 and 22 p.p.m. On a basis of one million gallons the results were: aluminium consumption 12·4 lb., current 275 kw., salt 350 lb.

With a power factor of 0·80 and assuming the efficiency of a motor generator set to be 80%, the costs, at the then ruling local prices, of the process were: aluminium $5·58, salt $1·05, current $0·92; total $7·55; with alum coagulation at 2 grains per gallon the cost was $9·80. These are operating costs only. The capital outlay for the electrical process would be much higher than for an alum plant, and this factor would partially offset the difference between the operating costs. It is obvious that such a process could only be operated where electrical power is exceedingly cheap.

From the scientific point of view the experiment yielded data of considerable interest.

(1) The loss of aluminium was only 0·085 grain per gallon, which is equivalent to 0·445 grain of commercial filter alum. When alum is used at least 2 grains per gallon is required to obtain the same colour reduction.

(2) The alkalinity of the water was unchanged. When alum is used each grain per gallon reduces the alkalinity by 6—6·5 p.p.m. and increases the carbonic acid by an equivalent amount. This increased carbonic acid content is deleterious in many ways, and it is often necessary to neutralise it by the addition of lime.

(3) The analysis of the "floc" gave information regarding the composition of the colloidal matter. The results are given in the subjoined table.

	Aluminium plates.		Iron plates.
	Top floc.	Bottom floc.	Mixed floc.
Organic matter (loss on ignition)	47·7	18·7	26·6
Al_2O_3	34·7	18·1	3·6
Fe_2O_3	2·5	8·2	56·6
SiO_2	11·7	50·9	9·6
CaO	2·8	1·5	2·2

The results show that the colloidal matter contains considerable quantities of inorganic material similar in composition to and probably derived from the granite which forms the superficial strata of the watershed. The iron content of the water (0·4 p.p.m.) would account for a portion of the colour, but the majority must be attributed to colloidal humic acid and its salts.

Iron electrodes.

An experimental run was made with soft iron electrodes, but it was found that the colour reduction was irregular and unsatisfactory and that there was a danger of iron going into solution in the ferrous state and being precipitated from the filtered water. The use of lime, as in Landreth's process, prevented the solution of iron but increased the colour and rendered its removal more difficult.

Discussion.

Mr. W. **Clifford** said that in relation to the volume of water treated per hour, water in passing through tanks did not flow through in a body, and after the current was turned on it might be some hours before the original water would be eliminated, so that an error might easily occur as to the amount of colour or alumina removed.

Mr. F. R. **O'Shaughnessy** said he had found in waters which had been filtered through special kinds of land containing ferrous material and ferruginous clay that the filtrate would at first be clear and colourless and that later on it would become cloudy, then, later still, it would become reddish-tinged, and finally would have a thick, flocculent, red deposit. In the electrical process described there might be danger of a complication in the production of carbon dioxide, which, if not attended to, would cause corrosion in the iron pipes.

Dr. **Maxted** inquired if the precipitation of the matter by the electrical process was purely an electrical one, or whether it was caused by the solution of the aluminium electrodes. It would be interesting to know whether precipitation took place under similar circumstances with platinum electrodes which would not dissolve.

Mr. **Race**, in reply, pointed out that although he had only referred to the decolorisation results obtained with alum treatment, the experiments were made with the Ottawa River water, which was polluted in addition to being highly coloured. At some periods of the year the bacterial content was very high, so that treatment of some description was imperative. That being so, it was advisable concurrently to remove both colour and other impurities. Treatment with alum increased the carbonic acid content, thus increasing the liability to produce red water trouble; but that occurred in the hot water systems only, the cold water supply being always colourless and free from excess of iron. He did not think that the facts supported the hypothesis that salt, under the influence of the current, produced chlorine or hypochlorous acid which caused bleaching of the colour through the agency of nascent oxygen. The suggestion that chlorine attacked the plates and produced aluminium chloride was, he thought, quite feasible. It was the aluminium going into solution that produced the flocculating effect. The current alone would not account for the results obtained. When platinum electrodes were employed, the colour was precipitated, but the action was very slow and might take weeks to proceed to completion. The electrical process could only be operated where electrical power was very cheap, and for this reason the process was of more academic and scientific interest than practical importance.

Communications.

THE EFFECT OF THE PRESENCE OF CHLORINE ON THE ABSORPTION OF NITROUS GASES.

BY H. W. WEBB, M.SC., F.I.C.

It is well known that the sodium chloride, present in commercial sodium nitrate, is converted during the manufacture of nitric acid into hydrochloric acid and chlorine, and, by a secondary reaction between nitric oxide and the chlorine, nitrosyl chloride is also produced. A series of tests was carried out therefore on a set of eight absorption towers, 3 ft. × 12 ft. 6 in., working in series on the counter-current principle, to determine the effect (if any) of the chlorine and hydrochloric acid present on the absorption.

It was noticed in determining the efficiency of each tower of the set that the increase in concentration of the nitric acid at one particular tower was relatively very much greater than in the other towers, and, furthermore, that the total acidity of the acid, starting down the top of this tower, was almost invariably between 30 and 40% (as HNO_3).

* The acid in No. 1 tower (gas inlet) is always stronger because the acid condensed in the fume main from the nitric acid plant runs down into this tower.

† Caused by the evaporation of nitric acid from previous tower owing to feed being too small, the evaporative effect of the inert gases passing through being comparatively great with acid above 65% HNO_3.

The above table gives typical examples of the progressive concentration of the nitric acid, each sample being drawn from the bottom of the tower.

It will be noticed from these results that there is a sudden rise in concentration when the absorbing acid attains a concentration of 30—40% HNO_3, and also that the tower at which this occurs varies (as would be expected) with the rate of water feed.

It was at first thought that the variation in the amount delivered down each tower by the air-lifts would account for this variation. This was shown not to be the case, however, by measurement of the feeds down each tower and calculation of the amount of nitric acid absorbed in each tower in grammes per minute. The following is a typical example:—

No. of tower.	% HNO_3.	HNO_3 absorbed, g. per min.
1	75·6	—
2	67·5	75·7
3	59·0	108·2
4	39·7	81·0
5	32·0	44·4
6	24·8	76·4
7	18·8	63·1
8	11·5	145·7

It was noticed, however, that in towers 4—8 the total acidity as HNO_3 was greater than that corresponding to the specific gravity.

The samples were therefore analysed for hydrochloric acid by adding excess of $N/10$ silver nitrate and back-titrating with standard thiocyanate.

No. of tower.	°Tw.	%HCl.	% HNO_3.	Incr. in % HCl starting from water end.	Incr. in % HNO_3 starting from water end.

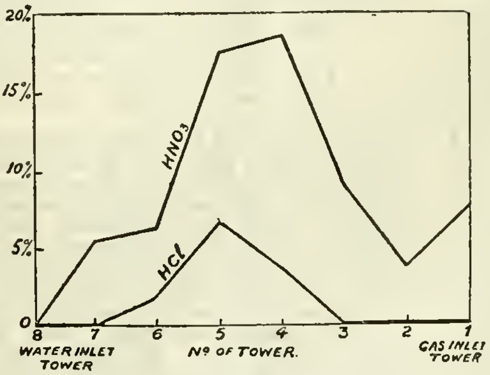
* Due to HNO_3 vapour carried over from first tower.

The greatest increase in concentration of nitric acid thus occurs in the same tower as the greatest decrease in concentration of hydrochloric acid; on plotting these results, it is seen that the rate of increase of concentration of nitric acid and rate of decrease in concentration of the hydrochloric acid are roughly proportional. The graphs illustrating the experiments of set No. 3 are given as typical.



This indicates, therefore, that the chlorine present in the inlet gases has an appreciable influence on the absorption of nitrous gases in the towers.

The following explanation is offered:—Nitric acid forms two main hydrates, HNO_3,H_2O and $HNO_3,3H_2O$, corresponding to acids of 77% and 54% HNO_3 respectively. Therefore at some point a little above 54% HNO_3, nitric acid contains no "free" water as such, but only "combined" water. Hence (as is proved by actual experiment) the reaction $HNO_3+3HCl \rightarrow NOCl+Cl_2+2H_2O$ takes place only with nitric acids above 55—60% HNO_3.

The nitrosyl chloride formed from the nitric oxide and chlorine meets only concentrated nitric acid in the first towers, and hence the main reaction is the conversion of all the hydrochloric acid present into nitrosyl chloride and chlorine, while the nitrogen peroxide dissolves in the ordinary way, giving nitric and nitrous acids. When, however, the gases meet acid with less than 55—60% HNO_3, and hence containing "free" water, the following reactions commence:—

$$NOCl+H_2O \rightarrow HNO_2+HCl \quad\ldots\ldots\ldots\ldots(1)$$
$$Cl_2+H_2O \rightarrow HClO+HCl \quad\ldots\ldots\ldots\ldots(2)$$
$$HNO_2+HClO \rightarrow HNO_3+HCl \quad\ldots\ldots\ldots\ldots(3)$$

The chlorine present now plays a very important part; it oxidises the nitrous acid formed from the nitrosyl chloride and accelerates the conversion into nitric acid of the nitrogen peroxide present in the gases by oxidising the nitrous acid formed in the reaction between nitrogen peroxide and water and by displacing the equilibrium, causing a more rapid absorption of nitrogen peroxide. Reactions 1, 2, and 3 proceed very rapidly until the concentration of nitric acid produced reaches such a value that there is no "free" water left; at this point the reaction $HNO_3+3HCl \rightarrow NOCl+Cl_2+2H_2O$ sets in again.

This, then, is probably the reason of the rapid rise in concentration of the nitric acid and the decrease in concentration of hydrochloric acid in the same absorption tower.

The nitric acid content of the acid entering the top of the tower increases rapidly by the oxidising action of the chlorine dissolving in the "free" water. When the acid nears the bottom of the tower, however, the nitric acid has become so concentrated that with the hydrochloric acid produced in reactions 1, 2, and 3 nitrosyl chloride and chlorine are produced; this reaction removes the hydrochloric acid without appreciably weakening the nitric acid, since 3 mols. of HCl are removed for each 1 mol. of HNO_3. The nitrosyl chloride and chlorine pass up to the top of the tower, and there the cycle is repeated. The net result is that practically the whole of the chlorine present in the gases is used up in the tower where the large increase in nitric acid concentration occurs, and that the gases passing on from this tower consist mainly of nitrosyl chloride, nitrogen peroxide, and air, and hence only the following reactions occur in the next towers:—$NOCl+H_2O \rightarrow HNO_2+HCl$; $2NO_2+H_2O \rightleftarrows HNO_3+HNO_2$; $3HNO_2 \rightleftarrows HNO_3+2NO+H_2O$, since these towers contain greater quantities of hydrochloric acid. The final exit gas should hence consist of nitrogen oxides, nitrosyl chloride, and hydrochloric acid, but no free chlorine.

It has already been stated that the concentration of acid coming from this one tower should be such that there should be no "free" water present (*i.e.* 55—60% HNO_3). The actual concentrations of nitric acid obtained from the tower where the rise in concentration of nitric acid occurred were:—(1) 59%; (2) 56·3%; (3) 50·7%; (4) 53·4%; (5) 59%; (6) 58·3%; (7) 49·1% (8) 54·0%. Each set of tests was carried out with varying water feeds, and the change took place each time actually in a different tower, but always in the tower with the nitric acid of a certain concentration. Furthermore, analysis of the exit gases showed that they contained 9·5 grains of acidity as chlorine and 15 grains as HNO_3 (=7·1 grains of NO). The ratio, therefore, of nitric oxide to chlorine actually found in the exit gases is 7·1:8·5=1:1·2 approximately. The ratio of NO:Cl in nitrosyl chloride is 30:35·5=1:1·2 approximately, thus indicating that the exit gas probably consists almost entirely of nitrosyl chloride, and also giving additional support to the theory of the action of the chlorine.

The results show, therefore, that chlorine, when mixed with nitrogen peroxide largely diluted with air, causes the peroxide to be absorbed very rapidly, with the formation of an acid containing 55—60% HNO_2 and also containing very little chlorine.

THE VOLATILE OIL FROM THE LEAVES OF *OCIMUM GRATISSIMUM*, LINN.

BY O. D. ROBERTS, F.I.C.

In 1913 Roure-Bertrand Fils (Bulletin, Oct., 1913, p. 17) reported on the examination of a sample of volatile oil stated to be derived from *Ocimum gratissimum*. This oil, which was prepared at Dabakala, West Africa, resembled ajowan seed oil in odour and contained 44% of phenols consisting almost entirely of thymol.

A small sample of oil was received at the Imperial Institute from the Curator of the Botanic Station, Seychelles, in 1917, together with herbarium specimens of the plant from which it had been distilled. It was stated that the plant grows as a common weed on the roadsides in Mahé, and that the green leaves had furnished 0·1% of volatile oil. The plant was identified at Kew as *Ocimum gratissimum*, Linn. The leaves and oil possessed a pronounced odour of cloves, showing clearly that the oil differed in character from the West African oil mentioned above.

The oil as received was pale brown and had the following constants:—Sp. gr. at 15°/15° C. 0·995, $\alpha_D=-14·0°$, $n_D^{21}=1·526$. It contained 62% of phenols.

A larger sample of the oil was received from Seychelles in 1919 and it had the following characters:—Sp. gr. at 15°/15° C. 0·996, $\alpha_D=-12·7°$, $n_D^{20}=1·532$. The oil contained 55% of phenols.

The latter sample of oil was examined systematically with the following results:—

Free acids and phenols. Identification of eugenol.

The free acids were extracted from the oil by shaking it with a dilute solution of sodium carbonate. On acidifying the solution and extracting with ether, an acid liquid equivalent to about 0·2% of the original oil was obtained. This product was readily soluble in water and appeared from its odour to consist mainly of acetic acid.

After the removal of the free acids the phenols were separated from the oil by means of 5% sodium hydroxide solution, and it was thus found that the original oil contained 55% of free phenols. This phenolic portion of the oil had the characteristic odour of eugenol, and was found to consist practically entirely of this substance. It boiled at 252°—253° C., and furnished benzoyleugenol melting at 69°—70° C.

Character of the residual oil.

The oil remaining after the removal of the free acids and phenols somewhat resembled in odour the oil of sweet basil, and had the following constants: Sp. gr. at 15°/15° C. 0·9013, $\alpha_D=-15·0°$, $n_D^{20}=1·513$, ester value before acetylation 4·5, ester value after acetylation 101·5.

Fractionation of residual oil.

The oil, after removal of the free acids and phenols, was distilled under 20 mm. pressure, and the following fractions collected:—

Fraction.	Per cent. (calc. on original oil).	B.p. (20 mm.).	Sp. gr. (15 °/15°).	α_D^{22} in 100-mm. tube.
1	16	70°– 85°	0·8077	+0·28°
2	15	85°–100°	0·8790	–18·5°
3	9	100°–135°	0·9230	–10·5°
Residue	5	—	—	—

Identification of ocimene.

After repeated fractionation over sodium under reduced pressure, fraction 1 was obtained as a colourless mobile oil which boiled at 70°—75° C. at

20 mm., was optically inactive, and had a sp. gr. at 15°/15° C. of 0·8029, and $n_D^{20}=1·4855$. The properties of this hydrocarbon corresponded with those of the aliphatic terpene ocimene.* On reduction with sodium and alcohol it was converted into a hydrocarbon having sp. gr. at 15°/15° 0·7777, $n_D^{17}=1·4500$, and molecular refraction 47·7. These constants agree with the figures which have been recorded for dihydro-ocimene (or dihydromyrcene),† a hydrocarbon obtained on the reduction of ocimene or myrcene. This reduction product combined with four atoms of bromine with the formation of a crystalline tetrabromide, m.p. 88° C. This is the melting point of dihydro-ocimene tetrabromide prepared by Enklaar (*loc. cit.*). The presence of ocimene in the oil is therefore confirmed.

Fraction 2 consisted of a colourless mobile oil having a pleasant aromatic odour recalling that of linalool. A portion gently oxidised with chromic acid mixture gave rise to a citral-like odour. An attempt to prepare a crystalline urethane from this fraction was, however, unsuccessful, probably owing to the fraction not being sufficiently pure. As the entire fraction amounted to only 8 c.c. its further investigation was impracticable.

Fraction 3 had a distinct odour of methylchavicole. Judging from its specific gravity, however, this fraction could not contain any large proportion of this compound, and no definite indication of its presence could be obtained with the small quantity available. A methoxyl determination on the oil remaining after the removal of the eugenol indicated the presence of 12·5% of methyl ethers (calculated as methylchavicole), which is equivalent to 5·6% in the original oil.

Summary.

The results of this investigation have shown that the volatile oil from the leaves of *Ocimum gratissimum*, Linn., from Seychelles had the following approximate composition:—

Terpenes, chiefly or entirely ocimene	16·0%
Phenols, eugenol	55·0%
Phenol ethers, calculated as methylchavicole ..	5·6%
Alcohols, probably linalool	13·0%
Esters (calculated as $C_{10}H_{17}OH$)	0·6%
Residue and loss (by difference)	9·8%

In conclusion reference may be made to the volatile oil derived from the leaves of a large-leaf variety of *Ocimum Basilicum* Linn., stated to be known in Java as "Selasih Mekah." This oil was examined by P. van Romburgh (*loc. cit.*) and appears to be rather similar in composition to the present sample of oil. Different samples of these leaves furnished from 0·18 to 0·32% of volatile oil, having sp. gr. at 26° C. 0·890—0·940, $\alpha_D=-11·25°$ to $-18°$. The oil contained from 30 to 46% of eugenol, and also the terpene ocimene.

Schimmel and Co. (Report, 1908, April, 123) have also recorded the results of the examination of a volatile oil obtained from an unidentified species of *Ocimum* found in the island of Mayotte, which had the following characters: Sp. gr. at 15°/15° 0·9607, $\alpha_D=-14°54'$. This oil also contained eugenol 38%, and had, moreover, the odour of methylchavicole.

THE RELATION BETWEEN COMPOSITION OF "MIXED ACIDS" AND THEIR SPECIFIC GRAVITIES.

BY ELWYN ROBERTS, B.SC.

Saposchnikoff (J. Russ. Phys.-Chem. Soc., 1903, 35, 1098; 1904, 36, 518, 669; 1905, 37, 374) appears to be the first to have made a systematic study of "mixed acids"—that is, mixtures of sulphuric and nitric acids and water. He studied them from various physico-chemical aspects: (1) vapour pressure; (2) composition of the vapours of mixtures of nitric acid with sulphuric acid; (3) electrical conductivity; (4) specific gravity. Further investigations were carried out by Kullgren (Z. ges. Schiess- u. Sprengstoffw., 1908, 3, 146), Schaefer and Niggemann (Z. anorg. Chem., 1916, 97, 285), and Pascal (Comptes rend., 1917, 165, 589).

Recently Pascal and Garnier (Bull. Soc. Chim., 1919 (iv.), 25, 142) have determined the specific gravities of a number of "mixed acids" of various compositions. Their results are represented on a ternary diagram in which there will be observed a dome corresponding to a zone of maximum sp. gr. in the neighbourhood of 89% H_2SO_4 (cf. Saposchnikoff, *loc. cit.*). They also state that, for "mixed acids" of which the composition lies in the zone of those used for the nitration of cotton, the sp. gr. is almost solely a function of the water content. They do not, however, state the nature of the function.

TABLE 2.

---

* P. van Romburgh, Proc. K. Akad. Wetensch., 1900, 446; Enklaar, Dissert., Utrecht, 1905.

† Semmler, Ber., 1901, 34, 3126; Enklaar, *loc. cit.*; Semmler and Mayer, Ber., 1911, 44, 2010.

The investigation which is the subject of the present paper was carried out previous to the publication of that of Pascal and Garnier; it covers a wider range than their measurements and throws light on the nature of the function which they mention.

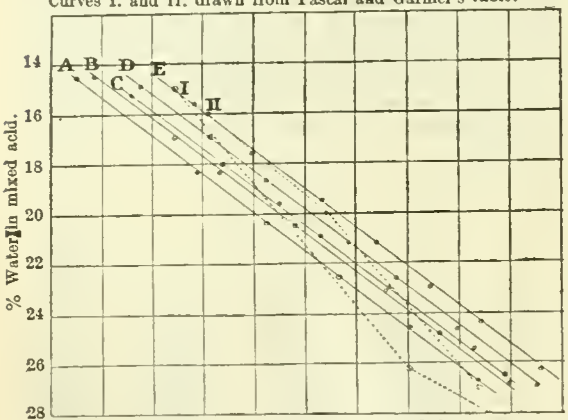
Table I has been constructed to show the strength of sulphuric and nitric acids which it is necessary to mix, in the proportion of 5 : 2 by weight, to produce mixed acids containing from 16 to 24% of nitric acid and from 14 to 26% of water. The nitric acid was freed from nitrous acid by means of a current of air free from carbon dioxide at 70° C. The mixed acids chosen for this investigation have compositions which lie in the zone of those used for the nitration of cotton.

Table 2 shows the composition of the mixed acids as determined by analysis after mixing, and their specific gravities; in brackets are given the composition of the mixed acids as expected from the proportions of the sulphuric and nitric acids. In the analysis of the mixed acids the total acidity was determined by direct titration with $N/1$ caustic soda, total nitrogen content with the Lunge nitrometer, and nitrous acid by direct titration with $N/10$ permanganate. The specific gravities were determined by means of a modified form of pyknometer.

In all cases the nitrous acid content was less than 0·02%.

It will be seen from Table 2 that the compositions as determined by analysis differ appreciably from those expected for the proportions of sulphuric and nitric acids used in mixing; yet all the mixed acids in any one series have the same nitric acid content.

Density-composition curves for "Mixed acids."
Curves A, B, C, D, E drawn from Table 2.
Curves I. and II. drawn from Pascal and Garnier's table.



The figure shows the sp. gr.-composition curves obtained from Table 2. It will be observed that (1) a set of five parallel lines is obtained which clearly indicates that, for each series of "mixed acids" of the compositions given, the sp. gr. is almost exactly a linear function of the water content when the nitric acid content of the series is kept constant; (2) if the perpendicular distances of the curves A, B, C, D, and E from the origin are plotted against the *nitric acid* content corresponding to each curve, a curve is obtained which shows that the perpendicular distance is almost a linear function of the nitric acid content.

In order to effect a direct comparison of the results of this investigation with those of Pascal and Garnier, the dotted lines I and II have been drawn from values given by them for the nitric acid contents 15·0% and 20·0% (*loc. cit.*). It will be seen that curves I and II cut across the curves A, B, C, D, and E, and apparently the sp. gr. is not a linear function of the water content. The irregularity of curves I and II appears to be accounted for by the fact that the percentage compositions of all Pascal and Garnier's "mixed acids" are represented by whole numbers, which indicate either that the numbers are the approximate results of analysis or are compositions assumed from the proportions of sulphuric and nitric acids used in the preparation of the mixed acids. If the sp. gr. values in Table 2 were plotted against the % H_2O values given in brackets, a series of irregular curves would be obtained similar to Pascal and Garnier's curves designated I and II.

Curves similar to those in the figure would be of technical use in the rapid analysis of mixed acids. If the nitric acid content be determined by the nitrometer and the specific gravity by a Twaddell's hydrometer, reference to the figure would give the complete analysis of the acid.

A NOTE ON THE CALCULATIONS INVOLVED IN THE PREPARATION OF ACID MIXTURES FOR THE MANUFACTURE OF NITROCOTTON.

BY R. A. FOWLER, B.SC., A.I.C.

An interesting algebraic method for the calculations involved in the adjustment of blends of mixed acid used in nitrating cotton has recently been described by W. Young (J., 1920, 315 T). A modification of the graphical method described by the present author (J., 1919, 34 T) and used at H.M. Factory, Gretna, would be found very convenient and expeditious.

It is the practice at some factories to give the refuse acid from the manufacture of nitrocotton a preliminary treatment with oleum and nitric acid, bringing its composition near to the specified composition for nitrating acid. This "bulked" acid is then corrected by the addition of calculated quantities of the necessary acids, *i.e.* nitric acid, oleum, and/or refuse acid. This calculation is the subject of the graph.

The composition of nitrating acid is fixed in the present case at HNO_3 23%, H_2SO_4 67%, H_2O 10%, and may vary only within certain definite narrow limits.

The composition of oleum (H_2SO_4 104·5%) and that of nitric acid (HNO_3 90%) are also fixed (with slight variations which do not greatly affect the calculation as explained in Young's article).

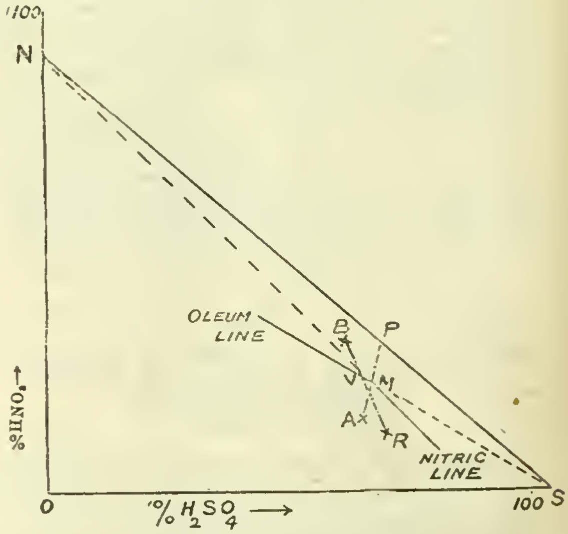


FIG. 1.

In Fig. 1 percentages of nitric acid are plotted on ordinates and percentages of sulphuric acid on abscissæ. If N represents the composition of the nitric acid available and S that of the oleum, the line NS shows the acids which can be produced by mixing N acid with S acid. If NS be divided into 100 equal parts the percentage of each constituent necessary for any definite composition represented by any point on the line may be read off. For example if the divisions be numbered from 0 to 100 from S to N, then at any point in the line the percentage of nitric acid is indicated; suppose the reading be 72, then the acid represented by that point may be made by mixing 72% of nitric acid with 28% oleum.

The point representing the nitrating acid, M, does not lie on the NS line but nearer to the origin. Join NM and produce. Join SM and produce. Since the points N, M, and S are fixed the lengths of NM and SM are constant and may be readily calculated. If now, the part produced in each case be divided as from point M into equal parts each equal to one hundredth of the lines NM and SM respectively, each division represents one hundredth of a unit of nitric acid or oleum as the case may be (the divisions are omitted in Fig. 1 for clearness).

The graph is used as follows:—

Case 1.—The point representing the composition of the bulked acid falls on the origin side of both oleum and nitric lines (*e.g.*, at A). A rule is placed through A and M, cutting the line NS at P, and the distances AM and MP and the reading at P are noted. Then tons of bulked acid multiplied by AM/MP gives tons of adjusting acids required, of which P% is nitric acid and the rest (100−P%) is oleum.

Case 2.—The point representing the composition of the bulked acid falls on the other side of the oleum and nitric lines (*e.g.*, at B). This may be adjusted by the use of refuse acid with nitric acid or oleum. When the points representing the bulked acid (B) and refuse acid (R) are joined the line will cross either the nitric or oleum line, *e.g.*, at V. The distances BV and RV and the reading at V are noted. Then tons of bulked acid multiplied by BV/RV gives tons of refuse acid required. And (tons of bulked acid+tons of refuse acid) multiplied by reading at V gives tons nitric acid (or oleum) required.

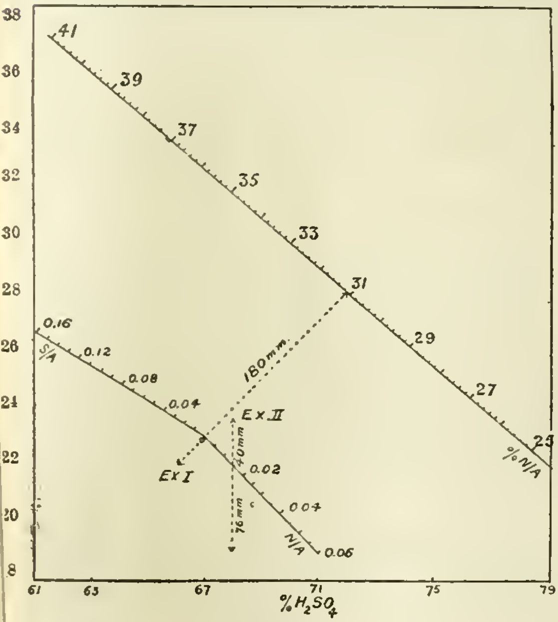

Fig. 2.

Case 3.—The point representing the composition of the bulked acid falls on the nitric or oleum line. Then tons of bulked acid multiplied by the reading at the point gives tons of nitric acid (or oleum) required.

It is not necessary to draw the whole of the graph for practical working. That portion only round the point M need be drawn, say HNO_3 18—36% and H_2SO_4 62—74% (see fig. 2). The higher limits are determined by the necessity for including a good part of line NS. The graph is prepared about 18 by 12 in., allowing one inch for 1%. Plot the point M (67, 23). Calculation shows then the line NS passes through the points 62·7, 36) and (73·15, 27) and it may then be drawn. Divide this line between these two points into ten equal parts (each 1·379 in.) and continue the divisions the whole length of the line. The first of these two points represents an acid of composition 40% nitric acid and 60% oleum, and the second 30% nitric acid and 70% oleum; they may then be marked 40 and 30 respectively and the other divisions to correspond.

The oleum line may now be drawn from M in the right direction by means of the tan of its angle with the abscissa 23/37·5 and divided into divisions each equal to $\frac{1}{100}\sqrt{23^2+37{\cdot}5^2}$ (=0·44 in. approx.). Similarly to the nitric line, the tan of its angle being 67/67 and the divisions being equal to $\frac{1}{100}\sqrt{67^2+67^2}$ (=0·947 in. approx.).

Two examples are worked out with the aid of the graph.

Example 1.—Take 100 tons of bulked acid with composition 22% HNO_3 and 66% H_2SO_4. Then from the graph AM/MP is 36/180 and the reading at P is 31·1. Then acid required for adjustment is 100×36÷180, or 20 tons, of which 31·1% is HNO_3, *i.e.*, 6·22 tons of nitric acid and 13·78 tons of oleum. The calculated composition of the blend resulting from this mixture is HNO_3 22·998% and H_2SO_4 67·002%.

Example 2.—Take 100 tons bulked acid with composition 23·6% HNO_3 and 68% H_2SO_4, and suppose the refuse acid available has composition 19% HNO_3 and 68% H_2SO_4. Then from the graph BV/VR is 40/76 and reading at V is 0·015. Tons of refuse acid required is 100×40÷76, *i.e.*, 52·6 tons. To this must be added 152·6×0·015, *i.e.*, 2·29 tons of nitric acid. The calculated composition of the blend resulting from this mixture is HNO_3 23·01%, and H_2SO_4 66·99%.

Should the composition of the nitrating acid be changed—a rare occurrence—a fresh graph would have to be constructed (this objection would apply equally to the tables used in connexion with the algebraic method). The one graph covers all changing conditions in composition of refuse acid and small changes in composition of nitric acid and oleum.

NOTE ON THE ACTION OF CHLOROFORM ON PHENYLHYDRAZINE.

BY W. LEIGH BARNETT, B.A., B.SC., A.I.C.

The author has already drawn attention to the fact that chloroform reacts with phenylhydrazine (J., 1921, 62 T). The crystalline compound formed was investigated in order to ascertain whether it was an addition product, or merely a hydrochloride of phenylhydrazine. It has been shown by Brunner and Leins (Ber., **30**, 2587) that when phenylhydrazine is heated with excess of chloroform at 100° C. in a sealed tube for eight hours, phenylhydrazine hydrochloride separates in the form of glistening scales. The author observed that these two compounds will react at normal temperatures provided that the chloroform is in excess. On warming a mixture of the two substances, very finely-divided glistening scales are formed after a short time. Experiments were carried out using freshly re-distilled phenylhydrazine and pure chloroform, free from traces of phosgene. The product of the reaction was carefully purified by solution in absolute alcohol and precipitation with ether, care being taken to minimise hydrolysis due to moisture. The purified products were analysed side by side with pure phenylhydrazine hydrochloride made from the base and aqueous hydrochloric acid. When freshly prepared and purified the melting point of the substance was always found to be lower than that for the phenylhydrazine hydrochloride, being about 221° C. with decomposition. On keeping for some time, however, the melting point was observed to rise, until after a few days it was the same as that of the hydrochloride, viz. 242° C. with decomposition. On titration of aqueous solutions of the compound with standard alkali it was observed that although a sharp end-point was obtained, yet a slight further acidity developed, which additional acidity was not obtained on titration of similar solutions of phenylhydrazine hydrochloride. The extra acidity was found to be due to small amounts of formic acid. It is probable, therefore, that the reaction is first of all a simple addition one between three molecules of the hydrazine and one of chloroform, when a very unstable compound is obtained, which splits up as shown in the presence of water into phenylhydrazine hydrochloride and formic acid.

1. $3C_6H_5.NH.NH_2+Cl_3CH \rightarrow (C_6H_5.NH.NH_2Cl)_3CH.$
2. $(C_6H_5.NH.NH_2Cl)_3CH+3H_2O = 3C_6H_5.NH.NH_2HCl+HCOOH+H_2O.$

The analytical results obtained from specimens which were analysed as soon as possible after preparation confirm this view that triphenylhydrazinochloromethane is the first product to be formed by interaction of chloroform and phenylhydrazine.

DETERMINATION OF ZINC BY THE POTASSIUM FERROCYANIDE METHOD.

Mr. C. E. Barrs writes as follows:—"Referring to the communication on the above subject by E. Olivier (J., 1921, 107 T), I should like to draw attention to the necessity for avoiding overheating when evaporating to dryness, as if this occurs manganese may pass into solution and so produce high and inaccurate results, as stated. In view of the slight solubility of potassium hydrogen tartrate (1—200) it is preferable to use normal potassium tartrate. Titration with potassium ferrocyanide in acid solution, using uranium acetate as indicator, is another method frequently used for Australian concentrates. An extended experience of the three methods for the determination of zinc has shown that concordant results can be obtained on Australian concentrates by all the methods. Personally, however, I prefer the acid ferrocyanide or the Schaffner method, with double precipitation of the iron and careful separation of manganese; the latter method is more frequently used on the Continent, and leaves very little to be desired if two burettes (assay and proof) are used side by side and glazed lead paper is employed as indicator."

---

[*] After keeping for a week in a moist atmosphere, then drying *in vacuo* at 85° C. to remove traces of formic acid, the preparation yielded almost pure phenylhydrazine hydrochloride, m.p. 240° C.

Meeting held at Birmingham University on Thursday, April 14, 1921.

DR. H. W. BROWNSDON IN THE CHAIR.

THE MANUFACTURE OF PURE HYDROGEN AND THE CATALYTIC HYDROGENATION OF OILS.

BY E. B. MAXTED, PH.D., B.SC.

Hydrogen suitable for use in catalytic processes is generated industrially by four methods, namely:

1. Electrolysis of aqueous solutions.
2. The low temperature separation of the constituents of water-gas.
3. The catalytic water-gas process, involving the replacement of carbon monoxide by hydrogen, by reaction with steam in the presence of a catalyst.
4. The cyclic water-gas process, in which the replacement of carbon monoxide by hydrogen is carried out in two separate phases.

Of these, the first and last give under suitable operating conditions a gas sufficiently free from inhibitants to be used directly for catalytic work, while the gas from the second and third methods requires, for most purposes, to be freed from carbon monoxide.

For the production of hydrogen for purposes such as the hardening of oils, it is as a rule desirable to instal a plant which will economically produce a gas of a high degree of purity, directly and without a complicated process of final purification. For this reason, the cyclic water-gas method is particularly suitable. In its primitive form, this method consists in generating hydrogen by the action of steam on heated iron, the resulting iron oxide being subsequently reduced to metal by means of water-gas. The cycle consists thus of two phases, which are denoted in practice as the periods of "make" and of reduction respectively. It is usual, before beginning the make, to reject the first impure portions of hydrogen produced. This period is known as the "rinsing" period.

Hydrogen produced by the cyclic process in its ordinary form contains a small percentage of carbon monoxide, which does not originate from the residue of reducing gas left in the retorts from the reduction phase, but is produced continuously during the steaming period and consequently cannot be eliminated by increasing the time of rinsing. During the reducing period, the contact mass, in addition to becoming reduced, causes the catalytic decomposition of the carbon monoxide into carbon dioxide and carbon; the carbon deposited persists into the steaming phase, where it reacts with steam, forming carbon monoxide simultaneously with the main production of hydrogen by the action of steam on the reduced iron.

This deposition of carbon, which is the *bête noir* of the cyclic process, may be prevented if the reducing gas contains carbon dioxide in amount in excess of the equilibrium percentage corresponding to the equation $2CO \rightleftarrows CO_2+C$, this percentage depending on the minimum temperature of reduction employed and on the partial pressure of the carbon dioxide and monoxide in the reducing gas.

Thus, a simple solution of the difficulty is effected by using, in place of ordinary water-gas, a gas somewhat richer in carbon dioxide, such as is obtained from a water-gas producer operating at an abnormally low temperature. The velocity of reaction between coke and steam is of course less at low temperatures and, since the coke is thus gasified more slowly, a larger producer is required to maintain a given output of reducing gas.

In addition to carbon monoxide, traces of air or its components are usually present, these impurities being derived from the steam used for generating hydrogen and from the gases dissolved in the water used for scrubbing, if open scrubbers are employed. For the hydrogenation of oils, traces of oxygen or nitrogen would appear to act principally as diluents, which, however, accumulate in gradually increasing quantities in the gas space in the hardening vessel, as absorption of hydrogen proceeds, the partial pressure of the hydrogen above the oil being thus lowered. For certain other catalytic reactions, traces of oxygen act directly as an inhibitant and, for these, water as free as possible from dissolved air must be employed for the generation of steam. In any case, it is usual in plants erected by the author to employ surface condensers in place of open scrubbers for the condensation of excessive steam from the hydrogen produced.

The general arrangement of a type of industrial plant embodying the various points dealt with above is shown diagrammatically in Figure 1. In this diagram the water-gas generator, A, is constructed for operating at a comparatively low temperature. From this producer the gas passes through the scrubber, B, which is the only open scrubber in the system and is of the ordinary type, containing coke or pumice, over which water is allowed to flow. The washed reducing gas flows into a balance gas-holder, C, and thence by way of a purifier, D, containing hydrated iron oxide, to the hydrogen plant proper.

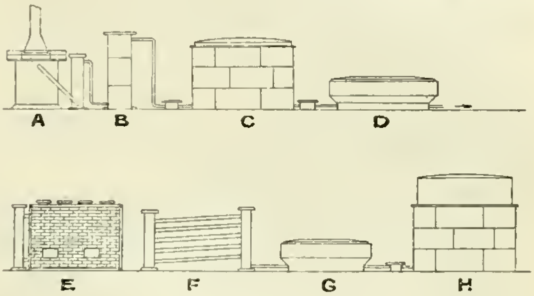

Fig. 1.

Reinforced concrete has been successfully used for the construction of the water-gas purifier and the corresponding hydrogen purifier, G, it being found readily possible to render this material impervious to hydrogen by subsequent treatment after erection. A concrete purifier can, moreover, be supplied for a small fraction of the cost of a purifier of equivalent capacity in cast iron and is, in addition, quick and simple to construct. A gas-holder of hydrogen, left standing in connexion with a treated concrete purifier, shows, even after many days, no further drop than the exceedingly small one usually observed even with purifiers in which all the parts are of metal.

The hydrogen furnace, E, is merely a firebrick chamber, containing a number of cast-iron retorts, which are filled with an iron oxide contact mass and arranged in such a way that the reduction, rinsing, or steaming phase of the process can be carried out at will. The hydrogen, which is free from carbon monoxide provided that the deposition of carbon on the contact mass has been prevented, passes through a surface condenser, F, in which the excess of steam is eliminated, and thence, by way of a purifier, G, which contains a mixture of iron oxide and lime, to the hydrogen holder, H.

The control of the above plant is simple, and no difficulty is encountered, even without the help of specially skilled workmen, in producing hydrogen sufficiently free from carbon monoxide and other impurities to exert no appreciable deleterious influence when employed for catalytic purposes such as for the hardening of oils. The hydrogen content of the gas should, if the plant is being operated in a proper manner, exceed 99·90%, and degrees of purity up to 99·97% have been obtained, not counting traces of entrained air or its components.

The method of hydrogenation usually employed consists in heating the oil to the desired reaction temperature, and, after the introduction of an amount of catalyst, which, in the case of nickel, may vary from 0·25 to 1% of the weight of the oil, agitating violently in an atmosphere of hydrogen, the absorption of the gas being allowed to proceed until the required degree of hardness has been obtained.

The course of the absorption of hydrogen at a given temperature was formerly thought to follow the unimolecular reaction law, but it has recently been shown by Armstrong and Hilditch that the gradual diminution in the velocity of absorption of hydrogen as saturation proceeds is not obtained with substances which are completely free from inhibitants, the true reaction curve following the linear equation up to a point in the neighbourhood of complete saturation, when the rate of absorption of hydrogen quickly drops to zero. This result is of considerable theoretical importance, in that it would seem to indicate that the real reacting system consists of a complex in which the concentration of the unsaturated substance is constant as long as a supply of this is available.

In practice, however, with oils of ordinary purity, non-linear reaction curves are obtained, and the activity of the catalyst is found to be decreased on employing it for a fresh charge of oil.

In many of the earlier plants, particularly those in which nickel oxide was used in place of nickel, a relatively high reaction temperature (200°—250° C.) was employed. It has, however, now long been recognised that relatively high temperatures influence adversely both the quality of the product and the speed of reaction. The optimum working temperature will depend to a large degree on the nature of the nickel catalyst employed and on the oil to be treated, particularly in view of the fact that certain of the catalyst poisons appear to be less toxic at high temperatures, this factor tending to compensate for the decreased reaction velocity due to a temperature above the optimum point.

The following comparative figures, relating to the influence of temperature on the velocity, were obtained with refined olive oil under laboratory conditions. The volume of oil taken for each test was 10 c.c., the catalyst consisting of 0·1 g. of nickel, reduced at 300° C.

TABLE I.

Time in mins.	C.c. of hydrogen absorbed at :								
	80°	100°	120°	140°	160°	180°	200°	225°	250°
1	0·9	7·4	17·5	28·0	32·0	31·8	28·8	18·0	7·7
2	1·9	14·8	35·0	54·5	63·0	60·3	53·5	32·5	13·8
3	2·8	22·5	53·0	79·5	91·5	84·3	73·5	43·0	19·0
4	3·7	30·0	70·0	104·0	116·5	104·5	90·0	51·3	24·0
5	4·7	37·9	87·0	128·0	140·5	120·8	103·0	58·5	28·5
10	10·4	78·8	167·0	228·0	238·0	182·0	152·5	88·1	45·8
15	17·1	119·6	237·5	305·0	309·0	224·5	187·0	111·5	59·0
20	25·6	159·0	301·0	368·0	369·0	260·0	219·5	133·7	68·
25	35·0	195·2	350·0	419·5	414·5	292·0	246·0	152·7	75·5
30	44·5	228·6	395·5	465·0	455·0	323·5	271·0	168·0	80·0

On plotting these figures graphically against the time, it is seen that each of the graphs, with the important exception of those at comparatively low temperatures, such as 80° and 100°, is curved in form. At relatively low temperatures, with pure substances, the activity of the catalyst usually increases somewhat after this has been used for a short time, probably owing to the catalytic reduction of the nickel oxide usually contained in nickel catalysts. This phenomenon is exemplified by the course of the reaction at 80° in the above table.

With reactions of this nature, assuming that the activity of a catalyst is to be measured by the effect produced by it, the simplest method for obtaining comparative figures for the relative activity of the nickel under given conditions is to assume this to be proportional to the initial velocity of absorption of hydrogen, a value which is easily obtained by differentiation from the equation to the reaction curve.

Table II. contains the results of Table I. treated in this way:—

TABLE II.

Temperature, ° C.	Relative activity of catalyst.
80	1·0
100	7·8
120	17·5
140	28·5
160	34·0
180	35·0
200	32·0
225	21·0
250	8·5

If the above results are plotted graphically, it will be found that the temperature of maximum activity appears to be about 175° C. The velocity of reaction is appreciable even at 80°, while at 100° it is sufficient for this temperature to be used for efficient hardening. This result is opposed to many of the earlier publications; for instance, Ipatiew (Chem.-Zeit., 1914, **39**, 374) stated that reaction between hydrogen and oil in the presence of nickel only begins at 150° C. The linear form of the reaction curves at low temperatures is well seen if the figures of Table I. for 100°, 160°, and 200° C. are plotted. It has been shown elsewhere (Chem. Soc. Trans., 1920, **117**, 1501; 1921, **119**, 225) that the addition of fixed amounts—*i.e.*, of amounts which do not increase during the progress of hardening—of many catalyst poisons has little effect on the curvature of the absorption graph, although the speed of reaction is of course decreased thereby, and it would thus appear highly probable, from the difference in curvature obtained with nickel at low and high temperatures respectively, that catalyst poisons which cause curvature and a corresponding decrease in the activity of the catalyst are produced during the hardening operation itself when carried out at relatively high temperatures. The employment of temperatures in the region of 100° C. is only possible with relatively pure oils. With most oils, of average commercial quality, a somewhat higher reaction temperature is rendered necessary by the catalyst poisons in the oil itself, and it is the ordinary practice in plants controlled by the author to begin hardening at about 120°—130° C., the temperature rising subsequently, by virtue of the heat of reaction, to a maximum of about 160° C.

A further factor of industrial importance in determining the speed of reaction is the pressure at which the hardening operation is carried out. An experimental examination of this point appeared to be called for by reason of the somewhat discordant results contained in the literature of the subject, and, with this object, the following experiments were carried out.

The apparatus consisted of the usual shaker, in which, however, the measuring burettes were replaced by a closed manometer. The whole apparatus was filled with hydrogen at an increased pressure, and, on shaking in the usual way, the absorption could be followed by the drop in pressure indicated by the manometer.

For the sake of simplicity, the reaction was carried out at 100° C., the course under these conditions, with the catalyst and oil employed, being, as already stated, linear when allowed to proceed without a variation in pressure.

If v represents the volume in c.c. of hydrogen absorbed after t minutes, and if the rate of absorption is, for the moment, assumed to vary as the nth power of the pressure

$$\frac{1}{P^n} \cdot \frac{dv}{dt} = k$$

where k is a constant.

From the manometer readings at various intervals of time it is, as already stated, easily possible to calculate the progress of absorption with the time, and, by differentiating the equations connecting these two quantities, the relative values of dv/dt corresponding to the various pressures are readily obtained.

Table III. summarises the results of a typical experiment with a varying pressure in a closed system of this sort. The striking constancy of the constant k, which has been calculated for $n=1$ in the above equation, would appear to demonstrate beyond doubt that the rate of absorption of hydrogen at a constant temperature varies directly as the pressure.

TABLE III.

Time in minutes.	C.c. hydrogen absorbed.	Pressure in atm.	$\frac{dv}{dt}$	k ($n=1$)
0	0	2·06	15·66	7·60
1	15·0	1·915	14·61	7·64
2	29·5	1·785	13·60	7·62
3	42·5	1·65	12·63	7·63
4	54·5	1·53	11·70	7·64
5	65·0	1·42	10·82	7·63
6	75·5	1·32	10·03	7·61
7	85·0	1·23	9·17	7·47
8	94·5	1·14	8·40	7·36
9	103·5	1·05	7·72	7·35
10	111·5	0·97	7·00	7·22

It may be of interest, in conclusion, to describe briefly a type of commercial oil-hardening plant with which the author has had special experience. The construction of the hardening vessel is shown diagrammatically in Figure 2. It consists of a relatively narrow portion, A, terminating in two broader chambers, B and D. In place of movable agitators, A contains a series of stationary propeller-shaped baffles, the blades of which are curved in such a manner that a substance, on being projected through this reaction cylinder, is rotated alternately in a clockwise and anti-clockwise sense by successive baffles; the charges of oil and of hydrogen, with which the vessel is filled, are projected at a high velocity through the central column, in opposite directions respectively, by means of the pumps C and E, fresh hydrogen being admitted as required to compensate for that absorbed.

The vessels are constructed of mild steel plates, welded together, and are made in various standard sizes; thus a vessel to hold a charge of 2 tons of oil has a total height of about 22 ft., the diameter of the upper and lower reservoirs being about 4 ft. 6in. The heating of the charge to reaction temperature is effected by means of a steam jacket. It is usual in the above plants to employ a hydrogen pressure of 40—80 lb. per sq. in., the gas being carefully dried either before or after compression.

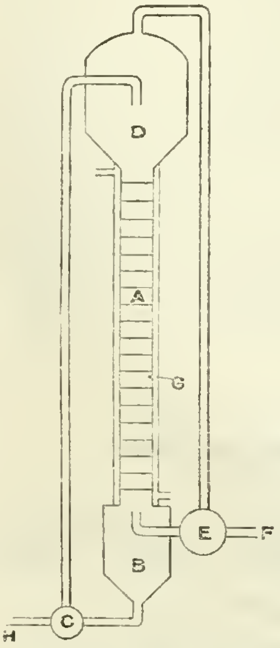

FIG. 2.

In a plant of this nature, a charge of, for instance, refined groundnut oil requires about 15—30 minutes for hardening to a brittle fat, the nickel catalyst employed being equal to 1% of the weight of the oil.

For controlling the course of hardening, the volume of hydrogen passed into the vessel may be read off from a meter provided for that purpose, and samples are usually taken out from time to time from a small cock. These samples may be filtered quickly through a small filter paper, a small quantity of the filtrate being utilised for determining the change in the refractive index, a property which changes regularly with increasing saturation of the oil, or, more roughly, a drop from the sample taken is allowed to solidify, the hardness of the resulting fat being estimated by touch. The determination of the iodine value is, of course, in view of the time involved, only of use subsequently.

As soon as the required degree of hardness has been obtained, the charge is pumped into a filtering tank and filtered at a temperature as near to its melting point as is compatible with convenience in working. The nickel catalyst, thus recovered, is utilised for a further charge of oil, the number of times that a charge of catalyst can be used depending on the nature of the oil and on the temperature to which it has been subjected both during the hardening operation and during filtration. The unnecessary exposure of mixtures of catalyst and oil to the air at high temperatures, in addition to exerting an inhibitive effect on the activity, results in the formation of nickel soap, which renders the filtering of the charge containing it slow and difficult. Under normal conditions, however, the oil runs quite freely through the filter cloth, and no difficulty is encountered in separating the hardened oil, as far as ordinary tests are concerned, in a completely nickel-free condition.

DISCUSSION.

Dr. H. W. BROWNSDON enquired what would be the effect on the velocity of reaction of changing the surface of the catalyst.

Mr. UDALL observed that about ten years ago he had been interested in the hardening of whale oil and the possibility of its conversion into edible fat; at that time the chief aim apparently had been to produce a good soap fat. The electrolytic method had been used for making hydrogen, and a good return obtained from the sale of oxygen.

Mr. KING suggested that, in the hydrogenation of oils, the rate at which hydrogen was dissolved, independent of the catalyst, might enter into the velocity equation.

Dr. Maxted, in reply, stated that the rate of absorption varied according to the amount of the catalyst used. The question of the influence of surface was extremely complicated because the surface of the catalyst might, under certain conditions, change under hydrogenation. Generally, the greater the surface of the catalyst the greater its activity. Colloidal catalysts were more active than the non-colloidal and more sensitive to poison. Before the war a limited amount of work had been done in Germany on the hardening of whale oil for edible fat, but it had been found that the oil was liable, by reason of its secondary constituents, to dissolve nickel, and the hardened fats were therefore deemed unsafe for edible purposes. The reaction depended not only on the pressure of the gas, but to a certain extent on the solubility of the gas in the liquid. He had carried out experiments with a view to connecting the solubility of hydrogen with the velocity; but it was certain that it could not depend entirely or principally on the velocity because if it did there would be no such thing as the intrinsic activity of any catalyst.

Communications.

THE APPLICATION OF A FRACTIONAL DISTILLATION METHOD IN THE PREPARATION OF SODIUM ETHOXIDE FROM CAUSTIC SODA.

BY T. KENNEDY WALKER.

Sodium ethoxide is a powerful reagent frequently used in the research laboratory, but little is generally known of its applications on a large scale, though it seems that at least tentative proposals have been made to apply it in the process for the manufacture of synthetic indigo (F.P. 322,536, June 20, 1902; U.S.P. 737,836, June 12, 1902).

Recently it was thought possible that the manufacture of sodium ethoxide on a very large scale might prove a necessary step in a process for the manufacture of synthetic glycerol. For such a purpose, even more than for ordinary industrial requirements, it was evident that the material would have to be prepared cheaply, and, therefore, that some method of manufacture entirely different from that hitherto used, namely, by the action of metallic sodium on anhydrous alcohol, would have to be devised.

Proposals have been made to manufacture alcoholates of the alkali metals by adding calcium carbide, with or without quicklime, to solutions of alkali hydroxides in alcohol (G.P. 164,297, 1904), but although this method would perhaps be less costly than those in which metallic sodium is used, it has evident drawbacks.

The author decided to ascertain whether the principle used by Young for dehydrating ethyl alcohol by distillation with benzene (Chem. Soc. Trans., 1902, 81, 707) could be applied to remove water from the system which results on dissolving sodium hydroxide in alcohol. As is well known, Young takes advantage of the fact that ethyl alcohol, water and benzene form a ternary mixture which boils at a lower temperature than any of the three constituents or any of the three possible binary mixtures formed by the pairs, so that a mixture of the three substances behaves on distillation like a mixture of three constant-boiling materials, namely, (1) the low-boiling ternary mixture with (2) one higher-boiling binary mixture and (3) the constituent, alcohol, water, or benzene which is in excess. If a still could be devised by means of which two volatile substances differing by only a few degrees in boiling point could be separated quantitatively by distillation, then by adding the amount of benzene required to form with alcohol and with the water present the ternary mixture boiling at 64·8° C., from any sample of moist alcohol perfectly pure dry alcohol would be obtained as soon as the ternary mixture had passed over. Unfortunately this is not the case in practice, especially with small still-heads, and a considerable excess of benzene has to be used, subsequently to be removed, mainly as a binary mixture boiling at 68·25°, and this involves further loss of alcohol from the still. Nevertheless the process, in spite of this drawback, seems to be a practicable one when the still-head is efficient, and the benzene and alcohol in the distillate can be recovered without serious technical difficulty.

If Young's method applied to the drying of moist alcohol suffers from the imperfections inherent in the practice of fractional distillation, it must be still more adversely affected when applied to remove water from the system $NaOH+C_2H_5.OH \rightleftarrows NaOC_2H_5+H_2O$, especially towards the end of the process, when the concentration of the free water and, therefore, the effective proportion of volatile ternary mixture is so very much smaller than the quantity which still has to be removed, being *cæteris paribus* inversely proportional to the quantity of sodium ethoxide present. Nevertheless it must be emphasised that, as far as the physics of the matter is concerned, and neglecting possible accidental changes, such as oxidation during distillation, it is only the imperfections in practical fractional distillation which prevent Young's method achieving theoretical efficiency in this process as in the simpler one to which it was first applied.

It was evident from the beginning that for the above reason anything approaching complete conversion of sodium hydroxide into ethoxide could not in practice be expected, but for many purposes a product containing a high percentage of the ethoxide would prove very useful. It was therefore decided to ascertain what efficiency could be obtained by working with laboratory apparatus, as even partially successful results in such a case would give assurance of better results with the larger and far more efficient still-heads used in the large-scale production of industrial spirit or benzene.

Experimental.

The progress of fractional distillation was followed in the first instance by noting the boiling points and quantities of the various fractions of distillates. From a knowledge of the composition and boiling points of the components of the ternary and of the binary mixtures it was possible roughly to determine, by the usual well-known rules, the quantities of the three volatile constituents which passed over. The character of the fluid in the still was at the commencement and at the end of the distillation checked by a more accurate determination of the total $NaOH+H_2O$ remaining, and in the following manner:—The total volume of liquid having been measured, 10 c.c. was removed, diluted with water, and the "total alkalinity" ($NaOH+NaOC_2H_5$) determined by titration against *N*/10 hydrochloric acid.

Another sample of 10 c.c. was mixed with 12·5 c.c. of ethyl acetate and 50 c.c. of anhydrous alcohol and boiled for some time, when the following reaction took place:—

$$xNaOH+yC_2H_5OH+zH_2O+wC_2H_5ONa+$$
$$vCH_3COOC_2H_5=(x+z)CH_3COONa+(w-z)C_2H_5ONa$$
$$+(v-x-z)CH_3COOC_2H_5+(y+x+2z)C_2H_5OH.$$

The whole was then cooled and titrated against a freshly prepared standard solution of benzoic acid in anhydrous alcohol. A "diminution in alkalinity" was thus observed as compared with the previous titration against $N/10$ alkali, and this "diminution in alkalinity" gave $(x+z)$, which was also the maximum quantity of sodium hydroxide which would be obtained by evaporating 10 c.c. of the alkaline fluid from the still to dryness, that is without further loss of water and in accordance with the equation:

$$x\text{NaOH}+z\text{H}_2\text{O}+w\text{C}_2\text{H}_5\text{ONa}=(x+z)\text{NaOH}+(w-z)\text{C}_2\text{H}_5\text{ONa}+z\text{C}_2\text{H}_5\text{OH}.$$

The "total alkalinity" evidently gives $(x+w)$, while $(w-z)$ was the minimum quantity of sodium ethoxide to be obtained by evaporation to dryness. The number $100\,(w-z)/(x+w)$ is what is termed in the following paragraphs the "molecular percentage yield" of ethoxide formed. Blank experiments indicated that the method gave results which were about 4% too low.

The benzene used in the experiments was carefully purified, dried, and redistilled. The anhydrous alcohol was prepared from commercial 96% spirit by dehydration first with lime and subsequently with metallic calcium, sufficient of the latter being used in each instance to form a solution of calcium ethoxide, a test portion of which after filtration and addition of water gave a jelly-like deposit of calcium hydroxide. In order to avoid the difficulties inherent in estimating the quantitative composition of samples of sodium hydroxide, the solutions before distillation were made up by mixing definite weights of dry alcohol, sodium, and water, so that the composition of the whole at the beginning was known with accuracy. The initial composition was checked as stated above.

In the first distillations the column used was of glass, 40 inches long and about ¾ inch in diameter, with numerous points projecting into the interior as in a well-known French pattern. As an example of what was done the following details will serve. The mixture taken contained ethyl alcohol (99·4% strength by weight) 399·5 g., benzene 250 g., water 15·66 g., and sodium 23 g. This corresponds with 40 g. of sodium hydroxide, no water, and 397·16 g. of anhydrous alcohol. The rate of distillation varied from 40 to 60 drops per minute throughout the range of the experiment. About 27·1 c.c. distilled below 65·8° C., yielding a turbid distillate, and in all 448 c.c. of fluid passed over before 78° C. was reached, when the distillation was stopped. The final product (230 c.c.) left in the still had to be diluted with dry alcohol before analysis. The "percentage yield" of sodium ethoxide found in the above case was 10·34 only, but was sufficient to give promise of better results with an improved still-head. Control experiments carried out in precisely the same manner but with anhydrous alcohol and without the addition of water gave percentage yields of 95·6 and 95·8, indicating that the analytical method gave results about 4% too low. Repetition of the experiment with identical quantities but with a slower rate of distillation gave a very decided improvement, the "percentage yield" of ethoxide rising to 25. The bulk of the residue arising from this experiment was re-dissolved in a mixture of benzene and alcohol and the distillation repeated, but this only served to raise the yield to 28·1%, the almost inconsiderable rise indicating that with the still-head employed no useful result was served by such repetition.

Experiments were next made with a type of still-head described by Dufton (J., 1919, 45T), the total length of head used being 1·5 metres and the annular space approximately 1·5 mm. wide. The efficiency was somewhat greater than that of the French column and the "molecular percentage yield" of sodium ethoxide produced in one operation was 33·8 as compared with 28·1 when the French column was employed and a similar rate of distillation was adopted.

Test distillations were ultimately carried out with the most efficient laboratory still-head that could be procured. This had a height of 6 feet and an internal diameter of 1⅝ in., and contained about 4000 "Raschig rings" of sheet iron, the still itself being a large copper flask. In the first experiment with this apparatus, 1400 c.c. of solution containing 77·6 g. of sodium hydroxide was distilled with a proportion of benzene corresponding with that in the previous distillation. In the first 55 minutes 130 c.c. of turbid distillate was collected at an average rate of 60 drops per minute, the temperature remaining constant at 64·8° C., the boiling point of the ternary mixture. After 65 minutes the temperature had risen to 65·8°, 163 c.c. in all had been collected, and the issuing liquid was no longer turbid. The "middle point" (66·55°) was reached after 2 hours 53 minutes and in all 320 g. had been collected. The quantity of water actually removed from the sodium hydroxide calculated from these data is 23·68 g. or 67·8% of the theoretical amount, while a sample removed and analysed gave a result approximately 5% lower than this. The distillation was continued until the temperature of the next "middle point," namely 73·2° C., was reached, but the quantity of alcohol-benzene binary mixture was so small as to indicate that the still-head had not quite reached its full efficiency with so small an excess of alcohol and benzene. Another distillation was therefore carried out, with 40 g. of caustic soda (23 g. of sodium and 18 g. of water), 1012 g. of alcohol, and 600 g. of benzene, in a glass flask, the heating being effected with the aid of an aqueous calcium chloride bath. The quantity of liquid which distilled up to the first "middle point" (66·55°) was 149 g., a somewhat larger proportion than in the previous mixture. The distillation was stopped at 68·2° C. and the residue in the flask then measured 785 c.c. Analysis of this residue showed a "molecular percentage yield" of 54·2, while from the quantity of ternary mixture obtained a number 61·2 was found. The true value was probably intermediate between these two figures, for as blank experiments had shown, the analytical method gave results several per cent. too low.

I wish to express my indebtedness to Professor A. Lapworth, F.R.S., at whose suggestion and with whose help this work was carried out. My thanks are also due to the Department for Scientific and Industrial Research for a grant which defrayed the expenses of the research.

THE EROSION OF BRONZE PROPELLERS.

BY O. SILBERRAD.

Author's reply to discussion.

In reply to the subsequent written contribution to the discussion on the Erosion of Bronze Propellers (J., 1921, 38—45 T), Dr. Silberrad wrote that he entirely agreed with Colonel N. Belaiew's observations (J., 1921, 58 T); indeed, he had obtained a good deal of evidence that the structure of the metal was a valuable guide to its capacity to withstand erosion of the type met with in guns. It was, he agreed, complicated by the influence of heat, and the differences in the capacity to resist erosion in different steels seemed to be traceable rather to variations in the recalescence points of steels of different structure than to be directly dependent on the structure itself. He hoped shortly to be in a position to publish these results.

He could not agree with Mr. Ramsay (J., 1921, 64—65 T) that the Propeller Committee's experiments were unconvincing; to him they had been very convincing. Nor could he agree that the Committee were not fully competent to deal with the subject; that they were fully competent was evidenced by the masterly and independent way in which they had dealt with this involved problem. The independence of thought illustrated by the fact that they had made so little use of existing knowledge only still further proved their capacity.

He felt obliged to take exception to Mr. Ramsay's comments respecting the late Sir William Ramsay. Sir William's conclusions had been, as far as Dr. Silberrad was aware, entirely drawn from first-hand observations; indeed, it would appear that Sir William had materially assisted in the solution of the problem by pointing out that electrons flowing from the zinc plates attached to the ship would protect both stressed and unstressed portions of the bronze propellers, and that consequently any possible differences in potential that might be set up by such stresses could hardly, as Mr. Ramsay suggested, be seriously regarded as the cause of the extensive deterioration under consideration. As to the late Sir William Ramsay's observation respecting the success and universal adoption of alloys of essentially β structure, this was common knowledge at that date; indeed, statistics showed that not only had the majority of the high-speed ships built since 1909 been fitted with propellers of this type of alloy, but also that many of the more important vessels launched prior to the discovery had been refitted with propellers of the new alloy. Thus at the date of Sir William's letter one firm alone had supplied sets of propellers of this new alloy for no less than 18 British battleships and cruisers, 16 destroyers, torpedo boats, etc., and 16 liners, including such well-known vessels as H.M.S. Thunderer, S.S. Mauretania, Lusitania, La France, Imperator, Carmania, Aquitania, etc. Since that date almost every battleship, destroyer, and fast liner, indeed practically every high-speed vessel throughout the world, had been fitted with propellers cast of this type of alloy.

With reference to Mr. Ramsay's assumption that the word "erosion" had been used only to refer to the subsequent washing away of damaged metal, Dr. Silberrad desired to remove any ambiguity that his paper might have left on this score; throughout the word "erosion" had been used to indicate mechanical wearing away (as distinguished from corrosion or chemical dissolving away) and to embrace all the mechanical operations involved, *i.e.*, the water-hammer action which pounded and crushed the metal, and also the wash and frictional rub of the rushing water which obviously was the operative cause in subsequently washing away metal so damaged, in a precisely similar manner that frost followed by rain form the combined operative agents in the erosion of exposed rocks. Indeed, so far back as January, 1912 (Engineering, 1912, 34), he (Dr. Silberrad) had pointed out not only that the deterioration was purely mechanical and therefore properly termed erosion and not corrosion, but also that it was brought about by the action of water broken by intervening evacuated spaces or vacuum bubbles combined with the frictional rub of said water.

Mr. Ramsay's experiments with jets which formed the negative and the metal (brass) the positive of the circuit were certainly interesting, but appeared scarcely relevant, as they took no account of the fact that the propeller of a ship was in direct metallic contact with the large zinc protecting plates attached to some adjacent part of the vessel, the presence of which obviously rendered it impossible for such a condition to exist in practice.

Dr. Silberrad agreed that his own experiments on the corroding action of sea water on stressed and unstressed metal did show a slightly greater corrosion in the case of stressed than of unstressed metal, nevertheless the increase was very small—about 0·0000018 cm. per year in depth; further, it should be observed that the metal in these experiments had not been protected by contact with zinc plates, as in the ship, which zinc would, as already pointed out by the late Sir William Ramsay, prevent the solution or corrosion of both stressed and unstressed bronze alike. That propellers working under great strain might be more subject to erosion than others less strained appeared likely, for it was reasonable to assume that metal already severely strained should be more readily disintegrated by the hammering effect of the collapsing bubbles than metal not so strained; but here again the effect was purely mechanical.

As regards the presence of distorted crystals being evidence of the mechanical nature of the deterioration, Dr. Silberrad agreed that this alone could not be regarded as an absolutely conclusive proof; but, taken in conjunction with all the evidence, he could not help feeling that anyone who read the paper with an open mind must be fully convinced that the deterioration of propellers was due to erosion, *i.e.*, to mechanical causes, and to causes now so well understood that it was possible to classify, produce, and remedy erosion at will (J., 1921, 42 T, Table II.), and by the help of Mr. S. S. Cook's admirable treatise on the collapse of water cavities (Trans. Inst. Naval Architects, 1919, 233), even to calculate the operative pressure which constituted the chief factor in the preliminary stages.

MR. JOHN ALLAN IN THE CHAIR.

WORKS ACCOUNTS FROM THE CHEMIST'S POINT OF VIEW.

BY RAYMOND CURTIS.

(*Abstract.*)

During the past few years developments in the direction of more accurate and detailed costing work in chemical works have been rapid; but while the value of such information for purposes of scientific management has long been recognised in the engineering industry, this aspect of costing (as distinct from its value for commercial purposes) is apt to be overlooked in many chemical works. It is from this point of view, however, that the technical chemist is primarily concerned with any system of works accounts.

In the first place it should be realised that the majority of questions relating to manufacturing processes can only be intelligently discussed with a full knowledge of costs; and if costing information is withheld from the technical chemist—as it too often is—his usefulness is so far curtailed that in most cases he merely functions as an intelligent foreman. Innumerable problems which demand considerations of cost will occur to every works chemist:—such problems as the extent to which an increased output might compensate for decreased percentage yield, what increased yield would justify capital outlay in improved plant, or the stage in the extraction of a product from waste material (*e.g.,* a dyestuff intermediate from gypsum) at which the cost of extraction exceeds the value of the material isolated. Such problems as here indicated do not, of course, occur every day, but there are daily problems incidental to efficient management—questions of yield, labour usage, cost of repairs, consumption of steam, press cloths, kilowatts, etc.—which for an intelligent handling demand a knowledge of monetary values. Moreover, this knowledge is of itself a very keen incentive to economy. Particularly is such information regarding costs essential at the present time. Pre-war comparative costs help us not at all, and if the chemist is to overhaul his processes in the light of these new and changing values he must have the necessary costing information to guide him. As an instance of this one may refer to filter cloth prices. Before the war the price of filter cloth was a negligible factor in the cost of most dyestuff intermediates. But a year ago it was costing in some cases over 1d. a lb. on products the pre-war selling price of which was about 9d. a lb. Now it may be that this expenditure is necessary, but until the chemist realises the cost involved it is unlikely that he will have explored every avenue that might lead to economies in press cloth consumption.

Since the war the costing system[*] introduced by the Factories Branch of the Department of Explosives Supply into the Government explosives factories has come in for a good deal of attention, and it is of interest to consider how far it meets the chemist's requirements.

In the first place it was the custom to cost each process separately, and not merely the final products. In some costing systems the cost of all intermediate processes is regarded as a debit against the manufacture of the final product; but this is not nearly so satisfactory a method from the chemist's point of view, since the effect of the costs and efficiencies of these subsidiary processes upon that of the final product may be obscured or lost sight of altogether.

The costing information—which was available to the technical staff monthly in the form of a cost analysis for each process—showed quite clearly the cost of the various items entering into the total manufacturing cost. For the solution of some of the problems of manufacture of the type indicated above this information was of great value, and by drawing attention to the monetary equivalents of efficiencies and charges it led the chemist to make considerable economies in manufacturing costs. Moreover, all the costs from the various factories were analysed and put on a comparative basis, so that the cost of any one product, say nitric acid at Queen's Ferry, could be compared as fairly as possible with that at Gretna, Oldbury, etc. These comparative costs, together with graphs constructed for easy comparison, were printed and issued to all the factories concerned. Besides this they formed the agenda for monthly meetings in London which were attended by chemists and engineers from the various factories. In this way each works chemist had not only the cost analysis for his own particular plant or product, but that for every similar plant under the Department; and he thus had a perspective with which to view his own achievements. Any cost item could not be considered satisfactory if it compared unfavourably with that on some other plant. Naturally such comparisons fostered a very keen rivalry between the staffs of the different factories and helped to reduce manufacturing costs.

Although it is not possible for most private firms to institute anything exactly comparable with these comparative cost summaries (unless they have several plants making the same products), they could, with advantage, give the chemist cost analyses for plants and processes other than his own; for sufficient similarity would exist for useful comparative purposes, and a healthy rivalry for economy could be stimulated. Moreover, monthly costs meetings for the technical staff on the lines of Mr. Quinan's meetings would prove to be a wonderful stimulus to efficient manufacture.

In one important respect the Government costing system failed to meet the requirements of the chemist. If costing information is to have its greatest value for the technical staff it should be available when the expenditure is incurred. The consideration of costing information which relates to manufacturing operations carried out even two or three months ago, as in the Government factories, to say nothing of eight or nine months ago as in some factories, tends to become very perfunctory. For, generally, monthly figures require further analysis before certain items of cost can be elucidated; sometimes the import of even serious items of expenditure has been forgotten, while the figures can afford no economising check on day-to-day expenses, nor do they enable the chemist to check the accountant's allocations. These are such serious objections that no chemist could be satisfied with merely monthly cost analyses.

Unfortunately the chemist, while admitting the inadequacy of such costing work, is too apt to be satisfied with the accountant's plea that more frequent analyses are out of the question. In this connexion it may be of interest to chemists to have some details of the system which was introduced in 1918 at H.M. Factory, Avonmouth.

This factory had to supply the London office with exactly the same type of information as the other Government factories, and a similar monthly analysis of manufacturing costs had to be made. In the other factories the system of works accounts

---

[*] Several reports bearing on this work have already appeared, and have been reviewed in this Journal, 1919, 179 R., 224 R.

with its allocation of costs was administered by the Finance sections, but at Avonmouth the Superintendent (Mr. R. P. Whitelaw) set up a works costs office to deal with the allocation of production costs and provide the necessary costing information required by the technical staff. The costs office routine was so organised that the costing information was collected *daily*, and each day an analysis of the previous day's expenditure was made. This was issued to the managerial and technical staffs in the form of a daily "cost sheet." There were three exactly similar sheets dealing with sulphur trioxide, ethylene, and mustard gas manufacture, the three products with which the Avonmouth factory was concerned. The expenditure* was analysed on the same lines as in the monthly cost sheets already referred to, but much more detailed information was given. Thus under the heading *maintenance labour charges* the following subdivisions of the Grillo plant were made—burners, scrubbers, converter house, blower house, absorption house, storage tanks.

The points of interest to the chemist in connexion with the Avonmouth scheme are firstly, whether it proved to be workable, and secondly, whether the results justified the expense of a daily allocation of costs. With regard to the first point, it can be said that the difficulties encountered in introducing the system were remarkably few, and the cost sheet for sulphur trioxide manufacture was issued daily during the whole of the time the oleum plant was running. The technical staff were unanimous as to its immense practical value in enabling them to effect economies in manufacture. One has only to compare the Avonmouth manufacturing costs for sulphur trioxide with those for the other Government factories to realise this. Thus the average manufacturing cost of sulphur trioxide during the period January—June, 1918, was £7·771 per ton at Avonmouth, as against £8·354 at Queen's Ferry†, despite the fact that at the latter factory the output was 25,300 tons, as against Avonmouth's 3800 tons. (The Avonmouth cost includes the charge for administering the works costs office.) It would, of course, be absurd to argue that the whole of the saving of £0·583 per ton was a direct result of the Avonmouth costing system, but, on the other hand, the fact that the economies effected were in labour usage (£0·56 per ton, as against £0·70) and maintenance charges (£0·138, as against £0·695) does indicate quite clearly that the technical staff were striving for economical manufacture. For this and for some of the success which attended their efforts full credit should be given to the system of daily cost analysis.

The development of works accounts is, of course, a part of the general movement in industry for "efficiency"; but works accounts, with their detailed cost analyses, and "efficiency," are not synonymous terms. The value of costing information lies in its application to the problems of production, and therefore in the hands of the technical chemist.

---

* The main items were raw materials, fuel, water, steam, lighting, power, process and labour charges, maintenance and repair labour charges, workshop costs, stores issues, overhead charges.

† For further details see chart in this Journal, 1919, 224 R.

Communications.

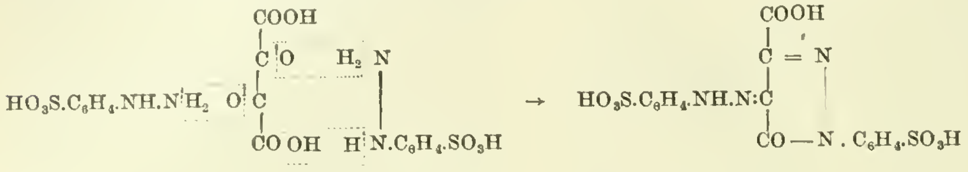
DYESTUFFS OF THE PYRAZOLONE SERIES.

BY MARY JOHNSON.

Notwithstanding the importance of tartrazine, very little is recorded in the literature of other dyestuffs of the pyrazolone class. Methods for the preparation of these substances in a state of purity have been worked out in connexion with another investigation and it may be useful if these are described.

Tartrazine. Trisodium salt of the p-sulphophenylhydrazone of 1-p-sulphophenyl-3-carboxy-5-pyrazolone.

The condensation of sodium dioxytartrate with phenylhydrazine-*p*-sulphonic acid to form tartrazine was first described by Ziegler (Ber., 1887, **20**, 834), and the reaction was shown by Anschütz (Annalen, 1897, **294**, 219; 1899, **306**, 1) to be represented by the following scheme:



Sodium dioxytartrate,

$$COONa.C(OH)_2.C(OH)_2.COONa+2H_2O,$$

was prepared successfully by the method described by Green ("Organic Colouring Matters," 1908, p. 71), but it was found advantageous to substitute a freezing mixture for ice water for the hydrolysis of the dinitrotartaric acid. Fischer's method (Annalen, 1877, **190**, 76) for the preparation of phenylhydrazine-*p*-sulphonic acid,

$$C_6H_4(NH.NH_2)(SO_3H)+\tfrac{1}{2}H_2O,$$

was found to be highly satisfactory; 60 g. of pure phenylhydrazine-*p*-sulphonic acid (2 mols.) and 42 g. (1 mol.+5% excess) of sodium dioxytartrate are rubbed together in a mortar with a little water. The mixture is transferred to a flask of suitable size and the contents of the mortar washed out with about 100—150 c.c. of water. The mixture is warmed on the water-bath, when the colour rapidly changes to a deep orange and solution is practically complete in a few minutes. The liquid is then heated to boiling to obtain complete solution and 159·0 c.c. of *N*/1 sodium carbonate solution is added. Tartrazine being a trisodium salt, it will be observed that, of the three sodium atoms, two are provided by the sodium dioxytartrate molecule and one by the addition of the calculated quantity of sodium carbonate during the condensation. The solution is rapidly filtered into 1200 c.c. of warm rectified spirit and the flask washed out with a little boiling water. A dense yellow precipitate of the dye is rapidly produced and the solution is allowed to stand for some hours. The dye is filtered on the pump, washed with a little aqueous alcohol, and dried in an evaporating dish on the water bath. Produced in this way, the dye has been found to be pure, and the yield obtained directly is 60% of that theoretically possible; the remainder is in the mother liquors and can easily be obtained from them.

For analysis the dye was recrystallised from 75% alcohol, and was obtained as an orange-yellow powder.

On drying at 120° C. the amounts of water evolved were 30·6 and 30·6% ($C_{16}H_9O_9N_4S_2Na_3,13H_2O$ requires $H_2O=30·4\%$). The anhydrous substance was found to contain 12·9 and 13·2% of sodium ($C_{16}H_9O_9N_4S_2Na_3$ requires $Na=12·9\%$). These analytical figures establish the formula of the dye and indicate its purity.

Trisodium salt of the m-sulphophenylhydrazone of 1-m-sulphophenyl-3-carboxy-5-pyrazolone.

This tartrazine, which is isomeric with ordinary tartrazine, was obtained by the condensation of two molecules of phenylhydrazine-*m*-sulphonic acid with one molecule of sodium dioxytartrate under conditions exactly similar to those found suitable for the preparation of ordinary tartrazine.

Phenylhydrazine-*m*-sulphonic acid, $C_6H_4.(NH.NH_2)(SO_3H)+2H_2O$, was not obtained when diazotised metanilic acid was treated with sodium bisulphite. The substance was accordingly prepared by the method described by Limpricht (Ber., 1888, 21, 3409). The yield of the acid only amounted, on the average, to about 42% of the theoretical.

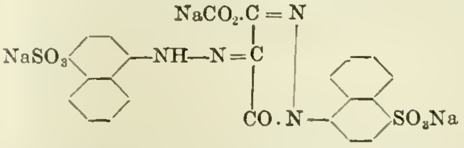
The condensation of the acid with sodium dioxytartrate was carried out in a manner precisely similar to that formerly employed. The quantities employed were 15 g. of phenylhydrazine-*m*-sulphonic acid, 11 g. of sodium dioxytartrate, 65 c.c. of water, 36·4 c.c. of sodium carbonate (1 c.c. = 0·053 g. Na_2CO_3), and 300 c.c. of rectified spirit. The yield was 70% of the theoretical, and the mother liquors were not worked up.

The product was recrystallised from somewhat dilute alcohol and obtained as a yellow powder, very much paler in shade than ordinary tartrazine.

On drying at 120° C. the product lost 17·3 and 17·6% ($C_{16}H_9O_9N_4S_2Na_3+6H_2O$ requires $H_2O=16·8\%$). The anhydrous substance contained 12·8 and 12·8% Na ($C_{16}H_9O_9N_4S_2Na_3$ requires $Na=12·9\%$).

There is thus no doubt that the substance obtained is a tartrazine, that it is the trisodium salt of the *m*-sulphophenylhydrazone of 1-*m*-sulphophenyl-3-carboxy-5-pyrazolone, and further that it is isomeric with ordinary tartrazine which has the sulphonic groups in the *para* position.

Trisodium salt of the p-sulphonaphthylhydrazone of 1-p-sulphonaphthyl-3-carboxy-5-pyrazolone.



This tartrazine was obtained by condensing together two molecules of 1.4-naphthylhydrazinesulphonic acid with sodium dioxytartrate under the same conditions as those previously employed.

1.4-Naphthylhydrazinesulphonic acid was prepared by the method described by Erdmann (Annalen, 1884, 247, 333). It was found that the crude acid could be conveniently purified by dissolving in boiling sodium carbonate solution and acidifying the filtered solution with hydrochloric acid. The condensation of the sulphonic acid with sodium dioxytartrate proceeds quite normally under the usual conditions. The yield of the tartrazine is, however, only 32% of the theoretical, but no attempt was made to work up the mother liquors. The product was recrystallised from aqueous alcohol, dried in a dish on the water bath, and obtained as a beautiful deep scarlet powder. On drying at 120° C. it lost 14·4 and 14·3% ($C_{24}H_{12}O_9N_4S_2Na_3+6H_2O$ requires $H_2O=14·5\%$). The anhydrous substance was found to contain 10·8 and 10·9% Na ($C_{24}H_{12}O_9N_4S_2Na_3$ requires $Na=10·9\%$).

There is thus every reason to believe that the substance is a tartrazine, and that its constitution should be represented by the formula given in the adjoining column.

Trisodium salt of the 5-sulphonaphthylhydrazone of 1-(5-sulphonaphthyl)-3-carboxy-5-pyrazolone.

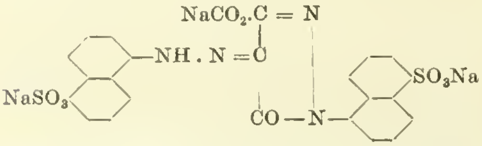
For the preparation of this tartrazine it was necessary to obtain some quantity of 1.5-naphthylhydrazinesulphonic acid, the preparation of which may be described fairly fully.

1.5-Naphthylhydrazinesulphonic acid. α-Aminonaphthalene-5-sulphonic acid was obtained by the reduction of the sodium salt of α-nitronaphthalene-5-sulphonic acid in the following way: 50 g. of clean, coarse iron filings, 75 c.c. of water, and 2·5 c.c. of glacial acetic acid were heated to boiling in a flask provided with an air condenser; the top of the condenser was fitted with a cork through which passed the stem of a dropping funnel and an open tube. When the contents of the flask were boiling, 56 g. of the sodium salt dissolved in 600 c.c. of water was run in during the course of an hour. The contents of the flask were kept boiling for a further two hours, and 75 c.c. of a $N/1$ solution of sodium hydroxide was then added and the solution rapidly filtered. The filtrate was acidified with hydrochloric acid and allowed to cool. The amino-acid was then filtered off, washed with water, and dried in the steam oven. The amino-acid, which at ordinary temperatures contains one molecule of water of crystallisation, was obtained as an almost white powder in a yield of 86% of the theoretical.

The amino-acid (29 g.) was dissolved in 130 c.c. of a $N/1$ solution of sodium hydroxide, and 9 g. of sodium nitrite was added. This solution was added very slowly to an ice-cold solution of 15 c.c. of concentrated sulphuric acid in 150 c.c. of water which was kept stirred. The diazo compound quickly separated and, when the diazotisation was complete, a solution of 56 g. of stannous chloride in 33 c.c. of concentrated hydrochloric acid and 48 c.c. of water was run in slowly. The temperature was not allowed to rise above 7° C., and the mixture was stirred for four hours after the addition was complete. The solution was then transferred to a large flask and boiled. After standing for some hours the precipitate was filtered off on the pump and washed with dilute hydrochloric acid. It was dried on a porous plate, and obtained as a pale brown, crystalline substance. The yield of the crude acid was 90% of the theoretical. The acid was purified by dissolving in boiling sodium carbonate solution, filtering from any insoluble material, and acidifying the filtrate with hydrochloric acid. The sodium salt, which is sparingly soluble, was found to lose 24·3 and 24·1% on drying at 120° C., and to contain 6·7 and 6·8% of sodium; $C_{10}H_9O_3N_2SNa,4\frac{1}{2}H_2O$ requires H_2O 23·8, Na 6·7%.

The condensation of the above 1.5-naphthylhydrazinesulphonic acid with sodium dioxytartrate proceeds quite readily under the established conditions. The following quantities were employed:—26 g. of 1.5-naphthylhydrazinesulphonic acid, 14·4 g. of sodium dioxytartrate, 70 c.c. of water, 26 c.c. of a $N/1$ solution of sodium carbonate, and 400 c.c. of rectified spirit. As was found to be the case in the preparation of the isomeric compound, so here the yield of the resulting tartrazine was small. It was obtained as a dark red powder which was recrystallised from aqueous alcohol. On drying at 120° C. it lost 28·6 and 28·6% ($C_{24}H_{12}O_9N_4S_2Na_3,14H_2O$ requires $H_2O=28·5\%$. The anhydrous substance contained 10·8 and 10·9% Na ($C_{24}H_{12}O_9N_4S_2Na_3$ requires Na = 10·9%).

This tartrazine has the constitution:



The absorption spectra of the compounds were determined, using aqueous solutions containing 0·01 g. of dye in 100 c.c. Panchromatic plates were used in conjunction with a compensating filter, and a "Pointolite" lamp was employed as the source of illumination. The spectra thus obtained were all of the same general type, characterised by a broad band originating in the green. In the case of ordinary tartrazine, this band extends from 4940, cutting out the blue end of the spectrum almost completely. In the case of the dye prepared from phenylhydrazine-*m*-sulphonic-acid, the band is slightly less extensive. It begins at 4860, with its crest in the neighbourhood of 4340. There is then a very slight falling off, continuing to the lower limit of the spectrum. The dyes prepared from the naphthylhydrazinesulphonic acids show a shifting of the band towards the red. In both, absorption begins at 5300 and ends at about 4000, with the crest at about 4800. It is difficult to distinguish between these spectra. The original tartrazine, therefore, shows the greatest absorption and the use of the newer dyes for photographic screen work offers no advantage.

The four compounds act as dyes towards wool and silk and their dyeing properties were subjected to comparison. Wool was dyed at 90° C. for 30 minutes in 0·5% solutions of dye to which 10% by vol. of one in two sulphuric acid had been added. The ordinary tartrazine gives a bright orange tint, whilst the compound from phenylhydrazine-*m*-sulphonic acid gives a yellower colour. The naphthylhydrazinesulphonic acids give bright red tints, but the dye from the 1.4 acid gives the brighter red of the two; that from the 1.5 acid is browner in tint. Exactly similar results were obtained with silk.

I desire to express my thanks to Prof. C. S. Gibson for his kind assistance in supervising this work.

Annual Meeting.

Montreal, August 29th, 1921.

ADDRESS BY THE PRESIDENT, SIR WILLIAM POPE, K.B.E., F.R.S.

This is the first occasion on which the annual meeting of the Society of Chemical Industry has been held in the Dominion of Canada. There is something peculiarly appropriate just at the present time in the inauguration of what I trust will prove an endless series of such meetings outside the British Isles. Our nation has but recently emerged victorious from the greatest war in the history of mankind; we feel that one of the most wonderful circumstances of that struggle—the one, perhaps, which will appeal more strongly than any other to the imagination of historians in centuries to come—is the unanimity with which all the multitudinous races included within the British Empire responded to his Majesty's call and poured out blood and treasure unstintingly in the common cause. The war proved that our Empire is no loosely-connected aggregate of countries but represents a single vast community of men and women; the smaller interests of districts or of people are indeed not identical, but we all share the one main interest, namely that of the welfare and the progress of the Empire to which we belong.

The Society of Chemical Industry stands out from amongst the majority of scientific and technical associations in being an Imperial Society; its activities are not limited to the small confines of the mother islands, but we have vigorous and prosperous Sections in many parts of the Empire. It is even more than an imperial Society in that it has a powerful Section in the United States; we can justly claim to represent not only the British Empire, but also the whole Anglo-Saxon race in matters of chemical technology, for we have large bodies of members wherever the English tongue is spoken.

The wide field covered by our Society makes it all-important that its many Sections should be managed energetically and should represent each an active body of members intent on the advancement of our subject; this is especially true just now when the scientific, industrial, and commercial activities of the whole world are undergoing reconstruction.

It is unnecessary for me to enlarge on this theme before an audience composed mainly of our Canadian members; you have already acted upon it and the Canadian organisation now consists of five Sections of the Society of Chemical Industry. The advantages of the new system of working are obvious, and we look forward with confidence to seeing their effect in increased numbers of papers on original work in our Transactions. In connexion with your reorganisation attention may perhaps be directed to one point. Great efforts are now being made by our Council and Publications. Committee so to alter the character of our Review as to make it more readable and of more general interest; most of us are anxious to be kept fully informed upon the doings of our members, and it is particularly difficult to collect information concerning those who are far from Headquarters. If in organising your Sections you can arrange to provide the Editors with prompt information on matters of interest you will do the Society a great service.

Two years ago the financial position of the Society was causing the Council grave apprehension; to-day, I am happy to say, our greatest anxieties concerning finance have vanished, and you will have seen from the balance-sheet that whilst economy is still necessary, the need for parsimonious conduct of the Journal no longer exists. In this connexion mention should be made of the munificent bequest to the Society by the late Dr. Rudolph Messel, one of our former Presidents, and one of the most devoted promoters of the Society's objects. The capital value of the bequest is in the neighbourhood of £20,000, and consideration is being given to the question of how best to apply the income to advantage; meanwhile, it has been decided to perpetuate the memory of our late friend by the establishment of a medal and a memorial lecture to bear his name.

Seven years ago the situation and the outlook in all branches of scientific industry were very different from those which now confront us.

In 1914, certain of the chemical industries of Great Britain were expanding slowly but steadily, whilst others were slowly but just as surely shrinking before foreign competition; in some of the chemical industries Great Britain was supreme, but in others we were losing ground. At that date, chemical industry was expanding rapidly in this great Dominion, and all the virility of a growing population was being devoted to the utilisation of the vast natural resources of a previously but partly developed country.

The interval has seen the commencement and the conclusion of a great conflict, a war which has reduced to mediocrity several of the dominant European powers, and has left nearly every nation struggling under an accumulation of debt. Throughout the war the Dominion, like every component of the British Empire, devoted itself actively to the production of food-stuffs and of munitions of war; although the great majority of the valid manhood of all countries entered active service we were successful in establishing on a grand scale the manufacture of the many and varied chemical products required for military purposes. One of the vast problems which the war has bequeathed to us is that of determining how the faculty which we exhibited in the manufacture of chemical products during a period of emergency is to be diverted and utilised for peace purposes, and for meeting the normal requirements of the world's commerce.

The problem is an entirely novel one in that it is accompanied by certain factors which were previously absent or which were at any rate of subsidiary importance. Thus, it cannot be doubted that the bonds uniting all parts of the British Empire have become far stronger in consequence of the events of recent years; further, we realise to a greater extent than ever before that for purposes of production our Empire must be, if not absolutely self-contained, at least in possession of modes which could be rapidly mobilised so as to render us self-contained. Before the war, we were dependent on Germany for bromine and for coal-tar colours and upon the Dutch colonies for quinine; the price of these and other essential products quickly rose to famine prices although no reason exists why they should not be produced within the Empire just as conveniently and just as cheaply as abroad. So completely has the necessity for a British production of great numbers of chemical products been brought home, even to the man in the street, that action has been taken in order to remove the former disabilities; the extent to which success has attended these efforts is open to comment, but it is at least certain that if we ever again find ourselves in a position of embarrassment owing to the absence of British sources of supply of essential chemical products, our political leaders will have to exhibit considerable agility in shifting the blame on to other shoulders than their own. All the bromine we require could be obtained as a result of the introduction of rational chemical methods into the production of salt from sea-water in India; all the quinine required could be furnished cheaply by the scientific cultivation of cinchona in our Colonies; and the British production of complex organic explosive materials during the war has entirely swept away the ancient propagandist doctrine that the manufacture of fine organic chemicals, including coal-tar dyestuffs, is incompatible with the British temperament. All these are matters of great importance; but one further consideration has become accentuated during recent years, and accentuated by the fact that the major portions of the tropical regions of the world are administered by the English-speaking and the Latin nations. In the past we have, I venture to think, endeavoured to build up our chemical industries far too much on the lines which proved so fruitful in Germany. I am speaking now not of the heavy chemical industry, in which we have always been to the fore, but of those industries which involve the production or the use of a great variety of more or less complex organic compounds. The organic chemist has long had before him, as one great object of his work, the artificial production of the myriads of organic compounds which we find amongst animal and vegetable products; he may be justly proud of his achievements in this direction and the success attained justifies our belief that we shall within quite a short time be able to prepare in the laboratory any compound substance formed by the animal or plant. Immediately some important natural product of commercial value is produced in the laboratory, the German technologist has sought to convert the laboratory method into a works process capable of competing with that of the plant or animal. From the standpoint of the German economist this course of action was sound; Germany had but few colonies and those few, since the German Government did not possess the art of colonial administration, were a source of considerable expense to the fatherland. We have relieved Germany of this expense and have probably thereby given a stimulus to the German instinct for making in a chemical works those chemical products given to us by tropical nature.

My point in suggesting that we have erred in adopting German views concerning the methods and aims of chemical technology, without reflecting that economic conditions in Central Europe are entirely different from those which prevail in the British Empire regarded as a whole, perhaps calls for some explanation; the necessary elucidation may be furnished by considering the ultimate object of technical chemical effort. The object of all technology consists in converting raw materials of inorganic or organic origin into products of greater value by expending upon them a certain amount of labour and a certain amount of energy. To a Central European nation labour means high wages to its population and energy means mainly coal or water-power; only one type of technological process is thus in the main to be considered, and this is one in which certain raw materials enter the works to be handled by costly labour and to be treated by the burning of fuel, which is another form of costly labour.

We have other methods for obtaining similar results, methods which are available in many cases but have been worked out in only a few cases. Let us consider one specific example. During the war, Germany was successful in producing indiarubber in her chemical works; as converting into a works process the method for the polymerisation of a hydrocarbon of low molecular weight to give rubber, discovered as a laboratory operation by Tilden and Bouchardat many years ago, this was a fine achievement, but there is no doubt that the costs of production were high. When we consider, however, that many of the rubber plantations are in British Territory, that curtailment of output has been necessary to keep last year's production down to about 350,000 tons—all the world could absorb—and that the cost of production was in the neighbourhood of 25 cents per pound, it will be realised that the British Empire has a technical method for producing rubber which is a far sounder business proposition than the German synthetic processes. Our raw materials result from rubber plantations, the establishment of which is not costly, the labour employed is cheap tropical labour, and the energy utilised is that of the sun's heat, which does not require to be mined and transported on railway trucks. Since the world's annual consumption of rubber will certainly increase rapidly and since our rubber plantations can already produce more than the world's present requirements, it is clear that we are in possession of a process for making indiarubber, using cheap labour and gratuitous energy, which if conducted on scientific lines will always defy competition from the chemical works of Central Europe.

It would not be fair to deprecate the installation of synthetic methods for manufacturing complex natural products. Nature in general furnishes us with but one very complex member of any particular class of organic compounds. Thus, the numerous plants which produce indigo yield but minute proportions of other compounds of a similar type and, in this instance, the chemical technologist has succeeded in manufacturing a whole range of valuable dyestuffs of the indigo family which do not occur among vegetable products; his efforts have to this extent been amply justified, but it is difficult to believe that synthetic indigo itself would ever have been able to compete in the market if a similar amount of scientific skill and intelligence had been devoted to the improvement of the cultivation and utilisation of the indigo plant. The work which is now being done by Armstrong, Davis and others on natural indigo may well result in the re-establishment of the Indian indigo plantations which many decades ago brought such a substantial contribution to the financial prosperity of our Empire.

Other similar examples are available. During the Russo-Japanese war large quantities of camphor were manufactured in the German chemical works, but this production was killed so soon as the Japanese camphor laurel started to produce after the war.

The wider recognition of the fact that chemical technology largely neglects what perhaps should be regarded as its most important mode of operation may, at no distant time, be forced upon us as an entirely economic necessity. The densely populated temperate regions of our globe will demand for their consumption and dissipation ever increasing quantities of energy, and the sources of energy in those regions—coal, oil, water-power, etc.—are diminishing rapidly. We shall be forced to set up a scheme for transporting to our northern countries the energy so lavishly sent from the sun to tropical lands. It is by no means impossible that the day may soon come when vegetable oils, produced in the tropics, will be brought northwards for use as an economical form of fuel. With these considerations in view, it seems time for our chemical technologists to devote more attention than they have heretofore to practicable methods for utilising the surplus energy of the tropics in supplementing the waning supplies of energy available in colder climates.

Another aspect of this question forces itself upon us. The last century has witnessed two great phases in the development of practical chemical work. Roughly speaking, it may be said that the progress of chemistry up to about forty years ago, great though that progress was, resulted from the application of rather fierce methods; a time came, however, when it was recognised that much was to be learnt, especially in organic chemistry, by the study of delicately balanced reactions in which the practical methods applied were devoid of violence and in which conditions, such as concentrations, temperatures, and the like, were carefully controlled. The organic chemistry of to-day does not distil fragile organic compounds through red-hot tubes; it proceeds by more subtle methods which, nevertheless, have greatly developed the broad knowledge of the science bequeathed to us by our predecessors. In its adoption of milder modes of operating and its consequent application of energy at a low potential, organic chemistry is approximating in its laboratory methods to those which occur in plants and animals; but the chemical changes which occur during the course of animal or vegetable life are still far more complex than those brought about in the laboratory. This complexity doubtless arises from the utilisation of low potential energy in the living organism; temperature changes of more than one degree Centigrade are not permissible in the healthy animal organism. The great majority of the chemical reactions which take place in living matter occur catalytically in colloidal media.

While the first great epoch in the history of organic chemistry was marked by the application of violent experimental methods, the second developed milder modes of procedure; the third epoch, which is in course of inauguration, will bring us into direct competition with the experimental chemical methods practised by living matter. It is impossible to doubt that a vast expansion of organic chemistry will be witnessed by many of us, an expansion which will result from an imitation of the gently effected chemical operations carried out in the animal and vegetable creation.

Whilst this prophecy is not a mere surmise as to the nature of the next step forward to be taken by the science of organic chemistry, but is rather of the nature of a logical deduction from past events, it is perhaps surprising that more use has not been made of the chemical methods of living matter for technological purposes. On a technical scale, the activities of living organisms have been harnessed in the production of alcohol, acetone, glycerol, and acetic and citric acids from sugars, and the pathologist has been wonderfully successful in directing similar activities towards the rectification of abnormal vital processes; much has also been done in the bacterial treatment of sewage and the separation thereby of valuable plant food-stuffs from the very dilute solution in which these occur in effluents. When the immense variety of chemical operations performed by living material is considered, it must be concluded that the manufacturing processes just mentioned, important though they are, are but a minute fraction of those which could be economically applied to the production of useful organic compounds if the scientific study of the subject had been sufficiently developed.

This subject would seem to be of particular importance to the development of chemical technology in the British Empire, which includes within its domain every range of climate and every species of animal and vegetable life. If we were able to establish an organisation for the study of methods and processes for the manufacture by biochemical agencies of useful chemical products we should reap a rich harvest.

Apart from questions of the desirability of plant culture for the purpose of increasing the yield of valuable products and of the study of biochemical methods for manufacturing necessary chemical substances, both of which are of vital interest to us, although perhaps of more purely academic interest to other nations, another problem presents itself to us. A wide expanse of Empire brings with it exposure to a great variety of different types of parasitic life; these may be merely vegetable pests, like the prickly pear which is giving so much trouble in North Australia, or they may be such as cause diseases which render European life precarious in certain regions. The chemical technologist of to-morrow will need protection in the shape of methods for combating these ills, and up to the present far too little progress has been made in this direction. It is true that the prickly pear is destroyed by spraying with arsenic chloride; but this is a mass treatment which is expensive, dangerous, and only locally effective. It is true also that great success has been attained in the prevention or eradication of tropical diseases by inoculation with serum or by the injection of chemical materials. But notwithstanding the progress which has been made in these directions the whole subject involved is but in its infancy; and although British institutions for the study of tropical diseases and of parasitic plants have contributed much, in comparison with their means, it cannot be denied that Germany has also done splendid service by the study in its state-supported institutions of the very vital problems which arise. This source of scientific help will not be available in the future; it cannot be expected that a nation which only retains an academic interest in ills which no longer affect its own economy will preserve an active interest in fighting these tropical plagues. That the question is an urgent one—one which should interest our great manufacturers and merchants—finds illustration in the fact that over 90 per cent. of the inhabitants of the Fiji Islands and of Malaya are infected with hookworm; it would be difficult to estimate the extent to which production is limited by this plague in regions which are among the most fertile in the world.

All the foregoing are questions which will necessarily become urgent at some no distant date, and most of them will call for the breaking of more or less new ground by the chemical technologist. Of others which seem to have been long ripe for study I may mention one. Although we are in possession of very complete knowledge of the constituents of coal-tar, a very common raw material, and have developed an elaborately detailed scheme for utilising those constituents in the manufacture of valuable chemical products, no real effort has yet been made to deal in a similar manner with crude petroleums. It is common knowledge that crude petroleums are very complex mixtures of organic substances, just as is coal-tar, and also that a great variety of mineral oils are available in large quantities, each quite different from the others in the chemical nature of the hydrocarbons of which it mainly consists. No systematic attempt has yet been made to classify the various petroleums according to their chemical character, to separate from them pure chemical compounds and to endeavour to utilise these in the chemical industries. So far as petroleum is concerned our present attitude resembles that which we maintained a century ago towards coal-tar; it is regarded as only fit to burn. A vast field of chemical activity lies before us in the scientific study of petroleums and in the device of processes for utilising the valuable individual compounds which they certainly contain in the expansion of chemical industries.

I have ventured to lay before you to-day a few thoughts concerning the manner in which the changed conditions of the world are likely to influence the future trend of development of chemical technology. Since no one can doubt that conditions are changed, I presume that all will agree that chemical industries, which depend upon these conditions, will also change. For this reason

I offer no apology for having directed your attention for a few minutes to the very large issues which necessarily arise. My own views may be erroneous, but their expression may be useful in emphasising the urgent need that our leaders in industry and chemical technology should reflect upon the whole subject and formulate sound views as to the development of the organic chemical industries of the British Empire.

Further accounts of the Annual Meeting will appear in subsequent issues of the Journal.

Sydney Section.

Meeting held on May 11, 1921.

THE ACID AND ALKALINE DECOMPOSITION OF POTASSIUM CYANIDE, WITH A NOTE ON THE DETERMINATION OF FORMIC ACID IN THE PRESENCE OF HYDROCYANIC ACID.

BY GEORGE HARKER, D.SC.

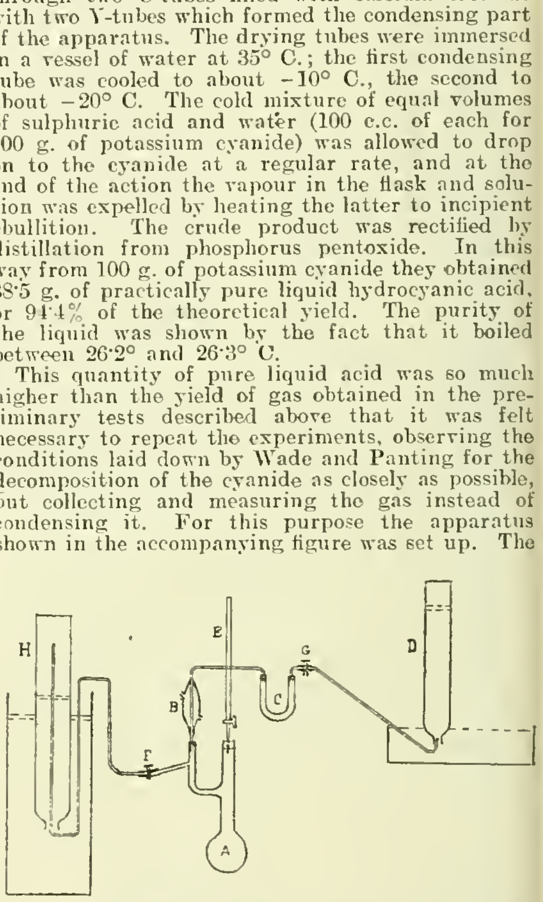
Contrary to expectation, the yield of gaseous hydrogen cyanide, obtained by the decomposition of potassium cyanide by sulphuric acid at ordinary temperature and pressure, was found to be surprisingly small, although Wade and Panting (J. Chem. Soc., 1898, 73, 255) have shown that liquid hydrocyanic acid can be prepared in a state of high purity and in practically quantitative yield from these reagents. Yet no matter how the proportions of acid, water, and cyanide were varied, the yields of gas measured at normal pressure were always very low. Further investigation revealed the cause of this low yield, and this aspect of the decomposition of alkali cyanides is first dealt with, as it has an important bearing on the somewhat extensive use of hydrocyanic acid gas for fumigation purposes.

Yield of gas obtained on decomposing potassium cyanide with sulphuric acid.

Unless definite information on the yield of gas had been required, it would have been assumed that a quantitative yield of gaseous hydrogen cyanide is obtainable when an alkali cyanide is decomposed with a fairly strong solution of sulphuric acid. A few tests were undertaken in which the apparatus consisted of a flask, provided with a dropping funnel and a bent tube leading to a measuring cylinder inverted over a suitable reservoir. The gas was collected over ligroin, in which it was found to be practically insoluble. Two grams of potassium cyanide broken into small pieces was placed in the flask, and the acid was dropped on to it. The acid used was made by mixing concentrated sulphuric acid with twice its volume of water, 6—14 c.c. of the mixture being added. The amount of gas evolved varied from 185 to 270 c.c. The theoretical yield from 2 g. of pure potassium cyanide is 740 c.c. of gas at 20° C. and 760 mm. On heating the flask to drive out dissolved gas another 150 c.c. was generally obtained, but the bulk of this was obviously due to expansion of the gas and air in the flask. Analysis of the contents of the flask, after addition of acid and without subsequent heating, showed that the bulk of the cyanide was left in the flask, in the form no doubt of a solution of hydrocyanic acid. As decomposition of the cyanide seemed to take place on heating, other acids such as acetic and formic acid were tried, but their behaviour, as judged by the amount of gas evolved on direct addition and on heating, was very similar to that of the diluted sulphuric acid.

The work of Wade and Panting referred to above then came under notice, in which it is pointed out that by the action of sulphuric acid upon potassium cyanide both hydrocyanic acid and carbon monoxide may be formed, and that by suitably varying the concentration of the acid a practically quantitative yield of either product can be obtained. In preparing pure, dry hydrocyanic acid, the potassium cyanide in the form of lumps was decomposed in a capacious flask provided with a dropping funnel and a delivery tube; this was connected through two U-tubes filled with calcium chloride with two Y-tubes which formed the condensing part of the apparatus. The drying tubes were immersed in a vessel of water at 35° C.; the first condensing tube was cooled to about −10° C., the second to about −20° C. The cold mixture of equal volumes of sulphuric acid and water (100 c.c. of each for 100 g. of potassium cyanide) was allowed to drop on to the cyanide at a regular rate, and at the end of the action the vapour in the flask and solution was expelled by heating the latter to incipient ebullition. The crude product was rectified by distillation from phosphorus pentoxide. In this way from 100 g. of potassium cyanide they obtained 38·5 g. of practically pure liquid hydrocyanic acid, or 94·4% of the theoretical yield. The purity of the liquid was shown by the fact that it boiled between 26·2° and 26·3° C.

This quantity of pure liquid acid was so much higher than the yield of gas obtained in the preliminary tests described above that it was felt necessary to repeat the experiments, observing the conditions laid down by Wade and Panting for the decomposition of the cyanide as closely as possible, but collecting and measuring the gas instead of condensing it. For this purpose the apparatus shown in the accompanying figure was set up. The reaction vessel, A, consisted of a Claisen flask of 250 c.c. capacity, provided with two rubber stoppers carrying a burette, E, for delivering a measured quantity of acid, and a condenser, B, through which water at a temperature of 35° C. could be circulated in accordance with Wade and Panting's experiments. After passing the condenser, the evolved gas went through the U-tube, C, and so to the measuring cylinder, D. During the addition of the acid, and afterwards in heating the flask, the clip, F, is closed while G is open. At the end of the heating, G is closed, thus preventing the ligroin from being sucked back into the flask, and F is opened, with the result that while the flask is cooling to its original temperature a measured quantity of air is drawn into it from the cylinder, H. The same procedure was adopted when the flask was not externally heated, so that in all cases the true amount of gas evolved from



the flask was determined by subtracting the volume drawn back from H.

The strength of acid used in these experiments was that recommended for the preparation of liquid hydrocyanic acid, viz., equal parts of sulphuric acid and water, and where solid potassium cyanide was decomposed 4 g., in the form of coarse granules, was taken. At the end of the operation the gas still left in the flask was rapidly displaced by a current of air, and the liquid contents, after being made alkaline with caustic potash, were diluted to 1000 c.c. The undecomposed cyanide was determined by titrating 50 c.c. with silver nitrate solution (1 c.c.=0·0129 g. KCN). When 4 g. of the potassium cyanide was dissolved in water and made up to 1000 c.c. and 50 c.c. titrated, 15·5 c.c. of the silver nitrate solution was required, giving the strength of the cyanide used as 99·97%. In order to get a satisfactory determination of the cyanide in acid solutions, it was found necessary to use pure caustic potash for destroying the acidity before titration with silver nitrate. The potash first used, owing to impurity, failed to give a sharp end-point.

The results obtained from experiments with the apparatus described confirmed the preliminary tests regarding the low yield of gas. It was also apparent that the cyanide in solution is rapidly destroyed by heat. Even the heat of the reaction causes decomposition. The actual figures obtained from a number of experiments are given in Table 1. The percentage yield of hydrocyanic acid gas was obtained by subtracting the volume of air drawn in on cooling from the amount of gas evolved on the addition of acid, whereby the volume of gas evolved at room temperature was obtained. The theoretical quantity from 4 g. of potassium cyanide at 20° C. (the room temperature) is 1480 c.c. The acid was added at an approximately constant rate during these experiments, and its addition took from four to six minutes.

TABLE I.

Exp.	c.c. 1 : 1 acid.	c.c. gas on adding acid.	c.c. gas on boiling.	c.c. air drawn in.	Gas evolved. %	Cyanide in flask. %	Total cyanide. %
1	8	495	—	50	30·1	45·2	75·3
2	12	465	—	70	26·7	32·3	59·0
3	8	455	—	25	29·1	58·1	87·2

* 1 : 3 acid.

The figures in the last column give the total percentage of original cyanide accounted for, both as gas and remaining in solution. The effect of the temperature of reaction, and also of the addition of a larger quantity of acid, is shown by exps. 1—4. In exps. 1 and 2 the flask, during the addition of the acid, was surrounded by air. In exp. 3 it was surrounded by water at about 15° C., and in exp. 4 it was cooled by a basin of ice-water. The figures in the last column indicate that less decomposition takes place when the temperature of reaction is diminished and also when a smaller excess of acid is added. On heating the solution to boiling the cyanide is rapidly decomposed, as shown in experiments 5, 6, and 7. Very little gas was actually expelled from the flask on boiling. The extra amount of hydrocyanic acid gas evolved by this heat cannot be calculated, as it is clear, rom the large volume of air drawn back into the flask on cooling, compared with the small quantity f gas expelled, that during the heating some of the hydrocyanic acid vapour in the flask disappeared. In addition to these experiments others were performed in which 12 c.c. of a solution of potassium cyanide (containing 4 g. of the salt) was acted upon by 8 c.c. of 1:1 acid, also in which the cyanide solution was added to the acid. The figures obtained were similar to those given above except that the yields of gas were somewhat lower.

In seeking for a reason for the low yield of gas it was found that, if a solution of potassium cyanide were run into a given quantity of acid and the gas evolved from the addition of each c.c. of solution measured, the volume of gas rapidly fell off. For the first one or two c.c. the evolution of gas would be little below the maximum volume obtainable, but it rapidly became less. If after the volume had fallen off a rapid current of air were passed through the acid solution, and then more cyanide solution added, the evolution of gas again improved. The conclusion was arrived at that the discrepancy between the yields of gaseous and liquid hydrocyanic acid must lie in the fact that in the preparation of liquid hydrocyanic acid the partial pressure of the gas over the aqueous sulphuric acid in the flask is very greatly reduced, because of the condensation of the gas by the application of low temperature; whereas when the gas is evolved from a flask without condensation this reduction of pressure does not take place. Hydrocyanic acid is extremely soluble in water, and following Dalton's law, the greater the pressure of its gas above the solution, the more soluble it must become. The gas cannot be removed from the solution by heat owing to decomposition. It was therefore decided to add the sulphuric acid to the cyanide under reduced pressure; and on dropping 8 c.c. of 1:1 acid into 12 c.c. of potassium cyanide solution, under a vacuum which varied between 16 and 30 mm., only 2·9% of the cyanide acted upon was left in the flask, and the reaction was carried out at a lower temperature. The flask became quite cold and copious crystals of potassium sulphate were deposited from the solution. Under these circumstances very little decomposition could occur and the practically quantitative yield obtained by Wade and Panting was at once explained. As these results have a somewhat important bearing upon the use of hydrocyanic acid for fumigation purposes a brief reference to this subject is perhaps not out of place.

The use of hydrocyanic acid for fumigation purposes.

Hydrocyanic acid is probably the most potent of all known agents for the destruction of insects and finds extensive use. It is employed for the destruction of moths in flour mills, and of insects in houses and other buildings, and very largely for the destruction of scale insects on citrus fruit trees. It is usually applied as a gas, and must therefore be introduced into a closed space. The gas is usually evolved from pots placed in the space to be treated, or from a portable generator from which a pipe conveys the gas to the point of use. One pound of potassium cyanide is generally recommended for every 1000 cb. ft. of space. The best proportions of acid and water for technical practice have been studied by R. S. Woglum, of the Bureau of Entomology, U.S.A. Department of Agriculture, who advises that in the case of buildings one fluid ounce of sulphuric acid and two fluid ounces of water should be used for every ounce of potassium cyanide, while for fruit trees the proportions should be one of acid to three of water. Quite recently in California, among the large citrus orchards, it has been found advantageous to apply the hydrocyanic acid in liquid form, and this method is rapidly coming into favour. The liquid acid is sprayed into the space to be treated and readily volatilises at ordinary temperatures (*cf.* Woglum, J. Econ. Entomology, 1919, 117—123). On account of its cheapness sodium cyanide is now used to generate the acid, and the amount of liquid acid actually obtained in practice (95—98% purity) is about 78% of the quantity theoretically available. Comparative fumigation tests carried out with a given quantity of sodium cyanide, with the liquid acid, and with the gas evolved from a generator, showed a slight but not marked advantage in favour of the liquid acid. Woglum estimates the yield of gas as 90% of the theoretical, but as shown in this paper the quantity actually obtained is only about 30%. If a generator were designed whereby the gas could be evolved under reduced pressure and then delivered for use, a high yield of gas would be obtained without any need for liquefaction and a much greater value obtained from the cyanide used. In Australia, so far as the author is aware, hydrocyanic acid is always applied by the pot method, in which more than half the cyanide used is wasted.

Acid and alkaline hydrolysis of hydrocyanic acid.

The rapid decomposition of a sulphuric acid solution of potassium cyanide when heated to the boiling-point directed attention to the products formed by the decomposition of hydrocyanic acid. Owing to the very low dissociating power of the acid, solutions of its alkali salts consist almost entirely of the free acid and alkali, consequently in both acid and alkaline solutions the free acid is present. Reference to the literature shows that an aqueous solution of an alkali cyanide is unstable, and that it decomposes slowly at ordinary temperatures and quickly on boiling with elimination of ammonia and production of formate. Hydrocyanic acid on warming with alkalis or mineral acids decomposes similarly. The nitrile formula $H.C{\vdots}N$ is generally assigned to the acid because of its ready hydrolysis by alkalis to formic acid. On the other hand, the isonitrile formula, $HN{:}C$, is often used for the metallic cyanides, and many chemists urge this formula for the acid itself.

Owing to the readiness with which hydrolysis takes place it has been proposed to make use of the decomposition of cyanides as a source of ammonia. Heise and Foote (J. Ind. Eng. Chem., 1920, **12**, 331) have examined the action of steam at different pressures on sodium cyanide and ferrocyanide. In the case of sodium cyanide the reaction takes place with increasing rapidity as the steam pressure is raised. An 80% yield of ammonia was obtained in two hours with steam at 50 lb. (148° C.), while with steam at 200 lb. (196° C.) a quantitative yield was obtained at the end of one hour. Virtually quantitative yields of sodium formate were also claimed, but unfortunately the method of analysis used was not satisfactory. The usual method of estimating formic acid by titration with permanganate in alkaline solution, adopted by the authors, gives high figures in presence of any undecomposed cyanide.

Although the hydrolysis of cyanide takes place fairly rapidly and completely when the cyanide is treated with high-pressure steam, it takes place slowly at a temperature of 100° C. and under ordinary pressure either in alkaline or acid solution. This is shown by the following experiments in which a sample of Merck's potassium cyanide was used, which on analysis showed a puriy of 95·6%. For the alkaline hydrolysis a 5% solution was boiled under a reflux condenser, with or without addition of caustic potash. The condenser was employed to prevent continual loss of hydrocyanic acid. The ammonia and any hydrocyanic acid evolved were caught in a bulb filled with standard acid. The amount of hydrocyanic acid which escaped from the flask was small and was less when caustic potash was added to the solution. The results of two experiments given below show that the yield of formate corresponded fairly well with the amount of cyanide decomposed :—

TABLE II.

Amt. KCN taken. g.	Vol. of soln. c.c.	KOH added. g.	Time heated. hrs.	KCN decomp. %	Ammonia formed. %	Pot. formate formed. %
1·666	30	0·5	2	20·9	31·0	87·9
1·666	30	—	10	68·6	73·3	85·1

The percentages of ammonia and formate are calculated on the amounts of cyanide actually decomposed. Only that portion of the ammonia driven out of the solution was estimated, and hence the figures are incomplete. Attention was directed chiefly to the rate of decomposition during the experiments, and the ammonia in the solution was overlooked. Of the total ammonia produced, the proportion remaining in solution would naturally be smaller after heating for ten hours than after two hours, and it is quite likely that, had all the ammonia been estimated, the figures would have corresponded, like those for the formate, fairly well with the cyanide decomposed. The results show that the alkaline hydrolysis of hydrocyanic acid takes place slowly.

For the acid hydrolysis 33·3 g. of potassium cyanide was dissolved and made up to 100 c.c.; 5 c.c. of this solution was added very slowly to 8 c.c. of 1:1 sulphuric acid, the quantities of salt and acid being in some cases doubled. The acid was contained in a test-tube and, by adding the cyanide solution very slowly from a pipette reaching to the bottom of the tube, loss of hydrocyanic acid in the form of gas was avoided. The test-tube was then connected to an upright condenser and the contents heated over the water-bath (at first slowly) for several hours. Any escaping hydrocyanic acid was caught in a potash bulb attached by a bent tube to the condenser. In two experiments, in which the heating was carried out for five and seven hours respectively, the hydrocyanic acid collected (12 and 16%) and the residual cyanide remaining undecomposed in the flask (12 and 9%) represented together about 25% of the original cyanide taken. The maximum amounts of ammonia and formate obtained were 39·9 and 47·3% of the quantities theoretically obtainable from the amount of cyanide actually decomposed, on the supposition that simple hydrolysis had taken place. It appears then that even with such a strong acid as 1:1 sulphuric acid the complete decomposition of hydrocyanic acid, at a temperature of 100° C., takes place slowly, and, further, that only about half the hydrocyanic acid is hydrolysed to ammonia and formic acid. The ammonia once formed is rapidly fixed as ammonium sulphate, whilst a blank experiment showed that no loss of formic acid occurred on heating sodium formate with 1:1 sulphuric acid for five hours at 100° C. Evidence was not forthcoming of any reaction between the formic and hydrocyanic acids under the conditions of the experiment. A considerable proportion of the hydrocyanic acid must therefore undergo some other change than that of simple hydrolysis. Nef, who supports the isonitrile formula for the acid, states (Annalen, **287**, 265) that it polymerises to a substance of three times the original molecular weight, which he describes as the nitrile of aminomalonic acid. The polymerisation of the acid favours the isonitrile formula, because the unsaturated character of the carbon atom would lend itself to further linkage. Wade in his support of the nitrile formula (Chem. Soc. Trans., 1902, **81**, 1613) maintains that while the actual products of hydrolysis do not discriminate between the nitrile and isonitrile constitutions, since the same products will be formed from each, the progress of the hydrolysis shows that the nitrile formula is correct. He states that hydrocyanic acid is readily decomposed by boiling alkalis in the same way as nitriles, whereas isocyanides are unaffected by these reagents; and whilst the isocyanides are rapidly and violently decomposed by mineral acids, hydrocyanic acid, like acetonitrile, for example, is hydrolysed by them comparatively slowly. While it is true that hydrocyanic acid is hydrolysed slowly by acids, it is equally true that it is hydrolysed slowly by alkalis. Werner and Fearon (Chem. Soc. Trans., 1920, **117**, 1356) have recently explained the constitution of cyanic acid as being an equilibrium mixture of the two forms $HO.C{\vdots}N$ and $HN{:}CO$; the constitution of hydrocyanic acid is probably best accounted for in the same way, viz., that it is an equilibrium mixture of the nitrile and isonitrile forms $H.C{\vdots}N$ and $HN{:}C$. In strongly acid solution a larger proportion of the isonitrile form would be expected, owing to the more basic character of the imino group, leading to a greater production of polymerisation products, and smaller quantities of ammonia and formic acid.

The determination of formic acid in presence of hydrocyanic acid.

The ordinary method for the determination of formic acid consists in titrating with standard permanganate in a warm solution made alkaline with sodium carbonate. Excess of sodium carbonate is without influence on the determination, and, if the solution is heated on the water bath, the manganese dioxide rapidly settles. The end-point is quite good and the estimation is easily carried out. H. C. Jones (J.C.S., 1895, A., ii., 463) has introduced a useful modification which consists in adding a known excess of permanganate to the alkaline solution. The solution is then acidified with sulphuric acid, a measured excess of oxalic added to destroy the permanganate and bring the precipitated manganese dioxide into solution; and finally the solution is titrated with permanganate just to destroy the excess of oxalic acid. Both methods were tried on a sample of Merck's sodium formate and found to give concordant results, the sample having a purity of 96·45%.

The permanganate method is, however, not applicable to the determination of formate in presence of cyanide without some modification, since the cyanide itself is so readily oxidised to cyanate. Baudrimont (Ber., 1880, **13**, 927) oxidised potassium cyanide with permanganate in both alkaline and acid solution. In alkaline solution he states that much nitrite was formed, whilst in acid solution there were several secondary products formed, including carbonate and nitrate.

On carrying out tests it was found that 0·1 g. of potassium cyanide (95·6%) required 23·5 c.c. of the permanganate solution ($N/5 \times 0{\cdot}918$) to oxidise it in warm solution. The end-point was fairly good but not quite so sharp as with a formate. 0·1 g. of sodium formate (96·5%) required under similar conditions 25·7 c.c. of permanganate. It is clear that the oxygen taken up by the cyanide was just about the amount required to convert it to cyanate. Examination of the cyanide solution after oxidation showed that nitrite and nitrate were present only in the merest traces, confirming the opinion that the oxidation is almost entirely to cyanate.

Cyanide and formate, when present together, can be determined very simply by first determining the amount of cyanide by titrating with standard silver nitrate in the ordinary way, and then adding a further quantity of silver nitrate solution exactly equivalent to the first, whereby the whole of the cyanide is precipitated as silver cyanide. After filtration, the faintly alkaline solution is made strongly alkaline with sodium carbonate, and the determination of the formate is carried out in the usual way by warming the solution and adding standard permanganate. Blank experiments with known quantities of formate and cyanide gave excellent results, and the method was used throughout the work described in this paper.

Summary.

It has been shown that only a small proportion of hydrocyanic acid is evolved as gas, when potassium cyanide is acted upon by sulphuric acid at ordinary temperature and pressure, but that greatly increased yields may be obtained by working at lowered pressure and temperature. This has an important bearing upon the use of the gas for fumigation purposes. Except where liquid hydrocyanic acid is prepared, great loss of cyanide is undoubtedly taking place. The means for avoiding this loss are indicated.

The acid and alkaline hydrolysis of hydrocyanic acid has been studied. The reaction proceeds slowly in both cases, and in acid solution the hydrolysis to ammonia and formic acid is very incomplete.

A simple method is described for determining formic acid in presence of hydrocyanic acid.

THE ANALYSIS OF FIBRO-CEMENT.

BY B. J. SMART, B.SC. (LOND.), AND P. C. PECOVER.

Theoretical.

Fibro-cement is the term applied in Australia to a product manufactured from asbestos and cement in the form of sheets either plain or corrugated. Ordinarily about 5 parts of cement are used to one part of asbestos. This material is primarily made use of on account of its fireproof qualities, but it has become very common to apply it in the construction of the walls of small houses, where its durability and strength become of practical importance.

Occasionally samples of the material are obtained which are particularly fragile, and it may become necessary to analyse it with a view of determining the proportions of cement and asbestos present. A number of samples were recently submitted to us to be examined in this way, and it appeared probable that some indication of the proportion of asbestos and cement present could be obtained by extraction with 20% hydrochloric acid. The samples to be tested were therefore macerated with the acid and washed several times, the residue being finally washed with water and dried at 100° C. The percentages of lime, silica, and iron and alumina were determined in the extract.

It was at first thought that the percentage of cement could be calculated directly from the lime value, the residue being an indication of the asbestos present. Unfortunately the figures obtained in this way were greater than the original quantity of material extracted, and it became obvious that there was some objection to this method of procedure. This was particularly noted when the proportions of lime, silica, and iron and alumina were very considerably below what would be expected from an ordinary cement.

This suggested that the asbestos residue remaining after extraction contained a proportion of adsorbed silica, and experiments showed that this was correct. Thus when sodium silicate was acidified and shaken with asbestos, silica was adsorbed by the asbestos. It therefore appeared desirable to calculate from the lime found in the extracted solution the proportion of silica which would normally correspond to the lime contained in ordinary Portland cement. In this way the deficiency of silica in the solution could be ascertained, and this figure deducted from the total weight of residue found. The net residue thus ascertained was finally taken as an indication of the percentage of asbestos present.

In order to confirm this, further tests were made in which the residue after extraction with acid was washed with alkali. From the data obtained in these experiments it was found that the adsorbed silica may be extracted with alkali, thus enabling a true value for the asbestos to be obtained.

The methods arrived at indicate the percentage of true asbestos residue remaining after extraction with acid, but since some varieties of asbestos are more readily attacked than others when extracted with hydrochloric acid, it is impossible to obtain strictly accurate figures. The figures given will, however, serve as a basis for comparison with different materials.

Experimental.

Five samples of fibro-cement were examined; samples 1 and 5 were imported, probably of British origin, whilst samples 2, 3, and 4 were locally manufactured. The total loss on drying and ignition was as follows:—No. 1, 27·5%; 2, 24·4; 3, 22·4; 4, 26·3; 5, 22·7%. The analyses subsequently carried out were calculated on the ignited and dried substance.

A quantity of the product taken from different parts of the sheets was broken into small pieces, and sufficient for each test (say 5 g.) was roughly pulverised and used for analysis. The weighed sample was placed in a porcelain evaporating basin 6 inches in diameter and covered with 200 c.c. of water; 40 c.c. of hydrochloric acid was then gradually added, with constant stirring, and the mixture allowed to stand for 24 hours. The residue was separated on a Buchner funnel and again washed two or three times with 20% hydrochloric acid until the washings were colourless, after which it was dried, ignited, and weighed. The filtrate, together with the washings, was made up to a known volume, and an aliquot part taken for the analysis of the dissolved substances. The following results were obtained when the material was treated in this manner:—

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.
Insoluble part: ignited, % ..	29·8	24·7	22·7	17·5	17·0
Soluble part:					
Lime, % ..	51·1	52·6	55·0	57·7	59·3
Silica, % ..	5·1	10·2	11·3	12·9	11·5

Thus the ratio of lime to silica in the solution does not correspond with the usual ratio present in an average sample of cement. The cement manufactured in New South Wales, which will certainly have been used in the manufacture of samples 2, 3 and 4, contains on an average 65% of lime and 22·2% of silica (calculated on the ignited cement). On this basis the percentage of silica corresponding to the lime would be:—No. 2, 17·9; No. 3, 18·8; No. 4, 19·7. From this fact it may be concluded that (1) the lime is made up of lime derived from cement, together with a certain amount extracted from the asbestos, or (2) the silica is low because a certain proportion of the soluble silica has been adsorbed by the asbestos and is included in the insoluble residue.

In order to ascertain which of these is correct, attention was directed to the character of the residue obtained. Samples 1 and 5 were white, whilst samples 2, 3, and 4 were blue, and it appeared probable that the latter consisted of crocidolite, the well-known blue asbestos.

The residue from No. 2 contained 18·05% of iron oxide, and was practically free from lime, whilst those from samples 1 and 5 contained 5·1 and 3·5% of lime respectively, and were practically free from iron. It appeared probable, therefore, that samples 2, 3, and 4 were derived from crocidolite, and samples 1 and 5 possibly from tremolite.

Tests were also made to ascertain the extent to which the lime present in asbestos is extracted with 20% hydrochloric acid. A sample of Merck's "special asbestos" was found to contain only traces of iron and calcium that could be extracted, whilst a sample of common asbestos used in the laboratory yielded 8·1% of iron and alumina and 5·3% of lime. Taking the latter figures as a basis, the total lime extracted would only be high to the extent of about 1%. Therefore this conclusion could not account for the deficiency in the silica found in the solution.

In order to test the second hypothesis, pure asbestos was shaken with an acidified solution of sodium silicate of known concentration, when it was found that the solution had lost 3% of silica.

The analyses given above indicate that the difference between the silica calculated from the cement ratio and that actually found represents the amount adsorbed by the asbestos. The figures are as follows:—

	No. 2.	No. 3	No. 4.
	%	%	%
Silica found	11·2	11·3	12·9
„ calculated ..	17·9	18·8	19·7
„ difference ..	7·7	7·5	6·8
Total residue	24·7	22·7	17·5
Net residue taken as asbestos	17·0	15·2	10·7

As a check on the figure thus obtained a determination of the silica in sample No. 4 was made, and from the average analysis of crocidolite (52·1% silica) the asbestos actually present was determined algebraically:—Silica found in residue, 63·0%; asbestos adsorbed silica, 17·5%; 0·52×asbestos adsorbed silica=17·5×0·63=11·0%. The difference between these figures represents 52% of the asbestos, which therefore amounts to 12·5%.

Tests on a sample of fibro-cement made in the laboratory, containing 16·7% of asbestos, gave a mean result of 16·68%.

In order to ascertain the quantity of adsorbed silica by a direct method, the residue which remained after extraction of the laboratory samples with hydrochloric acid was washed with caustic alkali; the insoluble part amounted to 16·6, 16·4, and 16·6%, whilst the amount of asbestos actually present was 16·7% (the insoluble part after extraction with acid alone amounted to 19·6 and 19·7%).

SOLS AND GELS OF VULCANISED RUBBER.

BY HENRY P. STEVENS.

Gels of vulcanised rubber are easily prepared by immersion in a suitable liquid; such gels cannot be dispersed within moderate ranges of temperature, however great the excess of solvent. If the temperature is high and the heating prolonged, complete dispersion may be obtained, but the caoutchouc is degraded, broken down, and decomposed. When recovered it is found to be soft and sticky and to have lost its useful properties.

The swelling of vulcanised rubber has been studied quantitatively both as regards the specific effect of different swelling agents and the condition, physical and chemical, of the vulcanised rubber. Broadly speaking, the higher the vulcanisation coefficient (*i.e.*, the percentage of combined sulphur calculated on the amount of rubber used in the mixing) the less the swelling. With very low coefficients, such as one-half unit or less, dispersion of the rubber may take place on long immersion, but with medium coefficients, such as are technically employed in soft rubber goods—say, 2 or 3 units—no dispersion takes place in any chemically inactive solvent, however long the specimen be immersed.

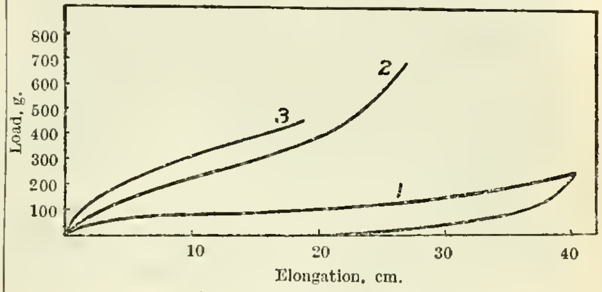
With a view to the preparation of vulcanised rubber sols with medium coefficients attempts were made to vulcanise the rubber in the presence of the solvent—that is to say, the raw rubber was dispersed in a suitable solvent of a sufficiently high-boiling point (xylene) with 10% of its weight of sulphur, and the vessel was then heated in an oil bath, the contents being stirred from time to time. After heating for an hour or so rubber began to deposit on the sides and bottom of the flask. The heating was continued for 2—3 hours and the more liquid portion poured off from the gel which had separated. The solvent was allowed to evaporate spontaneously and the two portions examined; the gel portion behaved like a fully vulcanised rubber and had a coefficient of about 4 units. The sol portion was weak and adhesive and contained only a little combined sulphur. Experiments with other solvents gave similar results. Vulcanisation took place, but the greater part of the vulcanised rubber separated as a gel as soon as formed.

In order to obtain results with more volatile solvents, *e.g.*, benzene, a mixture of rubber and sulphur dispersed as above was heated in a closed vessel under pressure by placing in water in a digester so as to enable the necessary vulcanising temperature to be reached. Under these conditions vulcanisation proceeds as in an open vessel, but the vulcanised rubber does not separate. The product obtained is an apparently homogeneous but viscous sol, unless the concentration of the original raw rubber or the coefficient is too high, when the whole sets to a gel on cooling.

These sols and gels were found to have interesting properties. When first formed the viscosity of the sols increases rapidly for the first few hours, and then only slowly if kept in the dark. All stages between a free-flowing but viscous sol and a stiff gel may be obtained according to the vulcanising conditions and concentration. The change from sol to gel form may be brought about by a short exposure to diffused light. In many cases the gel so obtained when placed in the dark reverts to sol form, and this will again gel on exposure to light. This change from sol to gel and reversion may be repeated several times with the same specimen. The sols may be diluted by shaking with fresh solvent, but gels only with difficulty, and generally not at all. When fresh from the vulcaniser and still warm a very viscous sol can be diluted to any extent. A gel which can no longer be dispersed may, however, swell when immersed in a fresh solvent. There is no sharp demarcation between the sol and gel. The sol gradually becomes more viscous and ceases to flow, the gel character then becomes more clearly defined, and the mass may be separated cleanly from the walls of the containing vessel. When the solvent is allowed to evaporate spontaneously a film or sheet of vulcanised rubber is obtained, which swells, but cannot be dispersed in fresh solvent. The increase in viscosity and gelation of the sol first produced are hysteresis phenomena; they correspond to the changes in vulcanised rubber which occur on ageing and are characterised by increasing stiffness, *i.e.*, greater resistance to stretching. The vulcanised rubber recovered from the sol is at first very soft and feels much under-cured, but on ageing it gradually stiffens. This change is promoted by exposure to light, and in this respect the behaviour is parallel to the increase in viscosity and gelation noted with the freshly vulcanised sol. The effect of exposure to diffused daylight is illustrated by the load-elongation curves obtained with strips of rubber 0·5 mm. thick, 2 mm. wide, and 30 mm. long, in a Schwartz hysteresis machine (fig. 1). The viscosity and tendency to gelation and properties of the recovered rubber can to some extent be controlled by mechanical pre-treatment of the rubber; a masticated rubber gives a less viscous sol which gels less readily for a given concentration and other like conditions than a sol prepared from unmasticated rubber.

The rate of combination of rubber in sol form with sulphur is influenced by the same factors which control the rate of combination in the dry way —that is, time and temperature of heating, proportion of sulphur and other ingredients, amount of accelerator, and specific character of the rubber used. There are also two new factors introduced —namely, the concentration of the rubber in the solvent and the specific character of the solvent. Details with quantitative experiments are given later.

Effect of exposure to light on the load-elongation curves of films of rubber recovered from vulcanised benzene sols.



Curve 1.—Kept in the dark.
„ 2.—Exposed to light 12 hrs.
„ 3.—Exposed to light 42 hrs.

Fig. 1.

Vulcanisation in sol form can also be effected without sulphur, *e.g.*, by heating with trinitrobenzene in the presence of litharge. The products so obtained are inferior in physical properties to those produced by vulcanising with sulphur, just as is the case when vulcanising in the dry way.

Cold vulcanisation with sulphur chloride or the little-used hydrogen persulphide[*] can be effected in sol form, and to this class of reactions belongs the vulcanised rubber gels obtained by Peachey by mixing a raw rubber sol treated with sulphur dioxide with a further quantity of the solvent saturated with hydrogen sulphide. Within certain limits of concentration, proportion of vulcanising ingredients, etc., there are obtained in a medium such as benzene, clear, transparent, pale yellow gels of the consistency of a 5—10% gelatin gel.

The formation of a rubber gel under these conditions was noted by Porritt[†] but remained an isolated observation. Some work has been done by Bernstein, Hinrichsen, and others on the reaction between sulphur chloride and rubber sols, but the object of these experiments was the preparation of a fully vulcanised rubber to investigate the con-

---

[*] Block, Ber., 1908, 41.

[†] The Rubber Industry, 1914, 168.

stitution of the caoutchouc chlorosulphide and for this purpose an excess of sulphur chloride was employed. This causes the more or less immediate separation of a dark brown product, the object of investigation. Of earlier work mention may also be made of the process of vulcanising rubber in sol form by exposure to ultra-violet rays.* The maximal coefficient of the vulcanised rubber so obtained is small—about one half unit—as further exposure to the rays causes degradation or decomposition.

By restricting the proportion of sulphur chloride to rubber and working with a sufficient quantity of the medium, sols are obtained which do not gel on keeping. On increasing the proportion of sulphur chloride and/or reducing the quantity of medium, sols are produced which gel in times varying from a few seconds to hours or days, as the case may be.

Syneresis of vulcanised rubber gels.—The gels so obtained are not as a rule stable; the more easily gelation takes place the less stable the gel. Contraction may take place with the expulsion of a part of the medium. This change is promoted by exposure to light. A gel which will remain unchanged in a dark cupboard for months will commence to change in a few hours when exposed to diffused daylight. The syneresis is of two types. In the first a gradual shrinkage of the gel takes place, the liquor expelled containing little or no rubber. In the second the gel liquefies or is partly changed back into sol form and separation then begins as a deposit on the sides and bottom of the containing vessel. In this case the separation is incomplete. The former type occurs with gels prepared with relatively large quantities of sulphur chloride in the dark, but will also be initiated by exposure to light. The latter type occurs only on exposure to light and often with gels produced with quite small proportions of sulphur chloride. With gels produced by vulcanisation with sulphur in the heat I have only observed syneresis of the first type, and that on exposure to light.

As in syneresis of the second type only partial separation takes place, the following figures may be quoted. The deposit is always more fully vulcanised, that is, contains a larger proportion of sulphur than the fluid part.

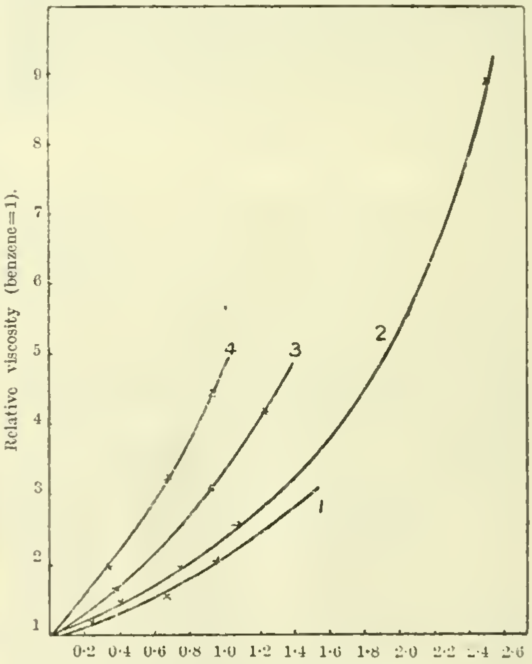
(1) In rubber from supernatant fluid	1·5	12·1
(2) In solid residue	11·1	29·0

Effect of heating on viscosity of rubber sols.—The vulcanisation of a dilute rubber sol does not bring about a great change in viscosity. Freshly prepared 1% vulcanised rubber sols have a viscosity similar to that of the raw rubber sols from which they are produced. This result was somewhat unexpected, as the vulcanisation should cause a peptisation of the rubber and, consequently, an increase in viscosity of the sol. The small change in viscosity may be attributed (1) to the relatively small decrease in viscosity of the raw rubber sol on heating corresponding to the reversion of vulcanised rubber when further heated in the dry way; (2) to hysteresis effects. Just as the rubber film obtained from the freshly vulcanised sol rapidly ages and becomes stiffer on keeping, especially after a short exposure to light, so the vulcanised sol tends to gel on keeping and very rapidly in the light. I found that the effect of heating a masticated raw rubber sol was much less than would be expected. The following figures give the viscosity of a 1% masticated rubber sol and of a parallel series of raw rubber sols heated with and without sulphur:—

Period of heating.	Viscosity (benzene=1). Without sulphur.	 With sulphur.
Nil	2·22	—
½ hour	1·57	1·10
1 „	1·57	1·54
1½ „	1·43	1·34
2 „	1·27	1·30
2½ „	1·25	1·36
3 „	1·20	1·13

It appears from these figures that there is at first a marked fall in viscosity in both cases, but with the raw rubber further small decreases take place with prolonged heating. In the presence of sulphur the initial fall in viscosity is much greater and is followed by a recovery, after which gradual decrease in viscosity takes place as with the raw rubber alone. The initial fall in viscosity in the presence of sulphur corresponds to similar observations made on the fall in viscosity produced by the addition of small quantities of sulphur chloride to a rubber sol. The subsequent fall is due to degradation of the rubber, and is more marked the lower the concentration of the solution.

The relative viscosity curves for vulcanised rubber sols resemble those obtained with raw rubber sols, as will be seen from the graphs (fig. 2). Nos. 1—3 were vulcanised as 2½% sols, and under these conditions viscosity increases with time of heating.



Concentration in benzene %.

Curve 1.—2½ % sol, 1½ hrs. heating.
„ 2.— „ 3 „ „
„ 3.— „ 4 „
„ 4.—10 % sol.

FIG. 2.

Effect of period of heating on the amount of sulphur combined.—The mixture used consisted of 90 parts of crêpe rubber and 10 parts of sulphur; 10 g. was dispersed in every 100 c.c. of benzene and the mixture heated in sealed tubes from which the air had been exhausted, in an autoclave for half-hourly periods up to 3 hours at 135° C. The films obtained by spontaneous evaporation of the benzene were extracted with acetone and the combined sulphur estimated.

---

* Helbronner and Bernstein, The Rubber Industry, 1914, 156-171.

Period of heating.	Combined sulphur. Total. %	Combined sulphur. Amount combined per half hour. %
½ hour	0·83	0·83
1 ,,	1·49	0·74
1½ ,,	1·88	0·63
2 ,,	2·59	0·65
2½ ,,	3·14	0·63
3 ,,	3·56	0·59

The rate of combination shows a reduction with period of heating. This is probably attributable to gradual degradation of the rubber, small amounts of vulcanised rubber being removed by the prolonged acetone extraction (about 40 hours).

Effect of concentration on the rate of combination with sulphur.—A mixture of rubber and sulphur similar to that employed in the previous experiment was treated with different proportions of benzene and heated in sealed tubes under the same conditions as before.

Slow-curing rubber.

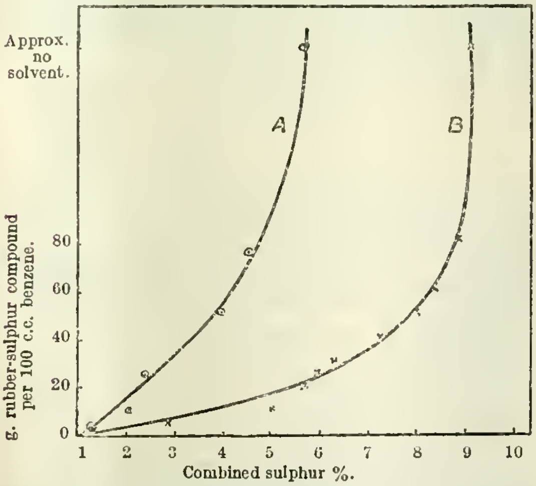
Wt. of rubber-sulphur compound per 100 c.c. benzene.	Combined sulphur. %
½ g.	1·19
2½ g.	1·24
10 g.	2·04
25 g.	2·36
50 g.	3·98
75 g.	4·55
Without benzene, vulcanised in steam	5·68

Fast-curing rubber.

Wt. of rubber per 100 c.c. solvent.	Combined sulphur. %
1 g.	1·33
5 g.	2·86
10 g.	5·00*
20 g.	5·69
25 g.	5·95
30 g.	6·31
40 g.	7·29
50 g.	8·00
60 g.	8·39
80 g.	8·90
No solvent (*in vacuo*)	9·19

* This figure is probably too high owing to loss of solvent through cracking of tube.

These figures show that a 10% sol vulcanises about half as fast as the dry mix. With higher concentrations the amount of combined sulphur approaches asymptotically the figure for the dry mix. The maximal concentration of 80 g. represents a concentration of about 50% by weight and the amount of combined sulphur is only 0·3 less than for the 100%, that is, the dry mix (fig. 3).



Curve A.—Slow-curing rubber.
,, B.—Fast-curing rubber.

FIG. 3.

Effect of nature of solvent on rate of combination with sulphur.—Raw rubber solvents have been classed in two groups, active and inactive. To the former belong such substances as benzene, ether, petroleum, and carbon bisulphide. The inactive solvents swell rubber to a slight degree only, and an excess does not result in the diffusion of the gel. These include water, alcohol, acetone, and most esters. Rubber may be vulcanised on heating with sulphur in the presence of both types of solvent. Parallel tests with a number of active solvents with the usual rubber-sulphur 9/1 mix are given below:—

Solvent.	Combined sulphur, %.
Benzene	2·29
Toluene	4·91
Xylene	4·74
Pseudocumene	3·88
Monochlorobenzene	3·38
Dichloroethylene	2·19
Trichloroethylene	2·17
Chloroform	2·85
Petroleum ether (b.p. 60°–80°)	2·61

The specific effect of the solvent is not very great. Toluene and xylene give higher figures than benzene, consequently the ordinary commercial naphtha gives a faster vulcanising sol than benzene. In this connexion it is interesting to note that water or steam appears to have little or no effect on the rate of combination of rubber and sulphur, as will be seen from the following figures:—Vulcanised *in vacuo* 8·99, in steam 8·97, in water 8·63.

Vulcanisation in the cold.—The usual method adopted was to prepare a raw rubber sol by immersing 10 g. of rubber for every 100 c.c. of solvent, usually benzene. After swelling, the contents were mixed by inverting the bottle at intervals. Experiments were made with a crêpe rubber masticated to varying degrees on warm, differentially geared rollers. A 10% sol of unmasticated rubber in benzene is very viscous, and takes several days to yield a mass of even appearance. A moderately masticated rubber disperses more readily, and was used for most of the experiments. The sulphur chloride was added as a 1% by volume solution in the solvent (almost 2% by weight in the case of benzene). After adding the measured amount the contents of the bottle were vigorously shaken and then put away in a dark cupboard.

With large proportions of sulphur chloride such as would be required to yield a product of the empirical formula C_5H_8SCl, gelation sets in very rapidly, and there is barely time to shake the contents of the bottle before the whole gels. With small proportions of sulphur chloride such as would be sufficient to produce technical vulcanisation, say 1 or 2%, the liquid slowly gels or may remain fluid according to the concentration of the sol. Thus 10 g. of masticated rubber dissolved in 150 c.c. of benzene and shaken with 25 c.c. of a 1% solution of sulphur chloride (by volume) began to gel in one to two hours. On halving the proportion of sulphur chloride and setting aside the viscosity increased, but the mass did not gel. As examples of more highly vulcanised gels, 50 c.c. of 10% masticated rubber in benzene was treated with 60 c.c. of a 10% solution of sulphur chloride in benzene; the liquid immediately began to thicken and in a few minutes had gelled completely. The bottle was placed in a dark cupboard overnight, when an appreciable amount of syneresis of the first type set in, the gel shrinking to a dark brown mass retaining the shape of the bottle; the liquid expelled was of a bright yellow colour. Another experiment with rubber and sulphur chloride in the same proportions (50:60), but using rather more than twice the amount of benzene (240 c.c. as against 110 c.c.), resulted in a gel more gradually formed which showed no separation when left overnight in a dark cupboard.

Summary.—Although vulcanised rubber swells, but does not dissolve in the ordinary rubber solvents, a vulcanised rubber sol can be obtained by heating a raw rubber sol with sulphur in a sealed vessel under pressure or by treating with sulphur chloride under controlled conditions. The sols on spontaneous evaporation yield films of vulcanised rubber which cannot be redissolved in rubber solvents.

Vulcanisation in sol form is subject to the same influence as vulcanisation in the dry state with the additional effect caused by degree of dilution and nature of the solvent.

Short exposure to light causes the sols to gel, and the effect is reversible when exposure ceases. Long exposure to light causes the gels to liquefy and gradually lose viscosity owing to degradation of the rubber. In the case of sols obtained with sulphur chloride, exposure to light may cause partial separation of the vulcanised rubber as a deposit.

THE BRIQUETTING OF CHARCOAL.

BY A. F. JOSEPH, D.SC., F.I.C., AND
B. W. WHITFIELD, A.I.C.

The problem of the utilisation of waste wood as fuel is always of importance in undeveloped countries, particularly where no mineral fuel has been discovered. This is the present position in the Sudan, where in various parts of the country there exist large supplies of wood which are useless as timber. The plants constituting the "Sudd" are examples of this, and the fuel capacity of this large store of material has been referred to in a previous paper (J., 1920, 91 T).

In many cases, however, the transport of such bulky material as a light wood renders its utilisation as fuel an unattractive proposition, and attention has therefore been directed to the possibility of its conversion into charcoal briquettes.

The question has also been under consideration for some time by the Government of India, and preliminary notes of the results appeared in the "Indian Forester" for March, 1918, and June, 1919. Further references to the work are to be found in the Annual Report of the Board of Scientific Advice for India (1916–17, p. 15, and 1919–20, p. 44): briquettes have been made using the gum of *Bauhinia retusa* as the binder and pressed in a hydraulic press.

The problem of the production of dense charcoal briquettes has been attacked from the opposite end by the American Forest Products Laboratory (Hawley, J. Ind. Eng. Chem., 1921, 301) by carbonising compressed (and treated) sawdust: the object of this, however, was the production of comparatively small quantities of high-grade charcoal for chemical warfare purposes, and, as far as we are aware, the principle has not yet been applied to fuel problems.

Another method which gives good briquettes is to use a large proportion of such a binder as wood tar or pitch, and after briquetting, to distil off the excess of binder at a low temperature; such a method has often been described for coal briquetting (*e.g.*, E.P. 127,940; J., 1919, 526 A, and U.S.P. 1,276,429; J., 1918, 646 A).

Description of materials.—The experiments described in the present paper have been carried out to compare the properties of different kinds of charcoal for briquetting purposes, dealing mainly with those woods which have so far found no useful application. The following is a description of the woods considered:—

(1) Sudd papyrus (*Cyperus papyrus*). For description see J., 1921, 91 T.

(2) The tamarisk (*Tamarix gallica*, Linn). The Arabic name for this is Tarfa. It is a large riverside shrub plentiful in places in the northern Sudan, where natural depressions become flooded in the rainy season.

(3) Ambatch (*Herminiera Elaphroxylon*, Gnill et Perr.). A small riverside shrub having an enlarged stem consisting of pith.

(4) Castor oil tree (*Ricinus communis*, Linn.) which grows sub-wild on the river banks, and is said to be easily cultivated as a quick-growing fuel tree.

(5) Sesaban (*Parkinsonia aculeata*). A small tree with light foliage; cultivated as a hedge plant on account of its quick-growing qualities.

(6) Heglig (*Balanites aegyptiaca* Del.). A large and important tree occurring in most parts of the Sudan. It is not at present used for fuel, but has been examined for future reference.

(7) Sunt (*Acacia arabica*, Willd.), an important timber tree, but also used for fuel; it has been examined as a typical heavy local wood.

The woods were examined in the air-dried condition for apparent density, ash, and yield of charcoal under laboratory conditions. The density was rapidly and conveniently found by measuring the upward thrust on the wood when immersed in a vessel of mercury standing on the pan of a pair of scales weighing correctly to about 0·5 g., the wood being kept from floating by a glass rod held in a clamp not in contact with the scales.

The charcoal was prepared by heating the wood cut into one-inch pieces in a small cast iron retort lagged with asbestos, the inside temperature being about 600° C. The retort was connected with a suitable condenser in order to collect the tar for later examination. Table I. gives the density and ash of these woods:—

TABLE I.

	Density.	Ash. %	Yield of charcoal at 600° C., %
Papyrus	0·174	6·5	33·0
Tarfa	0·609	2·9	30·0
Ambatch.. ..	0·071	3·1	27·8
Castor	0·385	2·7	30·0
Sesaban	0·591	2·2	27·0
Sunt	1·016	0·9	29·1

Relative weight and bulk of wood and charcoal.—The object in briquetting is, as stated above, to economise transport, and the following figures are given to illustrate the saving which might be effected. The calorific value of ashless charcoal may be taken as 14,000 B.Th.U. per lb. and 8000 B.Th.U. may be taken as that for wood.

TABLE II.

	Wood.		Charcoal.		Briquettes.	
	Sunt.	Tarfa.	Sunt.	Tarfa.	Sunt.	Tarfa.
Density (of 1-in. pieces) ..	1·0	0·61	0·475	0·325	0·9	0·6
B.Th.U. per lb...	8000	1800	13,500	12,800	13,500	12,800
B.Th.U. per cubic foot*	500,000	300,000	405,000	256,000	756,000	473,000
Lb. required for a million B.Th.U.	125	130	74	79	74	79
Cb. ft.* required for a million B.Th.U. ..	2·0	3·3	2·5	3·9	1·3	2·1

* Cubic feet of actual material.

As charcoal packs so much better than wood, in practice the saving in bulk transport would be much greater than that shown in the last line of the table; with wood there is probably as much air space as material, whilst with charcoal briquettes the air space can be reduced to quite a small percentage of the whole.

Properties of the charcoals.—Table III. gives the densities of the charcoals prepared at 600° C. and passed through a 20-mesh sieve. The density of the powder was determined in bulk, as is done in cement examination, and also absolutely by displacement of benzene in a specific gravity bottle, taking the usual precautions for the removal of air; it will be seen that whereas the former figures vary a great deal, the absolute density is practically the same for all. Attention may be directed to the extraordinarily low bulk density of ambatch charcoal. The percentage of ash in the charcoal is also given:

Table III.

	Ash. %	Bulk density, 20-mesh.	Absolute density.
Heglig	11·3	0·33	1·49
Sunt	2·6	0·32	1·51
Tarfa	10·3	0·27	1·51
Papyrus	21·0	0·15	1·51
Castor	16·1	0·13	1·48
Sesaban	10·7	0·11	1·49
Ambatch.. ..	20·5	0·027	1·51

Effect of heat on the density of charcoal.—As shown by Violette (see Guttmann, "Textbook of Explosives") and others, the absolute density of charcoal increases with the removal of carbon compounds and reaches a maximum when the composition approximates to that of pure carbon. We have examined the effect of heating some of the charcoals in a furnace heated electrically to 1000° C. for periods of 8 and 16 hours and obtained the following increases in density:—

Table IV.

	Tarfa.	Sunt I.	Sunt II.
(*a*) Prepared at 600° C..	1·51	1·51	—
(*b*) Prepared at 1000° C..	1·61	1·74	1·72 (prepared in kiln)
(*c*) (*a*) heated to 1000° C. 8 hours	1·64	1·64	2·04
(*d*) (*c*) reheated 8 hours..	1·71	1·71	2·04

The bulk density also is increased, that of sunt charcoal rising from 0·32 to 0·49.

The advantage of a high density charcoal for briquetting is shown later: its production is, however, accompanied by the formation of a much greater quantity of volatile products and a corresponding diminution in the yield of charcoal. Thus the yield of tarfa charcoal at 600° C. was 30% and at 1000° C. 21·3%.

Briquetting experiments.—The compression of powders into blocks may be effected in various ways, of which the most important are (*a*) slow or "dead" pressure as applied by a screw, hydraulic, or roller press; (*b*) a succession of blows as from a quick-acting cam press or a falling weight; (*c*) a rapid succession of less powerful blows than (*b*) as applied by a pneumatic hammer.

As far as our experiments go, (*b*) is the method which appears most promising: the attempts we have made with a screw press applying 16 tons per square inch failed to make a coherent briquette, where a few blows from a falling weight gave quite satisfactory results. Most of our experiments were carried out with a simple falling weight apparatus which allowed of a drop of ten feet and a weight up to 20 lb. This produced briquettes up to 2¾ in. diameter; generally, however, this was reduced to 1·3 in., as it allowed of much more rapid working.

Preparation of briquettes.—There is a considerable quantity of gum in the Sudan which, owing to colour or some other reason, does not readily find a market, and this has been the binder mainly used in these experiments; we have, in addition, used starch and dura (millet) flour—the latter being available in almost all parts of the Sudan—and a few experiments were made with wood tar and pitch.

In making the briquettes, the requisite quantity of charcoal ground to the prescribed degree of fineness was weighed out and mixed with the binder. The mixture was put in a cylindrical mould and compressed under the falling weight, withdrawn from the mould, and allowed 48 hours to dry.

The finished briquettes were usually examined (*a*) by a determination of the density, and (*b*) finding the crushing load as indicated on an ordinary testing machine.

Effect of varying the charcoal.—The following table shows that the kind of charcoal greatly affects the properties of the briquette. To make the tests comparable, all these briquettes were made from 20-mesh charcoal with 5% of gum and compressed by 10 blows of a 10 lb. weight falling 3 ft. 6 in.

Table V.

Charcoal.	Density of briquettes.		Crushing load, lb. per sq. in.	
	Individual expts.	Mean.	Individual expts.	Mean.
Tarfa	0·58	0·58	540	420
	0·61		400	
	0·57		350	
	0·58		400	
Sunt (low temp.) ..	0·73	0·68	600	700
	0·68		500	
	0·68		850	
	0·69		850	
Sunt (high temp.) ..	0·80	0·79	600	850
	0·78		800	
	0·80		1,150	
Heglig	0·58	0·63	350	380
	0·68		420	
Papyrus	0·59	0·60	460	420
	0·62		490	
	0·58		300	
Castor	0·68	0·65	600	630
	0·65		750	
	0·63		550	

We have not been successful in producing a coherent briquette from ambatch charcoal under standard conditions, and heglig makes very poor briquettes. The heavy, high-temperature sunt charcoal is easily the best.

Fineness of charcoal.—To determine the effect of the fineness of the charcoal on the properties of the briquette, tests were made using 10-, 20-, 90-, and 240-mesh powder.

Table VI.

Properties of the briquette made with 5% of gum.

Charcoal.	10-mesh.		20-mesh.		90-mesh.		240-mesh.	
	Density.	C.L.*	Density.	C.L.	Density.	C.L.	Density.	C.L.
Tarfa ..	0·60	600	0·58	550	0·63	300	0·62	200
	0·62	300	0·61	400	0·64	300	0·62	150
	0·59	400	0·58	350				
Mean ..	0·60	450	0·59	450	0·63	300	0·62	175
Heavy sunt	0·93	2,500	0·80	600	0·96	1,400	0·87	700
	0·93	2,600	0·78	800	0·97	2,100	0·87	
	0·90	2,100	0·80	1,150	0·91	1,150	0·83	800
Mean ..	0·92	2,400	0·79	850	0·95	1,550	0·86	750

* C.L. = Crushing load in lb. per square inch.

These results show irregularity with regard to density; the strongest briquettes, however, are clearly made from coarse rather than fine charcoal.

Nature and amount of binder.—It is obviously desirable to be able to utilise the cheapest possible material as a binder and only enough to make a sufficiently coherent briquette for the purpose in view. In our small-scale experiments the amount of binder has been comparatively large, and we have never attempted to go below 1 or 2%. There is, however, reason to believe that with more compression than we have used the amount may be reduced far below this and still produce a briquette sufficiently strong for practical purposes.

The results from 40 experiments are averaged out and given in the next table; they show the great improvement in strength resulting from the use of a high proportion of binder and the excellent binding property possessed by starch, 3% of which produces a stronger briquette than 5% of gum.

TABLE VII.

	Crushing strengths.				
	2% gum.	5% gum.	8% gum.	3% starch.	3·3% dura.
Tarfa ..	320	420	840	460	230
Sunt, heavy .	650	1,300	1,900	2,300	900
Sunt, light ..	230	840	1,550	1,000	550
Heglig ..	150	400	400	300	200
Papyrus ..	450	300	500	400	350

Effect of water on briquettes.—We carried out our first experiments using waste gum as a binder on account of the large supplies available in the Sudan and also because the method of manufacture of the briquettes appears simple. Under some circumstances, there would be difficulty in practice with briquettes made with a water-soluble binder, although a small amount of wetting does not cause the disintegration of the briquettes if they are not handled until dry. In the northern Sudan the climate is so dry that serious inconvenience is not likely to result from this cause, but the same does not apply to the southern parts of the country, and we have therefore experimented on the preparation of briquettes which are not affected by water, and this is best done by using pitch or tar as a binder with subsequent firing to distil off the volatile part of the binder.

Briquettes made with gum could also be rendered waterproof by firing, but unless a large proportion of gum is used, the strength of the briquette is so much diminished that we have not gone into this method in detail. As examples the following may be given for the crushing loads for briquettes made with 5% of gum with and without firing:—

	Before firing.	After firing.
Sunt	850	250
Tarfa	420	230

Briquettes made with starch and dura resist the the action of water fairly well.

Use of tar as a binder: Distillation of tarfa wood.—The use of wood tar would be specially convenient in places distant from the gum districts, as the manufacture would then be dependent only on local products. As an example we have worked with the tar and pitch obtained from the tarfa, the following results of distillation experiments showing the amount of tar and pitch available:—100 parts of air-dried wood yielded 33 of charcoal, 6·7 of tar and 22·4 of aqueous layer; this latter yielded 20·1 parts of acid liquor and 2·2 of dissolved tar which when added to the other tar furnished 3·6 parts of tar oils and 5·3 parts of pitch.

The total quantity of tar is 26% reckoned on the charcoal, and consequently this amount is available as a binder. Alternatively 16% of pitch could be used, but unless, on account of by-products, re-distillation of the tar appeared an attractive proposition, we should prefer to use the tar.

Briquettes made with tar and pitch.—The charcoal and binder were mixed and briquetted under the falling weight as usual, and afterwards heated to 600° C. until the evolution of gas ceased. This firing is necessary for good quality briquettes, which are otherwise too soft and burn with a very smoky flame.

The following results were obtained:—

TABLE VIII.

Charcoal.	Binder.	Density.	Crushing load, lb. per sq. in.
Heavy sunt	20% tar	0·95	2500
	25% tar	0·92, 0·98, 0·06, 0·96, 0·94 Mean 0·95	2800, 3000, 3000 2700, 2600 Mean 2800
	25% soft pitch	0·83, 0·86, 0·86, 0·87, 0·83 Mean 0·85	700, 1150, 800, 1250, 750 Mean 920
Tarfa ..	20% tar	0·64, 0·73, 0·70 Mean 0·69	1000, 1400, 1100 Mean 1200

These briquettes made with tar are clearly very satisfactory; the pitch, although not giving such a strong or dense briquette as tar, is certainly better than 5% of gum as shown in Table V.

Boiler test.—The laboratory experiments have now been carried as far as is necessary at present, and it remains to attempt the preparation and utilisation of this type of fuel for steam raising and in gas producers. We have carried out a demonstration experiment, in which 200 lb. of large-size briquettes (made with gum as binder) were used to fire a small boiler; the following are the results of the test:—Size of briquette, 4 in. diam. × 1¾ in. high; average weight, 0·6 lb.; ash, 18%; time of run, 2 hours; temp. of feed water, 68° F.; steam pressure, 80–110 lb. per sq. inch; weight of briquettes used, 204 lb.; water evaporated, 98·2 galls.; water evaporated per lb. fuel, 4·7 lb.

This performance compares favourably with that of good coal with this boiler. The appearance of the fire was excellent and there was no smoke. Although the percentage of ash in this charcoal was high, none collected in the ash pan, and only small quantities collected in the combustion chamber and fire tubes. The fire required no attention beyond feeding in the briquettes, and at the end of the run there was no sign of caking or sintering.

The briquettes handled well; they were too strong to crush in our testing machine, and could be dropped several times from a height of five or six feet on to a stone floor without breaking. When ultimately broken in this way, they did so into a few large pieces and without the production of dust.

Summary.

(1) The examination of charcoal made from a number of different kinds of Sudan woods at the same temperature show that whilst the "bulk" density of the charcoal varies widely, the absolute density is nearly the same for all.

(2) Powdered charcoal can be made into serviceable briquettes using gum or starch as a binder, the only disadvantage being the deleterious effect of water. Coarse charcoal appears to give a stronger briquette than fine, and starch is a better binder than gum.

(3) Briquettes made with gum and subsequently fired are unaffected by water, but are not so strong as unfired ones.

(4) Good briquettes may be made using as a binder wood tar obtained as a by-product in the charcoal manufacture, and subsequently firing. The densest and strongest briquettes were obtained in this way.

Communications.

THE PATH OF TRAVEL OF THE GASES IN THE COKE OVEN.

BY G. E. FOXWELL, B.SC.(LOND.), A.INST.P.

There are few subjects connected with the coking industry upon which more divergence of opinion exists than that of the path taken by the gases in the coke oven. The hypotheses advanced may be summarised as follows:—

(1) The gases pass mainly up the cool interior of the charge.

(2) They pass up the highly heated zone next to the wall.

(3) Some pass in each of the above directions—this view is not heard so frequently as the two former.

One of the difficulties attending investigation into all carbonisation phenomena is that direct observation is impossible. The true course of any particular phenomenon must be deduced either from known facts, which in many cases do not directly bear on the subject, or from purely laboratory investigations which may or may not be applicable to the conditions obtaining in practice. In the circumstances it is unsafe to accept as final conclusions drawn from one line of evidence only. Many converging lines should point to the same conclusion before it can be accepted. The present subject, however, does not appear to have been scientifically investigated hitherto, and it has been the author's endeavour to provide one of the above-mentioned lines of evidence.

The method adopted has been to determine experimentally the laws governing the flow of gases through coke, crushed coal, and coal in various stages of carbonisation. From these laws the probable path of the gases has been deduced by a mathematical analysis.

For experiments at atmospheric temperatures a litre flask, well lagged so that it should not be affected by draughts, was used to contain the gas. A large dropping funnel filled with water and arranged to act as a Marriotte's bottle was inserted into the stopper in the neck of the flask, which also held an inlet tube extending to the bottom for filling the flask with gas when required. By means of wide glass tubing, the resistance of which was negligible, the outlet of the flask was connected with a glass tube containing the porous material under examination, and a gauge containing xylene of sp. gr. 0·865 at 15°/15° C. was connected with this; this gauge was arranged so that it could be read by a horizontal microscope reading to 0·001 cm. The whole apparatus was so clamped that with ordinary care it was perfectly rigid.

When compressed coal was used, about 12 cm. of loose coal was inserted into the tube, and the required compression obtained by means of a stout glass rod with a four-pound weight on the end which was dropped on to the coal from a predetermined height; more coal was then put in and the compression repeated. Highly porous wire plugs were used to keep the material in position.

Before making an experiment the connexion on the end of the flask was detached and the flask filled with gas. While this was taking place the reading of the gauge level was noted on the microscope scale. Gas was then turned off and the connexion to the flask at once attached. Water was then allowed to drop at the required speed from the Marriotte's bottle, and simultaneously a stop-watch was started. After about three minutes the pressure shown by the xylene gauge was constant, showing that the apparatus was completely filled with gas and that a steady rate of flow had been established. The reading on the microscope was then again taken, the tap on the Marriotte's bottle turned off, and simultaneously the stop-watch was stopped. By measuring the water collected in the gas flask the volume of gas passed in c.c. per minute was determined. The reading of the xylene gauge was corrected for temperature and converted into mm. of water. Several such observations (6 to 12) were made consecutively, using the same porous material and the results plotted on graphs.

Early experiments showed that the graph was always a straight line, and moreover, since when no gas is passing the pressure is zero, the graph passes through the point O,O. The equation to any straight line passing through the origin being $y=mx$, where m is a constant for any particular line, the most convenient way to express the results is to give the value of m for each set of observations. This has accordingly been done. The physical meaning of m may readily be seen, for if we represent pressures along the y-axis and volumes of gas per minute along the x-axis, $m=y/x$, = pressure/volume, = pressure required in mm. of water to pass 1 c.c. of gas measured at N.T.P. through the material per minute.

I. *The laws governing the passage of gas through coke and crushed coal.*

The passage of gas through porous material follows different laws according as to whether the pores are very fine or not. It was thought probable at the outset that the law followed would be that of the latter. This case resembles that of flow through a capilliary tube, for which

$$P_1V_1 = P_2V_2 = \frac{(P_1^2-P_2^2)\pi a^4}{16\,l\eta} \quad .. \quad .. \quad (1)$$

where P_1,P_2, and V_1,V_2 are pressures in dynes and volumes in c.c. respectively of the gas at the ends of the tube a=radius of tube, l=length of tube, and η=coefficient of viscosity of the gas.

In the present case P_2 is the atmospheric pressure and $P_1=P_2+p$ where p is the gauge pressure as determined in the experiments. The formula then becomes

$$(P_2+p)V_1 = \frac{(P_2+p)^2-P_2^2}{16\,l\eta}\pi a^4$$

$$.\;.\;(P_2+p)V_1 = \frac{2P_2p+p^2}{16\,l\eta}\pi a^4$$

If p is small compared to P_2 (as in the present experiments) we may neglect p^2 in the numerator of the right hand fraction; further, P_2+p becomes P_2, and the formula reduces to

$$V_1 = \frac{p\,\pi a^4}{8\,l\eta} \quad .. \quad .. \quad .. \quad .. \quad (2)$$

and since $p=mV$, $m \propto \frac{l\eta}{a^4}$ .. .. .. (3)

Effect of length of material on resistance.—The size of coal used in each case was 0—⅜ in.

When $l_1=37{\cdot}5$ cm.; $m_1=0{\cdot}1906$; $l_2=18{\cdot}6$ cm.; $m_2=0{\cdot}0940$.

Then $l_1/l_2=2{\cdot}016$ and $m_1/m_2=2{\cdot}027$,.

therefore $m \propto l$.

Except where otherwise stated, the coal used was of the size common in coke-oven practice, viz., 0–3/8 in.; this was made up as follows:—

Above	¼ in.	18·2%	by weight.
Between	1/10 in and 1/4 in.	53·6%	„
„	1/30 in. and 1/10 in.	20·7%	„
„	1/90 in. and 1/30 in.	6·1%	„
Below	1/90 in.	1·4%	„

Effect of radius of tube.—In this case in order to get concordant results the tubes were packed with gas-coke, crushed to 1/10—1/60 in. mesh lightly tapped down into position. Although repeated several times with different tubes the results obtained were not very concordant, probably due to the difficulty of filling both wide and narrow tubes with powdered coke so as to give uniform packing in each case; nevertheless, it is evident that the value of m varies inversely with the square of the radius. This result does not show that the formula given above is inapplicable, since increasing the radius of the tube of porous material is not equivalent to increasing the radius of the capilliaries but increases the number of capilliaries, which of course varies as πr^2. A series of typical results is given below. The length of material was 26·7 cm. in each case.

No. of tube ..	1	2	3	4
	cm.	cm.	cm.	cm.
Radius ..	2·46	0·7931	0·6947	0·6058
m	0·0228	0·1514	0·2260	0·2830

Taking tubes 1 and 2 we have $(r_2/r_1)^x = m_1/m_2$.

For tubes 1 and 2 $x = 1·67$; for 1 and 3 $x = 1·82$; for 1 and 4 $x = 1·80$; for 2 and 3 $x = 3·05$; for 2 and 4 $x = 2·32$; and for 3 and 4 $x = 1·63$.—Mean 2·05.

Effect of using different gases.—If the flow follows the law for very fine pores the values of m will vary directly as the square roots of the densities of the gases; but, as pointed out above, if the law for larger pores is followed m varies directly with the viscosity of the gas.

The comparison was made by passing hydrogen, carbon dioxide, and air saturated with water vapour at temperatures varying between 17° and 19·5° C. through a tube of radius 0·675 cm. packed with compressed coal of 0—⅜ in. containing 8% of water. The length of coal was 32·3 cm. and the compression used was 1 ft.-lb. per sq. cm. applied 5 times at each 10 cm. of length.

It will be seen from the table below that there is no relation between the density of the gases passing and the value of m, hence the value of the viscosity of the gases, η, alone need be dealt with here.

The viscosities of the three gases mentioned may be given (Thomson and Poynting, "Properties of Matter") as under:—

Gas.	η	ρ (g. per l.)	m
Air	$1·9 \times 10^4$	1·19	0·3740
CO_2	$1·6 \times 10^4$	1·80	0·3146
H_2	$0·93 \times 10^4$	0·098	0·1868
Coal gas	—	0·73	0·3030

From the above results we have:—

$$\frac{m_{air}}{m_{CO_2}} = 1·19 \qquad \frac{m_{CO_2}}{m_{H_2}} = 1·67 \qquad \frac{m_{air}}{m_{H_2}} = 2·00$$

$$\frac{\eta_{air}}{\eta_{CO_2}} = 1·19 \qquad \frac{\eta_{CO_2}}{\eta_{H_2}} = 1·72 \qquad \frac{\eta_{air}}{\eta_{H_2}} = 2·04$$

Clearly, therefore, $m \propto \eta$, *i.e.*, the pressure required to force a given volume of gas through coke or crushed coal varies directly as the viscosity of the gas; hence the flow of gases follows the general laws expressed in equation (1). The above results can be used to infer the viscosity of the coal gas used in the present experiments. It is well known that the addition of a small amount of air to hydrogen raises its viscosity by an amount which is out of all proportion to the quantity added. In deducing the value of η for coal gas the values of m for air and carbon dioxide were, therefore, used in preference to that for hydrogen. From each of these we find $\eta_{15°C}$ for coal gas to be $1·54 \times 10^{-4}$.

Passage of gases through coke at high temperatures.—So far atmospheric temperatures only have been dealt with. For the practical problem under consideration, however temperatures up to, say, 1000° C. must be considered. Taking the linear coefficient expansion of coke as $5·5 \times 10^{-6}$, the cross-sectional area of a capillary increases by about 1·1% when raised in temperature 1000° C. The total number of the capillaries will be undiminished, but the radius of each will be increased. To fix ideas, take a capillary of 0·1 sq. cm. area; the radius is 0·1783 cm. At 1000° C. the radius becomes 0·1794 cm. But for a given capillary

$$m \propto 1 / a^4$$

$$\therefore m_0 : m_{1000} :: 1 : 0·979$$

This small decrease is, however, entirely masked by the increase in volume and viscosity of the gases and may for present purposes be neglected.

A number of formulæ have been proposed to represent the variation of viscosity with temperature. The author will throughout follow Meyer and Obermayer's expression $\eta_t = \eta_0 (1 + at)^n$ where a is the coefficient of expansion of the gas, t the temperature in °C., and n a constant which varies for each individual gas. From formula (2)

$$p \propto V\eta$$

$$\therefore m \propto (273+t)\, \eta / 273$$

$$\text{or } m_t = m_0 (1 + at)^n . (273+t) / 273 \quad .. \quad .. \quad (4)$$

where mt is the pressure required to pass 1 c.c. of gas per minute measured at N.T.P. through coke maintained at t°C.

This expression was verified by passing hydrogen and carbon dioxide over coke crushed to 1/60—1/10 in. contained in a hard glass tube. The tube was embedded in sand and placed in a gas-heated furance, the temperatures being taken by a thermocouple placed by the side of the tube. Rayleigh's values for n and a were taken, viz.,

$CO_2, n = 0·93, a = 0·0037$; $H_2, n = 0·681, a = 0·003665$.

Carbon dioxide.			Hydrogen.		
Temp.	m (obs.).	m (calc.).	Temp.	m (obs.).	m (calc.).
0° C.	—	0·0372	0° C.	—	0·064
17°	0·050	0·042	16°	0·0704	0·070
436°	0·242	0·236	416°	0·354	0·306
509°	0·338	0·338	670°	0·514	0·512
641°	0·372	0·386			

Determination of n for coal gas.—It is not necessary to determine η or m_0 in order to calculate n. By taking m for two temperatures, t and T, n can be found from (4) by the formula.

$$n = \log\left(\frac{m_t}{m_T} \cdot \frac{273+T}{273+t}\right) \div \log\left(\frac{1+at}{1+aT}\right) \quad .. \quad (5)$$

The experiments were carried out by the same method as those for carbon dioxide and hydrogen above. It was found necessary to take the resistance at atmospheric temperature after that at each high temperature, as on heating the tube the coke appeared to settle and the value of m at atmospheric temperature fell slightly.

The gas had the composition:—H_2 44·0%, CH_4 27·0, CO 14·3, C 2·0, CO_2 5·5, O_2 0·3, N_2 6·9%.

The results obtained are given below:—

Temp. ° C.	m.	Temp. ° C.	m.	n.
18·4	0·1950	240	0·570	0·897
17·4	0·1916	300	0·682	0·867
17·2	0·1916	440	1·052	0·897
17·2	0·1916	360	0·838	0·893
17·2	0·1916	400	0·940	0·897
16·4	0·1688	500	1·086	0·895
17·0	0·0964	591	0·764	0·897

Hence between the limits taken $n = 0·897$.

The laws governing the flow of gas through porous material such as has been considered are thus shown to be expressed by the formula

$$p = k l V \eta / S$$

where S is the cross-section area of the material passed through and k is a constant depending on the nature of the porous material; thus for crushed coke 1/60 in.–1/10 in., $k = 75{\cdot}4$.

For convenience and simplicity in dealing with the present problem, however, it is preferable to work with the values obtained for m, rather than to calculate k for each case.

II. *The resistance of coal and coke to the passage of gases under practical conditions.*

Resistance of compressed coal.—As the coal falls from the hoppers on to the peel plate it suffers a certain amount of compression due to its own weight and to that of the superincumbent coal. When the stamper legs descend it may be calculated that they do roughly 1 ft.-lb. of work per sq. cm. of surface on which they strike. This is applied several times. Some experiments have been carried out to find the effect on the resistance of compressing the coal, the results being given in Table I.:—

TABLE I.

Coal used 0–⅜ in. containing 12% of water.

Compression used.	Length of column of coal, cm.	Cross-sect., sq. cm.	*m.*	Value of *m* per 100 cm. coal per sq. cm. area.
1 ft.-lb. per sq. cm. every 9 cm. ..	29·8	1·225	0·288	1·184
Do. do. twice every 8 cm.	23·2	1·306	0·456	2·670
Do. do. five times every 8 cm. ..	24·5	1·731	0·506	3·670

If these results are plotted graphically it is clear that the first two or three compressions do most of the work, and too many applications of the stamper should be avoided as uneconomical.

Effect of size of coal.—The coal contained 12% of water and was compressed by 1 ft.-lb. applied 5 times every 7—8 cm.

TABLE II.

Size of coal. in.	Length of column of coal. cm.	Cross-sect. of tube. sq. cm.	*m.*	Value of *m* per 100 cm. coal per 1 sq. cm. cross-section.
0–⅜	24·5	1·731	0·506	3·67
0–¼	23·2	1·346	5·40	31·26

Clearly by decreasing the size of the coal the resistance is greatly increased; the importance of this observation will be apparent later.

Effect of moisture in coal.—The results obtained are given in Table III.:—

TABLE III.

Size of coal, in.	Water %	Compression given.	Length of column of coal, cm.	Cross-section area.	*m.*	Value of *m* per 100 cm. length per 1 sq. cm.
0–⅜	nil	1 ft.-lb. once every 8 cm.	12·5	1·306	0·066	0·690
0–⅜	8·0		25·7	1·306	0·224	1·138
0–⅜	8·0	1 ft.-lb. 5 times every 8 cm.	21·2	1·731	0·212	1·734
0–⅜	12·0		24·5	1·731	0·506	3·670
0–¼	8·0		23·3	1·346	0·774	4·48
0–¼	12·0		23·2	1·246	5·40	31·26

If the resistance of coal with x% of water be written R_x, the above results may be summarised as follows:—

Using coal 0–⅜ in. .. .. .. $R_0 : R_8 : R_{12} = 1 : 1{\cdot}65 : 3{\cdot}5$
" " 0–¼ in. .. .. .. $R_8 : R_{12} = 1 : 7{\cdot}0$

As the percentage of water is increased the resistance rises very rapidly. Thus increase of water has a greater effect on fine coal than on large. This is to be expected since the rôle of water is clearly to fill up the interstices.

Resistance of coke.—At the outset it was considered likely that the value of m would depend on the temperature to which the coal had been heated. The first series of experiments using coke was carried out to elucidate this point.

A hard glass tube of cross-section 1·346 sq. cm. was packed with compressed coal 0—⅜ in. in size, containing 8% of water, to a length of 12·3 cm., using a good Durham coking coal. The resistance, m, was then measured. The tube was placed in a furnace at 310° C. and maintained at that temperature for half an hour. At the expiration of that time it was removed from the furnace, allowed to cool to atmospheric temperature and m again measured. The tube and its contents were then returned to the furnace and heated to 380° C. for half an hour and m again measured at atmospheric temperature as before. This was continued at intervals up to 750° C. The results are given in Table IV.:—

TABLE IV.

Material.	*m.*	Value of *m* per 100 cm. per sq. cm. =M.	Calc. value of M at *t*° C.
Compressed coal 15° C.	0·248	2·72	2·72
Material heated to 310° C.	0·232	2·54	9·68
" " 380° C.	0·774	8·46	39·90
" " 480° C.	0·1232	1·32	8·20
" " 610° C.	0·039	0·42	3·48
" " 750° C.	0·0092	0·10	1·10

Heating the coal to 310° C. is at first sight equivalent to driving off the the water. If this was so, from previous results M should drop to under 1·7. The fact that the drop is only to 2·54 would seem to indicate that carbonisation commences at as low a temperature as 310° C. and the coal has commenced to fuse slightly.

The very low resistance at 750° C. may indicate that the coke had cracked and shrunk away from the tube walls.

The most interesting point is the very high resistance in the neighbourhood of 380° C. This result made it probable that in the neighbourhood of 380° C. there is a "critical point" at which the coal is in a pasty condition. It is well known that all coking coals assume this condition during carbonisation, and it was evident that the point could best be tested by measuring the resistance of the coal while actually carbonising; as long as the coal remains in a pasty condition the resistance will be very high. It is not, of course, possible to measure the value of m under these conditions, for gas is being continuously evolved from the coal; nevertheless, the resistance under certain specified conditions may be measured and yields interesting results.

In these experiments the Marriotte's bottle, as used in the first series of tests, was so arranged that at the start of the experiment 20 c.c. of gas per minute per sq. cm. area of coal was passed, and this was not further adjusted throughout the experiment. The hard glass tube was packed with dry coal, 0—¼ in., to a length of 6·5 cm., and placed in a sand bath in a gas-heated furnace. When gas was passing through the coal at the required speed the pressure was read on the gauge. The tube was then heated so that the temperature rose about 5° C. per minute, the temperature being indicated by a thermocouple placed in the sand touching the tube. Temperature and pressure readings were taken every two minutes. The results of three experiments are shown graphically in Fig. 1, that showing a maximum at 400° C.

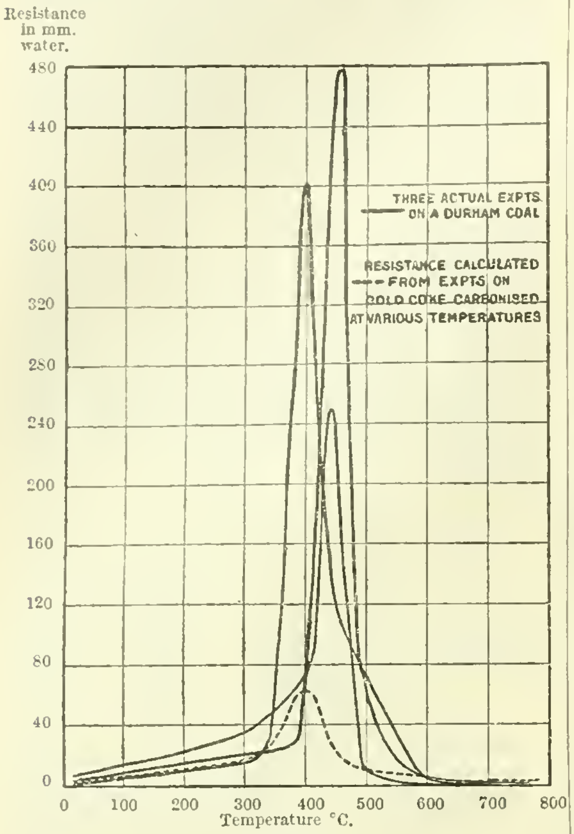

Fig. 1.

being the one used throughout in calculations as its maximum occurs at the same temperature as the maximum given by experiments on cold coke. Owing to back-pressure the rate of flow of gas from the holder slackened and flow ultimately ceased when the back-pressure was a maximum. Shortly after the flow recommenced and soon regained its initial rate.

It is clear that the coal starts swelling at 330° C., and between 380° and 430° C. is in a highly plastic condition, the resistance here being very much greater than at any other point. Immediately after reaching the maximum the plastic condition gives place to a solid cellular structure and the resistance falls rapidly. This method of investigating the physical structure of coal during carbonisation does not appear to have been used hitherto, and may, it is hoped, yield valuable results.

Porter and Ovitz have shown (*vide* Wheeler and Stopes, "The Constitution of Coal," p. 11) that taking the yield of gas at 1010° C. as 100, the amounts yielded by distillation at various temperatures are:—390°C., 6·3%; 474° C., 23·0%; 589° C., 39·2%; 705° C., 55·2%. Hence the critical point, 380°—430° C., where resistance is greatest occurs when evolution of gas is only just beginning.

The curve showing the theoretical figures for the pressures at various temperatures calculated from Table IV. is added to the graph (Fig. 1) for comparison, and enables an estimate of the actual resistance of the coal at 400° C. to be made. For present purposes we shall take M=320, when M=pressure required to force 1 c.c. of gas measured at N.T.P. through 100 cm. of coke of 1 sq. cm. cross-section maintained at 400° C.

Effect of tar.—It has been frequently suggested that during carbonisation tar distils forward and condensing on the coal in the interior of the ovens sets up a high back-pressure. This point was investigated. A tube was packed with dry coal of 0—⅜ in. to a length of 30·5 cm. and its resistance measured. It was then placed in the furnace and one end heated to 700° C., and the temperature allowed to fall steadily for a length of 10 cm., the remaining 20·5 cm. of the coal being at atmospheric temperature. A stream of gas was passed through the coal from the hot end to the cold end throughout the experiment to sweep the tar forward. When cold the resistance was again measured. Before heating M was found to be 4·21, and after heating 5·43. The value of M before heating, however, is not the one to be used to determine the effect of distilled tar only, as after heating the resistance of the first 10 cm. is altered. The resistance before heating may be approximately calculated by the aid of Table IV as follows:—20·5 cm. at 15° C.=4·21; 2 cm. at 70° C.=4·21; 2 cm. at 210° C.=4·21; 2 cm. at 350°=8·46; 2 cm. at 490° C.=1·32; 2 cm. at 630° C.=0·42; whence M=4·04.

The effect of tar in the special case studied was thus to raise the resistance by 25%. This is comparatively small and will be neglected in considering the results mathematically.

III. *Practical application of the above results.*

To visualise the progress of carbonisation it is necessary to have some record of the temperatures in the interior of the charge, and charts published by G. S. Cooper (J. Iron and Steel Inst., 1914, Vol. II.) have been selected for the purpose. By interpolation from these, Fig. 2. showing the temperatures at the 9th, 14th, and 20th hours, has been prepared.

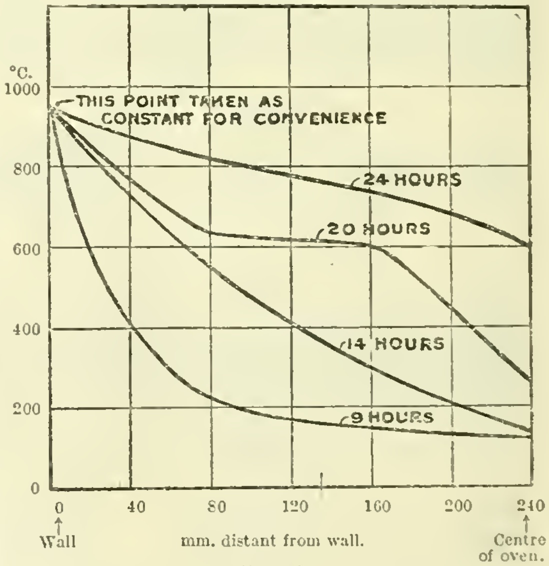

Fig. 2.

Hitherto m has been taken without reference to the length and cross-section of the material; m_t must now be re-defined for the purpose of mathematical computation as the *pressure in mm. of water required to force 1 c.c. of gas measured at N.T.P. through unit cube of the material, which is maintained at t°C.* By taking the most probable values of m_t from the previous experiments, Fig. 3, has been obtained, which shows the resistance of the several parts of the charge at the 9th, 14th, and 20th hours. This figure shows very clearly the effect of the progress of carbonisation on the resistance to the flow of gas. As coking proceeds, a layer of high resistance starts from each wall and advances continuously to the centre of the oven, which is reached about the 22nd hour. No information regarding the resistance of coke at temperatures higher than 750° C. has been obtained, but the slight increase of resistance shown near the hot wall can be assumed to be due to the fact that above 750° C. no further change in the structure of the coke takes place.

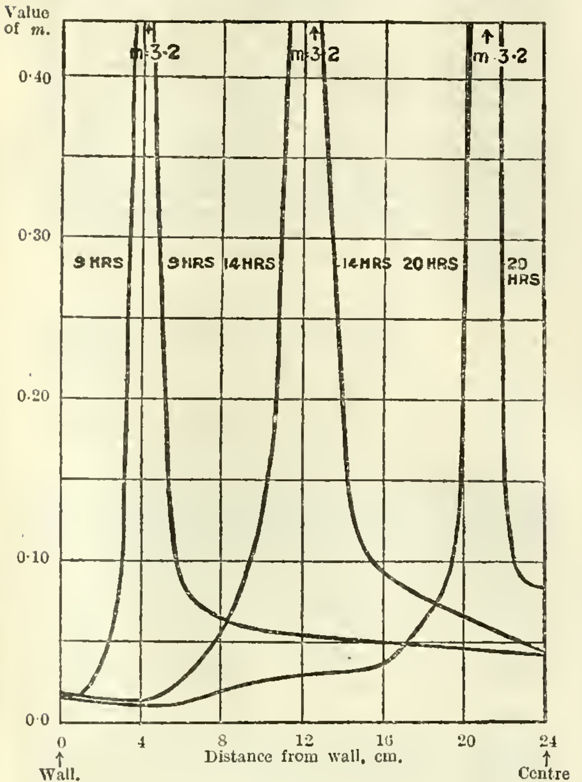

Fig. 3.

The layer of high resistance is a natural barrier dividing the charge into a zone of high temperature and a zone of lower temperature (300°—100° C.). Experiment shows (see later) that of the total gas yield roughly 5% is generated in the cool zone.

In considering the path of flow of gases mathematically only one-half of the oven will be taken (see Fig. 4), and the usual axes of coordinates will be used to describe directions.

Let the charge be divided into a number of rectangles such as A.A′, the length of which (lying along OX perpendicular to the high-resistance layer) is half the width of the oven, the height 1 cm. along OY, and the width 1 cm. along OZ. The layer of high resistance divides these into two portions, AB, BA′. In every case the suffix w will be used to denote lengths, volumes, etc., on the wall side of the layer (the hot zone), and suffix c will denote similar measurements in the centre (the cool zone).

Let the length (and therefore the volume) of each element AB $=d_w$ and of BA′ $=d_c$; the total height of charge (along OY) $=l$; mean resistance (m) of coke $=m_w$, m_c; pressure in mm. of water at any point h cm. above the oven floor $=p_w$, q_c; and quantity of gas in c.c. generated per second in each element, AB, BA′ $=q_w$, q_c.

As a simplifying assumption carbonisation is assumed to proceed in planes from the wall, *i.e.*, all points on any plane, OYZ, are at the same temperature and have the same value as m. Moreover, the effect of taper in the oven is neglected so that all points on any given plane, OYZ, are the same distance from the wall and from the layer of high resistance.

Suppose a particle of gas liberated at D, Fig. 4. It has the choice of any direction of travel lying in the plane, OXY, its actual path being determined by the resistance of the coke and the pressure. If the resistance to upward travel in the direction, OY, is greater than the resistance along either direction of the X-axis, then the first motion will be such as to convert all horizontal planes, OXZ, into isopiestic planes since the gas will take the path of least resistance. Calculation shows that this may actually take place, for the resistance to the flow of gas in an upward direction may clearly be much greater than the resistance to the flow in directions along the X-axis. That is to say, the layer of high resistance is not necessarily impervious to the passage of gas. Let v c.c. of gas pass through the high resistance layer per minute in the element, AA′ (*i.e.*, per sq. cm.) from the hot zone to the cool zone. To find the pressure at any point in the charge in the most general case, in the central (cool) zone, BA′, consider a lamina of height l, width 1 cm., and length d_c cm. At any point, h, the volume of gases passing upwards is $h(q_c+v)$.

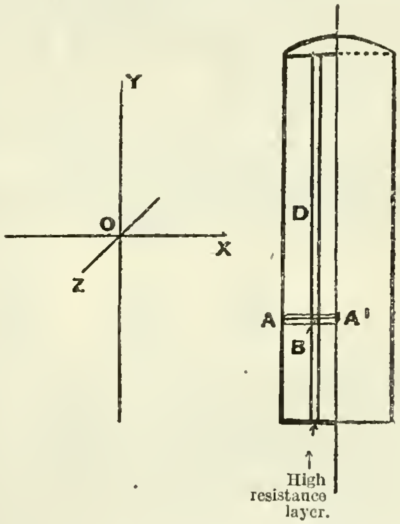

Fig. 4.

If no further gas is added to the volume at h the pressure at h is that required to force $h(q_c+v)$ c.c. of gas to the top of the charge in 1 minute, *i.e.*,

$$m_c(l-h)(q_c+v)h/d_c$$

But when the gas has reached the point $h+\delta h$ the volume is

$$(h+\delta h)(q_c+v)$$

The pressure required to force this volume of gas through a height, δh, is given by

$$\delta p=\frac{m_c(q_c+v)}{d_c}(h+\delta h)\,.\,\delta h$$

$$\therefore\ p_c=\frac{m_c(q_c+v)}{d_c}\int_h^l h\,dh$$

$$\therefore\ p_c=m_c(q_c+v)\,(l^2-h^2)/2d_c$$

Similarly $p_w=m_w(q_w-v)\ (l^2-h^2)\,/\,2\,d_w$

We may evaluate v as follows:—The volume of gas passing up any given part of the charge varies directly as the cross-sectional area and inversely as the resistance. If V_w, V_c represent the total quantity passing up the hot and cool zones respectively[*] we have

$$\begin{cases} \dfrac{V_w}{V_c} = \dfrac{d_w}{d_c} \cdot \dfrac{m_c}{m_w} \\ V_w + V_c = q_w + q_c \end{cases}$$

Whence

$$V_w = \frac{q_w + q_c}{1 + \frac{d_c m_w}{d_w m_c}} \text{ and } V_c = \frac{q_w + q_c}{1 + \frac{d_w m_c}{d_c m_w}}$$

$$v = q_w - \frac{q_w + q_c}{1 + \frac{d_c m_w}{d_w m_c}} = \frac{q_w + q_c}{1 + \frac{d_w m_c}{d_c m_w}} - q_c$$

In order to give numerical illustration the following values have been deduced from a consideration of Fig. 3.

High-resistance layer, width 4 cm. Mean value of resistance, m, per cm. cube $=1{\cdot}65$ $\therefore$ total resistance of layer, $4m=6{\cdot}6$.

Time since oven was charged :	9 hrs.	14 hrs.	20 hrs.
d_w	3cm. ..	10cm. ..	18·5cm.
d_c	17cm. ..	10cm. ..	1·5cm.
m_w	0·042cm...	0·026cm...	0·034cm.
m_c	0·058cm...	0·070cm...	0·090cm

Height of charge $=213$ cm.; length of oven $=1036$ cm.; semi-width of oven $=24$ cm.

Take first the case of dry coal giving a yield of 12,000 cb. ft. of gas per ton measured at N.T.P., the oven holding 10 tons of coal. In all cases we shall assume that between the fourth and twenty-fourth hours three-quarters of the total gases are evolved at uniform rate.

In each element, such as AA′, 4·8 c.c. of gas is liberated per minute; it has been previously mentioned that about 5% of this is evolved in the centre, hence $q_w=4{\cdot}56$ and $q_c=0{\cdot}24$ c.c.

On the assumption that $v=0$, *i.e.*, that the layer of high resistance is impermeable, at the bottom of the oven where $h=0$, and towards the top where $h=200$, say,

		9 hrs.	14 hrs.	20 hrs.
$h=0$	p_w ..	1448·0 ..	269 ..	190·0 mm. w.g.
	p_c ..	18·6 ..	38·0 ..	326·0 mm.
$h=200$	p_w ..	172·4 ..	32·0 ..	22·0 mm.
	p_c ..	2·2 ..	4·6 ..	58·2 mm.

As a difference of pressure of 6·6 mm. is sufficient to drive 1 c.c. of gas per min. through 1 sq. cm. of the layer of high resistance, it is clear that this layer cannot be regarded as an impervious medium preventing the passage of gases from the hot zone to the cool zone and *vice versâ*. It functions as a "semi-permeable" medium, allowing gases to pass through from the zone of higher pressure, but preventing the intermixture of gases in the two zones by diffusion. Thus if the pressure in the hot zone is greater than the pressure in the cool zone gas will pass through, but under these circumstances, once a particle of gas reaches the cool zone it can never pass in the reverse direction into the hot zone.

The true condition is therefore

	9 hrs.	14 hrs.	20 hrs.
$h=0$; $p_w = p_c =$ ..	375·6 ..	206·4 ..	191·2
$h=200$; $p_w - p_c =$	44·3 ..	24·6 ..	23·0
v	3·617 ..	1·06 ..	−0·10 c.c. per min. per sq. cm.

In the case of dry coal, therefore, during the first few hours most of the gas passes up the cool interior of the charge; between the 14th and 20th hours this condition of things is reversed; after about the 22nd hour the layer of high resistance coincides with the centre of the oven and the distinction between hot and cool zones disappears.

Wet coal.—The values for d_w, d_c and q_w will be taken as for dry coal; this is, of course, not strictly true, since as the proportion of water in the coal is increased the carbonisation proceeds more slowly; nevertheless, the error introduced will not affect the argument. There is no added water in the hot zone, as it is, of course, all evaporated in the cool zone. The water takes about 12 hours to evaporate if 9% is present, and about 16 hours if 12% is present; these times, of course, entirely depend on the wall temperature, and those taken merely represent a special hypothetical case. Assuming the water to come off at a constant rate, the effect is to increase q_c.

	Gases evolved in cool zone.	Water vapour from added water.	Value of q_c during evolution of water.
No water ..	0·24	nil	0·24
9% water ..	0·24	3·58	3·82
12% water ..	0·24	3·59	3·83

Further, from the experiments dealing with the effect of moisture in coal on the resistance, we can deduce by interpolation the effect of added water on the values for m_c for the coal just considered:—

	9 hrs.	14 hrs.	20 hrs.
No water; m_c ..	0·058	0·070	0·090
9% water; m_c ..	0·102	0·070	0·090
12% water; m_c ..	0·202	0·244	0·090

The effect of added water will be to increase the pressures in the charge owing to more rapid evolution of gas and to decrease the value of v:—

	9 hrs.	14 hrs.
No water; v	3·617	1·06
9% water; v	2·04	1·06
12% water; v	0·71	0·32

These facts have an important bearing on the ammonia yield. It has been found both experimentally and in practice[*] that the presence of water up to about 9% increases the ammonia yield; above this the yield commences to diminish. These facts have been hitherto explained by the assumption that up to 9% the beneficial action of the water as a diluent and negative catalyst is predominant, whereas above 9% the effect is to reduce the temperature so much that the Tervet reaction is impeded.

While no reason has been found for the fact that 9% of added water gives the maximum yield, it is evident that the previous explanation is unsound. Very little—if any—of the steam from the added water enters the high-temperature zone, as the layer of high resistance serves to keep the steam in the zone in which it is generated—the cool zone. The effect of added water is to increase the quantity of gases passing up the hot zone; this decreases the time of contact between the gases and the hot coke and thus conserves the ammonia. It also increases the possibility of the Tervet reaction taking place. If S denotes the area of the space up which the gases travel, the velocity at any point h cm. from the floor of the oven in the hot zone is $h(q_w-v)/S$. Let $t=$ time in minutes required by a particle of gas evolved at the point h to reach the free space. If the gases then travel upwards

---

[*] Gas passing up from points lower than the lamina under consideration (AA′) need not be taken into account as it will have already been distributed in accordance with the above laws and will, therefore, not affect the gas in the lamina AA′.

[*] See Gas World, "Coking Section," August, 1915, and Sept., 1915.

through an infinitely small distance, δh, the velocity may be taken as constant over this distance, hence the time taken is given by

$$\delta t = \frac{s\,\delta h}{h(q_W - v)}$$

$$\therefore\ t = \frac{s}{q_W - v}\int_h^l \frac{dh}{h} = \frac{s}{q_W - v}\log_e \frac{l}{h}$$

To compare the effect of added water on the mean time the gases remain in the hot zone, assume the coke to have a porosity of 40% (so that $S = 0{\cdot}4d_W$), and take the time of contact, t, from the point $h = 50$.

	9 hrs.	14 hrs.	20 hrs.
No water ; t	1·85	1·66	2·30 mins.
9% water ; t	0·69	1·66	2·30 ,,
12% water ; t	0·45	1·36	2·30 ,,

Hence the presence of water has considerable effect until about the 12th hour.

Fine coal.—If the theory here put forward is correct, an increase in the yield of ammonia should also result from charging the oven with fine coal, say, 0—¼ in., instead of 0—⅜ in. This would serve as a crucial test of the theory, but unfortunately a change in one condition in a coke oven cannot be effected without changing other conditions, and hence no direct evidence of a sufficiently reliable nature has yet been obtained.

If dry coal 0—¼ in. is used, the values v and t are as follows:—

	9 hrs.	14 hrs.	20 hrs.
v	1·32	—0·05	—0·20 c.c
t (at $h = 50$) ..	0·54	1·26	2·25 mins.

Path of the gases in the hot zone.—The gases will distribute themselves here in the inverse ratio of the resistances. The actual distribution can be deduced from Fig. 3.

By taking the average resistance over a series of short distances (½—1 cm.) from the wall, some idea of the relative volumes of gases flowing at different points in the hot zone can be obtained. The results are shown in Fig. 5. Here $q_W - v$ is taken as unity. If the proportion of gas flowing between the 6th and 7th cm. from the wall is found to be 0·08, this is plotted at 6·5 and so on.

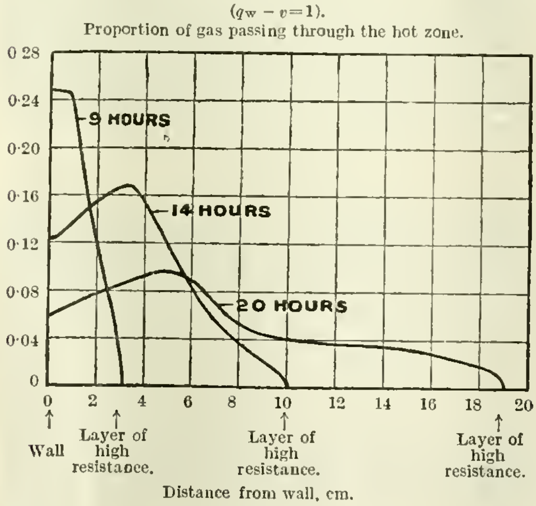

Fig. 5.

By this means we are also enabled to find the temperatures of the gas in the hot zone; this is given in Table V, where $q_W - v = 100\%$.

Table V.

9 hrs. from charging.		14 hrs. from charging.		20 hrs. from charging.	
Temp.	Vol. of gas.	Temp.	Vol. of gas.	Temp.	Vol of gas.
	%		%		%
Above 830° C.	24·9	Above 830° C.	27·4	Above 875° C.	13·7
830°–750° C.	24·9	830°–730° C.	32·8	875°–770° C.	17·1
750°–600° C.	34·7	730°–630° C.	23·6	770°–700° C.	19·0
600°–540° C.	9·5	630°–550° C.	11·2	700°–635° C.	14·0
540°–400° C.	6·0	550°–400° C.	5·0	635°–600° C.	30·1

These facts are very important in regard to the decomposition of ammonia. The reaction is so rapid at 850°—950° C. that if most of the gases passed up close to the wall very little ammonia would be recovered. The fact that this is not so supports the present theory. It is hoped in the near future to present a further communication dealing with the decomposition of ammonia under these conditions.

Resistance of fire-brick to the flow of gases.—One other point remains to be dealt with. As we have seen, theory postulates at the bottom of the oven pressures of the order of 200—400 mm. w.g. It was necessary to determine the resistance of fire-brick before accepting the theory. This was done by fixing a shaped piece of firebrick 8·37 cm. long and 5·68 sq. cm. cross-section to a piece of glass tubing. The sides of the brick were covered with a thick coating of wax. The resistance was then measured as usual.

Resistance per cm. cube, $m = 2{\cdot}61$ at 15° C. $= 55{\cdot}2$ at 1100° C. (calc.). The thickness of wall at the base of the coke oven may be taken as 12 cm., so that the total resistance is 662 mm. w.g. This resistance is so great that practically no gas leaks through the walls; the resistance of a brick rapidly increases when in use owing to deposition of carbon in the pores.

IV. *Quantity and composition of gas evolved in hot and cool zones.*

As soon as the important rôle of the layer of high resistance became evident, the interest and importance of determining the nature of the products actually evolved in the cool zone was apparent. It has been found by Burgess and Wheeler (Lewes, "The Carbonisation of Coal," p. 225) that much ammonia is formed as a low-temperature product; in every case investigated the largest yield of ammonia took place at the lowest temperature employed. The question at once presented itself: Is the greater portion of the ammonia evolved in the cool zone?

A tube was packed with 5 in. of broken firebrick at one end, and then with dry, somewhat compressed Durham coal to a length of 19·7 cm., 25·84 g. being taken in all. Each end of the tube was connected with a gas-holder (one for the high-temperature gases and the other for the low-temperature gases), the gases first passing through cotton wool maintained at 100° C. by a steam bath and then through U-tubes containing sulphuric acid, calcium chloride, and soda-lime. The firebrick was first heated, and then burners were turned on at regular intervals under the coal, starting from the end against the firebrick, so that the heat travelled along the tube at the rate of 10 cm. per hour. By manipulating the taps it was found possible to maintain a sufficiently level gauge, ±2 mm. w.g. between the ends of the distillation tube. Practically no tar was collected at the low-temperature end until the coal at this end was actually being heated. As soon as this occurred it indicated the breaking down of the high-resistance layer, and the taps at this end were, therefore, turned off. When carbonisation was complete the products were analysed.

The temperature of the firebrick was maintained at 810°—820° C. throughout, and that of the coal somewhat higher. The results are given in Table VI.

TABLE VI.

	Practical working results. %	Experimental results.	
		Low temp. end.	High temp. end.

H_2S (by wt.) ..	0·23	0·04	0·30
Gas at 15° C. and 760 mm., litres per 100 g. coal ..	30·6	1·06	21·9

Composition of gas.	% by vol.	% by vol.	Litres per 100g. coal.	% by vol.	Litres per 100g. coal.
CO_2	3·0	8·4	0·100	3·4	0·789
H_2S	—	2·4	0·029	0·9	0·216
CO	5·6	1·7	0·020	4·7	1·072
CnHm	4·3	0·5	0·006	3·4	0·789
CH_4, C_2H_6, etc. ..	28·6	52·4	0·622	33·2	7·599
H_2	57·2	14·9	0·177	53·2	12·154
N_2	1·3	19·7	0·234	1·2	0·285

About one-twentieth of the gas is generated at the low-temperature end. There is no evidence that ammonia is formed in any quantity in the cool zone, but it is interesting to note the large proportion of fixed ammonia from this zone, which may indicate that organic chlorine provides no inconsiderable portion of the chlorine which goes to the formation of ammonium chloride.

Another interesting fact is that half of the total free nitrogen is found in the gases from the cool zone. Much of this may have been due to occluded gases.

Summary

1. The laws governing the flow of gas through coke and crushed coal are found to be similar to those governing the flow through capilliary tubes and follow the law

$$V = kpS/l\eta$$

where V = volume of gas of viscosity η passed through l cm. of coke etc., of cross-sectional area S, per minute; k is a constant, depending on the nature of the porous material, and p in the pressure difference between the ends of the tube of material through which the gas is passing.

2. At higher temperatures, t, the viscosity of the coal gas used is given by

$$\eta_t = \eta_0 (1 + \alpha t)^{0.897}$$

where

$$\eta_0 = 1{\cdot}47 \times 10^{-4} \text{ and } \alpha = 0{\cdot}003665.$$

3. The resistance of crushed coal to the flow of gas increases when compression is used, but the increase is only slow after the first 2 or 3 falls of the stamper leg.

4. Finer coal when compressed has considerably higher resistance than dry coal; in the case studied coal of 0—¼ in. size offers a resistance 8½ times greater than that offered by coal of 0—⅜ in. size.

5. Water added to the coal increases the resistance. When over 9% is present the rate of increase of resistance with water added becomes rapid. This is especially noticeable with finer coal.

6. The resistance of coke to the passage of gases depends on the temperature of carbonisation reaching a maximum at about 400° C. in the case of Durham coal.

7. A new method of investigating the physical structure of coke during carbonisation has been used, and showed that in the case of a good coking coal the material is in a viscous plastic state at a temperature provisionally given as 380°—430° C. While in this state coal has a much higher resistance to the flow of gases than at any other temperature.

8. The internal conditions in the charge during coking are as follows:—Near the wall there is coke offering a low resistance. The oven is divided into hot and cool zones by a layer of semi-fused material of high resistance which is at a temperature of approximately 400° C. Gas is able to pass through this layer owing to the difference of pressure obtaining in the hot and cool zones. When it has passed through, however, it cannot diffuse back, and the layer mentioned may be considered as semi-permeable.

9. Whether the gases pass up the hot or cool zones is conditioned by the time which has elapsed during charging, the size of coal used, the moisture content, etc.

10. Added water does not in general conserve ammonia by acting as a diluent or as a negative catalyst. It remains for the most part in the cool zone, and its effect is to lessen the time of contact between the gas and the hot coke. Fine coal has a similar effect.

11. The path of gases in the hot zone is conditioned by the resistance of the coke, and only a small proportion of the gases is actually subjected to the fiercest heat in the oven.

12. About one-twentieth of the gas is generated in the low-temperature zone. This gas contains half the total free nitrogen and 7—8% of the total ammonia.

13. Formulæ have been deduced for the pressure at any point in the charge, and for the time taken by a particle of gas to travel to the free space from any point in the charge. The time taken under any given conditions depends on whether the particle is in the hot zone or the cool zone.

Note.—Throughout this paper no account has been taken of the shrinkage and cracking of the coke which occurs. This would, of course, alter the conditions of flow and cause a much greater proportion of the gases to travel in the hottest parts of the oven. This shrinkage, however, only takes place towards the end of the coking period, hence it has been neglected, but the argument has not been extended beyond the twentieth hour, up to which it is apparently valid. Coal when in the plastic state exerts an outward thrust tending to prevent shrinkage from the walls.

APPENDIX.

A more extended investigation into the formation during carbonisation of the layer of high resistance mentioned in the foregoing paper has been made, using the method already described. The temperature at which the resistance to the flow of gas becomes greatest—the temperature of maximum plasticity—is found to depend on the character of the coal. Non-coking coals do not show any appreciable increase of resistance during carbonisation; they do not fuse. Poor coking coals only show low maximum in the curve, and under proper conditions it is probable that the maximum pressure recorded will be a measure of the coking power of the coal and the method may prove more reliable than the unsatisfactory Campredon test.

The temperature of maximum plasticity is lowest in coals containing most volatile matter, though this statement must not be taken too literally. In general, coals with about 30% of volatile matter show a maximum at 400°—470° C., and Welsh coals with only 15—20% of volatile matter have maximum plasticity between 500° and 520° C. In addition, all the Welsh coals tested show a second much smaller subsidiary maximum between 540° and 580° C. Anthracitisation has resulted in the destruction of the more easily decomposable substances, or possibly in their partial destruction, the products formed having a high decomposing point.

The temperatures given for the beginning and ending of the plastic state are taken from the curves obtained. It is probable that a negligibly small proportion of the resin substances commences to fuse at temperatures below those given; likewise the same limitations will apply to the temperatures at which the plastic state is said to end. The results are shown below:—

Coal.	Temperatures between which coal is in the plastic state.		Temperature of maximum plasticity, ° C.	Character of coal (distillation results).

SOME PRACTICAL APPLICATIONS OF THE THEORY OF BIOLOGICAL PURIFICATION OF WASTE LIQUORS.

BY GUY T. P. TATHAM, B.SC.

The recently published paper by McGowan on the bacterial purification of trade wastes (J., 1921, 148 T) is of particular interest to chemists and engineers engaged in the purification of waste liquors, in that an attack is made on the problem of finding the capacity of plant required to treat various trade wastes as compared with that needed to deal with an equal volume of domestic sewage. The purification of domestic sewage being a universal problem, in the sense that it arises in every town which does not happen to lie on the sea coast, general experience enables the engineer to state by empirical rules the capacity of filters necessary to deal with a known flow of sewage of given strength in order to produce an effluent of standard quality. A trade waste presents a particular problem which cannot be solved in an empirical way, experience being insufficient. McGowan's paper is of special interest also to the author in that some five years ago he worked out in general terms the essential factors of the biological purification of any waste liquor ("Some theoretical considerations bearing on the performance of biological sewage purification plant," J., 1916, 711—715). Since that date, time and circumstances have not permitted of the experimental work necessary to apply the general theory there elaborated to particular problems, or to test the degree of accuracy with which the formulæ arrived at represent the facts; they can, however, be applied to elucidate in the theoretical way many of the points raised by McGowan, and, apart from the interest which always attaches to comparison of theoretical with experimental results, the application suggests important lines of enquiry.

The purpose of this paper is to apply the general theory to the experimental results arrived at by McGowan, taking note of points which seem to call for further investigation.

The general theory being developed in the mathematical way, it will be advisable in the first place to give in non-mathematical language a brief resumé of the original paper, where proofs of the results quoted will be found.

Summary of the general theory of purification of waste liquors.

The "mean time of contact" is defined as the average time that a particle of liquor remains in the purification apparatus. After working out the method of obtaining the mean time of contact from salt curves a number of these curves obtained by the Officers of the Royal Commission on Sewage Disposal at the experimental station at Dorking were discussed and it was pointed out that the general shape of the curves for a percolating filter resembles the graph of a well-known mathematical equation, which we will call the equation of the salt curve.

Furthermore, the well-established fact that the result of the five days' aeration test does not depend on the dilution used in making the test involves the corollary that the progress of the oxidation follows the same law as a "reaction of the first order" of chemical theory. That is to say, if we take as the measure of the pollute in a waste liquor the oxygen required for its complete oxidation, the rate of absorption of dissolved oxygen is proportional to the concentration of the pollute, or is equal to α times the concentration of the pollute. The coefficient α, which is characteristic of the liquor, is termed the "avidity constant." It is the numerical measure of the activity of the biological oxidation, or of the greed of the liquor for oxygen, and depends on the kind of liquor with which we are dealing and the circumstances under which the oxidation takes place, *e.g.*, coke percolating filter, or aeration bottle, but does not vary with the changing concentration of the pollute.

Using the law of the progress of the oxidation in conjunction with the equation to the salt curve for a percolating filter, it is shown that the percentage purification attained by the effluent and the mean time of contact are connected by an equation involving besides these two variables only the avidity constant; consequently for any waste liquor it is only necessary to determine the avidity constant and decide the degree of purification desired: the necessary mean time of contact can then be calculated, or read off from the tables provided, and the plant has to be designed to give the indicated mean time of contact.

To summarise—the important quantity which characterises a waste liquor is its avidity constant.

Application of the foregoing theory to the experimental results obtained by McGowan.

Since the oxidation of a waste liquor shut up in an aeration bottle progresses as a reaction of the first order, we can use the equation for such a reaction to calculate the ratio (A:B) of the dissolved oxygen absorbed in five days (A) to that required for complete oxidation (B), provided we know the avidity constant for oxidation in the aeration bottle under the conditions of the experiment; conversely the ratio A:B will give the avidity constant. Having given the avidity constant we can also find approximately the minimum time which should be allowed for completion of the long aeration, a period which is put at not less than three months in the paper. The ratio A:B is given for a number of waste liquors, so we can perform the calculations and compare results with the figures obtained by experiment.

For convenience let us denote the avidity constant for oxidation in an aeration bottle at 18° C. by β. It is necessary, also, to define the end of the long aeration by a convention, since the oxidation is theoretically never quite complete; it is a reasonable approximation to take 98% of total oxidation as marking the end of the long aeration, seeing that an experimental error of 2% is quite permissible in this determination.

Adopting this convention the results are as shown in the following table:—

A : B.		β		Time required to complete the long aeration.
1 : 2	..	0·0058	..	28 days
2 : 5	..	0·0043	..	38 days
1 : 3	..	0·0034	..	48 days
1 : 4	..	0·0024	..	68 days
2 : 9	..	0·0021	..	77 days
1 : 5	..	0·0019	..	86 days
1 : 10	..	0·00088	..	185 days
1 : 50	..	0·00017	..	960 days
1 : 100	..	0·000084	..	1940 days

Most of the liquors examined showed a ratio A:B between 2:5 and 1:5, so that the suggestion that three months should suffice to complete the long aeration is borne out by the above figures.

When McGowan's figures for the long aerations of the distillate from spent lees are examined in the light of the above table, the discrepancy noted between the duplicates is hardly remarkable in view of the slowness of the oxidation and the implied feebleness of bacterial life.

We have at present insufficient experimental data to find the relation between the avidity constant for the oxidation of a liquor in a percolating filter and that for the same liquor in an aeration bottle, but by making certain reasonable assumptions we can arrive at interesting provisional results which encourage further investigation.

For instance, if α be the avidity constant for the oxidation of a certain liquor in a percolating filter and β that for the same liquor in an aeration bottle, one would be inclined to expect that α and β bear an approximately constant ratio one to the other.

To get an idea of this ratio we may suppose the case of a sewage of which the dissolved oxygen absorption in five days is 30, that of the corresponding effluent 2, and the mean time of contact in the percolating filter 7 hrs. (Here again experimental data are rather meagre.)

The tables show that for such a sewage the value of α is 0·82.

Taking the ratio A:B as 1:3, β is 0·0034, so that the ratio $\alpha:\beta$ is about 240:1, that is to say bacterial activity in the percolating filter is 240 times that in the aeration bottle.

Turning to a case cited by McGowan, viz., a waste liquor from cotton dyeing and printing, for which the dissolved oxygen absorption in five days was 25, and the ratio A:B::1:4, we see that β is 0·0024, and on the assumption that α is 240 times β we get 0·576 as the value of α.

By reference to the tables we see that to purify this liquor so that the dissolved oxygen absorption of the effluent in five days shall be 2, that is to give 92% purification, the mean time of contact required is 8·8 hrs.

Furthermore, we may enquire as to the "strength"* of the sewage to which the cotton printing waste is equivalent, in the sense in which the word is used by McGowan. By giving a sewage for which α is 0·82 a mean time of contact of 8·8 hrs. we get a percentage purification of 95·4; if the dissolved oxygen absorption of the effluent in five days is 2, it follows that that of the original sewage must have been 43·5; a sewage of 43·5 is therefore equivalent to the cotton printing waste of 25 in the sense that treatment in a percolating filter giving a mean time of contact of 8·8 hrs. will in each case give an effluent with a five days' figure of 2.

If we repeat the calculation, working this time to an effluent for which the five days' figure is to be 4, we find our cotton printing waste is equivalent to a sewage of 39·5; so that, although the strength of domestic sewage which is to be regarded as equivalent to a given waste liquor varies somewhat with the quality of the effluent to be turned out, this variation is too small to be of practical account.

The University, Leeds.

---

* This definition of strength was used by McGowan about 1910; *vide* Fifth Report of the Royal Commission on Sewage Disposal, Appendix IV, p. 1, et seq.

PROCEEDINGS OF THE

FORTIETH ANNUAL GENERAL MEETING,

Montreal, August 29th, 1921.

The fortieth annual general meeting of the Society was held in the Chemistry Building, McGill University, Montreal, on August 29.

Sir Charles Fitzpatrick (Lieutenant-Governor of the Province of Quebec) extended a hearty welcome to the overseas and American members in the name of the Province of Quebec. He also brought a personal message from the Prime Minister of Canada, who had asked him to say how glad he was to welcome them to the Dominion. After referring to the great services rendered by British and American scientists in the war, he said that the problems of the past had been solved, temporarily at least, but the problems of the immediate future were peace problems, and scientists could do much to solve them. Canada was faced with difficulties geographically and ethnologically, and they wanted not only farmers and settlers, but scientists, to come and help them in those difficulties, to understand them, and help in their solution.

The American who came to Canada brought money, enterprise, and energy, and helped in the development of Canadian resources, and he also stayed to see that his investment prospered. Unfortunately, Englishmen in the past had been content to send their money into the country and leave it for other people to look after. In conclusion, he said that McGill University felt honoured by the presence of so many distinguished guests. McGill was synonymous with the public spirit and the munificence of the merchants of Montreal. In that province the universities were not State-owned or controlled. They were left to the control and the management of those who know something about university work, and it was for the State to cooperate with them.

Prof. Watson Bain extended a cordial welcome to the visiting members on behalf of the Canadian Institute of Chemistry.

Sir William Pope said that the very eloquent terms in which Sir Charles Fitzpatrick and Prof. Bain had welcomed the Society of Chemical Industry were a mere verbal expression of the hospitality they had enjoyed in the fullest measure during the past ten days. The reception given to the overseas visitors both in Quebec and in Montreal had been completely overwhelming both in its cordiality and in the lavishness with which both time and effort had been expended. The welcome just extended to them had, he was sure, greatly impressed all the overseas visitors, and it would be futile for him to attempt to depict in an intelligible way the feelings which actuated all of them and which had actuated them since they had arrived.

Over a year ago it had been decided to accept the invitation of the Canadian members to hold the annual meeting of the Society in 1921 in Canada. At that time it had been confidently anticipated that the English visitors would number hundreds. No one had foreseen the difficulties, economical, industrial, and political, which surrounded the British Empire, and more particularly the conditions at home at the present moment; and in consequence of the disturbed industrial conditions of the mother country their party, instead of numbering hundreds, numbered only a score or so. However, the party that had come over was a very representative one, but it consisted largely of the younger members active in the Society. Practically none of the senior members of the Society who had done so much in developing its resources during the last 25 years were present, but while they deplored their absence they might congratulate themselves that those who had come were among those who would control and develop the best that was in the Society for the next 25 years. One member of the Society whose absence they particularly deplored was the President of the Société de Chimie Industrielle, M. Paul Kestner; he had accepted the invitation to be with them, but affairs in France were similar to those in Great Britain and at the last moment he had had to draw back, greatly to his regret.

In conclusion he tendered to the Lieutenant-Governor and to Prof. Watson Bain and to all those individual members who were present the thanks of the Society for the very cordial manner in which they had welcomed them and for the magnificent manner in which they had entertained them during the past ten days.

Sir William Pope then took the chair. The minutes of the 39th annual meeting held at Newcastle having been taken as read, Dr. F. M. G. Johnson and Dr. G. S. Whitby were appointed scrutineers for the ballot for members of Council, and the ballot was closed.

The President then delivered his address (see Journal for August 31, 1921, p. 179 T).

Dr. R. F. Ruttan, in moving a hearty vote of thanks to the President for his scholarly address, said that they were all glad to know that the Journal of which they were so justly proud was to be still further developed and improved, and that the finances of the Society were sound. He also alluded to the great interest that Dr. Messel had taken in the welfare of the Society of Chemical Industry. As one interested in the field of organic and biological chemistry, he (Dr. Ruttan) had been particularly struck by the new note sounded in the President's address, which pointed to the development of industrial chemistry along the lines of biological chemistry. The activities of biological chemistry had hitherto been confined to helping out the biologist and the physiologist in the study of medicine and disease. They now saw a prospect of this growing and a very scientific branch of chemistry reaching out into the industries and being of actual value in the production of technical products. The contrast shown between the biological methods of production of organic substances and the German synthetic method was very well illustrated by the processes carried out in Canada for the manufacture of acetone by means of the Weizmann or Fernbach method. After the work had been established, they had succeeded in Toronto in turning out between three and four tons a day of acetone, besides a larger quantity of methyl alcohol. On the other hand, at Shawinigan Falls a synthetic process for making acetone and acetic acid from the elements in the form of coke and water had been perfected. The result was that they had been able to turn out during the war from eight to ten tons of acetone and twenty to thirty tons of acetic acid per day.

The solidarity of the British Empire was fully appreciated by all Canadians. The League of

Nations was a golden dream. The British Empire was a league of nations which was a solid reality and had developed from 300 years of experience. No constitution had yet been written for this league of nations—probably no constitution would ever be required—because it was bound together by ties which were invisible but strong, ties of loyalty and affection to the mother country and to the fellow-components of the Empire.

He had much pleasure in tendering to the President the hearty thanks of the meeting for his very delightful address.

Mr. H. W. Matheson seconded the motion, which was carried unanimously, and Sir William Pope replied briefly.

The Report of the Council was then taken as read.

Report of Council.

During the year ending July 31, 1921, the Council has held 10 Ordinary Meetings, and the following Committee Meetings have been held: Emergency, 3; Finance, 24; Publications, 19; Transactions and Abstracts Sub-Committee, 6; Review Sub-Committee, 6; General Purposes, 10; Technical Research and Allied Societies, 4; Government and Parliamentary, 2; in addition to these the Finance Committee has held 6 joint meetings with the Emergency Committee and one joint meeting with the Publications Committee.

The number of members on the Register at July 31, 1921, was 5654, as compared with 5612 last year.

Since the last Annual Meeting 467 members have been elected, 5 former members have been restored to membership, and the losses have been 430.

The Council regrets to record the death of 59 members (of whom 8 were original members), viz.: Charles E. Acker, Marcus Allen, Henry Bassett, Alfred E. A. Bettesworth, Soren H. Blichfeldt, Bertram Blount, David Brown, Dr. J. C. Cain, W. J. Chrystal, Lawrence Crawford, James Cuming, Junr., Alexander Cunningham, Fred F. Cutler, James Dore, Dr. Louis A. Dreyfus, B. P. Ducas, William Foster, Major John Garroway, Joseph W. Gilby, Armand Goffin, John R. Griffin, G. Luigi di Guelpa, George E. Hall, William A. Haward, Ernest G. Henderson, F. Wise Howorth, J. M. Irving, Frederick G. Kidd, Prof. E. Kinch, Alfred J. King, John Kinghorn, John W. Leitch, Dr. H. R. Le Sueur, Sir J. M. MacCallum, James H. Millar, Prof. E. J. Mills, F.R.S., Charles C. Moore, Dr. Russell W. Moore, Rt. Hon. Lord Moulton, K.C.B., F.R.S., Robert Parkin, J. D. Pennock, Herbert B. Ransom, Walter E. Rowley, John Ruffle, Albert F. Seeker, Dr. John Shields, Bertram J. Smart, H. J. Staples, Robert Tervet, Oswald J. D. Thomas, Fred. C. Tipler, Charles E. Watson, Frederick A. White, J. B. Wilkinson, David T. Williams, Peter Williams, Leonard P. Wilson (Chairman of the Birmingham Section and a Vice-President of the Society), Arthur Wingham, Dr. John H. Yocum.

Sir Wm. J. Pope's year of office as President of the Society expires after the Annual General Meeting, and, in view of the Annual Meeting in Canada, the Council requested the Canadian Sections to suggest one of their members for nomination to the office for 1921–22. The Sections proposed Professor R. F. Ruttan, Director of the Chemistry department, McGill University, Montreal; and the Council has nominated him for election at the Annual General Meeting.

Mr. E. V. Evans and Professor Henry Louis have been re-elected Hon. Treasurer and Hon. Foreign Secretary respectively.

The Council invited the Canadian Sections to nominate a Vice-President in place of Prof. Louis, who had been elected to the office of Hon. Foreign Secretary. The Sections nominated Mr. T. H. Wardleworth, who was duly elected for the remainder of Prof. Louis's term of office.

Sir John Brunner, Bart., was elected a Vice-President in place of the late Mr. L. P. Wilson.

Sir Wm. J. Pope, K.B.E., has been nominated a Vice-President, and to the other vacancies caused by the retirement of four Vice-Presidents Mr. Julian L. Baker, Mr. C. S. Garland, and Mr. Max Muspratt have been nominated.

The Council accepted with deep regret the resignation of Mr. W. J. A. Butterfield as an ordinary member of Council, and Mr. W. J. U. Woolcock, C.B.E., M.P., was elected an ordinary member for the remainder of Mr. Butterfield's term of office.

Four ordinary members retire from the Council, and to fill the vacancies thus created nine nominations have been received; a ballot will therefore be taken.

Dr. J. A. Cranston has been appointed Hon. Secretary and Treasurer of the Glasgow Section in place of Dr. G. S. Cruikshanks, resigned.

The following Chairmen of Local Sections retire: Mr. E. Walls (Bristol), Dr. D. S. Jerdan (Edinburgh), Dr. E. F. Armstrong (Liverpool), Mr. Julian L. Baker (London), Mr. John Allan (Manchester), and Mr. C. R. Hazen (Montreal). The following have been elected to succeed them respectively: Mr. C. J. Waterfall, Dr. H. E. Watt, Dr. G. C. Clayton, Mr. E. V. Evans, Dr. E. Ardern, and Mr. H. W. Matheson.

The following Hon. Secretaries of Local Sections retire: Dr. F. W. Rixon (Bristol), Dr. A. Holt (Liverpool), and Mr. G. D. McIntyre (Montreal). The following have been elected to succeed them respectively: Mr. A. Marsden, Mr. E. Gabriel Jones, and Mr. Wm. P. Dickson.

The Council desires to express its cordial thanks to the retiring officers for their services to the Society.

Sir Wm. J. Pope, K.B.E., and Professor Louis were elected Honorary Members of the Société de Chimie Industrielle of France.

Mr. John Spiller was elected by the Council an Honorary Life Member of the Society.

At the request of the Canadian Section, and of its three branches, the Section was dissolved and separate Sections were established at Montreal, Ottawa, and Toronto. A new Section has also been formed at Shawinigan Falls; so that the Society has now five Canadian Sections, namely, at Vancouver and at the four centres above mentioned. There has been formed an Executive Committee for Canada, consisting of the Chairmen and Secretaries of the five Sections, to arrange for the Annual Convention of Chemists and to take charge of matters affecting chemical industry that require action by the Dominion Government.

The Committee of the London Section presented to the Council for the general purposes of the Society the sum of 200 guineas out of funds which they had raised in connection with the Annual Meeting of the Society in 1919.

The Council has approved a resolution of the Glasgow Section to admit "Associates" to meetings of the Section at the nominal subscription of 5s. per annum. Associates are not entitled to be supplied with the Journal, have no voting powers, and are not eligible for election to the Sectional Committee.

A proposal has been received from the Chemical Society suggesting co-operation with the Society of Chemical Industry through the medium of the Local Sections of the latter Society. The Council has cordially approved the proposal, but before adopting the working procedure is consulting the Local Sections.

The Council has been approached with reference to the formation of another Subject Group.

In accordance with the Resolution passed at the last Annual Meeting the subscription payable by members is now £2 10s., and the Council has raised the subscription to the Journal payable by non-members to £4 4s. as from 1st January, 1921.

The scheme devised by the Council for the admission of members joining under the age of 25 at a reduced subscription was approved at the last Annual Meeting and has been taken advantage of to a considerable extent during the past year.

At the request of the Committee of the American Section, and for the convenience of members in the States, an account has been opened with the National City Bank of New York. American members may at present pay $10, as the amount of the annual subscription, to the Hon. Treasurer of the American Section, and these sums are paid by him into the account with this bank. The account is only operated on by the Council through its bankers in London.

The cordial invitation which was received from the Canadian Section to hold the Annual Meeting for 1921 in Montreal was unanimously accepted at the last Annual General Meeting.

At the same time an invitation was accepted to attend the Annual Meeting of the American Chemical Society, which will be held in New York early in September, and to visit the National Exposition of Chemical Industries which will be held in that city immediately thereafter.

The Council has received an invitation to hold the Annual General Meeting in 1922 in Glasgow, and recommends its acceptance.

The audited Balance Sheet and statement of Income and Expenditure for the year ending 31st December, 1920, which have already appeared in the Journal for June 30, will be laid before the Annual General Meeting.

The late Dr. Rudolph Messel, F.R.S., by his will left to the Society one-fifth of the residue of his estate subject to the payment of certain life annuities (*See* Journal, Volume 39, page 229 R). The executors have handed over to the Society Certificates and Bonds representing the following Trustee securities:—

£15,104 8s. 3d.	5% War Loan 1929–47.
720	London Electric Railway 4% Deb. Stock.
600	North Eastern Railway 4% Gteed. Stock.
1,000	Metropolitan Water Board Grand Junction 3½% Deb. Stock.
1,580	Metropolitan Water Board Staines Reservoir Joint Commission 3% Gteed. Deb. Stock.
200	London and North Western Railway 4½% Pref. Stock.
1,200	Exchequer 3% 1930 Bonds.
400	Birkenhead 5% 1924–34 Bonds.

The total value of these Securities as at July 28 is about £17,000, and the income receivable from them is £955 per annum.

The Council has under consideration the question of how the income should be appropriated, and has meanwhile resolved to arrange for the institution of a Memorial Lecture, and for the award in connection therewith of a Messel Gold Medal, to perpetuate the name of the Donor of the Fund, such Medal to be accompanied by an honorarium. A scheme for giving effect to this Resolution will be prepared next Session, and further means of applying the income will be proposed in due course.

The settlement of Dr. Messel's affairs has now been completed, and there is payable to the Society the further sum of £969 2s. 10d. in cash, and £370 5% War Loan is being transferred into the name of the Society.

On the deaths of certain Annuitants the Society will become entitled to one-fifth of other funds which have been set apart to provide the annuities.

The adoption of the new By-Laws at the last Annual Meeting was unanimously confirmed by an Extraordinary Meeting of the Society held on 9th August, 1920.

The Journal for 1920 contained 1636 pages of text (Review 448, Transactions 348, Abstracts 840), compared with 1866 in 1919. Advertisements: 1246 pages in 1920, 1298 in 1919.

Volume V of the Society's Annual Reports on the Progress of Applied Chemistry has been published this year, and the Council agreed to allow a considerable reduction in the price to purchasers of the set of Volumes 2 to 5. Volume 1 has long been out of print.

The Council agreed that after the issue of the Journal for 31 December last, authors of papers appearing in the "Transactions" should receive 50 reprints gratis. The Council is glad to have been able to return to the practice formerly in vogue but interrupted by stress of circumstances arising out of the war.

The Council decided to increase the present rate of Abstractor's Fees by 50% from the beginning of 1921.

A list of the Committees of the Council, with the names of the Chairmen and members in each case, is given in the Journal, Vol. 40, Page 3 R.

Mr. S. H. Davies resigned his membership of the Publications Committee.

With a view to expediting business and coordinating the preparation of the Society's publications, the duties which have hitherto been carried out by the Publication Committee and its three Sub-Committees, "Transactions and Abstracts," "Review," and "Annual Reports," were transferred to the "Publications Committee," consisting of twelve members of the Council, who have been given power to co-opt additional members who are not on the Council.

The Publications Committee has drawn up a very complete panel of referees to advise on the suitability of papers submitted for insertion in the "Transactions."

A communication was received from the Conjoint Board asking whether the Council would desire to make application to the Government for a Grant in aid of publishing the Society's Journal, and it was decided that it was undesirable to do this; but the Council has made through the Board an application for financial assistance in defraying the expense of a Collective Index to the Journal for the years 1906 to 1920 inclusive. The result of this application is not yet known.

The President submitted a Statement which he had prepared on behalf of the Federal Council for Pure and Applied Chemistry embodying suggestions for the promotion of closer co-operation between the Society of Chemical Industry and the Chemical Society in the matter of publications with the view of thereby effecting greater economy and increased efficiency. The Council nominated the President, Mr. Evans, Dr. Keane, and Dr. Miall to confer with representatives of the Chemical Society.

On the suggestion of the Institute of Brewing, the Council agreed to take joint action with the other Chemical Societies in approaching the Postmaster-General regarding reduction in the rate of postage on chemical journals.

A joint meeting of the Society with the Institution of Mechanical Engineers was held on 4th March, when Monsieur Paul Kestner read a paper (see Journal, Volume 40, page 67 T). This meeting was so successful that it is intended to hold another joint meeting of the Society and the Institution during next session.

The Council regrets that no essay was received in response to the generous offers of a prize from Messrs. Cross and Bevan, and of a Fellowship from Sir Thomas P. Latham, Bart., of Weybridge. The donors have put forward an alternative scheme which has been approved by the Council, and particulars of this will be announced in the Journal in due course.

The Council has renewed for 1921 its donation towards the expenses incurred in connection with the extension scheme of the Chemical Society's library.

A list of the Society's representatives on Outside Bodies is given in the Journal, Vol. 40, Page 3 R. To this list the following should be added: Imperial College of Science and Technology (Board of Governors), Sir Wm. Pearce, M.P., in succession to Dr. C. C. Carpenter, resigned.

A Conference on the Standardisation of Chemical Plant was held at the Institution of Civil Engineers in July, 1920. It was attended by representatives of Government Departments and of scientific bodies interested, including the Society of Chemical Industry. It was unanimously recommended that a Chemical Engineering Committee of the British Engineering Standards Association should be set up, and this was subsequently approved. The representatives of the Society on this Committee are Prof. Hinchley, Capt. Goodwin, Mr. Reavell, Mr. Garland, and Dr. Ormandy.

The Council appointed Mr. J. L. Baker, Mr. F. H. Carr, and Dr. Bernard Dyer as its representatives to confer with the authorities of the National Physical Laboratory regarding the "Tests of Graduated Glassware" carried out at the laboratory; and Dr. S. Miall was elected to represent the Society on the Council of the Exhibition to be held in April, 1922, by the Coal Smoke Abatement Society.

Following a communication received from the British Chemical Ware Manufacturers' Association, a resolution was passed by the Council to the effect that legislation to restrict the importation of foreign chemical, scientific and illuminating glassware is urgently needed in the interests of members of the Society as consumers, and of the nation in general, in order that the industry may be retained in this country; and this resolution was forwarded to the President of the Board of Trade.

A communication was sent to the Board of Trade drawing attention to points in the Dangerous Drugs Act which would tend to prevent or restrict the scientific development of research in the particular class of substances to which the Act refers, and emphasizing the importance of unrestricted scientific research in the preparation of new synthetic drugs.

The Council has been informed by the Institution of Civil Engineers that the Civil Engineers (Registration) Bill will not be proceeded with (*see* Annual Report, 1920).

Mr. Wardleworth, in moving the adoption of the Report, said that it was entirely satisfactory.

Dr. Milton Hersey, in seconding the motion, said that the Report again indicated how closely the Council attended to the business of their Society. The whole Report was indicative of most careful attention.

The Report was then adopted.

The President said that unfortunately their Treasurer, Mr. Evans, had not been able to attend the meeting, although until the last minute he had fully intended to do so, and he had cabled his regrets at not being able to be present.

Hon. Treasurer's Statement.

I am able to report to you that for the first time since 1917 there has been a slight excess of income over expenditure in the Society's accounts. Although this position is one which may be viewed with satisfaction, as it may be taken to represent the first signs of recovery of the Society's financial position, yet it should be realised that this result is the outcome of an increase in the Society's income from unusual sources and of the exercise of the strictest economy in the control of the Society's finances.

Examination of the balance sheet (see Journal of June 30) will show that there are two items on the income side of the account which are special to this year. One of these is the rebate of three years' income tax, which amounts to £685 8s. 5d., whilst the other is the generous gift of 200 guineas received from the London Section, and it is these two items which have to a large extent enabled the Society to show a credit balance. At the same time the policy of those who controlled expenditure has been to practise economy as far as was consistent with progress, and it is hoped that the services of the Society to its members and its contribution to the advancement of applied chemistry have not been affected adversely by the strict control which has been maintained over expenditure. The Council has throughout realised that a Society of the magnitude of ours cannot hope to keep abreast of the times and remain of real service to its members if its activities are restricted for want of money. It was on this account that the Council looked so gravely upon the Society's financial position last year, and in consequence decided, but with great reluctance, to increase the subscription. This increase in subscription had not begun to bear fruit at the time of closing the present accountancy period, but the additional income accruing therefrom should appreciably help in promoting the recovery of the Society's financial position. When it is realised that it was only 18 months ago that the finances of the Society were in such a serious position, I am sure you will agree with me that great credit is due to the Council and the Finance Committee for the way in which they laid the foundations of our financial recovery.

The munificent bequest of the late Dr. Messel will aid the Council in their efforts to be of greater and greater service to the cause of applied chemistry. As your Treasurer, I welcome their decision to allow the major portion of the Messel Fund to accumulate, at least for the moment, and I feel that you will be in agreement with their decision to convert non-trustee securities (which cannot be held by our Society) to 1929/1947 5% War Loan. Whilst referring to the Messel bequest, I should like to take this opportunity of thanking the Hon. Treasurer of the Royal Society, Sir David Prain, for the help he has afforded us in the matter of this joint bequest.

It will be seen that the depreciation on the purchase price of investments has now attained the high figure of 36·5%. This depreciation of our assets, which set in at the commencement of the war, has increased year by year, but it is hoped that the maximum has now been attained. Unless the world-wide slump in trade is found to be even more serious than it would appear to be at the present moment, there should be a slight appreciation of our investments in the present year.

I am pleased to report to you that the creation of the Advertisement Department of the Society has already shown itself to have been a sound proposition, the revenue from advertisements, after deducting full working expenses, having been greater than that obtained when operating through outside agents.

In conclusion, I wish to express my indebtedness to the Council and the Finance Committee for their valuable assistance and advice in all matters relating to the finances of the Society.

Mr. C. S. Garland said that on the last occasion that he had the pleasure of proposing the adoption of the Report and balance-sheet it had been a very different document from the one now under review. He had then had to congratulate the Treasurer on his courage in writing down the value of the Society's investments to market price, and he was glad to see that policy continued. He had much pleasure in moving the adoption of the excellent balance-sheet.

Mr. M. L. Davies seconded the adoption of the Report, which was carried unanimously.

Election of Auditors.

Mr. E. A. Alliott moved that the present auditors, Messrs. Price, Waterhouse and Co., of London, be re-elected. Mr. A. E. McRae seconded the motion, which was carried.

Vote of Thanks.

The President proposed a vote of thanks to the authorities of McGill University for having so kindly placed at their disposal the rooms for their meetings. They owed a very considerable debt of gratitude to the authorities for the kindness with which they had received them and the facilities they had provided.

Mr. S. R. Church, in seconding the vote of thanks, said that one of the great advantages of those meetings was the opportunity they offered those of the business world of communing with the professors. The Columbia University would have the pleasure of extending similar facilities to the members who came to the American Chemical Society's meeting later, and the American Society was looking forward to their visit with great pleasure.

The motion was carried unanimously.

Dr. F. M. G. Johnson, in the absence of Dr. Ruttan, acknowledged the kind words of Sir William Pope and Mr. Church in regard to McGill University.

The meeting then adjourned.

Tuesday, August 30.

The meeting was resumed next morning, the President, Sir William Pope, in the chair.

The scrutineers reported the result of the ballot for the election of Council as follows:—*President:* Dr. R. F. Ruttan. *Vice-Presidents:* Mr. Julian L. Baker, Mr. C. S. Garland, Mr. Max Muspratt, Sir William Pope. *Ordinary Members of Council:* Mr. John Allan, Dr. E. F. Armstrong, Prof. J. W. Hinchley, Mr. W. J. U. Woolcock, M.P.

Dr. Ruttan, in accepting the appointment of President, expressed his gratification at having been selected to represent the chemists of Canada as President of this great Society, but he realised that his election was due primarily to the fact that he was a Canadian chemist, and the Society had honoured him as a means of recognising and further promoting the interest shown by the Canadian Sections in the Society. In selecting a Canadian chemist as the titular head of the Society, it had paid them the highest compliment in its power, and on behalf of the Canadian Sections of the Society he expressed his sincere appreciation of this high recognition.

Further, in conferring upon them the honour of accepting their invitation to meet in Montreal, they recognised that the Society had done so at no inconsiderable sacrifice.

While they shared with the Society some regret that a larger representation of English chemists could not attend this annual general meeting, they fully realised the abnormal conditions which had made the voyage to Canada almost prohibitive.

The name of "Society of Chemical Industry" suggested co-operation between chemical science and its applications. It bridged to a great extent the gap between the university laboratories and the industries. It was expected then that such an organisation, with its ideals and traditions, should have played a large part in the great movement now in progress of consolidating the various interests of the British Commonwealth. That spirit of co-operation and desire for unity of purpose was especially evident at the present time, and there was in this annual meeting of the Society in Montreal evidence of a mutual desire to develop and strengthen the influence of British science and to bring into closer personal relations the chemists of Canada and England.

The present meeting served to accentuate the imperial character of the Society of Chemical Industry; to bring home to chemists both in England and in Canada the fact that this great Society has for its object the advancement of chemistry and its application to industries beyond the confines of the British Isles. It was a fond hope of many, including himself, that, as a result of that meeting, not only would the number of Sections of the Society in Canada be increased and each Section strengthened, but that in the near future Sections would be established wherever centres of industry existed throughout the whole Empire.

A discovery that stood out prominently among the many resulting from the war was that chemistry was the real basis of human industry, and that industrial progress was more closely dependent upon industrial chemical research than upon any other single factor. Every Section of the Society of Chemical Industry established in the British dominions was a point at which the public might be inoculated with appreciation of chemical investigation. By judicious publicity the great reserves of public opinion might be mobilised and brought to bear upon those in whose power lay the development of the industrial interests of the country. The parliaments of the various units of the Empire were but the reflected images of public opinion. To receive recognition by legislatures, chemists must be organised, active and public-spirited. No class in the community was more interested in such national questions as technical education, utilisation of waste products, controlling and directing the application of scientific methods to the development of industries and of the resources of the country; no one profession was so well qualified as that of chemistry to direct legislation along effective, economic lines. They must mobilize the forces of public opinion to reach the centres of government. In Canada and England they had rather ineffectually attempted to reach the heads of governments by convincing arguments and facts; let them reach them through the electors.

Dr. Herty, by his well-organised Chemical News Service of the American Chemical Society, was accomplishing a great work for our science through the press, by supplying interesting, popular, but exact information, emphasizing the national importance of chemistry. Should they not take similar steps to obtain in Canada a more complete recognition of the value of chemistry in the development of the industries of the country? He was fully convinced that the assistance of the daily press of Canada could be secured. To interest the public press it might be necessary to establish and maintain an official news service, analogous to the American Chemical Society's News Service. The united action of the three chemical organisations, the Institute of Chemistry, and the Committee of Chemists associated with the Research Council, would enable them, with some financial assistance from the Research Council, to attain that most desirable object.

A representative congress of chemists, such as the one now in session, emphasised not only the imperial, but also the international, character of the Society of Chemical Industry. He hoped that both Canada and the United States would be strongly represented at the next annual general meeting of the Society, to be held in Glasgow. It seemed important that those interested in chemistry and its applications to industry should acquire the habit of attending the annual gatherings of chemists on both sides of the Atlantic. Such a reciprocal attendance at meetings by large numbers of chemists would tend to eliminate any possible misunderstandings, would enable their outlook on science to become a broader one, and their common interest in chemical science would add another bond to those of a common language and a common national origin to link them all more closely together.

The effect of that meeting on Canada would be, he was convinced, far-reaching in its influence; it would not only stimulate interest in their science throughout the country, but would, by bringing the officers and members of the Canadian Sections into personal relations with the Executive of the Society, harmonise and unify the aims and ideals of the new and scattered Canadian Sections with the older ones in England and Scotland.

The directors of industry in Canada would, by that meeting and their tour through Ontario and Quebec, be reminded of the existence of an imperial organisation whose efforts were directed towards the application of science to the business of their lives.

Canada had as yet not much advanced beyond the pioneer stage of industrial development. Her natural resources were great, but they had not more than touched the fringe of opportunity in their utilisation.

The voyage to Canada of the President and chemists of England would have its highest fruition if that occasion, and their choice of a Canadian President, led to the further introduction of scientific method in their industries, for if Canada were to obtain full value from her natural resources and natural advantages, the footings of her industries must be established on the bed-rock of sound principles and scientific organisation.

An account of the Annual Dinner and other social functions will be found in the Review. The papers read at the meeting will appear in subsequent issues.

Manchester Section.

Meeting held at the Textile Institute on May 6, 1921.

MR. J. ALLAN IN THE CHAIR.

METHODS FOR THE COMPLETE UTILISATION OF NITRE CAKE.

BY W. H. H. NORRIS.

The subject of the disposal of nitre cake appears to be a perennial one, although many had hoped it would not be raised on return to peace conditions; but until the whole of our nitric acid is made by the oxidation of synthetic ammonia, we shall always have this objectionable material to deal with, and a complete solution of the difficulty will be welcomed, particularly if it utilises the cake to its best financial advantage.

For this reason the author considers that it will be of interest to describe a process, worked on the large scale, which utilises the material completely.

H. T. Calvert[1] and H. J. Bailey[2] have summarised the work done during the war, and described how sulphuric acid was economised, and nitre cake used in its place. A full account of the various methods suggested is given by J. Johnston[3], with 70 references, but it is clear that most of these were not carried out. Some were employed as war-time expedients, but very few will stand the competition of cheap sulphuric acid.

At the end of 1917 over 75% of the nitre cake was employed for its acid content alone, the chief constituent being run to waste, and only 21% for sodium sulphate as well, in the manufacture of hydrochloric acid[4]. This was the only pre-war process which completely utilised nitre cake and was worked to any considerable extent[4]. It has now become practically extinct.

The shortage of salt cake last year may be due to the fact that the Leblanc soda process has been almost entirely replaced by the ammonia-soda and electrolytic processes.

Methods of complete recovery are financially sound only when the saltcake content is utilised as well as the sulphuric acid.

The following methods have been published, but so far as the author is aware, none except the one described below has been carried out on the large scale.

The separation of sodium sulphate as Glauber's salts, proposed by H. M. Dawson[5] and E. Hart[6], is accomplished by refrigeration, but the sulphuric acid obtained is dilute, and thus the process is not a commercial proposition. F. A. Freeth introduces calcium sulphate[7], producing sodium sulphate and acid salts containing 75% H_2SO_4, but the handling of this material will probably be difficult and expensive. J. Mackenzie's method for heating in a mechanical furnace[8, 9] to produce saltcake and sulphuric anhydride has not been developed on a manufacturing scale, nor has I. P. Llewellyn's process for heating with pyrites and iron[10]. L. T. Sherwood ignites with sulphur[11], and treating with coke[12] or refuse[13] has also been suggested for reducing the excess acid to sulphur dioxide. Calcining with nitre and coke has been described by J. Grossmann[14], and heating with water alone by Zahn[15]. Nibellius[16] has suggested washing with alcohol, which is known to remove sulphuric acid. The calcium acid sulphite method proposed by Grossmann[17], ingenious though it is, involves many stages. Processes similar in some respects to the one in this paper are described, but they include the separation of Glauber's salts[18], sodium bicarbonate[19], or double salt in the last stage[20], which also appears inevitable in the saturator processes as mentioned by P. Parrish[21]; finally, Holmes[22] obtained an acid liquor from nitre cake, but not pure sodium sulphate.

At the suggestion of the Ministry of Munitions work was undertaken in 1916 and 1917 to substitute nitre cake for sulphuric acid in the manufacture of sulphate of ammonia.

Information received from the Department through Dr. Calvert indicated that up to then it had not been possible to replace by nitre cake more than 10% of the sulphuric acid used, but an impure product was obtained, and though it was subsequently shown that sodium sulphate had no harmful action on crops, dilution was undesirable. The formation of the double salt, sodium ammonium sulphate, had prevented further progress up to that date.

Having decided that partial replacement was undesirable, and would lead to difficulties in manufacture, and impair the usefulness of the product, a complete solution to the problem was sought.

In conjunction with H. S. Denny and C. W. Bailey, the author worked out a suitable process for ammonia absorption, which dispensed entirely with sulphuric acid. As we were engaged on some phase-rule work at the time, the available solubility data on the various salts were collected, and the intersolubilities of the salts studied.

The work of D'Ans between 1906 and 1913[23] is most instructive, and in his latter paper he proves the existence of the following sodium sulphates and acid sulphates, and shows their intersolubilities at the temperature of 25° C.:—

$Na_2SO_4,10H_2O$; Na_2SO_4; $Na_3H(SO_4)_2,H_2O$;
$Na_3H(SO_4)_2$; $NaHSO_4,H_2O$; $NaHSO_4$;
$NaH_3(SO_4)_2,1\frac{1}{2}H_2O$; $NaH_3(SO_4)_2$; $Na_2SO_4,4\frac{1}{2}H_2SO_4$;
$NaHS_2O_7$.

P. Pascal[24] indicated the properties of the above between −45° and 210° C., but his data, being only mapped thermometrically, do not agree very closely with other solubility work. D'Ans also investigated the system ammonia-sulphur trioxide-water at 25° C., while Martignon and Meyer[25] showed that the range of the double salt, sodium ammonium sulphate+2 mols. Aq, was between −21° and 59° C., and that above these temperatures it could not exist. The above work is summarised by H. W. Foote[26] and J. Johnston[3], while B. Saxton[27] draws conclusions from these data with reference to recrystallising nitre cake at 0° and 25° C. Subsequently, isotherms were published by Dawson[5].

No information was found on the quaternary system, Na_2SO_4, $(NH_4)_2SO_4$, H_2SO_4, H_2O, and fresh determinations were made. From these we deduced what salts would crystallise on concentration from liquors of any composition, and the change in the ratio of constituents left in solution. It was found possible to effect precipitations, first rich in one constituent, and then rich in the other. The first scheme proposed involved separation of the double salt, and suitable means for decomposing the product were studied.

Conditions of high solubility were chosen, thus limiting evaporation cost and plant required to work up large quantities, using all waste liquors, to make processes self-contained and cyclic.

It was then found possible to bring together nitre-cake and a solution of sodium and ammonium sulphates, which caused the precipitation of anhydrous sodium sulphate and formed a strongly acid liquor. This was employed in place of sulphuric acid for ammonia absorption, and pure ammonium sulphate was obtained from it on evaporation.

The first successful cycle was somewhat complicated as it involved seven operations, but the final method employed on the large scale was very much simpler. Mother liquor from the previous cycle was used as the precipitating medium. It contained 5800 lb. of $(NH_4)_2SO_4$, 2295 lb. Na_2SO_4, 318 lb. residual acidity as H_2SO_4, dissolved in 5800 lb. water. This was heated to 90° C., and 5550 lb. of nitre cake, preferably granular, was introduced. Its full content of 3880 lb. of Na_2SO_4 was separated in the anhydrous form and 1670 lb. of acid derived from the nitre cake dissolved, and passed on to the ammonia absorber. Liquor diluted by 6700 lb. of water and maintained at 3—4% H_2SO_4 was circulated in the ring-packed tower of a Mond producer recovery plant. Absorption was as efficient as with sulphuric acid alone. Having taken up 577 lb. of ammonia, produced by the gasification of 28 tons of bituminous slack, the liquor was evaporated in a Scott vacuum plant. Here 9300 lb. of water, used for dilution, was driven off, and 2240 lb. of ammonium sulphate resulted on allowing the density to reach a regulated value. The sulphate was removed by the usual salting box, "whizzed," and washed hot. The mother liquor and washings from the evaporation were returned to the original lead-lined heater, and used to digest a fresh charge of 5550 lb. of nitre cake.

The only additions required to the existing plant were the nitre-cake dissolver and the sodium sulphate filters, with necessary fittings, pipe lines, blowing eggs, and store tanks. The digester consisted of a cylindrical lead-lined vessel, fitted with revolving stirrers and a steam coil. Granular nitre cake was delivered into this from a small store by an inclined scraper-conveyor. The sodium sulphate was removed from the acid liquor by filtering in centrifugal machines. Construction costs for this plant are given below.

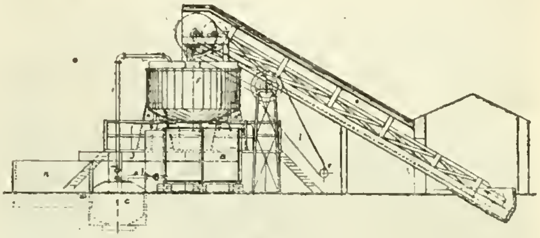

Fig. 1.

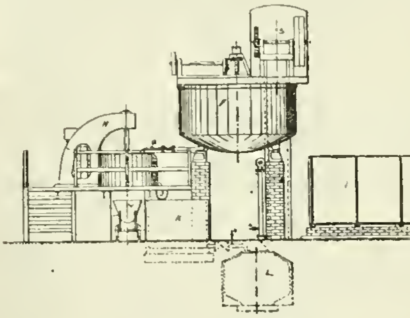

Fig. 2.

The resulting product was of good colour and contained 95% Na_2SO_4, 0·04—0·15% H_2SO_4, and 0·24—0·39% $(NH_4)_2SO_4$. It was also found to con-

tain less than 0·05% of iron when suitably washed, and this made it especially valuable to plate-glass makers. The ammonium sulphate produced was also of good colour, and contained over 24% NH_3. An average sample from a 10-ton lot sent to a large manufacturer tested as follows:—NH_3 24·47% (*i.e.*, $(NH_4)_2SO_4$=95%), Na_2SO_4 2·5%, H_2SO_4 0·22%, H_2O 1·5%.

The plant operated continuously for 4 months until just before the Armistice, and during this time it worked up 220 tons of nitre cake of average acidity 30% producing 157 tons of sodium sulphate 95% and 87 tons of ammonium sulphate, NH_3 over 24%.

The wear and tear on the plant proper during the period of operation was found to be light, and the supervision required was not unduly great when full precautions were taken to have all liquor tanks and lines lagged and steam-heated before operating. The filtering and washing of the sodium sulphate required most attention, but on suitable treatment it was found easy to obtain a medium-sized crystal grain which was readily washed free from ammonium sulphate down to 0·2%.

Costs.

The estimated expenses were as follows:—

Construction of plant (capacity 2 tons of ammonium sulphate from 5 tons of nitre-cake per day), £960.

Running costs.—Unloading nitre-cake 2·0s. per ton of nitre-cake; labour 7·7s.; steam and power 3·85s.; maintenance 3·85s.; sundry 1·93s.: total 19·33s. To this must be added losses of ammonium sulphate 1·35s.; losses of sulphuric acid 0·192s.; amortisation at 5% 1·89s.; royalty 3·85s., and nitre-cake 26·8s. per ton: total 53·412s. This leaves a margin of nearly £5 per ton on present prices.

The value of products from one ton of nitre-cake is calculated as follows:—30% H_2SO_4=0·385 ton of 78% acid, *i.e.*, 140° Tw. B.O.V. at £5 per ton, £1 18s. 6d.; 70% Na_2SO_4=0·73 ton of 96% saltcake at £8 per ton, £5 16s. 9d.; total, £7 15s. 3d.

The actual construction costs (of which labour amounted to 40%) were £1500. The maximum output was 2·6 tons of ammonium sulphate from 6·43 tons of nitre-cake per day.

During the experiment running costs exceeded the estimate, as was to be expected. It was found necessary to make a number of plant changes. The original vacuum filters were replaced by centrifugals; one electrically driven being replaced by two steam-driven. Various forms of acid lifts were tried (steam "blow-jacks" and an automatic elevator), but finally a large cast-iron egg was found most suitable.

The actual cost of plant alterations (for 2 months) was £1500. After this time additions were charged to maintenance. In the following statement interest has been calculated at 5% (1918) on £3000 capital, and depreciation of plant at 10% of the total, and the whole is described as amortisation at 15%. The above-mentioned changes inflated maintenance charges as described, and delays reduced the output, unduly raising the costs per ton of material.

During the last seven weeks 144·35 tons of nitre-cake yielded 57 tons of 78% acid and 103 tons of 96% sodium sulphate when actual costs were as follows (in shillings per ton of nitre-cake):—Unloading nitre-cake 5·0s.; labour 15·0s.; steam and power 3·85s.; maintenance and reconstruction 17·5s.; materials (mostly lead) 11·8s.; losses of ammonium sulphate 1·4s.; losses of sulphuric acid 0·25s.; amortisation at 15% 7·0s.; nitre-cake 26·8s.: total 88·6s. On these figures there is a margin of over £3 per ton on present prices.

By re-design of plant much of this expense can be reduced; as with all heavy chemicals of low value, cost of handling must be minimised, to show a good financial return; and considering that sulphuric acid is so easily manipulated by compressed air, first attention must be given to cheap methods of transporting and handling nitre-cake. Well-established costs are available for granulating and loading up, and in one case as shown in the Appendix (3), this amounted to 6s. 1d. per ton, whereas on granulation by air the cost is about half this amount; further, figures are obtainable for the wear and tear of railway waggons used for transporting nitre-cake.

Scraper conveyors had proved successful for dealing with damp, acid ammonium sulphate, and at once large factory many hundred feet of line gave no trouble when handling warm granulated nitre-cake; however, a conveyor improvised from scrap on this plant failed after two months. Their use is avoided in the following proposed plants.

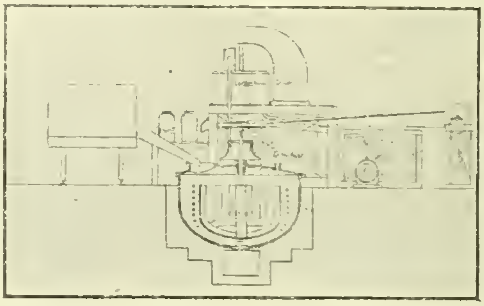

FIG. 3.

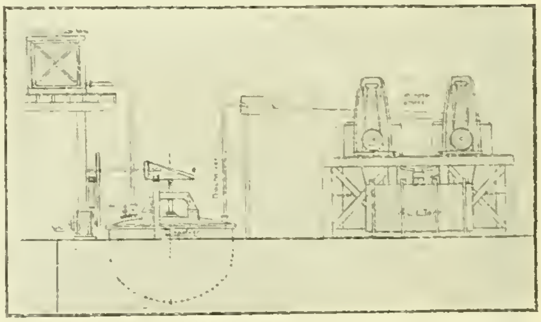

FIG. 4.

Figs. 3 and 4 show a sunk digester into which the complete contents of a waggon may be tipped or shovelled, the salt-cake gravitating from the centrifugal filters direct to railway waggons. Such arrangements will reduce labour charges to one-half and maintenance to one-third of the above, with a small increase for power. If employed by nitric acid manufacturers, fused waste may be run direct into the digester and granulated there, resulting in still further economies.

The ideal location for the new process will be on a works where both nitre-cake is produced and ammonium sulphate made by absorption of ammonia in sulphuric acid. If, however, the respective works are separated, it must be considered whether it will not be cheaper to produce strong ammonia liquor as made during the war, and carry 26 units by tank to the nitre-cake works, rather than convey 98 units of this corrosive solid to the ammonia plant; the gross weights to be carried are about as 4:1, and the ammonia liquor has the additional advantage of being transported by tank and pipe line instead of requiring manhandling or conveying as do solids.

The strong ammonia liquor may be run direct into an evaporator charged with acid liquor made by the process described, when the heat of reaction will drive off most of the 70% of water introduced and leave little further evaporation to be done. The sulphate of ammonia will be discharged as usual, and the mother liquor returned for treatment with more granulated or molten nitre-cake.

Summary.

A process for the complete utilisation of nitre-cake is described in which the material is washed with a strong mother-liquor from previous operations, whereby pure sodium sulphate remains undissolved and the sulphuric acid is recovered as a liquor which can be utilised for the absorption of ammonia. Large-scale tests have demonstrated the practicability of the process.

APPENDIX.

THE GRANULATION OF NITRE-CAKE.

Arrangement of granulating plant.—The plant was situated at the back of the retort house so that retorts were tapped straight into granulating pans.

The granulating pans, which were arranged in sets of two, were seated on a concrete bed. Rotating over the pans was a five-armed radial framework to which the granulating blades were attached. These blades dipped in the "liquid nitre-cake" to within an inch of the bottom of pan. Being arranged concentrically on the arms of framework, the necessary agitation of the liquid was insured, because every portion of it was cut by the blades each in rotation. This had the effect of making the liquid set as a powder.

Method of operation.—The hot liquid "cake" was run into the pans to a depth of five inches. The blades were then started and kept rotating during the whole of the operation. After the liquid had been granulated to a fine powder the door in the side of the pan was opened, and the rotating blades pushed the granulated cake to the outside of the pans, and eventually through the door, whence it fell on to a conveyor belt, from which it was discharged into elevator buckets to the storage bin. The bottom of the bin was built on a slope, thus allowing the granulated cake to gravitate into the railway waggons when the chute was opened.

The time occupied in the process was as under:—Filling pans with "liquid cake" 30 mins., granulating to a powder 1½ hrs., clearing pans 30 mins.: total 2½ hrs.

Cost of granulating cake.—The cost of granulating cake and conveying it to storage bins was carefully kept over a fortnight, and a detailed account was given for 309 tons of cake granulated: *Labour:* Piece-workers (3 men) £24 1s. 6d. *Maintenance:* Fitter, mate, and boy £6 2s. 6d.; beltman's wages 15s. *Materials and renewals:* 2 new "Gripoly" belts £8 8s.; 7 blades, 3s. each, £1 1s. *Power consumption:* 6101 units at 1½d., £38 10s.: total £78 18s., or 5s. 1d. per ton of cake; allowing for amortisation and interest on capital, this becomes 6s. 2d. per ton. The cost of the belting was obtained by taking the average life of "Gripoly" belts as two months. The length of the belts was 28 feet, and the cost 3s. per foot; eight were in use on the granulators.

Discussion.

Mr. **Hailstone** enquired how the fineness of division of the nitre cake affected the time required for complete reaction to take place. Could the sodium sulphate be readily separated by simple decantation or filtration when deposited?

Mr. **Curtis** asked whether experiments had been made with filters other than centrifugal machines. It would seem that the ordinary type of such machines would require frequent renewal when using 30% sulphuric acid.

Major V. F. **Gloag** asked what would be the effect on the technical control of the plant of the large variation in the percentage free sulphuric acid in the nitre-cake from different works.

Mr. R. H. **Clayton** said that to use concentrated liquor in the kind of plant described was scarcely a commercial proposition. It was extremely expensive first to make concentrated ammonia and then re-work again for sulphate. Also, the losses of ammonia would probably be high. In the ordinary course ammonium sulphate was made direct from the liquors.

Mr. E. F. **Morris** enquired whether there was any record in the literature of nitre-cake being used in conjunction with waste smelting mattes. With antimony matte—a waste product—the acid was eliminated as sulphur or sulphur dioxide; magnetic sulphide of iron had been obtained as a by-product in some experiments.

Mr. D. M. **Paul** said that the fact that the ammonium sulphate produced contained only about 24% of ammonia would depreciate its value. He understood that the sodium sulphate obtained was contaminated to a considerable extent with acid liquor; was there any prospect of using sodium sulphate of this nature? As regards the cost of production, he thought the process was essentially a war-time proposition, and that the author's estimate of the cost of renewals and repairs was optimistic.

The **Chairman** said that it was significant that a large quantity of strong ammonia liquor had been transported by tank wagons for great distances in Germany, and it might be concluded it had been made an efficient process. He did not think that the losses could have been so great as Mr. Clayton forecasted, for it was not likely that wasteful procedure would have been adopted even as a war-time expedient.

Mr. **Norris**, in reply, said that the fineness of the nitre-cake had little to do with the completeness of the reaction. After the liquor and cake were suitably heated, the latter fell to pieces and deposited anhydrous sodium sulphate in the form of a fine powder. With good stirring the reaction was complete in 20—30 mins. With about 2 hrs.' heating a large-grained crystal was obtained which filtered well and could be more easily washed. The salt produced, being denser than the mother liquor, settled quickly, and could be separated by decantation and filtration. The original filters were of the Nutsch type, and a woven asbestos cloth was used, but these were slow in action, and had been replaced by centrifugals. The acid liquor, which

was saturated with sodium and ammonium sulphates, had very little corrosive action on iron—certainly much less than 30% acid—and apparently none on lead. The presence of the large quantity of neutral sulphates evidently reduced the dissociation of the remaining sulphuric acid and consequently minimised its attack on metals. In actual practice there was no greater corrosion in the filtration of these liquors than in centrifuging ammonium sulphate made in a gas-works saturator, which always contained acid liquor. The same autogenously lead-lined centrifugals were employed and gave very little trouble. Phosphor-bronze baskets have been tried with success for ammonium sulphate, and could also be employed. The nitre-cake obtained from Government factories was of consistently low acid content; when the acid content of the nitre-cake altered the charge was varied to correspond to a definite quantity of sodium sulphate. With increased acidity the charge was greater, and larger yields of ammonium sulphate per cycle resulted. The transport of ammonia in the form of concentrated liquor required careful attention to prevent loss, but he understood it had been done effectively. Suggestions had been made to treat hot slag with nitre-cake, but it was not clear how the constituents were to be suitably recovered, nor had the author any account of the successful employment on the large scale. Suitable washing would increase the grade from 24·5% to 25% ammonia, and the resulting product was of better appearance than that obtained by the use of sulphuric acid on the same plant. This was possibly due to the fact that owing to the high content of sodium sulphate in the liquors more tar was precipitated than normally separated without it. The sodium sulphate produced was particularly pure, and being precipitated in strongly acid solution was free from iron and other impurities. It found a market for plate-glass making at an increased price. The process certainly had been a "war proposition" in its inception, but since that time the sodium sulphate had proved its most valuable asset, and, given normal trade conditions, would make the process a more profitable one than when devised.

Communications.

THE MANUFACTURE OF NITRIC ACID BY THE POT PROCESS.

BY H. W. WEBB, M.SC., F.I.C.*

Experimental investigations on the manufacture of nitric acid have already been carried out by Volney (Amer. Chem. J., 1892 and 1898) and by Winteler (Chem.-Zeit., 1905, 29, 820—823), and a criticism of the latter is given by O. Guttmann (Chem.-Zeit., 29, 939).

The object of the present investigation was to determine the effect of individual variables, by altering only one variable in any particular set of experiments. Other work published on this question is somewhat vitiated by the fact that several variables were allowed to alter at the same time. Winteler states that to obtain nitric acid in good yield and high concentration the following conditions must be maintained:—(1) The distillation temperature must be as low as possible. (2) The contents of the retort must not be superheated. (3) The rate of heating must be slow, the actual rate being determined by the size and shape of the retort. (4) The best yield of the strongest acid is obtained by using 92% H_2SO_4 and dry nitre. (5) The introduction of atmospheric oxygen into the retort increases the yield of strong acid. (6) Rapid cooling of the distillate is advantageous.

Some of the above points were of such importance as to merit further experimental investigation, particularly the influence of the sulphuric acid concentration on the strength and yield of nitric acid.

It is evident that the distillation should be carried out in such a way that the following conditions are fulfilled:—(1) The yield of nitric acid should be as nearly as possible theoretical. (2) The concentration should be as high as possible. (3) A minimum amount of nitrogen oxides should be produced, as these have to be recovered as weak nitric acid in the absorption system. (4) The concentration and quantity of sulphuric acid used should be as low as possible.

The main variables which influence the reaction, and which are important from the commercial standpoint, are:—(*a*) The concentration of sulphuric acid used (or the percentage of total moisture present). (*b*) The ratio of sulphuric acid to nitre. (*c*) The heat treatment (*i.e.*, rate of distillation). (*d*) Rate of cooling of nitric acid vapour. (*e*) Purity of nitre. (*f*) Pressure.

Of these (*a*), (*b*), and (*c*) are probably the most important, and these were investigated first.

Experimental.

Distillations were carried out in small glass retorts, and also in a specially-designed small-scale cast iron still.

Glass apparatus.—The glass retort apparatus consisted essentially of a glass retort of 1 litre capacity, fitted with a tube containing thermometers at different levels so that gas and cake temperatures could be read simultaneously. The end of the retort was bent at a right angle to fit into a Liebig's condenser. The condensed acid was collected in a funnel, and any nitrous gases passing over were mixed with air and absorbed in a series of bottles containing caustic soda. The apparatus was kept under a slight suction by means of a water pump at the end of the system. The sodium nitrate used was pure (free from potassium nitrate, chlorides, chlorates, iron salts, and iodine compounds). The sulphuric acid was pure and free from arsenic and carbonaceous matter.

The visible stages of the reaction were examined, as a preliminary measure, and the following points were noted:—

(1) The first visible reaction occurred at approximately 80° C. (cake temperature) with the vigorous production of nitrous fumes. As this invariably occurred, although pure sodium nitrate and pure sulphuric acid were being used, it is clear that the production of nitrogen oxides in the early stage of the distillation is not due to impurities such as chlorides etc. in the nitre.

(2) At 85° C. (cake temperature) a brisk evolution of nitric acid commenced, and during this period the strongest nitric acid distilled over. As the temperature was raised the rate of distillation slowed off, becoming much slower when the cake temperature was 100° C. Volney (*loc. cit.*) considers that the composition of the material left in the retort at this stage is $NaH_3(SO_4)_2$, and that it is probably formed thus:—

$$NaNO_3+2H_2SO_4=NaH_3(SO_4)_2+HNO_3.$$

This polysulphate has also been described by Uebel (E.P. 27,240 of 1898).

(3) A second vigorous reaction set in at approximately 120° C. (cake temperature) and was complete at about 150° C. This was the most vigorous reaction in the distillation.

---

* Much of the experimental work indicated was carried out by Messrs. G. B. Stones, M.Sc., R. H. Callow, B.Sc., and H. M. Dawson.

(4) The final stage in the reaction took place above 150° C. and probably consists in the reaction:—

$$NaHSO_4 + NaNO_3 = Na_2SO_4 + HNO_3.$$

At this temperature also the amount of nitrous fumes increased largely, which was undoubtedly due to the decomposition of some of the nitric acid at the temperature 150°—170° C.:—

$$2HNO_3 = N_2O_3 + H_2O + O_2.$$

The following figures are given by Volney (1898) for the above reaction at various temperatures:—

Temp. (° C.)	Percentage decomposition.	Temp. (° C.)	Percentage decomposition.
86°	9·53	190°	49·34
100°	11·77	220°	72·07
130°	18·79	250°	93·03
160°	28·96	256°	100·00

At this stage also, with increase in temperature, other reactions set in, such as $2NaHSO_4 = Na_2S_2O_7 + H_2O$, sodium pyrosulphate being formed.

Heat treatment.—After these preliminary observations it was necessary to find a standard method of heat treatment, so that strictly comparable results could be obtained.

It was found by experimental distillation that the minimum (cake) temperature required to reduce the amount of nitrogen compounds retained in the cake to a figure comparable with works practice was 200° C. The period of distillation was fixed arbitrarily at 310 minutes, as this was convenient for observation and control. In all cases two distillations were made simultaneously, the two retorts being placed side by side in the same heating vessel, and distillations were carried out until concordant results were obtained.

Various methods of heating the retorts, such as immersion in an oil bath, sulphuric acid bath, etc., using both external gas heating, and internal resistance heating, were tried; the final method adopted was to cover the whole of the upper part of the retorts with a lagging of soft asbestos putty, leaving a small circle at the bottom of the retort exposed to the action of hot gas. The two retorts were fixed into a sheet asbestos box, which completely protected them from draughts. The asbestos chamber was then heated by a standard ring burner also encased in asbestos to keep away draughts. The temperature treatment was then as follows:—

Standard rate of heating for distillations.

Time.	Temperatures.		Time.	Temperatures.

155	278	237			

It must be emphasised that this heat treatment was chosen merely to give a convenient standard, and not as being in any way the best treatment to secure maximum efficiency.

Concentration of sulphuric acid.

The best treatment having been fixed, the effect of variation in the concentration of sulphuric acid used in the distillation was investigated.

Pure nitre (250 g.) was distilled with 275 g. of sulphuric acid of concentration varying from 85% to 97% H_2SO_4 Since the weight of sulphuric acid used each time was constant, the ratio of $H_2SO_4 : NaNO_3$ was varying as well as the concentration of sulphuric acid, but this was done to save time, as in the experiments in the cast iron still, described later, the amount of actual H_2SO_4 was kept constant, while the concentration varied. Six pairs of distillations were carried out with each concentration of sulphuric acid, and provided that the whole series was concordant, the mean value was taken as the true result. At the beginning of each distillation the sulphuric acid and nitre were analysed, and at the end of the distillation the total condensed nitric acid was weighed and analysed for nitric and nitrous acids. The nitrous acid was determined by means of permanganate and the nitric acid by Bowman and Scott's ferrous sulphate method. The amount of nitrite and nitrate in the absorption bottles was determined by titration with standard acid, using methyl red as indicator, and checked by the Devarda reduction method. The amount of nitrogen compounds in the nitre cake was determined, and also the total acidity as H_2SO_4. The amount of sulphuric acid used was calculated to give a nitre cake of about 35% acidity as H_2SO_4.

From these figures the percentage efficiency was obtained, which figure expresses the weight of real nitric acid obtained as a percentage of the theoretical yield of nitric acid.

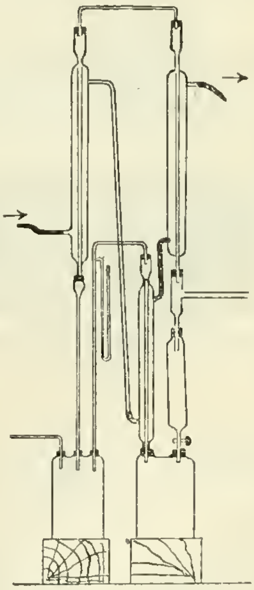

Fig. 1.

Small-scale cast iron retort.—This consisted of a cast iron pot, 14 in. deep by 12 in. diameter, seated in a wheel flue and heated by a standard ring burner.

Two thermometers, one for reading the cake temperature and one for the gas, were also fitted. As a condensing apparatus, a series of glass condensers was adopted (see Fig. 1) and formed a very efficient system. After leaving the bottles shown, the gases passed through two wash bottles containing water to absorb most of the nitrous gases, and then through a third bottle containing $N/1$ caustic soda solution; air was drawn in before this last bottle to oxidise any nitric oxide present. In earlier experiments three additional absorption bottles containing alkali were used, and a final bubbler containing acidified permanganate, but these were found to be unnecessary since the last bottle never contained more than 0·1% of the total nitrogen recovered.

The apparatus was kept under a slight suction (as with the glass apparatus) by means of a water pump.

The time of distillation was again arbitrarily fixed at five hours, and a standard method of heating adopted similar to that used for the experiments in glass apparatus.

In each distillation 7 lb. of commercial nitre and 7·65 lb. of H_2SO_4 (as 100%) were used. While the concentration of sulphuric acid was varied, the weight of actual H_2SO_4 was kept constant.

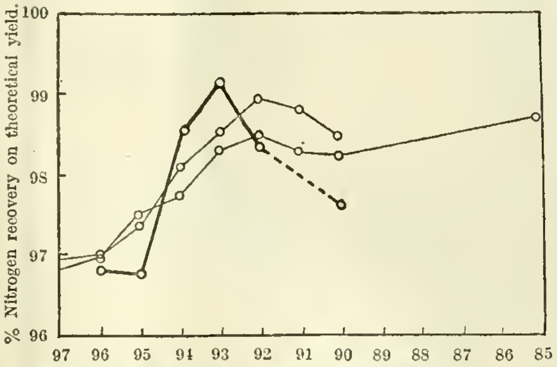
Tables I. and II. show the summary of the averaged results obtained from the experiments in glass apparatus by using varying concentrations of sulphuric acid. The accuracy with which pairs of distillations could be repeated are illustrated by the following figures for per cent. nitrogen recovery, taken at random from a large number of tests:—97·03, 97·63; 97·01, 97·18; 97·31, 96·93, 96·96, 96·79; 98·38, 98·90, 98·22, 98·57.

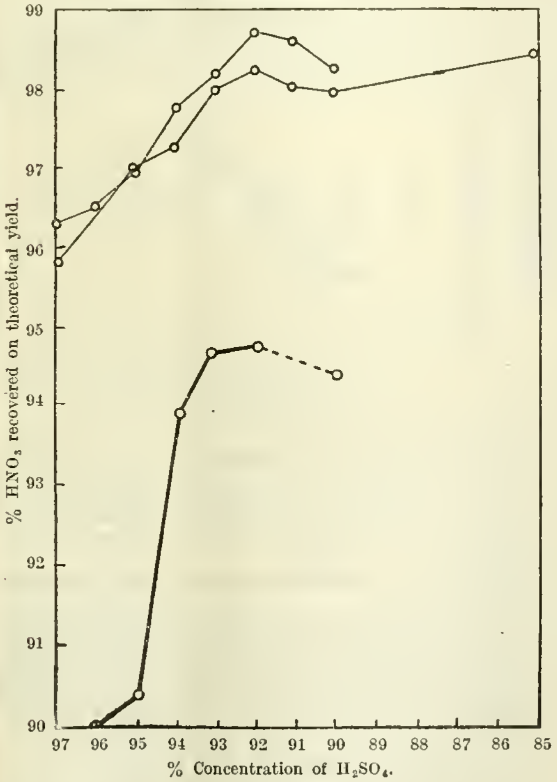
Note: In all these graphs the thin lines show the experiments in glass apparatus, the thick ones those in small-scale works plant.

Curves showing the relation between efficiency as total nitrogen recovery and concentration of H_2SO_4.



Graph 1.

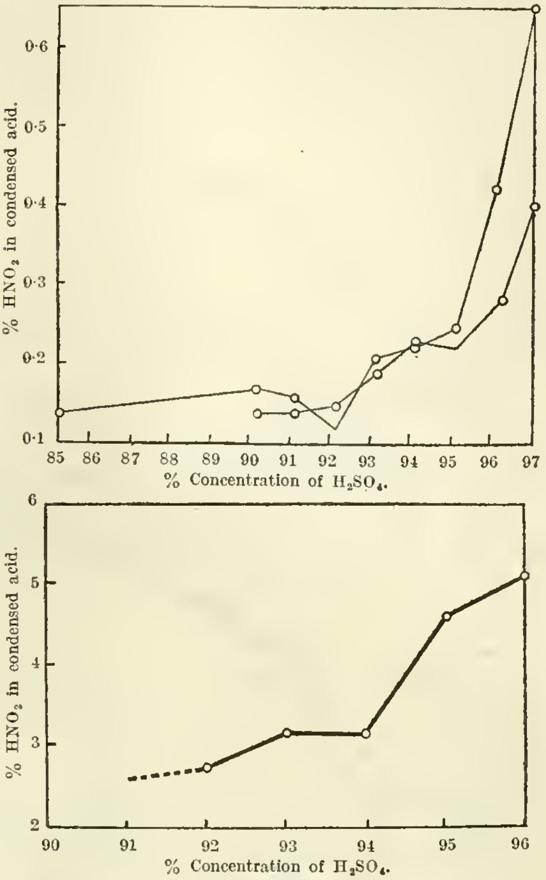
Curves showing the relation between efficiency (as HNO_3 recovery) and concentration of H_2SO_4.



Graph 2.

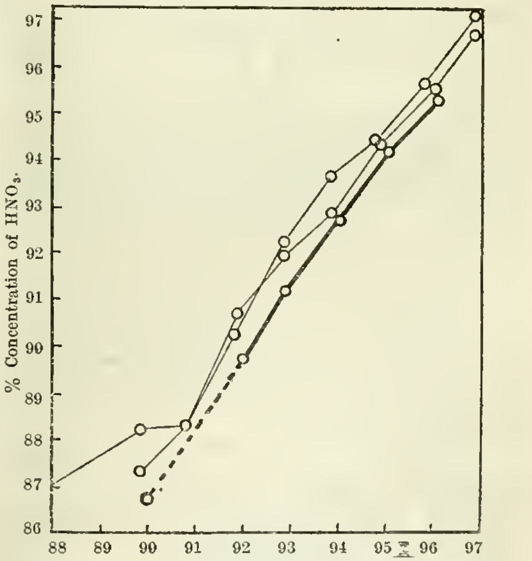
Table III. shows the averaged results obtained under similar conditions in the small cast iron still. The following figures indicate the accuracy obtained in comparable experiments:—Nitrogen recovery %: 96·80, 97·31, 96·2: average, 96·78. 98·87, 98·05, 98·54: average, 98·49. 99·03, 99·28, 99·15; average, 99·15.

Curves showing increase in percentage of nitrous acid in condensed acid with increase in concentration of sulphuric acid.



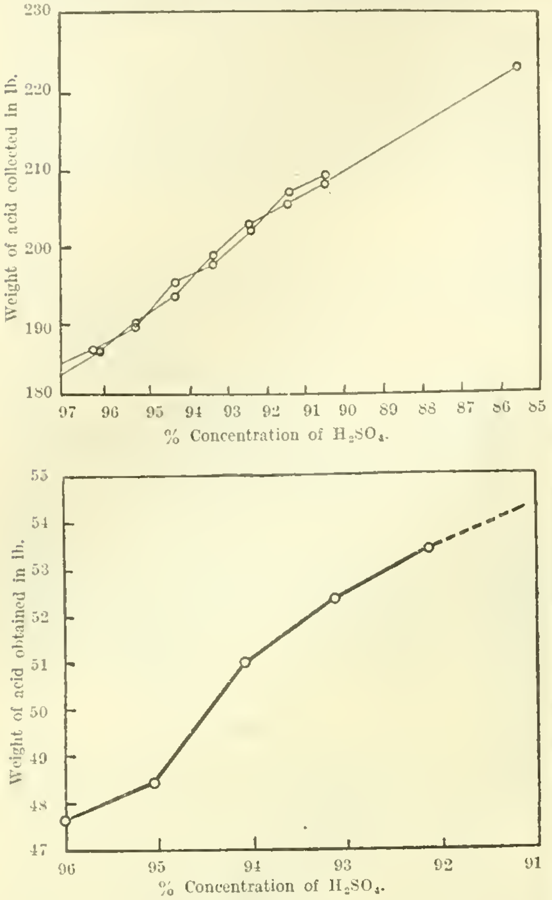
Graph 3.

Curves showing increase of concentration of nitric acid obtained with concentration of sulphuric acid used.



Graph 4.

Curves showing increase in weight of acid condensed with decrease in concentration of sulphuric acid.



GRAPH 5.

The results are expressed graphically in Graphs 1—7, and show the effect of variation of sulphuric acid concentration on (*a*) the total efficiency (Graph 1), (*b*) the real nitric acid recovered (Graph 2), (*c*) the amount of nitrous acid in the condensed acid (Graph 3), (*d*) the concentration of nitric acid produced (Graph 4), (*e*) weight of acid condensed (Graph 5), (*f*) amount of nitrogen compounds retained in the nitre cake (Graph 6), while Graph 7 shows the relationship between total moisture present and the total nitrogen recovery.

The net conclusions to be drawn from the results were as follows:—

(1) The best concentration of sulphuric acid, from the point of view of nitric acid recovery, was found to be from 90 to 92 % H_2SO_4.

(2) The amount of nitrous acid in the condensed acid decreased continuously with the reduction in strength of the sulphuric acid used, between the limits 97%—85% H_2SO_4.

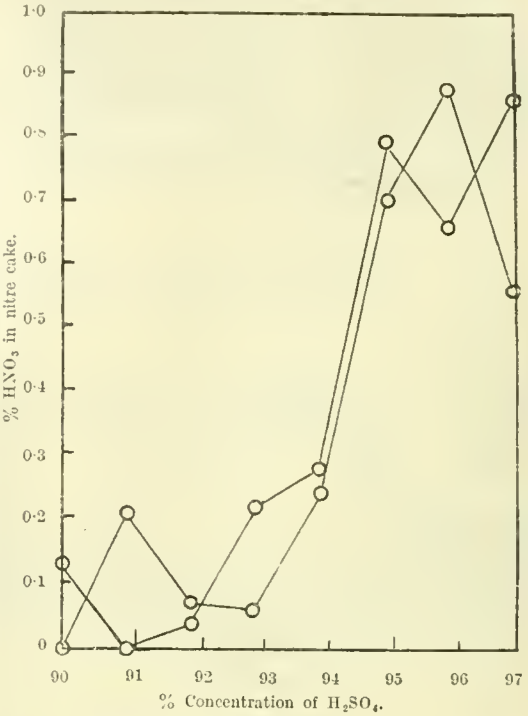
(3) The amount of nitrogen compounds retained in the nitre cake was greater with increased concentration of sulphuric acid.

(4) The amount of actual nitric acid condensed, increased, as would be expected, with decrease in sulphuric acid concentration.

(5) The concentration of the condensed nitric acid was greater, the greater the concentration of sulphuric acid used.

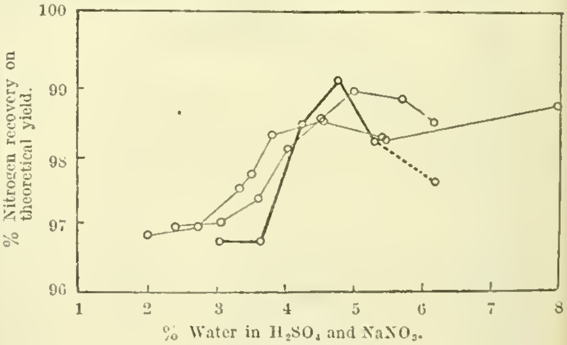
(6) The point at which the "blow" period occurred became less marked as the concentration of sulphuric acid was decreased, *i.e.*, there was less probability of "blows" with lower concentrations of sulphuric acid.

Curves showing the increase in nitrogen compounds retained in the nitre cake, with increase in concentration of H_2SO_4 used.



GRAPH 6.

Curves showing relation between efficiency (as total nitrogen recovery) and percentage of water present in materials at beginning.



GRAPH 7.

(7) The greatest production of nitrous gases occurred at the beginning of a distillation, and also at the end, and was very small in the intervening period.

(8) Nitrous oxide (N_2O) was produced during the distillation.

As an addition to these investigations further experimental work on exactly similar lines was carried out to determine the effect of altering the ratio of sulphuric acid to nitre, the cause of loss of combined nitrogen during the distillation, the effect of variation of the rate of distillation, etc.

Ratio of sulphuric acid to nitre.

The previous results had been obtained with a ratio of $H_2SO_4:NaNO_3=1·10:1·00$. Experiments were then carried out in which the concentration of sulphuric acid was fixed arbitrarily at 91% and 92 % H_2SO_4, and the amount of sulphuric acid used was varied, in order to give nitre cakes of different degrees of acidity. The averaged results obtained in glass apparatus are summarised in Table IV, while Table V shows the averaged results for the small cast iron still. Each result given in this table is the average of three representative distillations.

The results obtained from the distillations in glass apparatus and iron apparatus do not, in this series, agree in every respect. The results common to both are:—

(a) The amount of nitrogen compounds in the nitre cake remained practically constant irrespective of the amount of sulphuric acid used (but not of the concentration of sulphuric acid).

(b) The concentration of nitric acid remained approximately constant.

The results of the distillations in the iron still, however, showed two important generalisations which could not be drawn from the experiments in glass apparatus, viz.,

(a) The total nitrogen recovery began to fall off when the quantity of sulphuric acid used was insufficient to yield a nitre cake of 35% acidity as H_2SO_4.

(b) An extra efficiency in total nitrogen recovery of approximately 1% was obtained if a cake acidity of 35% H_2SO_4 or more was maintained, as compared with a cake acidity of 34% H_2SO_4, and this efficiency was about 2·5% greater than that obtained if the cake acidity was lowered to 32% H_2SO_4.

In view of the important bearing of these results on commercial practice, the investigations were repeated on a large-scale plant with approximately thirty 2-ton stills.

The plant was operated in the usual way, using ordinary nitre and R.O.V. containing approximately 93% of H_2SO_4. Each charge of nitre was sampled and the samples bulked as a day's average, and analysed. The sulphuric acid used was also analysed before use. The plant was run for seven days, using a ratio of sulphuric acid to nitre which would give a nitre cake of 30% acidity, and then for seven days on a ratio giving 35% acidity.

All the condensed acid was run into calibrated cisterns, where it was measured and sampled, and the absorber acid was collected in carboys, weighed and analysed.

The results are shown in Tables VI and VII, and show an increase of about 2·5% in the total nitrogen recovery when using a ratio giving a 35% acidity as compared with a 30% acidity, while the nitric acid produced is also higher in concentration. The result is important as showing that the practice of using as little sulphuric acid as possible, *i.e.*, cake acidities of 28—30% H_2SO_4, is false economy, inasmuch as the loss of nitric acid more than compensates for any economy in the relatively cheap sulphuric acid.

The fact that this result was not obtained in the experiments carried out in glass apparatus suggests that the iron of the still may possibly exert some influence on the decomposition of nitric acid or nitrogen oxides in the presence of sulphuric acid.

Loss of combined nitrogen during the distillation.

Although the absorption of the evolved nitrous gases during the distillation was complete, and the amount of combined nitrogen retained in the nitre

} Cake acidity=30% H_2SO_4.

cake was allowed for, there was always a certain loss of nitrogen on the theoretical yield, which required to be accounted for.

During a series of distillations in the glass and in the cast-iron apparatus, samples of the evolved gases were drawn off at intervals and analysed. The amount of gas evolved in the glass apparatus was small, owing to the relatively small amount of nitre being decomposed, and it was hence difficult to obtain samples continuously throughout the distillation. The results obtained with this apparatus, however, were sufficient to show that:—

(1) The ratio of nitrogen to oxygen decreased continuously throughout the distillation.

(2) Nitrous oxide was produced towards the end of the distillation.

The experiments conducted in the cast-iron still, however, showed that:—

(a) After the period of violent action, the percentage of nitrogen in the evolved gases gradually increased.

(b) Nitric oxide was formed in increasing quantity towards the end of the distillation.

(c) Nitrous oxide was also evident towards the end of the distillation.

The fact that in the one case the nitrogen/oxygen ratio decreases, while in the other it increases, again suggested that the material of the still exerted an influence. Typical analyses of the exit gases from the glass apparatus are as follows:—

	A.					B.		
Time after start of reaction.	2 hrs.	2½ hrs.	3½ hrs.	4 hrs.	5 hrs.	2 hrs.	3½ hrs.	5 hrs.
O_2, % ..	19·8	20·0	21·4	26·2	21·6	24·1	27·4	25·0
N_2, % ..	80·2	80·0	78·6	73·8	77·0	75·9	72·0	74·7
NO, % ..	—	—	—	—	0·4	—	—	0·3
N_2O, % .	—	—	—	—	1·0	—	0·6	—

In the case of the cast-iron still the following results were obtained:—

Time after start of reaction.	1¾ hrs.	2 hrs.	2¾ hrs.	3¾ hrs.	4¼ hrs.	4¾ hrs.
O_2, %	20·8	20·6	20·0	13·0	7·6	1·4
N_2, %	79·2	79·4	79·4	86·6	91·2	92·6
NO, % ..	—	—	0·6	0·4	1·2	5·2
N_2O, % ..	—	—	—	—	—	1·8

The results therefore offer an explanation of the fact that while variation in the amount of sulphuric acid used did not appear to affect the total efficiency when the distillation was carried out in glass apparatus, a marked effect was shown in iron apparatus.

It should be stated that the iron used in casting the small still was of the same composition and quality as that used for the large-scale 2-ton pots.

In order to determine if any appreciable solution of iron occurred, a balance-sheet of the dissolved iron before and after the distillation was made out by estimating the amount of iron present in the sulphuric acid and nitre, and then determining the amount in the nitre cake after distillation. The following results were obtained:—

Analysis of cake:—Iron, 1·55%. Iron in nitre, 0·07%. Iron in R.O.V., 0·18%. Total weight of iron in cake, 58·01 g. Total weight of iron in R.O.V., 5·02 g. Total weight of iron in nitre, 1·90 g. Difference (dissolved iron), 51·09 g.

It is thus clear that a certain amount of iron is dissolved from the pot in each distillation, but the mechanism of its action in producing nitrogen, whether direct or catalytic, is still a matter for investigation. The work of Thomas and Williams (Chem. Soc. Trans., 1921, 758) suggests that the production of nitric oxide may also be a determining factor on the amount of iron dissolved.

Owing to lack of time, and the fact that no apparent effect was produced by altering the time of distillation from 5 hours to 3 hours, no further distillations were carried out on the small-scale works plant.

Rate of distillation.

This variable was investigated in a similar way to the previous variables, by retaining the same temperature intervals as before in the standard heat treatment, but the time interval between the passage from one temperature to the next was varied from 2 minutes to 6 minutes, and thus a series of distillations at different rates were obtained under strictly comparable conditions. The duration of the distillation was 2 hrs. 4 mins., 3 hrs. 6 mins., 4 hrs. 8 mins., 5 hrs. 10 mins., 6 hrs. 12 mins., etc., according as the temperatures shown in the heat treatment table were attained in 2, 3, 4, 5, or 6 minute intervals. In case of the iron pot the distillations were carried out only for 2, 3, and 4 minute temperature intervals.

Table VIII. shows the results obtained in glass apparatus (each result being the average of five separate distillations), and Table IX. shows similar results for the iron apparatus.

While the number of distillations carried out in the iron still was small, the results of both sets of experiments seem to show that neither the total nitrogen recovery, nor the strength of the nitric acid produced, is appreciably affected by the rate of distillation, and the investigation of this variable has not been pursued further. The question of the effect of pressure during distillation and the advantages of distilling under reduced pressure have already been effectively dealt with by Lunge, Valentine, and others, and this point was also not investigated.

The results obtained as a whole confirm in part those due to Volney and Winteler, but suggest important points in addition for consideration in the economic manufacture of nitric acid.

A CHEMICAL INVESTIGATION OF MUTTON-BIRD OIL.

Part I.

BY C. L. CARTER, M.SC.

Mutton-bird oil is extracted from the stomach of a petrel (*Aestrelata lessoni*), peculiar to Australasia. When disturbed the petrel ejects this oil from its nostrils with considerable force. It is reported also that the oil serves as a food for the young birds.

These petrels are killed in large numbers every year on the islands near New Zealand and Tasmania for food. The oil expressed from the dead birds has not proved to be of material value up to now, and samples were sent to this University for analysis.

Some constants for the oil have been given by L. H. Smith (J., 1911, 405). Mutton-bird oil is light straw coloured and has a faint, not unpleasant odour resembling to some extent that of linseed oil. At ordinary temperatures it is a fairly thin, non-drying oil which has no tendency to thicken or gum when exposed to the air. At 6° C. it deposits a solid wax (spermaceti); at 0° C. it solidifies to a pasty, translucent mass.

On saponification with alcoholic potash 100 g. of oil gave 38·38 g. of alcohols, 61·38 g. of mixed fatty acids, and 3 g. of soluble colouring matter etc.

The oil gave a solid elaidin in 24 hours, and solidified when left in contact with nitric acid for 12 hours.

The alcohols.

The ethereal residue extracted from the saponification products is a pale yellow wax (m.p. 31°—31·5° C.); it is easily soluble in cold alcohol, ether, and chloroform, separating from alcohol in a semi-crystalline mass. Since it is completely soluble in cold rectified spirit, no hydrocarbons are present. Hydrolysis of the acetylated alcohols with alcoholic potash gave 247 as the equivalent weight of the alcohols (calculated for cetyl alcohol 242). The m.p. of the acetate was 18·5° C.; cetyl acetate has m.p. 18°—18·5° C. (Beilstein, I., 411). B.p. of acetate at 15 mm.=200°—205° C.; cetyl acetate has b.p. 199°—200·5° C. at 15 mm. The alcohols thus appear to consist chiefly of cetyl alcohol.

The fatty acids.

When freshly precipitated the mixed fatty acids were obtained as a deep red-brown oil, sp. gr. at 15·5° C. 0·905. On standing partial solidification took place. Titration with alcoholic potash indicated a mean molecular weight of 294·2. A quantitative separation by the lead salt-ether process gave 96·5% of acids of the oleic acid series and 3·3% of the stearic acid series. Oxidation of the mixed fatty acids by means of potassium permanganate gave a 75% yield of dihydroxystearic acid, mol. wt. 314, acetyl value 198·5, m.p. 125·5 C. The molecular weight was determined by titration with standard alkali. It thus appears that the greater portion of the mixed fatty acids consists of oleic acid.

The high iodine values obtained for the oil and the acids, while not in agreement with those obtained by L. H. Smith, point to the presence of acids of the linolic or linolenic series.

The formation of an amount of insoluble bromides, by the action of bromine on an ethereal solution of the potassium soaps, points to the highly unsaturated state of a portion of the acids.

Mutton-bird oil resembles sperm oil in a remarkable manner, as shown by the following constants:

	Sperm oil.	*Mutton-bird oil.*	
		L. H. Smith.	Author.
Sp. gr. at 15·5°C.	0·881	0·8819–0·8858	0·884
Freezing point	Solid at 0°	Solid at 0°C.	
Free fatty acids	1·2	2·23	2·23
Higher alcohols	39·1%	36·88%	38·4%
Saponif. value	120	125·9	119·6
Iodine value	84·4	71 Wijs.	130 Wijs; 108 Hübl
Viscosity	0·3915		0·3724
		Mixed alcohols.	
M.p.	31·5°–32·5°C.	30°–31·5°C.	31°–31·5°C.
Saponif. value of acetate	184·0		189
		Fatty acids.	
Iodine value			150 Hübl; 178 Wijs.

On account of this striking resemblance to sperm oil, mutton-bird oil should be of value as a lubricant and as a dressing for leather; but as supplies are small it may have only local importance.

Its chemical nature would render it unsuitable as a food since the ordinary digestive juices cannot split cetyl esters; but if the oil serves as food for the young mutton-birds it is of interest physiologically to ascertain what enzymes in the gastric juice of the birds can hydrolyse the oil.

Qualitative tests have been carried out in an attempt to split the oil with pancreatin and with pig's pancreas and in each case a certain amount of hydrolysis was observed. A series of quantitative measurements of the action of different fat-splitting enzymes may give interesting results.

In conclusion, the author wishes to thank Professors Inglis and Malcolm for much valuable advice and for their kind interest shown during the research.

Otago University, Dunedin, N.Z.

THE PATH OF TRAVEL OF THE GASES IN THE COKE OVEN.

BY G. E. FOXWELL.

Errata.

This J., Sept. 15, 1921, p. 198 T, col. 2, line 3 from bottom, and p. 199 T, col. 1, in formulæ at top, for $(q_W—v)$ read

$$(q_W - v)\,\frac{273+T}{273}$$

where T is the temperature at the point considered.

The first table on p. 199 T, col. 1, should be replaced by the following:—

	9 hrs.	14 hrs.	20 hrs.

THE ACTION OF THIOCYANATES ON CELLULOSE.

BY H. E. WILLIAMS.

It has been known for some time that a concentrated solution of zinc chloride or of mercuric-barium iodide will dissolve cellulose, and Deming (J. Amer. Chem. Soc., 1911, 33, 1515) has shown that cellulose will dissolve in solutions of certain metallic chlorides strongly acidified with hydrochloric acid; in the latter case the cellulose is profoundly modified by the hydrolytic action of the acid before solution takes place.

Dubosc (Bull. Soc. Ind. Rouen, 1905, 318) first noticed the action of certain thiocyanates on cellulose, and states that solutions of ammonium and potassium thiocyanates dissolve cellulose, forming a cellulose thiocyanic ester. P. Weimarn (G.P. 275,882) claimed the action of a solution of any neutral salt on cellulose—the term action being here used in its widest sense. No technical developments followed from these observations.

The subject matter of this paper is the outcome of work carried out some years ago (1907–8) on the properties of the metallic thiocyanates.

Several years later (1916), although the author was unaware at the time of the work of the investigators mentioned above, his attention was directed to his previous observations in a systematic study of the concentrated solutions of metallic thiocyanates, and it was found that a number of these solutions (*e.g.*, of strontium, magnesium, manganese, lithium, etc. thiocyanates) when heated were capable of dissolving cellulose.

These results were then subjected to a critical examination, and a theory of the action of these solutions on cellulose was evolved by means of which it is possible to predict the action in terms of definite physical constants, a detailed description of which has been given elsewhere (Manchester Lit. and Phil. Soc., Apr. 12, 1921) and will shortly be published. It will suffice here to state that the results of the work demonstrated that to dissolve cellulose, a concentrated aqueous solution of a neutral or acid salt must consist of a liquid hydrate—an associated molecular complex of salt and water—which must have a viscosity above a certain minimum and a positive heat of dilution between certain well-defined limits.

By the aid of this knowledge it was possible to make any of the thiocyanate solutions dissolve cellulose, either singly or in admixture with one or more other thiocyanates. For example, sodium thiocyanate solution is not a cellulose solvent at any concentration under atmospheric pressure, the viscosity of its most concentrated solution falling below the minimum required. As this salt solution has a positive heat of dilution when concentrated, it follows that additions which increase its viscosity but which do not reduce its heat of dilution will render the solution capable of dissolving cellulose. This result may be accomplished by the addition of sufficient manganese, aluminium, zinc, or other thiocyanate, the two latter not being of themselves solvents for cellulose. The same result may also be obtained by dissolving in the solution the insoluble or sparingly soluble thiocyanates, such as the mercuric, cuprous, cadmium, silver, or lead salts.

The possible industrial applications of these observations include the spinning of filaments, mercerisation of cotton fabrics, parchmentisation of paper, and the preparation of "vulcanised" fibre.

Of all the cellulose solvents examined, the concentrated solution of the calcium thiocyanate has the most profound and far-reaching effects, and as it has the further industrial advantage of having a cheap base, it is the one that has been most closely studied from the industrial standpoint.

As mentioned above, cellulose is soluble in the concentrated thiocyanate solution only if neutral or acid, careful investigation having shown that if the solution is alkaline, no solution of cellulose takes place. This result has been found to be true for all the thiocyanate solutions. Calcium hydroxide dissolves in calcium thiocyanate solution in increasing amounts as the concentration of the thiocyanate rises, and a solution containing 2 g. or more of calcium hydroxide per 100 c.c. may be obtained. The alkali may be neutralised by careful addition of dilute sulphuric acid, or by diluting the solution to a specific gravity of 1·2, when practically the whole of the hydroxide will be precipitated in the free state, and the solution may be filtered and re-concentrated.

A solution of calcium thiocyanate of such a concentration that it boils between 135° and 150° C. will dissolve bleached cotton or chemical wool pulp when heated to 80°—100° C. The fibre first swells and then gradually passes into colloidal solution, no trace of the original fibre being visible when a drop of the solution is examined under a microscope; on cooling, the mass sets to a clear, firm jelly. That a solution boiling below 133° C. or one boiling above 150° C. will not dissolve cellulose may be easily demonstrated by adding a few fibres of chemical wood pulp to a neutral solution of the thiocyanate boiling, say, at 110°—115° C. and allowing the mixture to boil slowly on a sand bath; it will be noticed that, apart from some swelling action, no solution of the cellulose takes place as the temperature of the boiling point rises during concentration until it reaches 133°—134° C., when the fibres pass into solution in a few seconds. If the thiocyanate solution is further concentrated and the cellulose then added, it will be noticed that solution of the cellulose becomes more and more difficult, and when added to a solution boiling at 150° C. or over no cellulose passes into solution, although the fibre is strongly parchmentised and swollen.

This retardation of solution ending in complete stoppage, is not due to the increased viscosity of the solution, which would naturally retard the rate at which the cellulose dissolves, but to a more deeply seated cause. In a solution of a very soluble salt with a positive heat of dilution, as the amount of total solids increases on concentration, the remaining water must be held by the salt with greater and greater affinity. If, therefore, such a solution will bring about a chemical reaction between another compound and water, it is obvious that as the concentration of the solution increases, the salt will tend to hold the water in a stronger and stronger union, and thus retard more and more the desired hydrating action. A point may therefore be reached where the affinity of the water for the salt is so great as to transform any hydrating action into a dehydrating one. This point appears to be reached in the hydration of cellulose by calcium thiocyanate when the concentration of the solution rises to the point at which the b.p. is 150° C. and over. The addition to such a boiling solution containing cellulose of a few drops of water sufficient to lower the boiling point to 148°—149° C. will cause solution of the cellulose in a few seconds.

When cellulose is dissolved in the neutral calcium thiocyanate solution boiling between 133° and 140° C. the fibres first swell enormously, the whole mixture becoming intensely thick and gelatinous, and very difficult to stir if the proportion of cellulose is 3½—4 g. or more per 100 c.c. of solution, but on further heating the mixture gradually melts down to a thick fluid. The addition of a weak acid such as glacial acetic acid, in the proportion of 2—4 g. per 100 c.c. of solution, enables the cellulose to dissolve without passing through this intense gelatinous stage, and the mixture may be easily stirred during solution. By this means solutions of 10—12 g. of cellulose per 100 c.c. of solution may be as easily and readily made as those of lower strength.

For the preparation of a concentrated solution of cellulose the most suitable calcium thiocyanate solution is one which boils at 134° C. or slightly over, but not exceeding 140° C.; 3—4 c.c. of glacial acetic acid per 100 c.c. of solution is then added, followed by 5 to 10 g. of cellulose according to the strength of the solution required, and the mixture allowed to stand until the fibres become thoroughly wetted and impregnated with the solution. The mixture is then heated to 100° C. and maintained at that temperature until the fibres become separated and highly swollen, and the whole liquid thickly fluid. The temperature is then raised to 110°—120° C. and the mixture stirred until complete solution results. The temperature should not be allowed to rise much higher or the solution may become distinctly brown in colour.

A portion of the calcium thiocyanate solution may be replaced by a solution of certain salts which do not react chemically with it, but maintain its boiling point and other necessary properties, without altering the solvent properties of the solution for cellulose. Such a solution of mixed salts will, so far as present experience goes, serve the same purpose as a cellulose solvent as the pure calcium thiocyanate solution.

There are but few salts capable of fulfilling this function, for such a salt must have high solubility in water, high boiling point in concentrated solution (over 133° C.), it must be viscous and have a positive, but not too great heat of dilution, and it must not act chemically on the calcium thiocyanate.

These properties and conditions are fulfilled to an admirable extent by calcium chloride, which further has the advantage of cheapness. A solution of this salt boiling at 133° C. may be mixed with calcium thiocyanate solution boiling at 133° C. in the proportion of one volume of calcium chloride solution to two volumes of calcium thiocyanate, without in any way interfering with the properties of the calcium thiocyanate solution for dissolving cellulose. The same maximum amount of cellulose may be dissolved in the mixed solution, whether netural or acidified, with equal ease. A larger proportion of calcium chloride solution cannot be employed when working with solutions of the concentration mentioned above, without the viscosity of the mixed solutions falling below the minimum necessary for a cellulose solvent.

If, however, both the solutions are concentrated until the boiling point rises to 140° C. under normal pressure, equal volumes of calcium chloride and calcium thiocyanate solutions may be used. This mixture will be found to dissolve the same maximum amount of cellulose and with the same ease as the original pure calcium thiocyanate solution boiling at 133° C.; in fact in some respects it is superior. The substitution of greater amounts of the calcium thiocyanate solution by calcium chloride solution have not been attended with success, and conclusions based on theoretical considerations render it unlikely that the substitution can take place to any greater extent, since the heat of dilution of the mixed solutions is too great.

A solution of cellulose in the calcium chloride-thiocyanate solution prepared as above described, containing about 7 g. of cotton or wood cellulose per 100 c.c., and kept warm, may be spun through a fine orifice for the preparation of cellulose filaments. The best precipitating medium for the spun threads so far found is dilute alcohol (50—90% C_2H_5OH). The precipitated filament, which is firm and easily handled, may be washed and dried in the usual manner, yielding threads which are strong and lustrous.

In the methods described above the cellulose dissolves in the thiocyanate solutions only on heating, but Mr. C. F. Cross, F.R.S., who has taken a deep interest in the results of the work, has made the interesting observation that solution of the cellulose may be effected in the cold by the following method. Chemical wood pulp is allowed to soak for some hours in the cold in a mixture of four parts of calcium thiocyanate solution of sp. gr. 1·38, and one part by volume of 40% formaldehyde. The fibre swells in the mixture, and no other apparent change takes place, but when the solution is diluted with an equal volume of cold water, the cellulose rapidly passes into solution. If the original mixture, after standing but before dilution, is gently warmed, and small quantities of water are gradually added, it becomes thicker and thicker until finally all the cellulose passes into solution. Solutions containing up to 4% of cellulose have been obtained in this manner.

As similar results may be obtained by using solutions of zinc chloride, strontium thiocyanate, or lithium thiocyanate, etc. of appropriate strength, mixed with 25% of 40% formaldehyde, it would appear probable that the reaction is a general one. The partial substitution of calcium chloride solution for the calcium thiocyanate in the formaldehyde mixture has a retarding effect, probably due to its powerful dehydrating action.

If the thiocyanate solution is diluted with the same amount of water in place of the formaldehyde solution, no apparent effect is observed and no solution of the cellulose takes place on dilution.

The addition of the formaldehyde to the thiocyanate solution lowers the surface tension, but does not materially lower the viscosity or the heat of dilution of the mixture; the addition of water, however, while hardly altering the surface tension, considerably lowers the viscosity and the heat of dilution.

If the cellulose is soaked for some hours in calcium thiocyanate solution of b.p. 134° C., and water is then added to bring the sp. gr. to 1·26 (b.p. 115° C.), solution of the cellulose occurs on heating to 60°—70° C.

A careful examination of the action of calcium thiocyanate in the cold on chemical wood pulp has shown that whereas no cellulose passes into solution when digested either with very dilute or very concentrated thiocyanate, traces are dissolved in the slightly less concentrated solutions, rising to a maximum of about 0·5% of the added cellulose in the solution of sp. gr. 1·3 and gradually falling to zero in the weaker solutions.

If the thiocyanate is diluted with varying amounts of formaldehyde in place of the water, gradually increasing quantities of cellulose are dissolved on the addition of water, rising to a maximum of 100% and then rapidly falling off to zero. The curve expressing the percentage of cellulose dissolved for each dilution of the thiocyanate solution with formaldehyde reaches its maximum at the same point as the thiocyanate-water curve.

If chemical wood pulp be worked in a beater for 24 hours with the cold thiocyanate solution of sp. gr. 1·3 (b.p. 120° C.) a considerable portion of the cellulose may be found in solution after filtration. The remainder of the fibre passes into apparent solution on heating to 60° C., setting to a firm jelly on cooling. There is still some doubt as to whether this jelly is a true colloidal solution, as although the fibres are invisible under the microscope in the warm solution, they appear to be faintly outlined in the cold solution as enormously swollen, and distinct evidence of fibre structure may be perceived in the precipitate obtained on dilution.

Parchmentising action.

If unsized paper is passed through a solution of calcium thiocyanate, or better the 50/50 calcium chloride-thiocyanate solution concentrated until the boiling point rises to 155°—157° C. and cooled to 130° C., an excellent parchment paper or vegetable parchment results. The paper should be preferably of open web and a good absorbent, and is passed through the bath at such a rate that it is in contact with the hot liquid for not less than 30 secs., then washed in running water and dried over steam-heated rollers.

A weaker thiocyanate bath, which would be a cellulose solvent, obviously cannot be used with any great success for the preparation of parchment paper. It will partially dissolve the cellulose and leave a solution of the salt and cellulose on the surface of the paper; on washing the paper the light flocculent film of cellulose hydrate on the surface of the sheet will be removed by the water before precipitation of the gel occurs, thereby causing loss. On drying a paper so treated and washed, the precipitated cellulose hydrate will shrink considerably, crack, and expose some of the untreated fibres underneath, and thus the paper will not be rendered air- and grease-proof.

At the same time it is only permissible to attack the surface of the paper, for otherwise it would become too soft to handle in the washing operations, and would dissolve or disintegrate on more prolonged treatment in the bath. It is therefore preferable that the parchmentising solution should not be a solvent for cellulose, and such a solution is obtained by concentrating the calcium thiocyanate-chloride solution to a boiling point of 155° C.

From a large number of experiments it has been found that the temperature at which such a solution has the most marked parchmentising effect is 130°—135° C., though it may be varied from 125° to 140° C. with but little effect.

At the present time parchment paper is manufactured by passing unsized cotton rag paper through a bath of sulphuric acid (sp. gr. 1·7) maintained at 10° C. The paper must be passed through the solution at such a rate that it is not in contact with the acid for more than about ten seconds; the temperature of the bath must not be allowed to rise above 10°—15° C., and the paper must be very rapidly washed. If the temperature of the bath is allowed to rise, or the paper kept in contact with the acid for more than about 15 seconds before washing, the action of the acid becomes so great that the paper partially dissolves, becomes soft, and cannot be handled in the washing operation.

The use of the calcium chloride-thiocyanate bath, prepared as above, for parchmentising has the advantage that the time of contact with the parchmentising bath may be prolonged, and the temperature may be varied between wide limits; also the washing operation may be delayed for any length of time without damage resulting.

Again, sulphuric acid chars and blackens lignocellulose and can therefore only be used to parchmentise pure cellulose paper; but any class of unsized paper may be parchmentised with the thiocyanate solution, whether it consists of pure cotton rag, or contains lignocellulose such as mechanical wood pulp or jute, etc. The process may therefore be used for parchmentising and at the same time strengthening wrapping paper, jute half-stuff, etc.

It is, of course, necessary to recover the chemicals carried over by the paper from the parchmentising bath. The amount of liquid carried over into the washing plant is very considerable; experiment has shown that after passing the squeezing rollers, whether sulphuric acid or the calcium chloride-thiocyanate solution is used, the amount is roughly 4—5 times the weight of the paper used.

In the sulphuric acid process the paper, after leaving the parchmentising bath, must be plunged as quickly as possible into an excess of cold dilute acid to stop the action of the strong acid on the paper. This difficulty does not arise with the thiocyanate process, as the paper after leaving the parchmentising bath may be washed on the complete counter-current principle, with a recovery of 95% of the solution at a concentration of 1·33 sp. gr. (*i.e.*, half the concentration of the original parchmentising bath).

Paper prepared by the thiocyanate method has been examined by Messrs. Cross and Bevan, of London, with the following results:—

	Standard parchment.	M. O. Co. parchment.
Moisture	11·5	12·2
Loss on boiling with 2% NaOH, 60 min.	8·2	3·9
Loss on boiling with 2% H_2SO_4, 60 min.	2·4	0·7
Following H_2SO_4 treatment with boiling NaOH, 60 min.	26·7	17·7
After washing and drying	brittle	retains flexibility.
Mercerising action of NaOH. Cross & Bevan method:—		
α–Cellulose	98·9	98·54
β „	0·27	0·00
γ „	0·83	1·46

The bursting strains of several varieties of paper parchmentised by the thiocyanate method are appended:—

Paper used.	Bursting strain. Original.		
	Original.	Parchmentised.	With glycerin added.
	lb.	lb.	lb.
Thin white blotting	17	67	68
Thick „ „	39	97	112
„ grey „	31	118	127
Thin „ „	14·5	51	64
Thick blotting pink	35	96	101
„ wood pulp	36	97	79
Cheap thin brown wrapping	11	23	21
„ thick „ „	16	29	25
Unbleached wood pulp	22	41	35
Thick brown wrapping	35	69	65

Mr. J. Huebner, of the Manchester College of Technology, has experimented with the paper after parchmentising with the calcium chloride-thiocyanate solution, by exposing it to the action of various vapours for different lengths of time; considerable improvement was obtained in the strength of the paper. The bursting strain of the original paper was 8 lb., or if washed immediately after parchmentising in the usual manner, 35 lb. After exposure to the atmosphere for 3 hrs. the bursting strain was 52 lb., 5 hrs. 51 lb., 20 hrs. 55 lb., 2 days 62 lb., 7 days 60 lb. After exposure to ethyl alcohol vapour for 3 hours the bursting strain was 33 lb., 5 hrs. 48 lb., 20 hrs. 56 lb., 2 days 64 lb., 7 days 69 lb. After exposure to acetone vapour for 3 hrs. the bursting strain was 38 lb., 5 hrs. 42 lb., 20 hrs. 59 lb., 2 days 64 lb., 7 days 75 lb. After exposure to methyl alcohol vapour for 3 hrs. the bursting strain was 38 lb., 5 hrs. 44 lb., 20 hrs. 45 lb., 2 days 61 lb., 7 days 71 lb. If washed in alcohol instead of with water the bursting strain was 55 lb.

Preparation of vulcanised fibre.

The paper leaving the parchmentising bath is passed through a second bath at 40°—60° C. containing the same mixture of calcium thiocyanate and chloride but of slightly lower strength (namely b.p. 135°—140° C.), then through squeezing rollers, and rolled up on a drum of large diameter; when the required thickness is obtained the mass is heated for half an hour at 120°—130° C., cooled, washed, and dried. In this manner a very fine vulcanised fibre results resembling vegetable ivory in hardness. It can be sawn, turned, and tapped, and will take a very high polish. The dried mass contains no indication of the original layers of paper, nor are any of the fibres of the paper visible, and there is no tendency to split in the direction of the layers.

The passage of the paper through the second and weaker bath after parchmentising is necessary, because the surface of the parchment paper has feeble adhesive properties, and it is difficult, if not impossible, to obtain a compact mass by superimposing and pressing a number of such sheets. In the passage through the somewhat weaker bath the surface of the paper is wetted with a solution which will dissolve cellulose when heated, but the temperature of this bath is kept below the solvent point. When the prepared mass is subsequently heated this solution dissolves some cellulose on the surface of the paper and cements the sheets together uniformly and completely; on cooling, the fibre sets in a matrix of jelly.

The preparation of the vulcanised fibre at present on the market is effected by means of a concentrated solution of zinc chloride. Sulphuric acid is useless for this purpose, as the solvent action of the acid is so rapid that it has been found impossible to cement more than two or three layers of paper together before it pulps. In the zinc chloride method, the paper is passed first over a heated drying cylinder into a bath of concentrated zinc chloride of sp. gr. 1·8 at 40° C., the concentration and temperature of the bath varying slightly according to the quality of the paper used. It is then rolled up over a large heated drum to the required thickness. The treated fibre is washed in zinc chloride baths of successively diminishing concentration until it contains less than 0·1% of zinc chloride. This washing process is difficult owing to the great tendency of the zinc chloride to hydrolyse, and deposit zinc hydroxide and oxychloride in the fibre; it is very slow and cannot be hastened, or blisters may be produced in the fibre and an inferior product results. For sheets ½ in. thick the washing operation is said to take 3—4 weeks, and for 2-in. sheets 6—8 months. The washed fibre is dried at 40°—60° C., pressed, and sometimes calendered.

In the calcium thiocyanate method the solution required is less concentrated, and the washing operation is rapid and complete. The certain absence of zinc or other metallic hydroxide or chlorides, is of advantage in using the fibre for electrical insulators etc.

Mercerising action.

Strong mercerising effects may be obtained on cotton fabrics by immersing them in calcium thiocyanate solution; the fabric shrinks and lustre and increased dyeing properties are obtained. If immersed in hot solutions the lustre is decreased and the fabric becomes stiff and is permanently altered so that after washing it still retains its stiffness. Treatment in the cold solution, however, leaves the fabric soft and pliable.

Experiments with cotton hanks in cold calcium thiocyanate solution of decreasing strength show that the best effects are obtained with a solution containing 60 g. of calcium thiocyanate per 100 c.c.; the cotton shrinks about 16% of its original length when added to the bath dry, and 21% when wetted out first. With both stronger and weaker solutions the effect decreases, and scarcely any effect is observed with calcium thiocyanate solution of sp. gr. 1·25.

A large number of experiments on cotton hanks have been carried out, which show that the effects such as shrinkage, dyeing properties, etc. vary with the concentration of the solution, time of immersion, temperature, and the composition of the solution. Different effects are obtained with different thiocyanates, and even by the addition of small amounts of other thiocyanates.

The effects obtained on cotton by these means have so far not proved superior to those produced by the action of caustic soda, and as the latter is the cheaper this process does not offer any apparent advantage. The possible variations of the number of factors involved are, however, so great that further investigation may bring to light effects of industrial interest at present unsuspected.

Action on raw jute.

If raw jute is boiled for ½ hr. in calcium thiocyanate solution of sp. gr. 1·3, and washed and dried, the fibre bundles are more or less broken down, and the fibres themselves become soft and curly, while still retaining their strength. With stronger solutions the action is too severe, the fibres becoming gelatinous and partially dissolving; in weaker solutions little effect is seen.

Preparation of calcium thiocyanate.

It will not be out of place here to give a short description of the manufacture and properties of calcium thiocyanate. In the purification of coal gas, the cyanogen compounds may be extracted in the form of ammonium thiocyanate by scrubbing the crude coal gas, before the removal of the ammonia, in a specially designed scrubber containing spent oxide kept moist with water. The mechanism of the reactions involved has been fully described in the technical literature. Practically all the hydrocyanic acid in the crude coal gas is recovered in the form of ammonium thiocyanate, which is periodically removed as a solution of 15—20% strength by spraying the scrubber with water. This method has been in commercial use in England for some years. The solution of crude ammonium thiocyanate is readily converted into the calcium salt and purified by special, but simple methods.

Calcium thiocyanate may also be readily obtained by fusing calcium cyanamide with sodium chloride, dissolving the melt in water, digesting the crude sodium cyanide with free sulphur to convert it into sodium thiocyanate, filtering and concentrating the solution. During the course of the evaporation, the sodium thiocyanate will react by double decomposition with the calcium chloride present in the solution, forming sodium chloride which will be deposited quantitatively as fine crystals, leaving a solution of pure calcium thiocyanate. These reactions may be expressed as follows:—

$$\begin{aligned} &\mathrm{CaCN_2+C+2NaCl} &&= \mathrm{2NaCN+CaCl_2.} \\ &\mathrm{2NaCN+CaCl_2+S_2} &&= \mathrm{2NaCNS+CaCl_2.} \\ &\mathrm{2NaCNS+CaCl_2} &&= \mathrm{Ca(CNS)_2+2NaCl.} \end{aligned}$$

Calcium thiocyanate may also be obtained from calcium cyanamide by preparing thiourea as an intermediate product.

Calcium thiocyanate is a very soluble and deliquescent salt, but may be obtained in crystals containing three molecules of water. The concentrated aqueous solution is very viscous, and dissolves not only cellulose, but also natural silk, acetylcellulose, and gelatin; it has no action on wool. It dissolves a number of metallic hydroxides such as lead, zinc, cobalt, nickel, cadmium, stannic, and ferric hydroxides, all of which are reprecipitated on dilution. Tricalcium phosphate will dissolve to a small extent in the hot, concentrated solution, while on the other hand certain water-soluble salts, such as sodium chloride or potassium chromate, are practically insoluble.

THE BRIQUETTING OF LIGNITES.

BY LESLIE R. THOMSON, M.E.I.C.

One of the first studies made by the Canadian Honorary Advisory Council for Scientific and Industrial Research, established in November, 1916, was that of the fuel supply in Canada. The Council soon came to the conclusion, however, that the question of fuel supply for the whole of Canada was too large to be handled by a body with such limited powers, and thereupon appointed a sub-committee to prepare a detailed investigation of the fuel situation in the Canadian West.

The situation there was indeed of great interest. Manitoba possesses no coal whatever. Saskatchewan has vast deposits of lignite, the quality of this lignite improving greatly as one moves toward the West. Alberta possesses some of the greatest coal deposits of the whole world. In spite, however, of these great natural deposits, the Canadian West has been importing for many years past large quantities of American coal. Practically all the coal for domestic heating in the towns and cities has been American anthracite, and the price naturally increased as one went westward. It continued to find a market, however, until the price became so high that the consumers were forced to use the much cheaper Alberta coals in spite of their disadvantages for domestic heating. The "peak" line where the price of American anthracite reached the highest point, runs in a general north and south direction through the eastern parts of Saskatchewan. Directly beneath this area there are very large deposits of rather low-grade lignites, known generally as the Souris or Estevan lignites. These deposits fall into three main fields, the Estevan field, the Willow Bunch field, and the Wood Mountain field, of which the Estevan lignites are the poorest. The Souris lignites in general are of a distinctly low grade in their raw state, but after carbonising and briquetting, are capable of being converted into a fuel possessing high calorific value.

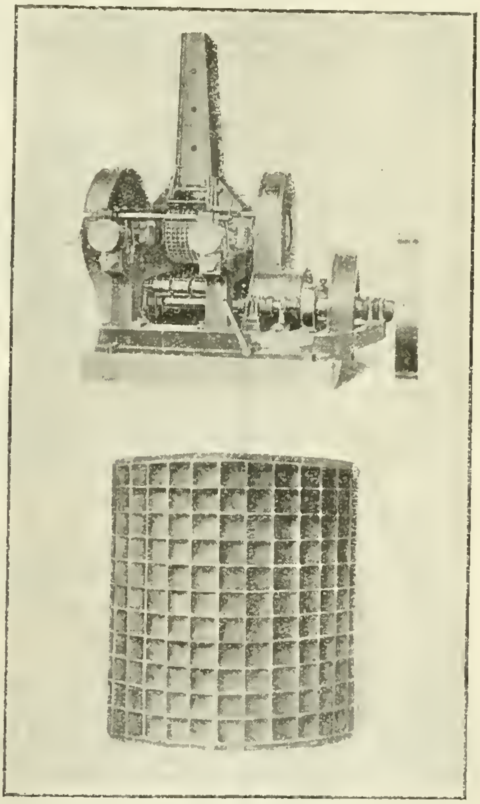
The above outlined circumstances seemed to point to the fact that the Western domestic fuel problem might be attacked and solved locally without prejudicing in any way any subsequent general solution of the whole Canadian problem.

As a result of a report, entitled "Briquetting of lignites," by R. A. Ross, presented by the Research Council in 1917, the Government in 1918 appointed a Lignite Utilization Board with the express objective of demonstrating, if possible, the feasibility of producing a satisfactory domestic fuel from low-grade Souris lignites by the method of carbonising and briquetting. The Board is composed of three members, Dr. R. A. Ross, Chairman, representing the Dominion Government, J. M. Leamy, representing the Manitoba Government, and the Hon. J. A. Sheppard, representing the Province of Saskatchewan. The three Governments also agreed to finance the Board jointly. On October 1, 1918, the Board started its work with head office in Montreal.

An investigation of all existing briquette plants in North America showed that no commercial briquetting of North America lignites had ever been accomplished. Carloads of more or less carbonised lignite had been pressed into briquettes of one kind or another in one or two experimental laboratories, but nothing had ever been accomplished on a commercial scale. It was found that American experience on briquetting had been confined entirely to bituminous coal and anthracite culm. On the other hand, the European experience had been very extensive, especially the industry in Germany in connexion with brown coal, but it was soon discovered that the widely different physical characteristics of the German brown coals and the Canadian lignites precluded a wholesale transposition of German methods to Canadian conditions.

It therefore became necessary for the Board to institute an independent series of investigations. These were authorised and approved in February, 1919, and it was decided to erect in Ottawa a special laboratory in which these studies could be made. This course of action was possible owing to the courteous co-operation of the Mines Branch of the Department of Mines. The author wishes to take this opportunity of recording the deep sense of obligation felt by the Lignite Utilization Board toward the Department of Mines for their unfailing and very valuable assistance.

In the course of the investigation of the briquetting plants in North America it was noted that only three types of presses are used, viz., roll presses, Rutledge presses, and Komarek presses. The last named is a modified roll press, while the Rutledge is an American plunger press turning out briquettes of from 10 to 16 ounces in weight. Of 13 briquette plants examined (one of which has two installations) eight use the simple roll press producing small briquettes, two use the Komarek roll press producing small briquettes, and four use the Rutledge plunger, producing large briquettes. The output of one of the last named four is destined practically entirely for export to South America. British, French, and German practice has been in the main to produce a large briquette of from 12 oz. to 2 lb. or more in weight, but a good proportion of the output of the British plants is made for export, as the large briquettes are usually superior in their shipping qualities.



Roll press and roll.

Fig. 1.

As the duty of the Board was to prepare a fuel for Western Canadian domestic consumption it was decided that a small briquette, either pillow-shaped or ovoid, would be more suitable for the domestic furnaces in the West (which, without exception, are designed to burn American anthracite), and that for the production of small briquettes of about 2 oz. the roll press would be cheaper in first cost, simpler in handling, and more economical in maintenance. The Board has therefore limited all its research work to briquetting with a roll press (see Fig. 1).

Carbonising temperatures.—The investigation into the relative suitability of lignite carbonised at different temperatures was not prosecuted completely owing to other factors in the situation. As the direct objective was to produce a fuel, it was essential that the greatest possible number of B.Th.U. should be left in the lignite residue after carbonisation. As a result of the Board's researches on carbonisation* it appeared that carbonisation at approximately 600° C. yielded a residue having the highest B.Th.U. content. The residue produced by carbonising at this temperature was therefore laid down as the desired objective, and no special difficulty was anticipated or discovered, as standard briquettes had been made with residues carbonised at widely different temperatures.

The following table gives the chemical analyses and calorific values of the carbonised residue as discharged at varying intervals from the semi-commercial carboniser:—

	2 min.	2½ min.	3 min.	4 min.
Moisture, %	0·0	0·0	0·0	0·0
Ash, %	19·6	19·6	18·8	22·7
Vol. matter, %	18·6	17·8	13·2	6·5
Fixed carbon, %	61·8	62·6	68·0	70·8
B.Th.U.	11,140	11,080	11,180	11,150

Fineness.—The investigations to determine the best fineness of material to be briquetted were not carried to a final conclusion owing to the fact that fineness is not an independent variable, but is intimately connected with the binder discussed below.

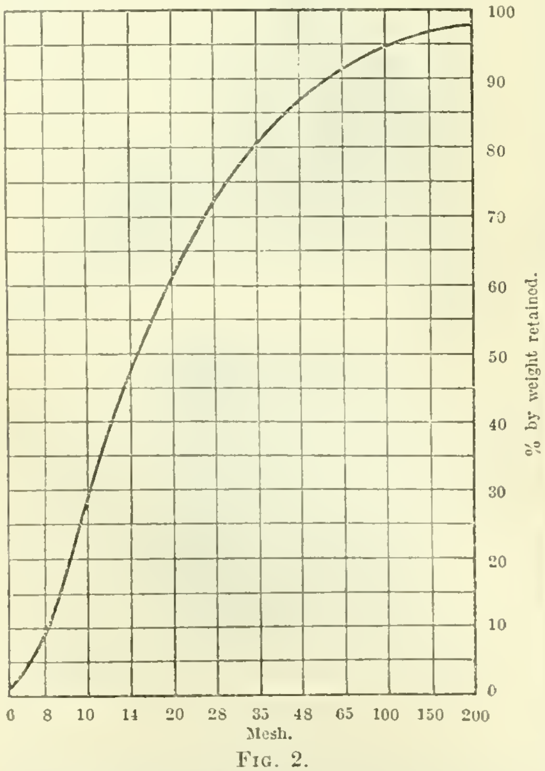


FIG. 2.

Average screen analyses of carbonised residues from about 15 batches.

A roll press for pulverising lignite was installed in the Ottawa laboratory, and in addition there was a small coffee mill, which proved extremely useful, because it was found to produce a material that on the whole made excellent briquettes. Consequently this size was adopted more or less as a standard size.

The following is a screen analysis of some lignite passed through the coffee mill and carbonised at 600° C.: −10+20, 60·1%; −20+40, 21·8%; −40+60, 8·0%; −60+80, 3·3%; −80+100, 2·1%; −100, 4·5%. Loss, 0·2%. It will be noted that there are no lumps over ⅛ in. in size. Fig. 2 represents an average screen analysis of fourteen samples of carbonised residue. The curve shows that on the whole the material is of fairly uniform consistency.

Binder investigations.—Bulletin No. 24 of the Bureau of Mines, Washington, and the previous work of Messrs. E. Stansfield and R. E. Gilmour, of the Department of Mines, Ottawa, constituted the starting point for the Board's further researches in briquetting. The following is a list of the binders investigated either specifically by the Board or indirectly by reference to the work of other experimenters.

Single binder: High, medium, or low melting-point coal tar pitch, oil pitch, asphalt, lignite pitch, and hardwood pitch; also sulphite liquor, sulphite pitch, etc.

Treated binders: Chlorinated or sulphonated tars, oxidised asphalts, treated sulphite pitch (with alkali, or with salts to render insoluble), etc.

Combinations of binders: Combinations of the above alone, or in mixtures with the addition of coal tar, lignite tar, hardwood tar, soft asphalts, flour, starch, clay. water-glass, cement, straw, etc., with or without the addition of water.

In recording the amount of binder used the expression "mixing ratio" (M.R.) is applied to indicate the number of parts by weight of binder added to 100 parts by weight of the carbonised residue. A briquette made up of 100 parts by weight of carbonised residue, 8 pts. of coal-tar pitch, and 4 pts. of sulphite liquor solids would be described as coal-tar pitch M.R. 8, sulphite liquor solids M.R. 4.

After much experimenting, and following a thorough exploration of the markets, all but a few binders were excluded from further consideration. The binders retained for further study were coal-tar pitch, petroleum pitches, sulphite liquor pitches, starches, glutens, and straw jelly. The last three were considered only as auxiliary binders to be used in conjunction with one or more of the standard pitches. By a process of elimination, due to prohibitive cost, petroleum pitches and sulphite liquor pitches were next dropped, at least temporarily, until their price at Estevan was reduced, and attention was concentrated on coal-tar pitch or combinations of pitch with waste flour screenings.

The minimum amount of coal-tar pitch found to be necessary when used alone to make a first-class commercial briquette as standardised by the Board is M.R. 13.

Within certain rather narrow limits 1 part of weed seed (waste flour screenings) will replace 2 parts of pitch. Thus a very good briquette was produced with pitch M.R. 9 and weed seed M.R. 2.

It is interesting to note that carbonised lignites require almost double the quantity of binder necessary to produce a physically similar briquette of anthracite fines. This fact alone vitiates many of the conclusions reached by certain writers on the subject who venture to transfer results obtained from anthracite briquetting into the field of lignite briquetting.

As a result of these investigations the Board decided to initiate its work at Bienfait with a straight coal-tar pitch briquette, M.R. 13. The

analysis of our straight coal-tar pitch briquette is: Moisture, 4·3%; volatile combustible matter, 19·4%; ash, 16·5%; fixed carbon, 59·8%; B.Th.U., 11,280.

Mixers.—From time to time claims have been made for the high efficacy of paddle mixers and of masticators (sometimes termed edge-runners or Chilean mills). Edge runners are installed in a number of plants, and certain of the operators felt that they were indispensable. On the other hand, certain other operators reached the conclusion that intimate mixing by paddle mixers was quite feasible. Owing to the high cost of these various mixers, it was decided to defer experimenting with them until the main plant was constructed. Examples of each are installed and arrangements have been made to by-pass the material as may be desired.

Speed of rolls.—The rolls of the Board's small press are 2 ft. ½in. in diameter and operate at 10-11 r.p.m., making a tangential speed of about 70 ft. per minute. These speeds are capable of reasonable variation without impairing the quality of the resulting briquette.

Secondary heat treatment.—The question of secondary heat treatment is mainly one of cost owing to the difficulty of constructing a furnace or a retort in commercial sizes in which the process can be made continuous. The extra handling and capital charges all add naturally to the cost of the finished product, and the question arises as to whether the resulting smokelessness is worth the cost.

So far as laboratory methods go the Board has accomplished the carbonising of several types of briquettes. One of the most interesting examples is a test on a batch of standard coal-tar pitch briquettes, M.R. 13. The carbonisation of this briquette was carried out in a large metal retort, immersed in a bath of molten lead, having a temperature about 500° C. About 5¼ lb. of briquettes was used, producing hard briquettes, possessing a smooth surface, somewhat difficult to distinguish from the untreated briquettes. In this particular experiment the temperature was not quite high enough, and the resulting product showed a slight trace of smoke, but it was very slight. The treatment of this briquette resulted in a 10% loss in weight. After being allowed to stand for two days, the treated briquettes were analysed with the following result:—Moisture, 2·9%; volatile matter, 8·3%; fixed carbon, 72·3%; ash, 16·5%. B.Th.U. per lb., 11,760.

It was finally decided to postpone further investigations until the Board's main plant was in operation, and a commercial briquette was actually on the market.

Briquette testing.

In addition to the mechanical tests, freezing and thawing tests were carried out to ascertain the probable behaviour of briquettes in the extremely cold western weather. Typical briquettes were first immersed for 24 hours in water and then placed in the "sharp freezer" of Wm. Davis and Co., Montreal, for 24 hours; the temperature of this was from 0° to −12° F. The briquettes were then removed and thawed for 24 hours in water. This alternating treatment was continued for four complete cycles, and the briquettes examined. On the briquettes that the Board classified as good and waterproof, no signs of deterioration were visible. This test is a very much more severe one than any natural freezing or thawing tests could be.

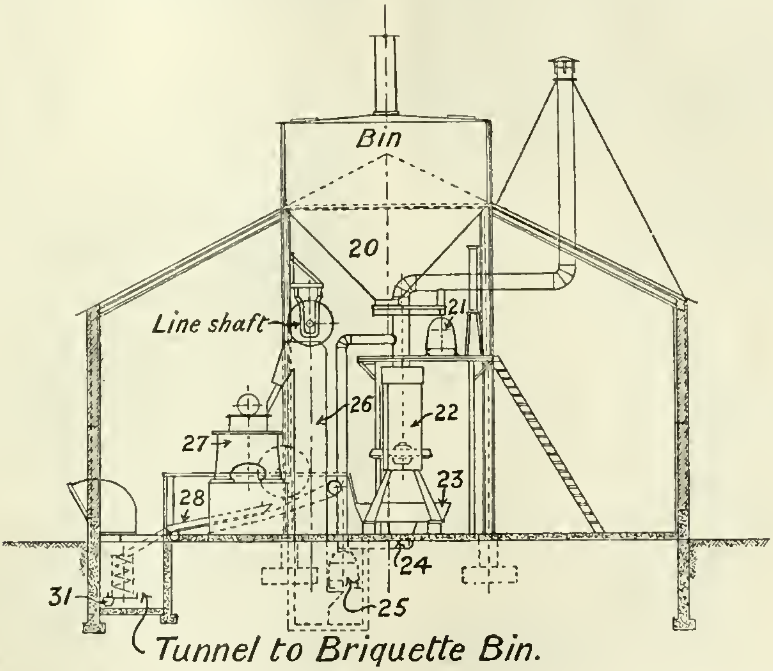

Fig. 3.

Construction of the main plant.

Upon the generally successful termination of the experimental programme above described, the Board felt satisfied in proceeding with the erection of its main plant near the town of Bienfait, Sask. This plant is to have a capacity of 100 tons of briquettes per day. The briquetting department is shown in sectional elevation in Fig. 3.

The mixing and briquetting equipment consists of two type M-1 10-ton horizontal, steam-jacketed mixers, manufactured by the Mashek Engineering Co., New York (one of these is used as a tempering mixer); one vertical fluxer 42 in. by 8 ft. (Traylor Engineering Co.); one 15-ton 8-ft. diameter masticator manufactured for the General Briquetting Co., New York; one 15-ton Belgian roll press—rolls 26½ in. in diameter by 11½ in. face containing six rows of ovoid moulds with 36 moulds to one circumference. The weight of the briquette produced is approximately 2 oz. The press was manufactured by the Gilley Machinery Co., Gilley, Belgium.

The routine of the process is as follows:—The carbonised residue is taken from the base of a large steel bin (20) with pyramidal bottom through a short conveyor to the first horizontal paddle mixer (21), into which also the coal tar pitch binder is run.

Leaving the mixer, the mixture is fed to a vertical fluxer (22), which discharges directly into the edge-runner (23), whence it passes through a short conveyor (24) to the tempering mixer (25), which is steam-jacketed and capable of controlling the temperature of the whole mass. From there it is hoisted by a vertical conveyor (26) and discharged into the main press (27). Arrangements are also made to by-pass one or more of the mixers in order to determine the utility of each machine. After being formed, the briquettes pass over a shaking screen (28) which removes all fines and broken parts, and returns them by means of a special inclined shoot to the tempering mixers (25). The good briquettes are passed over the screen (28) and slide down a series of inclined shoots to a cooling conveyor, where they are cooled under air draught. This long conveyor operates through an underground tunnel connecting the briquetting building with the storage bin. This tunnel is cooled by forced draught operated by a 7½-h.p. motor connected to a fan discharging 20,000 cb. ft. of air per minute, and which is arranged so that every briquette will be on the belt for at least four minutes subject to high-velocity air cooling. The two mixers and the fluxer are provided with ventilating ducts, which permit ample ventilation for any gas, excess steam, etc.

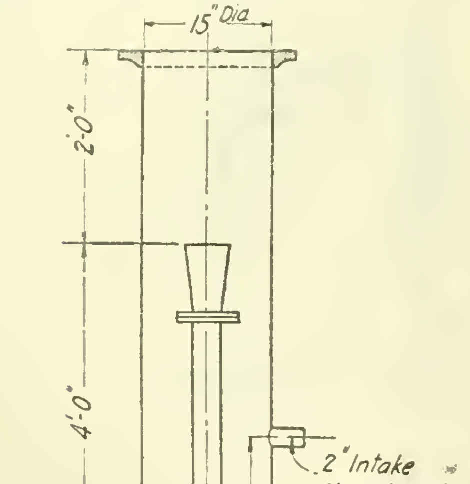

Fig. 4.

The binder is delivered to the plant in tank cars, which are emptied by gravity into an underground concrete storage reservoir. The pitch used has m.p. 140° F. (usually determined by the ball and ring method). A complete steam heating system at the bottom of the storage tank keeps the pitch fluid. The binder is pumped to a small overhead control tank, made from a section of 15-in. black cast-iron pipe 6 ft. high. This tank is fed by a 2-in. feed pipe, opening into the tank at a point about 24 in. from the bottom. The discharge pipe is also 2 in. in diameter, and leads from the bottom of the tank.

In order that the control of quantity of binder should be as simple as possible, it was decided to limit it to one valve, and in order to insure a constant discharge, arrangements were made for the pitch to be kept at a constant temperature (giving constant viscosity) and operate at a constant head (giving constant pressure). Uniform temperature is to be obtained by having all binder piping steam-jacketed. A uniform head is obtained by providing the control tank with a bell-mouthed 3-in. overflow pipe, the lip of which is 48 in. above the bottom. By this means a head of 48 in. will always be operating in the discharge pipe. The details are shown in Fig. 4.

The control valve in the discharge pipe will be calibrated empirically after the plant has been in actual operation.

As already mentioned, the Board produced a pillow-shaped briquette at its Ottawa plant. At Bienfait an egg-shaped briquette of about 2 oz. will be manufactured.

Summary of results.

The summary of the Board's briquetting results is as follows:—

1. It is possible to make a first-quality commercial fuel briquette from carbonised lignite using any one of such binders as coal-tar pitch, petroleum pitch, hardwood-tar pitch, sulphite-liquor pitch, or combinations of them.
2. The quantity of binder required is much in excess of that necessary to make a correspondingly good briquette from anthracite fines.
3. A waterproof briquette of carbonised lignite cannot be made using sulphite pitch as a single binder unless the briquettes are heat-treated subsequently.
4. The choice of binder does not rest so much with the technical difficulties involved in its use, but with the economic supply of that particular binder. In other words, the Lignite Board has succeeded in making good briquettes with many binders.
5. The Board has decided to use as a binder coal-tar pitch for the preliminary period of operation, in the proportion of 13 parts by weight to every 100 pts. of carbonised lignite.

In preparing this paper the author, as Secretary of the Lignite Utilization Board since its inception, has had certain privileges and opportunities in observing the progress of the work undertaken and of the designing and construction of the main plant. He wishes to record the fact that the credit for the work must be given to Dr. R. A. Ross, the Chairman of the Board, and to Mr. Edgar Stansfield, and later Mr. R. A. Strong, in connexion with the chemical researches, and to Mr. R. De L. French in connexion with the engineering.

The author wishes to extend his thanks to Mr. John MacLeish, Acting Director of the Mines Branch, Ottawa, to Mr. French, to Mr. Stansfield, and to Mr. Strong for their courtesy in permitting him to use certain results and diagrams.

Discussion.

In reply to questions, the author said that the price of the briquettes was to be $12·25 per short ton at the plant or $17·50 a ton at Winnipeg, as against $20 for American anthracite. Winnipeg would be the limit of eastern distribution. The briquettes would have about ten-elevenths of the calorific power of American anthracite, but better burning qualities. The briquettes would not clinker in the stove.

THE AIR-DRYING OF PEAT.

BY ERNEST V. MOORE, B.SC., M.E.I.C.

An undrained peat bog contains 90—95% of water and even with the best drainage conditions this water content cannot be reduced below about 87%. In order to make the peat of any commercial value the water content must be reduced to about 30%, which means that to get a ton of commercial product 12,000 lb. of water must be disposed of.

Only a small amount of this water will drain away naturally, and the only means left to get rid of the remainder is either to squeeze it out or to evaporate it. None of the attempts so far made to press water out of peat has been successful, since well-decomposed peat has many of the properties of a colloid, and when an attempt is made to press out the water, the peat substance will follow the water through any sort of filtering element available, and even should a satisfactory filtering element be discovered it is highly probable that the operation would be so slow, and the machinery necessary so expensive, as to make it economically impossible with such a low-grade material as peat. For this reason it is generally agreed that pressing water out of peat is not practicable.

An effort has been made to destroy the colloidal property by heating the raw material in a closed container to about 150° C. A great deal of money was spent on this venture, but although there was some change in the physical properties of the peat little was accomplished of practical value. Electricity has also been tried to make the peat yield up its water more easily, but so far without success.

There remains then only evaporation to get rid of the water, and this again has been attempted in many different ways. No matter what the method, however, it takes a definite number of heat units to evaporate a pound of water, and even with 100% efficiency there are not enough heat units in the 200 lb. of dry peat substance to evaporate the associated 1715 lb. of water, let alone to produce a surplus for other uses, so that the possibility of putting the raw peat through any sort of artificial dryer is out of the question, except perhaps in cases where waste heat might be available.

A careful examination of the many schemes that have been brought forward in which it was proposed to remove water from peat by a combination of pressing and artificial drying shows no evidence of an economic process, and there remains only the evaporation of the water in peat by natural drying in the open air.

Practically all the peat which has been manufactured anywhere for commercial use has been made in this way, and it appears to me that any real advances which have been and are to be made in the process of recovering peat for use have been, and must be along the line of improving methods of handling the raw material to permit it to be air-dried.

The process of air-drying has one serious drawback in that, more particularly in the northern countries, where most of the peat is found, frost is encountered and air-drying can only be carried on for a portion of the year, since if peat is frozen before it is dried down to about 40% water content it loses its cohesion and the blocks fall apart into fine powder. Any plant or equipment for carrying on the process must therefore lie idle for more than half of the time; but while this is a serious drawback, it is not prohibitive.

The process of manufacturing air-dried peat fuel, simply stated, consists in excavating the peat, thoroughly macerating it, and spreading it on the adjacent surface of the bog, moulded in suitable pieces, to dry. Since peat at best is a low-grade commodity and approximately 10 cubic yards of material has to be handled to produce a ton of fuel, the question of the labour employed enters very materially into the success of the operation. In order to reduce labour, mechanical devices have had to be designed and in connexion with mechanical excavating the first of a number of mechanical difficulties was encountered. Owing to the soft, yielding nature of the surface of the bog, mechanical excavators used for other purposes are too heavy. On the other hand, the excavator cannot be built too light as almost every bog contains more or less undecomposed roots and the excavator shovel or shovels must be made strong enough to withstand the shock when such obstacles are met. The surface of a well-drained bog will not carry safely more than 2—3 lb. per square inch, so that even a comparatively light excavator, combined with the plant necessary to operate it, must necessarily have a large supporting area and still be free to move as desired.

At first portable tracks were laid, as is done with an ordinary steam shovel, but this was not found satisfactory owing to the labour entailed and delays caused in laying the tracks on the soft surface, and caterpillar carrying elements, on the same principle as those used to support the tanks in the war, have been worked out to support a specially designed peat excavator and the macerator to treat the peat, together with plant to operate these machines, and the accompanying conveying equipment. This macerating device is essentially a shaft supplied with cutting knives with a forward pitch, which alternate with fixed knives held in the framework of the machine, against which the revolving knives rub. The fixed knives serve the double purpose of cutting the roots into small pieces and also keeping the revolving knives clean. The macerator thoroughly mixes the peat, cuts up the larger undecomposed parts, and also performs a kneading operation, and the quality of the fuel depends to a large extent on how completely these operations are carried out. It is found in practice that the more water there is in the peat, the easier it is to macerate and the better fuel it produces ultimately, but the amount of material which has to be moved imposes practical limits in this respect. About 90% water content seems to be the best suited to meet all conditions.

The macerated pulp must then be delivered to the surface of the bog and spread uniformly to dry. If it is desired to manufacture peat for domestic use this operation cannot be too carefully carried out, as the appearance, and to a certain extent the quality, depend on the peat being laid out very uniformly. If, however, the peat is ultimately to be burnt as a powder, or briquetted, or used for fertiliser purposes, this great care is not essential.

The greatest mechanical problem in the laying out of the peat is one of transportation, since it requires about 700 sq. ft. of drying area for each ton of peat produced, and therefore for a production of say 100 tons per day, practically two acres must be covered every 24 hours. In this climate peat takes from 30 to 40 days to dry from 90% water down to about 30%, so that 80 acres of drying field is necessary to handle an output of 100 tons per day and every part of this 80 acres must be readily reached by any transportation system used.

Many schemes have been tried, from the primitive method of taking the peat slop out in modified wheelbarrows, to a very complete system of cars hauled over portable steel tracks by a continuous cable system. An overhead cable way 1000 feet long, which could be moved from time to time, was also built, but it would appear that the best solution to this problem is in the use of a belt conveyor. Even the most advanced portable track system was open to two objections in that its capacity was limited to the speed with which the cars might be dumped into the spreading device, and it also required a very large amount of labour. This objection is also true with regard to the overhead cableway, and both objections are removed in the use of a belt conveyor.

The peat slop is continuously unloaded from the belt conveyor into a spreading device which deposits the peat on the ground in a uniform layer from 3 to 6 inches in depth, depending on the climatic conditions existing on the bog and the time at which the operation is being carried on, it being found desirable to reduce the depth of spreading towards the end of the season, when drying conditions are less favourable. The peat so laid out is then cut into blocks, the size of which depends on the ultimate use to which the fuel is to be put. Practice heretofore has been to mould the blocks about 5 by 5 by 10 inches, but I do not know of any arguments to show that this is the best size; in fact, I am convinced that a much smaller block will ultimately prove more satisfactory.

About ten days to ten weeks after the peat is laid down it has shrunk very considerably and has become firm enough to be handled. Owing to a peculiarity of the peat, after it has been exposed to the atmosphere for two or three days, it is not affected by rain, and while wet weather retards the drying, the peat does not take up any more water. Should there be a heavy shower immediately after the peat pulp is laid down, from 5 to 10% of the blocks is washed away and the ultimate appearance of the fuel is somewhat spoiled, but this damage has never been considered of serious consequence. When the peat has become sufficiently solid to stand handling it is disturbed so that the wet underside of the block is exposed to the air and to a certain extent the top surface is given an opportunity to dry out. Up to date this operation has been done by hand, the blocks being turned completely upside down, and, until very recently, the blocks were later piled into small stacks, called " cubes," a short time after the turning, to facilitate drying further. This second operation, however, although it facilitated the drying of some of the blocks, actually retarded the drying of those on the bottom of the stack, and less uniform drying was obtained in this way than when the blocks were not stacked at all.

As already stated, from thirty to forty days after the peat slop has been laid on the bog surface, it has dried to an average water content of 25—30%. Peat with this water content is in the best condition to handle into storage, or into railway cars, and appears to give most satisfaction for domestic use. If the peat is left on the field for longer periods its water content may be reduced to 18%; below 25% it rapidly becomes very brittle and is difficult to handle without a great deal of waste. It is therefore desirable to harvest the peat with as little delay as possible as soon as it has reached 30% water content, and this operation may be carried out by standard equipment designed for this purpose, although some special machinery has been installed at Alfred, Ontario.

When the peat is put into the store pile it does not materially change, except on the outside of the pile where it is exposed to the air, and it may be kept in open storage indefinitely without any greater depreciation than coal, and, unlike coal, as far as is known, peat is not subject to ignition from spontaneous combustion.

A ton of air-dried peat blocks as manufactured at Alfred, Ontario, occupies from 70 to 72 cub. ft., which is about twice the volume of coal. It is possible, however, to put 20—25 tons of peat in most of the open cars used to transport coal by rail.

Without further treatment, air-dried peat is a low-grade fuel suitable for domestic use and, under certain conditions, for industrial use. For domestic purposes it is used to advantage as a cooking fuel, in furnaces, in open-grate fires, and as a kindling and for auxiliary use with coal during the severe winter months. Industrially peat has been used recently for steam-raising in boilers, in some drying operations where very clean fuel is desired, and in burning lime, but very little progress has been made along this line, chiefly because there has not been enough peat fuel available to warrant investigations tending to its use industrially. Progress, however, has been made in turning air-dried peat into a more efficient fuel in three ways: by briquetting, which increases the density of the fuel, makes it more uniform, and greatly improves its appearance; by further drying and reducing it to powder, in which condition it is being very efficiently used for steam raising; and by converting air-dried peat, through a by-product recovery producer, into fuel gas, at the same time recovering valuable by-products. A fourth industry which has not yet been fully investigated is the retorting of air-dried peat to produce a high-grade charcoal or coke and at the same time recover by-products.

Reference may also be made to the use of air-dried peat powder for fertiliser purposes. A large portion of the peat recovered in the United States is either sold without any treatment other than drying and powdering, as humus, or, mixed with concentrated fertilising elements, as a commercial fertiliser. The use of air-dried peat for this purpose has attained considerable importance in the United States, and will undoubtedly be taken up in Canada soon.

ACTIVATED CARBON.

BY E. G. ARDAGH.

One of the most characteristic properties of amorphous carbon is its power to remove coloured and certain other substances from solutions. This property has found its largest application in the manufacture of sugar[1]. About 150 years ago wood charcoal was found to be suitable for removing colour from sugar solutions and was used for this purpose until 1812, in which year it was superseded by bone-black—a much more efficient decoloriser. Lignite was suggested as a substitute for bone-black in the eighties, but with that exception, very little progress was made during the nineteenth century either in producing vegetable carbons to take the place of bone-black or in elucidating the phenomenon of colour removal. In the first half of the nineteenth century, it is true, French chemists had succeeded in increasing the activity of animal and vegetable chars, but this fact had been well-nigh forgotten.

We may then credit the major portion of the progress made along the lines indicated to the twenty years which have just passed. The efforts put forth during the twentieth century to produce active vegetable carbons intended to replace bone-black (and fuller's earth also in the vegetable oil industry) have been largely empirical. Much of the work has been carried on behind closed doors, the results of this experimentation appearing in a series of vegetable carbons advertised under such trade names as Norite, Eponite, Filtchar, Superfiltchar, Carboraffin, etc., concerning the manufacture of which we are told practically nothing.

In pleasing contrast to the above secrecy C. F. Bardorf[2], in his interesting paper on " Decolorising blacks " last year, described in detail the preparation from sawdust and bone-black dust of a carbon (Karbos) quite equal in activity to Eponite. Bardorf also produced from peat a carbon that behaved identically with Eponite under every chemical and physical test applied. This process, a very simple one, he also fully described.

All the secret process active carbons come upon the market in the form of a fine powder, a small percentage of which is to be added to the coloured solution under certain conditions of temperature, acidity, etc. In this respect they differ greatly from bone-black, which is used in granular form and through which the coloured solution is filtered. Moreover, the new carbons contain a high percentage of carbon (over 90% on a dry basis), while bone-black when new contains only about 11% of carbon [3], and this falls materially with repeated regeneration.

An excellent account of the preparation and properties of these new carbons is given by F. W. Zerban and his co-workers in Bulletins 161 and 167 of the Louisiana Agricultural Experiment Station and in the articles referred to there, of which he tabulates a number, the majority appearing between the years 1911 and 1918. It is almost certain that these carbons were all produced by *practical trials* with animal or vegetable matter of one kind or another. As far as we are aware to-day the factors governing the experimental work resulting in these carbons are the following:—(1) Selection of raw material. (2) Impregnation before carbonisation. (3) Temperature and duration of carbonisation. (4) Atmosphere in which carbonisation takes places. (5) Extraction of mineral matter subsequent to carbonisation. (6) Fineness of material before marketing.

Every one of these factors [4] has been found to exercise an influence on the activity of the product. About them we are to-day in a position to make the following general statements:—

(1) Material high in silica, lime, or nitrogenous substances usually yields an active carbon, *e.g.*, rice hulls, filter-press cake in sugar factories, and certain seaweeds.

(2) Impregnation with inorganic salts or oxides that remain solid or volatilise at the temperature of carbonisation, or impregnation with nitrogenous substances, such as casein, generally yields an active carbon.

(3) High temperature and prolonged heating increase the activity of the carbon obtained.

(4) Steam and carbon dioxide under an optimum temperature increase the activity of the carbon in certain cases [5].

(5) Extraction of the mineral impregnating agents subsequent to carbonisation increases the activity of the carbon.

(6) Fine grinding increases the activity of the carbon [6].

The above general statements are not intended to sum up all our present knowledge of this subject, but they do summarise the bulk of it.

If some cheap and abundant carbonaceous material is selected as a starting point, the most obvious practical method of proceeding to produce therefrom an active carbon seems to be to impregnate the raw material with various inorganic compounds and then to carbonise under varying conditions. The mineral matter can then be extracted in order to produce the greatest possible porosity. Not only does such treatment with certain inorganic salts and oxides yield an active carbon, but if the same mineral matter occurs naturally in the material an active carbon results, provided, of course, the mineral matter is extracted from the char. The author, working in conjunction with his own students, has fully confirmed certain of the general statements that have already been made. A short account of this work may be of interest.

As raw material hard maple (*Acer saccharum*) sawdust was selected. Everything that failed to pass a 20-mesh screen was rejected.

The carbonisations were carried out in a 9-in. length of 2-in. iron pipe threaded at the ends on to which caps were screwed. The caps were drilled at the centre, threaded, and ¼-in. iron pipe screwed in. The pipe intended to serve as inlet for gases was left straight; the other was bent at right angles so that the open end could, if necessary, be dipped beneath the surface of water to prevent entrance of air.

The furnace in which this container was heated consisted of a housing of lap-riveted steel pipe 12 in. in diameter × 12 in. long, inside which was placed an alundum muffle $3\frac{3}{4} \times 5\frac{1}{4}$ in. in cross-section by 12 in. in length. The packing was kieselguhr, and the ends of the housing were closed with asbestos-cement shingles sawn to fit and fastened in place with angles and bolts. Rectangular openings were cut in the ends into which the muffle ends were fitted. The muffle was wound with 20 ft. of 17 B. and S. gauge No. 2 nichrome resistance wire, the spacing in the centre being made slightly wider than at the ends in order to render the temperature inside the muffle more nearly uniform. After winding the outside of the muffle was plastered with a grout of alundum cement which was allowed to dry and harden before fitting the muffle in place and filling in with kieselguhr. The open ends of the muffle were closed with asbestos board, through each of which a hole was bored in the centre to admit of the passage of the inlet and outlet pipes. An outside rheostat made of coils of wire enabled us to cut down the current flow on the 100-volt circuit to 2 ampères. It was possible with a current of 12 ampères to raise the temperature of the muffle from that of the room to 950° C. in 50 minutes. A Pt—Pt-Rh thermo-couple was used to determine the temperature. The temperature lag in the centre of the carbonisation cylinder when this was empty was found to be very slight.

This very simply constructed furnace and container enabled us to carry out carbonisations (1) at any desired temperature up to 950° C., (2) for any desired length of time, (3) in any desired atmosphere, (4) in a current of any desired gas, (5) under increased or diminished pressure.

The method employed to determine the activity of the carbons produced consisted in comparing the percentage of caramel colour removed from a standard solution under carefully controlled uniform conditions, with the percentage removed by the same weight of Superfiltchar under the same conditions. Superfiltchar [7] is a carbon made from wood sawdust by the Industrial Chemical Co. of New York. It is a fine, deep black, amorphous powder, 60% of which will pass through an 80-mesh screen. It contains about 3% each of ash and moisture. A Schreiner colorimeter was employed to make the colour comparisons.

The usual method of carrying out the carbonisation was first to heat the charge at a relatively low temperature (slowly to 500° C.), drawing off the gases as fast as they were formed, for 1½ hrs., and then to raise the temperature to 850°—900° C. and hold it there to break down the "primary carbon complex."

No remarkable results were obtained, but in general our experiments, though not nearly so numerous as we could wish, point to the following general statements, which do not differ from those of Zerban and others:—

(1) When sawdust is heated in an atmosphere of nitrogen to 850° C., the capacity of the char for adsorbing caramel increases when the duration of the carbonisation is increased.

(2) Whether sawdust has or has not been impregnated with inorganic salts or oxides, treatment of the char with hydrochloric acid increases its adsorptive capacity for caramel.

(3) The effect on the adsorptive capacity of the char for caramel of the impregnation of the sawdust

with inorganic salts or oxides varies greatly with the impregnating material.

(4) Impregnaton of the sawdust with ammonium magnesium chloride, or mixing intimately with calcium phosphate in the proportion of 1 to 1 gave the best results. These two carbons were practically identical with Superfiltchar in their capacity for adsorbing caramel colour.

The following suggestions are put forward for others who wish to carry on further work in this field in the hope that they will be helpful.

When carbonaceous material such as sawdust is soaked in a solution of any soluble inorganic salt, on drying the salt is transported to the surface of each particle and is left there as a deposit when the water evaporates. Hence on carbonisation it would be anticipated that any influence the inorganic salt might exercise upon the activity of the carbon would be confined to the surface of the particles. The same might be expected when the sawdust is mixed with insoluble substances such as calcium phosphate. One would be justified then in expecting that fineness of subdivision of the material before carbonising, in other words, increasing the surface area, should result in the production of a more active carbon from impregnated raw material or from raw material mixed with insoluble mineral matter. In the latter case, prolonged grinding together of, *e.g.*, sawdust and calcium phosphate might be very effective.

Another method of procedure that suggests itself in the case of insoluble inorganic substances, is to impregnate the raw material with a soluble salt such as calcium chloride, then precipitate calcium phosphate within the particles by subsequent impregnation with a soluble phosphate. In this way precipitation of such insoluble salts as phosphates, carbonates, silicates, etc., could be effected within each particle. [Indeed, a double effect might be secured by precipitating a substance like magnesium carbonate within the particles. Owing to the low temperature at which this substance liberates carbon dioxide, this gas would be given off at an opportune time, viz., during the formation of the "active carbon" (see Chaney) at comparatively low temperatures; this liberated carbon dioxide would assist in removing the hydrocarbon vapours quickly from the neighbourhood of the active carbon—a great desideratum indeed.] Carbonisation of material within the particles of which insoluble substances had been precipitated, followed by extraction by the most suitable solvent, would in all probability yield a very porous carbon and one that would possess great "capillary capacity." If Chaney's[8] contention is correct that the rôle of inorganic impregnations is to break down during carbonisation the "primary carbon complex" and expose "active carbon," then a carbon prepared as suggested might be expected to possess to an unusual degree what Chaney calls "specific capacity" for adsorption.

The mineral matter should invariably be removed as completely as possible in order to produce the greatest possible porosity. This fact should be kept in mind when deciding on the solvent, and, indeed, when selecting the impregnating substance also, since some of these are much more easily dissolved out than others. The question of cost, however, must not be forgotten.

To reduce the extent of the adsorption of hydrocarbon vapours by the active carbon during the first stage of the carbonisation, the removal of these vapours by a brisk current of nitrogen, or other inert gas, should prove very effective.

As to the reasons for the above, little was really definitely known till very recently. Any investigation carried on till the war was well advanced to determine the cause of the removal of colour by carbon rested on the theory that amorphous carbon possessed the property of adsorbing certain substances by virtue of its physical structure, *i.e.*, the nature and extent of its porosity. This theory has been found to account satisfactorily for the phenomenon only in certain cases.

With so many factors influencing the result it is scarcely conceivable that much light could possibly be shed upon the nature of activated carbon. Practical progress no doubt could be made in the production of carbons intended as absorbents for colour or gas, and, indeed, some noteworthy progress was made, but not until the number of variables had been considerably reduced and attention focussed upon the problem at close range could the cause and nature of the action of activated carbon be brought within measurable distance of elucidation.

The stimulus that eventually resulted in the concentration of scientific skill and attention upon the elucidation of the phenomenon of adsorption by carbon was the war-time necessity of producing an efficient absorbent for poison gases. Naturally some form of carbon would be expected to constitute one of the ingredients in any mixture intended for the canisters of gas masks, hence one branch of the U.S. Chemical Warfare Service was charged with the production of such a carbon in sufficient quantity to provide the American Expeditionary Force with efficient gas-fighting equipment[9].

The problem resolved itself into two parts: (1) The investigation and discovery of the nature of activation, and (2) the application of this discovery to the production on a commercial scale of the product required.

In his most interesting paper, "The Activation of Carbon"[8], N. K. Chaney, who was one of those engaged in this difficult task, gives an account of his efforts to confirm his working hypothesis that ordinary amorphous carbon is a mixture of two forms, an active form which he calls "α-carbon," and an inactive form, "β-carbon."

Chaney comes to the conclusion that "active carbon" is essentially a form of pure amorphous carbon deposited at low temperature and (1) free from adsorbed stabilised hydrocarbons which are normally associated with it and which lessen its power of combining with other substances, and (2) free from inactive carbon formed by gas treating, *i.e.*, by the decomposition of hydrocarbons upon its surface at high temperatures. In general this "active carbon" is formed when carbon is deposited by chemical or thermal decomposition of carbon-bearing materials at temperatures below 500°—600° C. The "inactive carbon" arises from similar decomposition at temperatures above 600°—700° C. The temperature at which the molecular carbon is set free is probably the controlling factor. The "α-carbon" is easily oxidised by oxidising agents, and readily adsorbs hydrocarbons vaporised during carbonisation. Owing to his inability to discover any transition temperature Chaney could not determine if these two forms of carbon are true allotropes.

On distilling carbonaceous material "active carbon" is first formed, provided the temperature of decomposition is low enough. This "active carbon" adsorbs a further quantity of hydrocarbons, resulting in the formation of a wonderfully stable complex. Such a stabilised carbon Chaney calls "primary carbon" because it is the first product occurring in low-temperature distillation. "Primary carbon," then, is "a stabilised complex of hydrocarbons adsorbed on a base of active carbon." Many commercial grades of animal and vegetable charcoal are of this character, as well as cokes prepared from bituminous coals and bitumens by low temperature distillation. Anthracite may be classed as a natural primary carbon. Indeed, the U.S. Chemical Warfare Service, applying the results of Chaney's investigation, succeeded in producing from anthracite an active carbon to which they gave the name "Batchite"[9]. Batchite is made by removing from anthracite as much of the adsorbed hydrocarbons as possible by a process of heating at an optimum temperature in an atmosphere of steam, thus bringing about a selective oxidation and distillation as a result of which the active carbon is freed from at least part of the blanketing substance.

"Secondary carbon" is primary carbon partially or completely broken down with the formation or introduction of inactive carbon by the high-temperature decomposition of hydrocarbons self-contained or from without.

The problem of producing "active carbon," according to Chaney, consists merely in selecting or producing a primary carbon, and then by differential oxidation or distillation, or by both, removing the hydrocarbons from the base of active carbon by which they have been adsorbed. This task is, however, not nearly such a simple one as at first appears, because the active carbon itself is also easily oxidised. Moreover, the proper selection of the raw material is also very important. Bituminous coals, for example, are not suitable for the preparation of primary carbon, since on heating the hydrocarbons evolved deposit inactive carbon. Certain woods and nuts are not open to this objection, and hence are used not, as Chaney says, because of any inherent impossibility of preparing active carbon from coals, petroleum, etc.

The activated coconut charcoal prepared by a method (steam) developed as a result of the above conclusions was given the name "Dorsite"[5] by the U.S. Chemical Warfare Service. "Carbonite" is a synthetic product made from lampblack, powdered coal, or other suitable materials. For making Dorsite from coconut shell or mixed nut shells steam was later on in the work replaced by a mixture of carbon dioxide and steam.

Common opinion among authorities has maintained that the impregnation of wood sawdust etc. with mineral substances before carbonisation, followed by the extraction of the mineral matter, has yielded an activated carbon as a result of an increase in porosity of the product. Chaney contends that the presence of these mineral substances assists in breaking down the stable complex (primary carbon) so that active carbon is freed more or less from the adsorbed hydrocarbons.

There is not the slightest doubt that the extraction of the mineral matter does leave a very fine and effective capillary structure capable of adsorbing large quantities of gas at high concentrations. German war charcoal was made in this way[5]. This type of adsorptive capacity Chaney calls "capillary capacity." It differs fundamentally from the adsorption due to the presence of active carbon, a property characteristic of the material of which the adsorbent is constituted. The latter type Chaney calls "specific capacity."

"Capillary capacity" is distinguished by large capacity at high gas concentrations and by rapid equilibrium between adsorbent and gas phase, in either direction, the gas being removed as easily as adsorbed. "Specific capacity," on the other hand, is characterised by very considerable capacity at low gas concentrations and by extremely low rate of loss during reversal of the adsorptive process[11]. The "retentivity" of the adsorbent is a measure of the proportion of active carbon present. In German war charcoal the ratio of capillary to specific capacity is a very high one.

Admirable though Chaney's work may be, we must not exclude all other possible causes to which adsorption by carbon may be attributed. For example, in 1910 Patterson[10] showed the power of boneblack for removing colour to be lodged in a dark, humus-like substance soluble in concentrated sulphuric acid. Horne[11] maintains that nitrogen plays a part in colour adsorption, and Zerban[4] has shown that raw materials high in nitrogen or impregnated with albumin yield chars that are good colour removers. Michaelis and Rona[12] contend that in adsorption actual combination takes place between an impurity and the substance adsorbed.

Moreover, a carbon that is an active adsorbent for colour in an oil may be very ineffective with sugar solutions. For an oil a carbon may be poor, and yet effective for glycerin.[12]

The extreme difficulty of preparing a carbon that is free from everything except carbon no doubt accounts for most of these anomalies. Michaelis and Rona contend that we do not know how to make carbon that is nothing but carbon.[12]

The papers published by permission of the U.S. Chemical Warfare Service on the subject of activated carbon are exceedingly valuable contributions to the chemistry of amorphous carbon.

The paper by Dr. A. B. Lamb and others on "Gas Mask Absorbents"[5] gives us incidentally the following interesting information: "The mixture used in the American canisters for the last nine months of the war contained 60% of 10—14 mesh coconut shell charcoal (or other shell charcoal) and 40% of 8—14 mesh soda-lime-permanganate granules. "A superior mixture about to be adopted when hostilities terminated was 75% of specially impregnated coconut charcoal and 25% of soda-lime containing no permanganate." A detailed account of the method of making activated carbon from coconut shells (Dorsite) and from anthracite (Batchite) is given.[9]

The U.S. military authorities have set a splendid example in courageously giving to the world the results of these war-time investigations. It is to be hoped that the other belligerent nations will shortly profit by this excellent example.

NEED FOR REFORM IN THE EDUCATION OF CHEMISTS.

BY W. LASH MILLER.

(Abstract.)

The author considers that the reason why so few chemists have a real grip of the mathematical side of chemistry—particularly thermodynamics—is to be sought in the early training of the chemical student. The right mental outlook cannot result while chemical terms are so vague and elastic in their meaning as they are at present, and a reform in our chemical terminology is of the first importance. Atoms and molecules should not find a place in elementary instruction; until a man has learned to think without them they are a mental poison, and supply the imagery that takes the place of clear definition. Further, it is desirable to lay as much emphasis on the mode by which conclusions are reached as on the conclusions themselves.

At Toronto University a course of fifty lectures is provided for the second-year student, in which the experimental material is restricted to that provided by a table of the densities of sulphuric acid solutions; in solving the many problems which are to be found in such a table the need for exact definition of terms is made apparent, and great stress is laid on method. The student is given a practical demonstration of the meaning of the mathematical symbols employed in the study of thermodynamics, and thus the difficulties of the subject are removed, and the work of Gibbs becomes comprehensible and applicable.

INDUSTRIAL RESPIRATORS.

BY DR. LEONARD LEVY, M.A., F.I.C., AND
D. W. WEST, A.C.G.I., A.I.C.

Before the war respirators specially designed for use in industry were, practically speaking, non-existent. Self-contained breathing sets, fitted with an auxiliary oxygen cylinder, were of course well known, and found extended use for mine rescue operations, smoke helmets for firemen, etc. Respirators so designed that the toxic atmosphere was purified from its poisonous constituent, thus rendering the air suitable for breathing, were not used. Practically the only type of respirator then employed was a simple dust-filtering device.

It is obvious that the lessons learned in connexion with the purification of toxic atmospheres during the war should be capable of useful application to similar problems in industry.

In the case of respirators designed for use of armies in the field, the problem to be faced is the production of a protective appliance which must fulfil the following desiderata:—(1) It must be capable of being correctly placed on the wearer in a few seconds. (2) It must not interfere with the free movement of the wearer. (3) It must afford adequate protection against all known toxic substances capable of being used in chemical warfare, and in addition it should provide protection as far as can possibly be anticipated against unknown substances which may be produced for this purpose.

There are numerous other factors which require consideration, such as low resistance to breathing, light weight, resistance to exposure, etc., into which it is not necessary to enter.

In the case of respirators designed for use in industry, the problem is much simpler. As a general rule a respirator will be required for protection against only one or two toxic substances, and it should therefore be possible to provide within the same compass and weight a much longer protection against the same concentration. Apart from this, respirators for industrial purposes should fulfil the same requirements as have been found necessary for military use.

The first respirators to be described represent the transition from military to civil use. In other words they are, broadly speaking, modified forms of the small box respirator. The carbon monoxide respirator which will be described later is a new device.

Respirators intended for use against toxic gases or vapours can be considered as composed essentially of two parts—the face-piece and the purifying canister.

The face-piece is the same in most types, and as it differs very considerably from the face-piece used for the small box respirator it will be described in some detail. In the case of the face-piece used in the small box respirator, two lines of protection are afforded to the wearer, viz., (1) the mouth piece and nose-clip and (2) the line of junction between the mask proper and the face. The latter affords the protection to the eyes which is, of course, not afforded by the first line of protection.

The chief drawback to this face-piece is the considerable discomfort experienced by the wearer after about ½—2 hrs. This is due to two causes—the area of contact between the mask and the wearer's head is very small, so that the pressure exerted by the elastics is supplied to a small area, and causes considerable discomfort. Secondly, neither the mouth-piece nor the nose-clip is conducive to comfort.

The Puretha respirator.

These defects have been obviated in the new type of face-piece designed by Mr. Rosling. The face-piece proper is composed of fairly thick rubber, covered on the outside with a flexible fabric. This face-piece is prepared by moulding upon special formers, the rubber being vulcanised *in situ*. The face-piece is attached to the head of the wearer by means of an adjustable elastic harness composed of four tapes, the lengths of which can be varied. The angle at which these elastics are attached to the face-piece is of importance, as if incorrectly placed a pucker may be produced leading to a slight leakage. The eye-pieces, which are set fairly close to the eyes, are composed of triplex safety glass; they are kept free from moisture during use by means of a device, due to Tissot, by means of which the cold inspired air is led by ducts to the base of the eye-piece glasses, and in passing over them prevents the deposition of moisture thereon. The glasses remain perfectly clear even if worn for hours. The expired air is passed out through a novel type of non-return valve, which cannot be accidentally fouled. There is thus only one line of protection in this face-piece; numerous trials have proved that this is quite adequate. The area of contact is much greater than in the box respirator face-piece, and owing to the stout construction there is no risk of tearing, as in the case of the comparatively thin army box respirator face-piece.

The purifying chamber.—The canisters employed in the "Puretha" respirator are unused small box-respirator canisters. These are difficult to improve upon, and are readily obtainable in large quantities.

The fillings of the canisters are, however, quite different from the army filling. There are two main characteristics of a purifying substance or mixture intended for use in respirators for whatever purpose the latter may be required. These characteristics are *capacity* and *reactivity.* The capacity of the filling is a measure of the total amount of toxic substance a given quantity can absorb before it is so saturated that it ceases to remove the greater part—say 99·8%—of the toxic substance presented.

The reactivity is a measure of the rate at which the filling will absorb a toxic substance from the atmosphere presented to it. The reactivity of an absorbent substance or mixture must be such that no trace of the poisonous substance passes, and the optimum substance or mixture is that which only allows the poisonous substance to pass when the contents of the canister are completely neutralised by the absorbed substance. Such a condition, however, can never be fully realised in practice.

It is also obvious that the reactivity of the absorbent mixture will be a function of the speed of the air stream through the respirator and of the cross-section of the absorbent. The smaller the latter the more rapid the air stream; on the other hand, with the same total volume, the depth of layer to be traversed will be greater. It is a matter of experience that, with certain absorbent mixtures above a certain minimum thickness, the life of the respirator in a given concentration of toxic substance is nearly independent of the cross-section of the absorbent, the volume of the latter being constant.

The superior limit of rate of flow of the inspired air past the absorbent is fixed by the rate of flow in the case of a man doing heavy work. This is about 2000 litres per hour intermittent inspiration.

The methods of testing various absorbent mixtures may now be considered.

Tests on the man in a gas chamber filled with various concentrations of the toxic substances are very useful, but the most satisfactory test is made with a physiological pump giving intermittent aspirations which closely imitate the action of the man breathing. Such a pump is set to give 17 to 20 aspirations per minute with a total flow of 960 litres per hour. Experience shows that a respirator, when tested upon such a pump, will have the same life as it would have if worn by a normal man during gentle exercise.

When carrying out a test the mixture of air and toxic substance is drawn through the respirator by a pump, and the time which elapses before the toxic substance begins to pass in an intolerable concentration is noted. This intolerable concentration varies enormously with the nature of the poisonous substances, and for practical purposes is taken as that concentration which cannot be breathed for more than five minutes without considerable discomfort being experienced.

When testing respirators for industrial purposes it is often necessary to change the nature of the toxic substance applied. The most convenient method of effecting this has been found to be to arrange for the generation of the poisonous gas or vapour by aspirating the main air stream through a liquid reagent to which another liquid reagent is added at a measured rate, the two reagents causing the evolution of the required substance, which is removed as formed by the air stream. Blank tests, made without a respirator, in which the toxic substance is removed by liquid absorbents in absorption bottles, enable the rate of addition of the second reagent to be determined so as to maintain the concentration accurately at the desired value for the whole period of a test, which may last several hours.

For example, ammonia respirators are tested against the concentration of 1% ammonia in air. This is obtained by drawing the air stream at the rate of 960 litres per hour through a mixture of one volume of ammonia (sp. gr. 0·880) to 12 volumes of water. In order to maintain the concentration of ammonia constant 0·4 c.c. of 0·880 ammonia is added every minute. Similarly, tests against chlorine are made by adding strong sodium hypochlorite solution to hydrochloric acid, and against sulphur dioxide by dropping a strong solution of sodium sulphite into 50% sulphuric acid.

The determination of the point at which an intolerable concentration of toxic gas first begins to pass the respirator is best effected by means of special test-papers, which change to a certain colour upon the application of this concentration for a given period. For example, in the case of ammonia, paper impregnated with 2% cobalt sulphate solution and used moist, was found to give the most satisfactory indication. The following table shows the relation between the time of colour change, physiological effect, and concentration of ammonia.

Ammonia concn.	Physiological effect.	Time to turn full blue.
1/800	Intolerable	14 secs.
1/900	"	20 "
1/1000	"	22 "
1/1200	About limit tolerance	30 "
1/1500	"	35 "
1/1800	"	40 "
1/2000	Limit for respirators	42 "

In the case of chlorine, potassium iodide-starch papers are employed. The following table shows the results obtained:—

Chlorine. concn.	Time.	Physiological effect.	Colour.
1/150,000	60 secs.	Very faint odour	Brown, faint purple.
1/50,000	25 "	Uncomfortable	Brown, purple tint.
1/30,000	14 "	Unbreathable	Brown, purple tint.

Similar tables have been prepared for other gases, such as sulphur dioxide, hydrogen sulphide, etc.

Routine testing.

When a canister has been filled ready for attachment to a face-piece it is tested in order to ensure its perfection and freedom from defects. This is effected by giving a three minutes' test against a very high concentration of the toxic substance against which it is designed to protect. Should the test-paper show the faintest alteration the canister is rejected. A few of each batch of canisters are tested for complete breakdown.

Application to various problems.

The fillings in general use are at present restricted to three main types.

(1) *Ammonia respirators.*—These find extensive application in cold-storage plants. The most satisfactory absorbent is crystalline copper sulphate. In this case both the capacity and the reactivity are very high, and it is found that no trace of ammonia is passed until the respirator is almost completely exhausted.

(2) *Neutral vapours.*—Respirators are required for the absorption of hydrocarbon fumes in oil-fields, for cleaning out oil tanks, and other purposes. The best filling for this purpose is a very highly activated vegetable charcoal. The latter can by a suitable after-treatment have its efficiency as an absorbent increased very many times, and such charcoal can now be activated to a very high degree of efficiency. This is the most suitable absorbent at present known for neutral vapours of all kinds. This applies to any gas or vapour which at ordinary temperatures is not too far removed from its boiling point.

(3) *Acid fumes.*—In dealing with acid gases such as hydrochloric acid, chlorine, hydrogen sulphide, phosgene, sulphur dioxide, nitrous fumes, hydrocyanic acid, etc., it has been found that certain special alkaline granules possess a very high capacity. As, however, in many cases these gases are highly toxic (concentrations of as low as 1/50,000 being unbreathable), it is obvious that a very high degree of reactivity of the canister filling

is also called for. Highly activated charcoal has a very high reactivity with respect to practically all acid gases, but its capacity is not very great. It has been found that a uniform mixture of alkaline granules and charcoal is the filling which, generally speaking, has the longest life in any given concentration. Presumably the alkaline granules absorb very nearly all the acid gases, the last traces being removed by the charcoal present. The alkaline granules which have been developed for use in the Puretha respirator have the greatest efficiency for a variety of acid gases. They are composed of slaked lime, kieselguhr, ferric hydroxide, and activated charcoal.

The following table gives the life of Puretha respirator canisters in various concentrations:—

Gas.	Approx. limit of tolerance.	Approx. life in 1% toxic gas.	Approx. life at limit of tolerance.
NH_3	1/2000	4 hours	80–100 hours
Cl_2	1/30,000	1¼ „	500 „
HCl	1/10,000	1¼ „	350 „
SO_2	1/5000	¾ „	40 „
H_2S	1/2000	¾ „	10–15 „
$COCl_2$	1/50,000	1 „	400 „

Particulate clouds.

The respirators already described are intended to protect against toxic or irritant substances in the form of true gases or vapours. Another class of respirator is required for protection against poisonous substances in the form of fine dust or clouds of solid or liquid particles which may be of ultramicroscopic dimensions. Such particles pass completely through a respirator provided only with a chemical filling. A good example is afforded by tobacco smoke, which passes straight through a respirator canister without undergoing any obvious absorption. It has been found that particulate clouds, even if composed of ultramicroscopic particles, of whatever nature, can be completely removed by filtration. The finer the particles the more stringent must the filtration be. For example, cotton-wool will filter fumes of stannic chloride, but it allows the passage of a considerable proportion of a cloud of sulphur trioxide. A filter such as cellulose wadding, which retains the latter, still allows tobacco smoke to pass in quantity.

On consideration of the problem from an industrial point of view, it is seen that there are two sub-divisions:—(1) Cases in which protection has to be afforded to the mouth and nose only. (2) Cases in which protection has to be afforded to the eyes as well.

The filtering medium employed in each case is a fine felt. This filters out completely even the finest particles of ultramicroscopic size, and, what is also most important, the resistance to breathing is relatively low. It is obvious that the total resistance to breathing of the mask is proportional to the specific resistance to breathing of the filtering medium and inversely proportional to the area of the filtering device. For this reason the area of filtration is kept as large as possible. Two types of industrial masks for protection against particulate matter have been designed by Mr. Rosling.

(1) *The Pulvafilta full mask* is designed to afford complete protection against solid or liquid particles to the eyes, nose, and throat. A large filtering area is obtained by making the whole of the face-piece of felt. This is lined with rubber to which two inlet ducts are fitted. The air is inspired through the felt and led over the eye-pieces, thus clearing them as already explained. The particles are filtered off, and the expired air is passed out through a non-return valve which completely closes on each inspiration.

(2) *The Pulvafilta half-mask* is a simple device for affording protection against clouds to the nose and throat only. Felt is employed for the filtering medium, and the mask is adjusted to the contour of the face by bending a lead strip which is placed inside the edge of the mask so that perfect contact is obtained everywhere between the mask and the face. Special attention should be paid to the junction at the top of the nose. The inside of the felt is lined with rubber and fitted with an inlet valve, whilst the expired air passes out through the usual non-return valve. Both types of Pulvafilta masks can be washed, and are then as good as when first used.

The question of a special respirator for carbon monoxide can now be considered. The production of a respirator for use against this gas presents some novel problems not encountered in the cases to which reference has already been made.

(1) There is no known absorbent suitable for use in a respirator canister for the removal by chemical means of carbon monoxide from an atmosphere contaminated with this gas. The only method by which this result has been achieved so far is by oxidation.

(2) Carbon monoxide differs from nearly every other known toxic gas or vapour from the fact that it has no smell, irritant, or lachrymatory effect. This fact introduces a complication into the question of a respirator for use against this gas. In practically all other cases, should a respirator canister fail or become exhausted, the wearer has ample warning.

(3) The toxic concentration in the case of carbon monoxide is much higher than in the case of most irritant and paralysant gases, and hence the purifying device in the respirator has to do far more work, from a chemical point of view, in order to afford complete protection for a reasonable period of time.

These points and their application to the successful production of a satisfactory carbon monoxide respirator, suitable for industrial and other purposes, will now be considered.

The destruction of carbon monoxide by oxidation.

There are two known methods by which this can be effected in a practical manner. In one method use is made of the fact that a mixture of iodine pentoxide and fuming sulphuric acid oxidises carbon monoxide at ordinary temperatures to carbon dioxide. This mixture employed as a respirator filling has two serious objections, viz., its cost is high, and it requires several minutes for the respirator to work up to its full efficiency, and during this preliminary period a certain proportion of the carbon monoxide passes through the respirator. The amount of carbon monoxide which is thus passed, and the period which elapses before which the respirator functions perfectly is a function of the concentration of carbon monoxide.

The other method by which the destruction of the carbon monoxide can be effected is by means of catalytic oxidation by the oxygen of the atmosphere, using certain special mixtures of oxides. The development of a mixture of oxides whereby the catalytic oxidation of carbon monoxide in air is effected at ordinary temperatures was due to the American Chemical Warfare Service, and a full description of their experiments and of the mixtures recommended has been published in J. Ind. Eng. Chem., 1920, 12, 212—221. The mixture which they finally developed as the most suitable is composed of finely-divided manganese dioxide, copper oxide, cobalt oxide, and silver oxide. Such a mixture, if a true catalyst, should function indefinitely, the carbon monoxide being oxidised with the concomitant removal of half its volume of oxygen from the air. The catalyst, however, is poisoned by traces of water vapour, and before it can be applied for use in a respirator the latter has to be provided with a preliminary layer of calcium chloride granules. The life of such a respirator is in effect the life of the calcium chloride layer. As soon as the latter begins to allow the passage of water vapour in more than the most minute quantities, the catalyst loses its efficiency and carbon monoxide begins to pass through the respirator.

The authors have carried out a large number of experiments on the variation of the oxide mixture, chiefly with a view to the simplification of its preparation and the reduction of its cost. By modification of the methods of preparation they have been able to prepare a catalyst mixture which is far less easily poisoned by water vapour.

According to the original method of preparation, the catalyst has a life of about four hours in 1% carbon monoxide at a rate of 960 litres of air stream per hour, a 250-c.c. layer of calcium chloride granules being used. The best preparation made by the author had a life of over 22 hours under the same conditions, and the test was only stopped then owing to the calcium chloride forming a solid cake. The catalyst was then removed and it lasted for another two hours without any protection from water vapour.

The silver oxide is required to give the catalyst what is known as a good "pick-up." This means the instantaneous working up to a 100% efficiency directly the carbon monoxide is introduced. A large number of experiments were made in order to replace the silver oxide by a less expensive ingredient. Cerium dioxide gave excellent results in every other respect, but the "pick-up" was by no means so good as when silver dioxide was employed.

A respirator filled with the calcium chloride layer and followed by a layer of the catalyst was proposed by the American Chemical Warfare Service as protection against carbon monoxide. It did not, however, appear to the authors that such a respirator was suitable for use for industrial purposes. There is the important question of the accidental failure of the respirator or its gradual exhaustion. Catalysts are notoriously somewhat unreliable and readily poisoned, and this particular one is not an exception. It therefore appears that before such a respirator can be used practically, it must be fitted with a reliable detector which will indicate the failure of the catalyst to function efficiently. It is obvious that the only suitable type of detector is one which functions by a physiological effect upon the wearer. Any form of detector which indicates by a colour change or which requires any manipulation on the part of the wearer is obviously impracticable.

The problem has been successfully solved by including in the respirator a thin layer of iodine pentoxide and fuming sulphuric acid on pumice granules, which oxidises carbon monoxide with the liberation of iodine. The vapour of the latter exerts a strong lachrymatory effect and also irritates the membranes of the nose and throat, and it is possible to adjust the detector layer to give any desired degree of sensitiveness. An additional advantage of this arrangement is that the carbon monoxide is destroyed in the detector, and this in effect increases the useful life of the respirator by about 25%.

In the Puretha carbon monoxide respirator the detector is adjusted so that when the concentration of carbon monoxide passing the catalyst is 1 to 1000 a pronounced and unmistakable lachrymatory nose effect is produced, the concentration of the carbon monoxide passing being at the same time reduced to 1 to 2000—an innocuous concentration.

As carbon monoxide is not lachrymatory, a face-piece is not essential, a simple mouthpiece and nose clip being quite suitable. In this case the detector functions by the action of the iodine vapour upon the throat. This effect is far less pronounced than upon the eyes and nose, and the detector therefore is increased in potency so as to give unmistakable indications with the same concentration. It should be emphasised that the effect of the iodine vapour in such a dilute concentration is absolutely harmless even if breathed for an hour, and its physiological effect is not so pronounced as to interfere in any way with the general avocation of the wearer.

The detector has also to be protected from the action of water vapour, which soon destroys its efficiency. For this reason it is desirable not to make the catalyst too insensitive to water vapour, and as an additional precaution an extra drying layer of calcium chloride granules is inserted before the detector granules.

The inspired air is considerably heated by the heat of oxidation of the carbon monoxide. Its temperature is reduced by the well-known device of passing the inspired air over a cooling box containing crystals of sodium thiosulphate, which melt in their water of crystallisation with considerable absorption of heat, thereby keeping the air quite cool.

In order thoroughly to test the detector a number of chamber tests with 1% carbon monoxide were made. In some of these a catalyst with a poor "pick-up" was employed. A pronounced lachrymation and slight nasal and throat irritation were produced, and after three quarters of an hour of this unmistakable indication, the blood was found by Dr. Leonard Hill to contain only traces of carbon monoxide.

Another chamber test with 1% carbon monoxide was carried out with good catalyst. This was continued for two hours, at the end of which period the respirator was still functioning perfectly. A considerable proportion of this paper was written in the chamber during this test, in which a mask with a complete face-piece was used. Dr. Leonard Hill also carried out the blood test on this occasion and did not find any trace of carbon monoxide whatsoever. A further point in connexion with the carbon monoxide respirator is that the drying layer is equally deteriorated by breathing whether carbon monoxide is present or not. Therefore the life of a canister is restricted to a certain number of hours' actual wearing. For this reason it is desirable where possible to test the suspected atmosphere for the presence of carbon monoxide.

It is, of course, obvious that the carbon monoxide respirator can only be used in atmospheres in which the amount of oxygen present is adequate.

Discussion.

The **Chairman** said that the liberation of free iodine as suggested seemed to be a rather unpleasant way of bringing the presence of carbon monoxide to the notice of the wearer of the mask. It appeared possible to arrange that the wearer of the mask could see from the change in colour of potassium iodide paper that the mask was not working properly.

Dr. T. M. Legge said that to those concerned with industry, gassing at the front seemed a more or less easy matter to deal with, once the appliances were available, because danger to life was always imminent, and therefore, the apparatus always had to be at hand. Moreover, the apparatus was always in working order, the material was renewed periodically, and the apparatus had to be regularly inspected and cleaned. In the factory—in an iron and steel works, for instance—on the other hand, carbon monoxide poisoning occurred only occasionally; unexpectedness in a factory constituted the difficulty, and when the gassing occurred the rescue was a matter of minutes, whereas at the front and in rescue work in mines the risk was there for hours. Therefore, seeing that the danger was not always imminent, the question of discipline in factories was of paramount importance. It was impossible to get that discipline in the factory, where gassing was accidental and not incidental to the work. The Mines Rescue Apparatus Research Committee had shown what pitfalls there were in self-contained breathing apparatus which the legislature required to be worn by the miner, necessitating rescue stations scattered over the country to supervise the apparatus and, most important of all, to train the persons who had to wear the respirators. All this caused the Committee itself to say that, unless a man was properly trained, the wearing of such self-contained breathing apparatus was nothing less than a death trap. The consequence was that for factory use they were perforce compelled to recommend absolutely the simplest thing that it was possible to get. In this connexion he referred to the admirable apparatus which Messrs. Siebe Gorman made, called the Gassman's Respirator, which was a face-piece with a self-acting expiratory valve for the expired air consisting of a mica flap without any brass hinges or anything to get out of order. This face-piece had an expansible equalising tube going to the waist, and then a hose-pipe arrangement going, perhaps, 40 ft. to an uncontaminated atmosphere, so that the worker breathed the air 40 ft. away. There was, of course, the objection to the "tail" in such an apparatus, and although it was a serious objection, nevertheless, this apparatus was a thoroughly good one. Where work had to be done in a stationary position, as in factories during the war, in filling mines with calcium phosphide, with its nauseating odour, that apparatus had been worn continuously by girls. Similarly, in the spraying of the timbers in Westminster Hall to destroy the grub that brought about the destruction of the 13th-century timbers, that apparatus had been used by the Office of Works on the recommendation of the Home Office for spraying with a solution of 90% tetrachloroethane. He had been up to the rafters of Westminster Hall occasionally and seen the men wearing the apparatus and breathing the air from 40 ft. away without any risk and without undue discomfort. This was the kind of apparatus he advised in iron and steel works and in blast-furnace operations in preference to a self-contained breathing apparatus. He asked the authors whether, in the present state of our knowledge of these chemical masks to counteract carbon monoxide, it would not be safer to recommend the Gassman type of respirator. He had been struck by the proportion mentioned in the paper of 1% of CO, in which the mask had been tested, but in a blast furnace flue or in a lime kiln the workman might have to encounter an atmosphere containing 25—30% of the gas. For these reasons he thought it would be safer at present for the workman to use the Gassman's type of respirator than a respirator of the type described in concentrations of gas such as had been mentioned.

Captain Pratt said that in the case of blast furnaces where the concentration of carbon monoxide might be as high as 25% the percentage of oxygen would almost certainly be too low for respiration. Although much work on the problem of the carbon monoxide respirator had been done by the American Chemical Warfare Service, the French were really the pioneers in this work. The Americans had developed a fairly efficient respirator which suffered from the defect peculiar to all such respirators, and from which he thought they were likely to suffer for some considerable time, *i.e.*, the lack of a really suitable detector. All sorts of devices had been suggested; there was the device depending on thermometric methods for measuring the temperature of the partial or complete oxidation over platinum of that carbon dioxide which passed through. That method was quite convenient for certain work, but was impracticable for a respirator. There was also the colour detector, to which the authors had referred, but that was useless because the man might be colour blind. In the Hoolamite detector devised by the Americans, which was of this type, and in which a mixture of iodine pentoxide and fuming sulphuric acid was used, a visible reaction took place at a concentration as low as 1 in 2000. Provided an efficient detector could be produced, there seemed no reason why a carbon monoxide respirator should not be obtained which would be absolutely reliable. In industries where respirators were employed only occasionally, the apparatus would lie about probably without proper attention, and unless some information were available as to the life of the respirator when not in use, it might fail badly when it was wanted through deterioration of the active mixture or corrosion of the container, or some similar defect.

The authors did not mention whether consideration was being given to the problem of providing a combination mask which would protect not only against smoke or dust, but also against vapours, as it might often happen that fine organic dust or fine particles mixed with a gas or organic vapour might be encountered; under these circumstances it would be necessary to have a special filter pad in addition to a box containing charcoal or granules. Combination respirators of that type were being supplied in America, and had been on the market for nearly a year and a half, and he believed they were also obtainable in this country.

Dr. T. L. Bailey asked how far these respirators had been tested in connexion with oxides of nitrogen. A man would be poisoned by oxides of nitrogen and yet not know at the time that he was poisoned; many cases of this type had come under the speaker's notice. The man went home and gradually became ill, apparently suffering from pulmonary trouble, but it was often impossible to effect a recovery and he was dead possibly within 24 hours, having apparently suffered no inconvenience at the time he was poisoned. Oxides of nitrogen were very slowly and incompletely absorbed by alkaline substances, and unless it was certain that the mixture which was used was capable of satisfactorily removing the oxides of nitrogen it would be fatal policy to advise the use of the respirator.

Sir William Wayland said that in many factories there were irritant dusts which affected the nose as well as the eyes and mouth, and there was no respirator to his knowledge that had proved efficient under these conditions. It would be efficient, perhaps, for 10 or 15 minutes, but after that time the men complained that they were getting the dust down their throats or noses just as badly as before putting on a respirator. In a factory with which he was connected there was sometimes a very bad escape of sulphur dioxide, and respirators were kept for the men to use when going to stop a leakage. He had only known of one case, however, in which a man had taken the trouble to put on the respirator, and when he did so he said that his own domestic respirator, which consisted of a pocket handkerchief stuffed into his mouth and upon which he fixed his teeth, was far more efficient than the one which had been in stock at the factory.

Mr. P. Parrish thought the important thing from the point of view of the chemical works manager or chemical engineer was to avoid respirators as far as possible, and to take such steps as would render the workman immune from the trouble due to poisonous gases. Dr. Bailey had raised the question of nitrous oxides. He had had experience of these in large sulphuric acid works and in connexion with Gay-Lussac towers. He had suggested to the Alkali Works Inspector the advisability of creating by means of a fan a downward draught on the Gay-Lussac towers in order that the men discharging such towers would be breathing air, and the Chief Alkali Inspector had in most works enforced that method of discharge. He had seen men go home quite well in the evening, but next morning extraordinary care had to be taken to prevent their demise. Nitrous oxides were peculiarly insidious. One point the author had not touched upon was the blurring on the eye-pieces. For instance, there might be a serious leakage in connexion with an ammonium sulphate saturator and the contents had to be emptied rapidly and compressed air blown in, but whilst every step was taken to eliminate toxic gases, the conditions under which the chemical plumber worked were such that there were traces along with a good deal of steam when he got inside to do the job, and he could not carry on his work because of the blurring of the eye-pieces.

Dr. Levy, in reply to the chairman, said that in his opinion a man should not be called upon to watch for a colour change or the like as an indication whether his respirator was working satisfactorily or not. He thought it best that the indicator should function as a physiological effect upon the wearer himself. Iodine certainly was unpleasant to a certain extent and caused lachrymation, but the effect was very slight and only persisted for a short while. He himself had been lachrymated for an hour in this way in the course of a chamber test, but a quarter of hour after he came out all effect had vanished. As a general rule five minutes would be all that the wearer would have to put up with. It was essential that the indication should be made unmistakable. He agreed with Dr. Legge that the workman would never use a respirator or anything of that kind if he could avoid it, but many men in England now were thoroughly used to the small box respirator, and they would probably look with less disfavour upon something which was far more comfortable to wear. In certain instances it might be impossible to use the appliance with the long tube to which Dr. Legge had referred, and in other cases it would not be necessary. Ordinary type Puretha respirators, for instance, were so perfect and convenient that the long pipe type would never be employed. In the case of a blast furnace with 25% of CO, there would be no oxygen present, and a self-contained apparatus fitted with an oxygen cylinder was the only thing that could be used.

The Hoolamite detector, as stated by Captain Pratt, suffered from the objection that the wearer might be colour blind, and as it functioned by colour change, had the same drawbacks as the potassium iodide starch paper. The limit of detection of carbon monoxide by the lachrymatory effect of the iodine could be made far less than 1/1000 if it were so desired. They had arranged that when the catalyst was so far exhausted that it was passing 1/1000 of carbon monoxide, the detector gave unmistakable signs that carbon monoxide was passing, and when there was 1/1000 passing, the detector passed 1/3000. The remainder was destroyed in generating the iodine which gave the effect; 1/3000 was an innocuous amount unless it persisted for a very long time. There was no doubt as to the efficiency of the detector. With regard to a combination respirator to deal with fine particles as well as gases, the ordinary Army mask had filtering pads, and these had been included in the apparatus described. If a greater degree of protection was required against particles, the canister could be jacketed. He had carried out chamber tests for one hour against 1% nitrous fumes which had been perfectly satisfactory; 1% was, of course, an enormous concentration—about 100 times the limit of filtration.

THE ACTION OF SULPHUR ON CEMENT IN THE TROPICS.

BY ALEXANDER BRUCE.

Within the last 15 years Colombo has developed a sewage scheme, and during that period many of the pipes have remained unused for some years. The earthenware pipes used were of the improved Stanford type joined by cement and river sand 1:1 with a waterproof ring of "galanack." Examination of some of the older pipes showed considerable cracking longitudinally and circumferentially. The cement had altered considerably in appearance, until in some cases it resembled white plastic putty. The appearance of the galanack had also altered.

Galanack is a mixture of sulphur, tar, and oil, and has a crystalline structure due to the sulphur. The fresh product had a biscuit fracture. Older specimens taken from sewer connections had lost these characteristics. Fresh galanack when ground with water or alcohol did not give an acid reaction, while old galanack gave an acid reaction and was easier to grind with water than the fresh material. Alcohol extracted more from the old material than from the fresh. Some specimens of the composition ring had a high content of ash (45%) rich in lime; these specimens were not acid. Fresh galanack when melted with 1% of lime and ground with water gave an alkaline reaction. The lime present in the galanack had probably acted as a preservative against acid.

The altered cement was of a soft, chalky appearance; it was easily scraped with the finger nail, and sometimes had a fine crystalline structure, the limit of action being defined by a brown boundary line, often of a fine crystalline mass.

The following are the analyses:—

	8 years old.	4 years old.	Two portions of cement from fillet of the joint.		Two portions of cement from between fillet and outer rim.	One portion of cement from between two patent rims in plastic condition.	Cement.
			White portion.	Cement portion.			
Loss on ignition ..	18·0	13·0	17·6	8·1	17·0	22·7	2·0
CaO	27·8	54·0	—	—	—	—	—
MgO	1·5	1·1	—	—	—	—	—
SO_3	39·2	2·9	26·1	1·5	26·8	37·4	1·7
Fe_2O_3 and Al_2O_3 ..	2·0	10·0	—	—	—	—	—
Soluble silica	10·4	17·0	36·0	46·5	37·7	15·2	21·5
Insoluble matter ..	0·8	1·2					
Moisture at 100° C. ..	—	—	10·3	5·8	10·3	14·8	—
Free acid as H_2SO_4 ..	—	—	—	—	—	0·3	—

There is thus an increase in the sulphates and loss on ignition, with a decrease in the lime, iron and alumina, and soluble silica. The brown demarcation mark is due to soluble iron salts meeting the unaltered cement. The conversion of cement into gypsum is undoubtedly due to the oxidation of the sulphur to sulphuric acid and subsequent action on the cement, changing its character and strength and causing cracking in the pipes. Mineral samples containing pyrites have been known to change to ferrous sulphate and sulphuric acid on keeping in the laboratory, where the temperature is 80° F. and the mean humidity 80%. In the sewers the temperature would rise to 85°—90° F.

The exact conditions for the change apparently depend on the manner of application of the galanack rather than on the climatic conditions, as cracked and uncracked pipes are found in the same sewer. Used and unused sewers have been similarly affected. Soil factors seem to have no influence.

Laboratory, Hyde Park Corner, Colombo.

BLEACHING POWDER IN THE TROPICS.

BY CAPTAIN A. F. MACCULLOCH, M.A., B.SC., A.I.C.

Many attempts have been made to render bleaching powder stable at high temperatures. Rettie, Lorrain-Smith, and Ritchie (J., 1918, 311 T) have investigated the stability of dry bleaching powder, and found that bleach mixed with 20% of powdered quicklime ("stabilised bleach") lost its available chlorine, at high temperatures, at a very slow rate compared with ordinary bleach.

A consignment of 2 cwt. of this "stabilised bleach" was received by the Government Medical Stores Depôt, Madras, in June, 1919, for a test of its stability in India. The product arrived in cases (3-ply wood) containing 1 cwt. each, and was immediately transferred to 2-lb. amber bottles with ground-glass stoppers. The powder was tested over a period of two years alongside a sample of ordinary bleaching powder received at the same time. The sample of ordinary bleaching powder arrived in a clear glass bottle inside the box of stabilised bleach and was immediately transferred to an amber-coloured glass bottle with ground-glass stopper. The following were the results obtained:—

	Ordinary bleach. % Cl.	Stabilised bleach. % Cl.
Analysis in England	35 ..	25
On arrival in Madras	20·04 ..	18·4
6 weeks after arrival ..	12·52 ..	16·56
10 " " " ..	4·68 ..	15·9
14 " " " ..	0·42 ..	15·05
26 " " " ..	— ..	12·08
42 " " " ..	— ..	10·0
52 " " " ..	— ..	8·5
104 " " " ..	— ..	3·48

It is thus obvious that "stabilised bleach" is a much more reliable article than ordinary bleaching powder for use in the tropics. It has also the advantage that it remains a dry powder, even although it only contains 3·5% of available chlorine and has been kept for two years in a high temperature. The rate at which bleaching powder loses its available chlorine increases owing to the formation of water during decomposition. The rate of decomposition of "stabilised bleach" is fairly steady.

After two years in Madras this sample of stabilised bleach was found to contain 5·9% of calcium chlorate, so that it would not be advisable to use "stabilised bleach" for sterilising water after a period of one year as this amount of chlorate would give a nauseating taste to the water.

The author is indebted to the Director-General, Indian Medical Service, for permission to publish this information.

Annual General Meeting.

Paper read at Montreal on August 30, 1921.

THE MANUFACTURE, PROPERTIES, AND EMPLOYMENT OF HEAT-INTERCEPTING STRUCTURAL GLASS.

BY GELLERT ALLEMAN.

Several years ago the late Sir William Crookes conducted an investigation on spectacle glasses with the object of securing a glass which would absorb heat and ultra-violet rays, transmit luminous rays, and reduce glare, and would therefore protect the eyes of labourers employed in glass works. It is stated that these workmen develop cataract in consequence of the great amount of infra-red energy emitted by molten glass. After an exhaustive research (*cf.* J., 1914, 646), Crookes concluded that cerium salts were best adapted for the production of an almost colourless glass which would interfere with the passage of heat rays and certain deleterious light rays. He also called attention to the fact that when black mica (biotite) was added to the melt, a remarkable glass was obtained which almost completely obstructed invisible heat rays, cut off 94% of heat radiation, and allowed 34% of incident light rays to pass through. It was opaque to ultra-violet rays of wave-length shorter than λ3610. In consequence of the great expense of the production of glasses similar to those made by Crookes, one would not have expected that such glasses could be manufactured commercially and employed for structural purposes.

About five years ago, Mr. L. T. Sherwood, then chief chemist of the Pennsylvania Wire Glass Company at Dunbar, Pennsylvania, began to experiment, using a glass pot furnace, with a view to produce a glass which would absorb heat and ultra-violet rays, transmit luminous rays, and greatly reduce glare. In all 227 experiments were carried out, about 50 lb. of batch being melted in large Hessian crucibles. The composition of these glasses varied markedly, and included the oxides of cerium, chromium, nickel, cobalt, titanium, uranium, manganese, and iron. It was determined that the addition to the batch of what might be termed artificial biotite resulted in the production of a glass having many of the properties desired. Later a more brilliant glass was produced by a slight manipulation of the temperature of the furnace. Specimens of the glasses were then referred to Dr. George de Schweinitz, the celebrated ophthalmologist of Philadelphia, who selected the glass most desirable from the standpoint of an oculist.

The batch used for making these glasses contains sand 1300 lb., soda ash 400 lb., borax 20 lb., lime 200 lb., nitre 40 lb., manganese dioxide 85 grams, titanium oxide 30 g., nickel oxide 35 g., artificial biotite 40 lb. The artificial biotite consisted of micaceous hæmatite 40 lb., precipitated alumina 5 lb., solid sodium silicate 50 lb., magnesite 5 lb., manganese dioxide 30 grams, all finely ground and thoroughly mixed before adding to the batch.

The tank in which this glass is made is 57 ft. long, 12 ft. wide, and contains molten glass to a depth of 56 in. The arch rises 5½ ft. above the surface of the glass. The furnace is heated by means of producer-gas and gas obtained from by-product coke-ovens. A regenerative system is used, and the temperature of the glass, when removed from the tank, is about 1100° C. The temperature of the tank is controlled by means of recording pyrometers. It was found that after a batch had been added at the dog-house, 72 hours was required before it was converted into glass and flowed to the dipping ring. It was also observed that the glass was not uniformly distributed throughout the tank, but passed through as a stream near the centre, and that portions of the banks frequently fell into the stream, causing considerable variation in the colour of the finished product. When a reducing flame is used the resulting glass has a smoky green colour and is lacking in brightness, probably owing to the production of an excess of ferrous compounds. With an oxidising flame the objectionable colour was not produced.

In making this actinic glass it is interesting to note that the experimental work conducted, using the small pot furnace, did not wholly anticipate what happened in a continuous tank holding approximately 225 tons of molten glass. When a "day tank," holding 6 tons, which was heated quite rapidly, was employed, it was found that a very poor glass was obtained, entirely unlike the desired product made in the larger tank—the same mixtures having been used on both occasions.

The material is now a commercial product known as actinic or heat-intercepting glass, manufactured into plate, polished plate, wire plate, rough wire, "aqueduct" wire, ribbed wire, and corrugated wire glass.

"Aqueduct" wire glass (drip-proof) contains deep, semi-capillary grooves, and is used for roofs and skylights where moisture is likely to condense. This glass will retain a large amount of condensed moisture, and, if inclined at a slight angle, will carry the condensate to a water conductor at the bottom without allowing it to drip from the glass.

Corrugated wire glass is in form very similar to corrugated iron. The deep angle is 2½ in. from the centre of one corrugation to the centre of the next, and the shallow angle is 2$\frac{11}{16}$ in. from the centre of one corrugation to the centre of the next. It can be used alone to make a building entirely of corrugated wire glass, or in conjunction with corrugated iron or corrugated asbestos. Corrugated wire glass is particularly valuable because of its great physical strength and its resistance to shock.

Since corrugated glass is subjected to greater stresses than ordinary glass, the annealing of its various forms is of the utmost importance. All internal strains are removed by keeping the glass at a temperature of 520° C. in the first oven of the lehr for a period of five minutes, and then passing the sheet through the other ovens, the temperatures in which are reduced as rapidly as practicable. The sheets are cut with a diamond, and the wire broken by a hinge-like movement of one part of the sheet. Pieces of pasteboard are placed between the jaws of the so-called glass hinge in order to prevent injury to the sharp edges of the glass.

The resistance of corrugated wire glass to shock is illustrated by the falling of two ¼-in. steel smoke stacks, 24 in. in diameter and about 25 ft. in length, on the corrugated wire glass roof of a large boiler house. Two plates were destroyed, and the remainder of the glass was cracked and bent, but not shattered, and it was not necessary to replace the latter as it did not leak. The steel beams on which the glass rested were bent out of line about 3 inches.

In addition to the advantages regarding the transmission of light, the absorption of heat, and the elimination of glare, buildings made of this glass can be erected more rapidly and more cheaply than when other materials are used.

Specimens of this actinic glass, ¼ in. thick, have been examined, and it has been found that the polished plate glass transmits approximately 42% of light, and absorbs about 78% of heat. It eliminates all glare.

In order to demonstrate on a practical scale the light- and heat-transmitting properties of this glass, in comparison with the same properties of other building materials, fourteen small houses were erected, and hourly temperature readings were made over a period of 28 days. The tests clearly demonstrated the advantages of actinic glass over ordinary glass, and also showed the reduction in temperature which resulted from ventilating such houses. The readings show that in the ventilated, actinic, corrugated glass house a temperature may be maintained almost equal to the outside temperature in the shade. It is of interest to note that the roof temperatures of all actinic glass houses are much higher than the roof temperatures of ordinary glass houses, due to the absorption of heat rays by actinic glass.

The transmission of the luminous rays by different forms of glass varies considerably, and is as follows (the figures are for ¼ in. thickness of glass):—Plain polished plate (no wire), 92·26% of transmission; plain polished wire, 68·76%; plain aqueduct wire, 40·88%; plain cobweb wire, 46·98%; plain ribbed wire, 41·96%; plain corrugated wire, 44·45%; actinic polished plate, 42·02%; actinic rough wire, 39·74%; actinic aqueduct wire, 21·48%; actinic ribbed wire, 32·57%; actinic corrugated wire, 29·88%. The transmitted light measured included only that which emanated perpendicular from the face of the glass.

The following figures show the amount of illumination (due to reflexion as well as transmission) in houses of various kinds of glass:—Plain polished plate, 94·3% of illumination; plain aqueduct wire, 81·8%; plain ribbed wire, 81·7%; plain corrugated wire, 86·0%; actinic rough wire, 72·7%; actinic aqueduct wire, 47·2%; actinic ribbed wire, 77·3%; actinic corrugated wire, 77·0%.

From a practical standpoint, in consequence of the large surface of glass exposed to the light, it has been found that the natural illumination in these actinic houses is more than adequate. When the illumination of an ordinary building is entirely dependent upon the light entering through skylights, it is necessary to increase the surface of such skylights if actinic glass is used, the percentage increase varying with the particular form of glass employed.

The wire glass is absolutely fire-proof, and is approved by the National Board of Fire Underwriters. A specimen of corrugated wire glass 3 ft. wide and 6 ft. long, when placed on two knife edges, almost 6 ft. apart, will sustain a weight of 400 lb. near the centre. After the glass has been subjected to great heat, and then sprayed with water until it cracks, a man may walk over the cracked glass with safety.

Manufacturers of chemicals which are affected by light should find this glass of considerable interest and value, and the hazard of rapid changes in certain of the products of explosives manufacture, due to the action of light and heat rays, should be considerably decreased.

Objects viewed through polished plate actinic glass appear in more striking contrast with their surroundings than when seen through ordinary glass. This is probably due to the fact that the glass acts as a screen and eliminates the blue haze from the visual image. When rain drops appear on actinic wind shields, one can see clearly through the glass; this suggests an additional employment of this product. Street-car motormen have found it of great service in reducing the glare from automobile headlights, thereby aiding in a better view of the road.

My grateful acknowledgment is extended to Mr. Walter Cox, President of the Pennsylvania Wire Glass Company, for his courteous and energetic co-operation during this investigation.

THE DISCONTINUITY OF VULCANISATION IN THE PRESENCE OF ORGANIC ACCELERATORS.

BY D. F. TWISS.

In a recent paper (J., 1920, 125 T) S. A. Brazier and the author reported some observations on the vulcanisation of a mixture of rubber and sulphur (90:10) in the presence of 0·5% of hexamethylenetetramine, with and without the addition of 1% of zinc oxide; in the presence of the zinc oxide the points representing the extensibility at a load of 0·5 kg. per sq. mm. after various periods of vulcanisation, did not agree so well with the course of a smooth curve as did those for the same standard rubber-sulphur mixing alone, or as those for this mixing with either the zinc oxide or hexamethylenetetramine separately. This irregularity found a more detailed description a little later (Twiss and Howson, J., 1920, 287 T), when it was shown that with a similar rubber-sulphur mixing containing 1% of hexamethylenetetramine and 1% of zinc oxide the actual course of the curve representing the extension of the rubber at a load of 0·5 kg. per sq. mm. is roughly ∽ shaped, the extent of the elongation with progressive vulcanisation first decreasing to a minimum, then increasing to a maximum, and finally decreasing once more. The inflexion in the curve is surprising because it has generally been assumed that the extensibility of rubber decreases steadily with progressive vulcanisation.

For the vulcanisation of most mixtures the decrease in extensibility is indeed continuous, but the curve obtained on plotting the extensibility against the period of vulcanisation does not always have the simple course, almost rectilinear during the earlier stages, given by plain mixtures of rubber and sulphur (*e.g.*, see Twiss and Brazier, *loc. cit.*, Figs 1—7 etc.; Twiss and Howson, *loc. cit.*, Figs. 1—3). In the presence of some organic accelerators, especially in the presence of zinc oxide, the relationship is frequently far from rectilinear.

The irregularity, however, in the case of the hexamethylenetetramine mixing referred to above is exceptional in character because the ordinary effect of vulcanisation appears temporarily to be reversed. The phenomenon is not an example of "reversion" or mere increase of extensibility caused by prolonged heating after the consumption of the free sulphur. This is obvious from the fact that the normal effect reasserts itself later. No explanation of the observed facts was offered earlier, but the following considerations appear to throw considerable light on the matter.

The author at this stage desires to express his great indebtedness to Messrs. S. A. Brazier, M.Sc., C. W. H. Howson, B.Sc., and F. Thomas, B.Sc., for their valued and expert assistance in making the various vulcanisation experiments recorded.

For the occurrence of the abnormality of behaviour during vulcanisation the proportion of the accelerator is immaterial within reasonable limits, *e.g.*, 0·5% and 2·5% of hexamethylenetetramine in the presence of 1% of zinc oxide show it equally well (Fig. 1)*. It is surprising, however, that if the proportion of zinc oxide is increased to as little as 2%, the abnormality disappears; the extensibility curve then comes down with a continuous sweep giving no sign whatever of any reversal of direction (Fig. 2). With 0·5% of zinc oxide the behaviour is similar to that of the mixing containing 1%.

---

* For convenience of comparison it should be stated that the rubber used throughout these experiments when mixed with sulphur alone, in the proportion 90 : 10, needed vulcanisation for about 90 min. at 148°C. for the attainment of maximum tensile strength or an extensibility of 650% at 0·5 kg. per sq. mm.

There are evidently three distinct sections to the ∽ curve under consideration. The first and last are accompanied by decrease in extensibility and presumably represent behaviour approximating to the normal, except that in the first section the physical effect is exceptionally rapid and in the last section relatively slow. The abnormality is essentially restricted to the short ascending middle section, throughout which further "vulcanisation" effects an increase in the extensibility. It would appear, therefore, that under the conditions in question two periods of more or less normal vulcanisation behaviour become separated by the occurrence of an abnormal softening effect in the rubber such as can conveniently, although possibly not correctly, be termed "depolymerisation"; this term, for lack of a better one, is used throughout this communication.

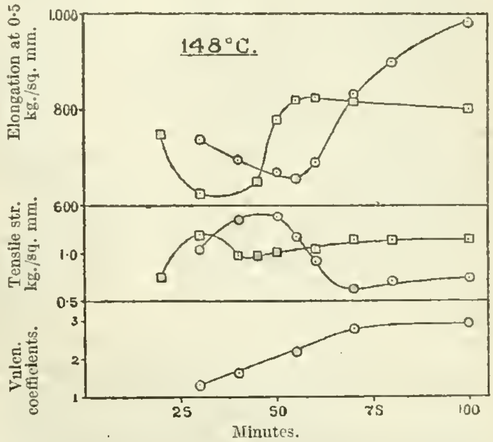
Δ " 1, " " 5.
∇ " 2·5, " " 5.

Fig. 2.

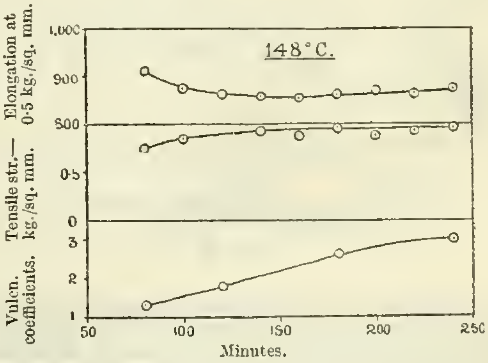
As was shown in the earlier communication (Twiss and Howson, *loc. cit.*), this "depolymerisation" process occurs whilst there yet remains more than 4% of free sulphur, which is indeed responsible for the subsequent return of the curve to a normal course. If this additional sulphur could be diminished in quantity, the upward section of the curve should be extended and show a more marked "depolymerisation" effect.



O Rubber 97, sulphur 3, hexamethylenetetramine 1, zinc oxide 1.
□ " 95, " 5, " 1, " " 1.

Fig. 3.

Vulcanisation of similar mixtures containing less sulphur confirmed this expectation (Fig. 3). With 5% of sulphur the maximum increase in extensibility is less marked than that observed with 3%, but is more developed than that of the corresponding 10% mixing; with an initial concentration of 3% of sulphur, the "depolymerisation" process once more sets in but proceeds unchecked, very high extensibility values therefore being attained. That this unusual behaviour is not attributable merely to the presence of the zinc oxide is demonstrated by Fig. 4, showing the behaviour of a similar mixing of rubber 97, sulphur 3, and zinc oxide 1% without any hexamethylenetetramine; in this case "depolymerisation" certainly sets in after the disappearance of the sulphur into combination, but is relatively slow and of the normal extent arising from "overheating" or "reclaiming." The discontinuity in the extensibility curve for the mixing containing hexamethylenetetramine consequently cannot be explained merely by "reversion," or softening caused by overheating.

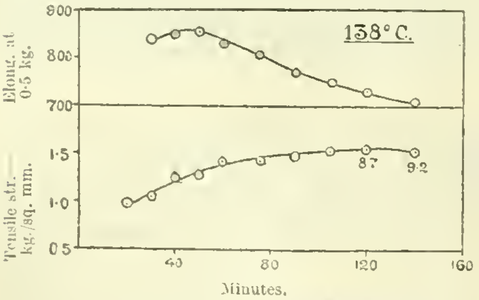


Rubber 97, sulphur 3, zinc oxide 1.

Fig. 4.

The evidence renders it probable that during vulcanisation of the mixtures represented in Fig. 1, hexamethylenetetramine gives rise to some substance capable of effecting the depolymerisation of rubber. This fact is of particular interest because although the view has been expressed that accelerators of vulcanisation also accelerate the removal of combined sulphur from vulcanised rubber, and therefore aid "reclaiming" (Spence, E.P. 126,397, 1919), the depolymerisation effect produced by hexamethylenetetramine, which resembles a reclaiming process in that it is accompanied by an increase in the extensibility of the rubber, occurs without the removal of combined sulphur, and indeed may occur whilst sulphur is still entering into combination (Twiss and Howson, *loc. cit.*, Fig. 7). The independent application of hexamethylenetetramine to the purpose of reclaiming as independently suggested by Dubosc (J., 1919, 264 A, 782 A) cannot be based on the peculiarity represented in Fig. 1, because this particular process also is definitely described as being dependent on the removal of the sulphur of vulcanisation.

Closer examination of some of the earlier experimental results confirms this remarkable conclusion that hexamethylenetetramine can induce in vulcanised rubber, whilst vulcanisation (in the sense of combination with sulphur) is still proceeding, a physical alteration which is the reverse of that customarily associated with vulcanisation. Reference to the vulcanisation results reproduced earlier (J., 1920, 125 T, Fig. 11) reveals the fact that with a rubber-sulphur mixing (90:10) containing 1% of hexamethylenetetramine without zinc oxide, the position of the attainment of maximum tensile strength is much less sharp than with most mixings containing the same proportion of sulphur; a high tensile strength is maintained over an exceptionally long period whilst the rate of decrease in the extensibility, with progressive vulcanisation, is low relative to the blank rubber-sulphur mixing.* A similar result is represented in Fig. 5, showing the vulcanisation behaviour of a rubber-sulphur mixing (90:10) with 2½% of hexamethylenetetramine; the protracted tensile strength curve is most characteristic and the maximum is not reached until the attainment of a coefficient of vulcanisation approximating to 9. The simultaneous occurrence of normal vulcanisation and an abnormal reverse depolymerisation effect appears to cover the facts.



Minutes.

Rubber 90, sulphur 10, hexamethylenetetramine 2·5. Vulcanisation coefficients inset.

FIG. 5.

It is not surprising, therefore, that the tensile strength does not rapidly diminish in the usual manner above a vulcanisation coefficient of value 5.

A similar phenomenon is still more clearly observable under the conditions which give rise to the ∿ curve (Fig. 1). Here the period of most marked depolymerisation is naturally that over which the extensibility curve follows an upward course; throughout this period the actual consumption of free sulphur is more rapid than elsewhere (Twiss and Howson, *loc. cit.*, Fig. 7). No indication of over-vulcanisation is given by the tensile strength curve until the coefficient of vulcanisation attains an exceptionally high value near 7, whereas the customary figure is approximately 5.

The fact that, after the abnormal upward section, the extensibility curves in Fig. 1 again finally resume their downward direction suggests that the substance responsible for the abnormality decomposes or, at any rate, undergoes chemical alteration, so that most of it is of short existence. This is confirmed by the tendency of the upward section of the extensibility curves in Fig. 3 to revert gradually to a horizontal course. The presence of a larger proportion of sulphur possibly aids its disappearance.

It is remarkable that the presence of undissolved solid matter seems to be necessary for the development of the ∿ curve. Not only zinc oxide, but also lampblack, gas black (carbon black), and china clay all induce this abnormality over a wide

* This behaviour of hexamethylenetetramine calls for a qualification of the statement ("Plantation Rubber and the Testing of Rubber," Whitby, p. 336) that "any factor which increases the rapidity of vulcanisation such as . . . the presence of natural or artificial accelerators, will tend to accentuate the sharpness with which a maximum occurs in the vulcanizates obtained by progressive curing." At the same time it is in accord with the statement (*ibid.*, p. 199) as to the tendency of hexamethylenetetramine alone to yield vulcanizates of greater extensibility.

range of percentages. Fig. 6 shows the behaviour with 0·4% and 7% of gas black and Fig. 7 represents the corresponding results with 0·5% and 7% of a refined china clay; with 15% of either ingredient the curves possess a similar outline. The results with 0·4%, 7%, and 15% of lampblack resemble those with gas black. Again, the phenomenon occurs only for a short time, but the subsequent vulcanisation effect is relatively slight. Although sulphur still disappears steadily into combination, sufficient of the depolymerisation process seems to persist to mask almost completely the effect of further vulcanisation; indeed, the extensibility curve finally becomes almost horizontal. In this case the stage of "rottenness" due to the over-vulcanisation is not attained until a coefficient of 8 or 9, which is distinct evidence of the existence of a change operating in the opposite direction to the change produced by the concurrent vulcanisation.

The effect of the presence of an inert powder such as that of gas black, lampblack, clay, or zinc oxide alone, on a reaction occurring in the surrounding medium is not exceptional and other cases are well known, being commonly attributed to the influence of surface energy. The well-known "time-reaction" between sulphurous and iodic acids in aqueous solution with formation of free iodine is influenced in a marked manner by the extent of the surface of the liquid.

Of the numerous accelerators tested so far hexamethylenetetramine appears to be the only one giving good tensile strength for soft rubbers at very high vulcanisation coefficients. It is therefore probable that the characteristic responsible for the abnormal course of vulcanisation represented by Fig. 1 is not exhibited to a comparable degree by the other common accelerators.

The lower initial rate of vulcanisation with hexamethylenetetramine alone and the absence of any minimum in the extensibility curve, indicate the probability that not the hexamethylenetetramine itself, but some decomposition product is the accelerator. Probably for this reason the "depolymerisation" section of the vulcanisation curve with hexamethylenetetramine and 10% sulphur is not observed when more than 1% of zinc oxide is present; the formation of the direct catalyst is then favoured so that less of the hexamethylenetetramine becomes available for decomposition into the unstable depolymerisation agent. Possibly also the depolymerisation agent is acidic and excess of zinc oxide may tend to annul the activity of any small quantity that may be formed. These views receive support from the fact that the position of the maximum in the tensile strength curve given in Fig. 2 for the mixing containing 5% of zinc oxide occurs at a vulcanisation coefficient between 4 and 5, thus giving an indication of the absence of depolymerisation in the presence of larger proportions of zinc oxide.

That other accelerators do give rise in a milder degree to the phenomenon shown by hexamethylenetetramine is very probable. In several cases of comparable mixings containing rubber and sulphur in the proportion 90:10, together with an organic accelerator and 1% of zinc oxide, although the extensibility curve may not assume a sharp minimum and maximum, there is observable a distinct temporary change of direction in the curves. Presumably in these cases also, a decomposition product of the accelerator is responsible, but none is capable of effecting such strong depolymerisation as occurs with hexamethylenetetramine under suitable conditions.

Fig. 8 shows the behaviour of the standard mixing (rubber 90:sulphur 10) containing 1% of *p*-toluidine with and without 1% of zinc oxide. In the absence of zinc oxide the alteration in extensibility with progressive vulcanisation follows an almost rectilinear course, but with 1% of zinc oxide the curve suggests a distinct delay in the physical alteration, although, as is evident from the inset vulcanisation coefficients, combination with sulphur proceeds steadily. With more zinc oxide the flattened portion of the extensibility curve tends to disappear.

FIG. 9.

Fig. 9 reproduces the values of the physical alteration in the same standard mixing plus 1% of thiocarbo-*p*-toluidide and 1% of zinc oxide. In this case there is a distinct inflexion in the curve marking the occurrence of depolymerisation analogous to that observed in the corresponding hexamethylenetetramine mixing; the inserted vulcanisation coefficients demonstrate that the effect again occurs in spite of the presence of much free sulphur. With the isomeric thiocarbo-*o*-toluidide and the analogous thiocarbanilide the results are of very similar character. Again, with increase in the proportion of zinc oxide the inflexion in the curve becomes less marked and the extensibility curve tends more and more to assume a continuously downward course. In the case of all three compounds with rubber and sulphur but no zinc oxide the extensibility curve is normal and almost rectilinear (*e.g.*, see also Twiss and Howson, *loc. cit.*, Fig. 3). The vulcanisation experiment with thiocarbanilide and zinc oxide, reported earlier (Twiss and Brazier, *loc. cit.*), extended over too short a period to reveal clearly the inflexion in the extensibility curve.

The dithiocarbamate class of accelerator, of which the commonest are obtained by the interaction of secondary amines with carbon bisulphide, also give exceptional behaviour in the presence of zinc oxide. When used alone in a rubber-sulphur mixing they act as moderate accelerators (see also Whitby and Walker, Chem. and Met. Eng., 1921, 24, 835, and Tuttle, J. Ind. Eng. Chem., 1921, 13, 519), and the extensibility curve shows no marked inflexion. When 1% of zinc oxide is introduced into the mixing there is a very rapid physical change for a short period at the commencement of vulcanisation, followed by an almost stagnant condition, although the fixation of sulphur proceeds steadily. Once more therefore the physical alteration relative to the chemical is incommensurately great during the initial stages of vulcanisation. With more zinc oxide the extensibility curves sweep downwards steadily, but always with a marked bow. Fig. 10 shows the effect of 0·25% of piperidinium piperidyldithiocarbamate without and with 1% of zinc oxide at 128° and 118° C. respectively; the corresponding diethylammonium diethyldithiocarbamate gives closely similar curves under the same conditions.*

FIG. 10.

The behaviour of furfuramide, which has received considerable recommendation as a vulcanisation catalyst, is closely comparable with that shown for *p*-toluidine. Without zinc oxide, furfuramide accelerates vulcanisation relatively feebly and the extensibility curve is roughly straight, whilst with 1% of zinc oxide a marked inflexion is developed in the extensibility curve (Fig. 11). As usual, with more zinc oxide the extensibility curve becomes steeper and less irregular. It will be observed that with all the preceding organic accelerators the physical alteration due to vulcanisation relative to the chemical alteration is exceptionally great during the initial period. This peculiarity indeed appears to be characteristic of all organic accelerators in the presence of zinc oxide.

□ „ 90, „ 10, „ 1, zinc oxide 1
△ „ 90, „ 10, „ 1, „ 5

FIG. 11.

Experiments with mixings containing other organic accelerators, *e.g.*, *p*-nitrosodimethylaniline, aldehyde-ammonia, *p*-phenylenediamine, quinoidine, anhydroformaldehyde-aniline, and diacetonamine, likewise, in the absence of zinc oxide, show that the extensibility at 0·5 kg. per sq. mm. is a linear function of the period of vulcanisation, but that with the addition of 1% of zinc oxide the extensibility curve has a contour somewhat resembling the corresponding curve for furfuramide. With a higher proportion of zinc oxide the extensibility in each case tends to decrease continuously with progressive vulcanisation, but the representative curve is never rectilinear.

A more intimate knowledge of the actual chemical changes involved in the mechanism of acceleration by organic accelerators is much to be desired. The particular efficacy of zinc oxide as an activating agent is evident from the above tests, even although the phenomena are complicated by the concomitant depolymerisation effect.

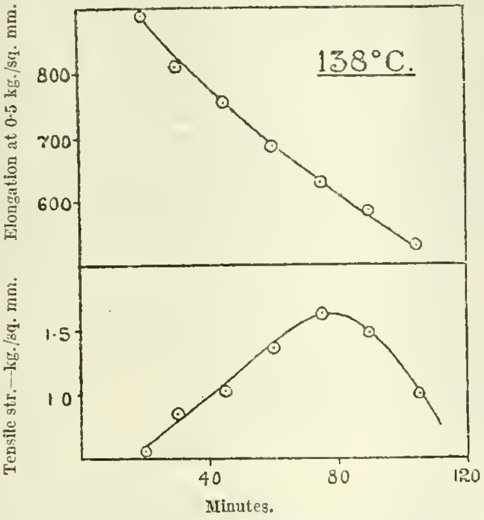
The view that zinc oxide functions in mixings containing certain organic accelerators by reacting with the latter and sometimes simultaneously with sulphur with formation of the real catalyst, appears to be gaining general favour. Kratz, Flower, and Shapiro had suggested (J. Ind. Eng. Chem., 1921, 13, 128) that in the case of thiocarbanilide during vulcanisation an acidic decomposition product is formed and is subsequently converted by the zinc oxide into a zinc salt which is responsible for the acceleration effect. Scott and Bedford (J. Ind. Eng. Chem., 1921, 13, 125) have divided the organic accelerators into two classes, distinguishing between (*a*) those which on account merely of basic character act by first forming hydrosulphides, and (*b*) those which contain or develop the carbosulphhydryl group :C.SH. Both classes are believed to act by adding sulphur with formation of "polysulphides" capable of liberating the additional sulphur in an active form for vulcanisation.

Evidence of the correctness of this view for the first class is forthcoming from the experiment repre-

---

* Later experiments by Mr. F. Thomas show tetramethylthiouram disulphide and zinc diethyldithiocarbamate also to give similar sets of curves: it is remarkable that the latter, even in the absence of zinc oxide, is but little more active than the alkylammonium alkyldithiocarbamates under comparable conditions.

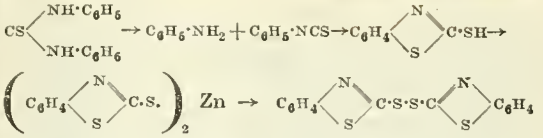
sented in Fig. 12. Potassium hydroxide is well known to expedite vulcanisation (*e.g.*, see Twiss and Howson, *loc. cit.*), and could be included in class (*a*); it is conveniently applied as a roughly 25% solution in glycerol. If such a solution is saturated with hydrogen sulphide before use so as to produce potassium hydrosulphide, its activity is unimpaired; the effect of potassium hydroxide is therefore not dependent on the presence of the hydroxyl radicle, but is presumably due to its power of conversion into the sulphhydryl group.



Rubber 90, sulphur 10, glycerol-potash (3 : 1) saturated with hydrogen sulphide 2.

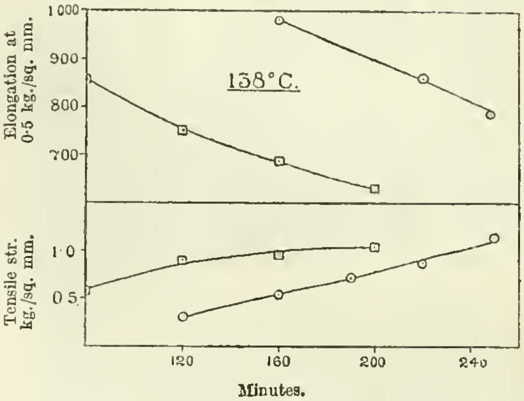
FIG. 12.

The view of Scott and Bedford with respect to class (*b*) has undergone subsequent modification because in a paper by Bedford and Sebrill (Chem. and Met. Eng., 1921, **24**, 835) the suggestion is made that the mechanism of the carbosulphhydryl accelerators involves the formation of very active zinc salts. This is in agreement with a more detailed and independent explanation by Bruni and Romani (Indiarubber J., 1921, 62, 63; Romani, Atti R. Accad. Lincei, 1921, V., 30, 283), in which it is held that the accelerators of class (*b*) function by the direct or indirect formation of zinc salts which are capable of behaving as "ultra-accelerators"; thus zinc alkyldithiocarbamates, applied as such or formed during vulcanisation from an alkylammonium alkyldithiocarbamate and zinc oxide, are exceptionally powerful*; the action is believed to depend on conversion by sulphur into the corresponding thiouramdisulphide which forms the vulcanising agent functioning by decomposition with scission of sulphur in an exceptionally active form for vulcanisation; by repeated regeneration from its decomposition products and free sulphur it is able to supply a relatively large quantity of sulphur to the rubber. $2NMe_2{\cdot}CS{\cdot}S{\cdot}NH_2Me_2 \rightarrow (NMe_2{\cdot}CS{\cdot}S{\cdot})_2Zn \rightarrow NMe_2{\cdot}CS{\cdot}S{\cdot}S{\cdot}CS{\cdot}NMe_2$. The remarkable accelerating power of the nitrogen-free zinc ethyl xanthate is attributed similarly to its conversion into dixanthogen $(OEt{\cdot}CS{\cdot}S{\cdot})_2Zn \rightarrow OEt{\cdot}CS{\cdot}S{\cdot}S{\cdot}CS{\cdot}OEt$ whilst that of thiocarbanilide and its analogues is attributed to the formation of the zinc salt of the acidic mercaptobenzothiazole (*cf.* Kratz, Flower, and Shapiro, *loc. cit.*), phenyl isothiocyanate occurring as an intermediate product.



A strikingly similar view of the mechanism of the accelerating effect of the amine alkydithiocarbamate accelerators has been expressed independently by Maximoff (Caoutchouc et Gutta-Percha, 1921, 18, 10,944, 10,986).

The occurrence of phenyl isothiocyanate as an essential intermediate stage in acceleration by thiocarbanilide, as postulated by Bruni and Romani, receives some confirmation from the experiments recorded in Fig. 13, in which the effect of this substance on the vulcanisation of the standard 90:10 rubber mixing was examined with and without the assistance of zinc oxide; alone, phenyl isothiocyanate is ineffective, but in the presence of zinc oxide there is distinct acceleration, due, according to the above theory, to the further successive conversion of the isothiocyanate into mercaptobenzothiazole, its zinc salt and the corresponding disulphide compound. The magnitude of the effect produced is possibly less than would be expected from the theory and suggestive of a necessity for further confirmation of the view as to the details of the mechanism of the action of thiocarbanilide.



○ Rubber 90, sulphur 10, phenyl isothiocyanate 1
☐ „ 90, „ 10, „ „ 1, zinc oxide 5

FIG. 13.

According to Scott and Bedford hexamethylenetetramine belongs to both groups (*a*) and (*b*), and acts by giving rise to decomposition products which in part undergo further conversion into a hydrosulphide and in part to a carbosulphhydryl compound, probably a dithiocarbamic acid derivative which will then undergo conversion into a zinc salt. The behaviour of this and other accelerators is, however, evidently still far from fully investigated, and the identity of the agent responsible for the depolymerisation effect observable still requires recognition.

The view of Bruni and Romani as to the effect of many organic accelerators being attributable to the formation of a compound which is capable of supplying active sulphur is satisfactorily applicable to the above described irregularity in the course of the action of various organic accelerators in the presence of a limited proportion of zinc oxide. The interaction of the zinc oxide with the accelerator to give rise to the necessary intermediate compounds, capable of imparting sulphur in an active form to the rubber, must of necessity be rapid, and its effect will be seen from the earliest stages of the vulcanisa-

---

*See footnote on p. 246 T.

tion process. In the presence of a restricted amount of zinc oxide, however, the formation of the intermediate product or its regeneration from its decomposition products will soon cease, probably by conversion of the essential zinc oxide into the ineffective zinc sulphide. In such a case, therefore, the rapid initial rate of vulcanisation will soon disappear and the extensibility curve will develop a sharp bend and assume a more nearly horizontal course. If at the same time a "depolymerising" agent is formed amongst the decomposition products of the accelerator, the curve may even assume an upward trend as it does with hexamethylenetetramine; as soon as the depolymerising agent has disappeared by further decomposition, the ordinary effects of vulcanisation again begin to appear. The extraordinary modification of the almost straight extensibility curve of the plain rubber-sulphur mixing thus finds a complete explanation.

The foregoing results generally indicate the remarkable effectiveness of zinc oxide in modifying or developing the activity of many organic accelerators of vulcanisation, particularly those recognised as belonging to the dithiocarbamate or "carbosulphhydryl-polysulphide" class. Other basic oxides are not so effective and the peculiar power of zinc oxide is explained by its ability to form intermediate compounds of the requisite degree of stability or instability. The observation that zinc oxide is less effective in increasing the activity of certain organic accelerators such as aldehyde-ammonia (Fig. 14) is to be attributed to their activity being more particularly of the "hydrosulphide-polysulphide" type. The fact that the progress of vulcanisation, as evidenced by the slope of the extensibility curve, undergoes temporary retardation after a short initial period, suggests that even in the case of aldehyde-ammonia, the zinc oxide causes a modification of the mechanism of the accelerating effect and that there may be temporary formation of a small quantity of "depolymerising" agent. Probably all organic vulcanisation catalysts when used in conjunction with zinc oxide act to some extent as "carbosulphhydryl-polysulphide" accelerators. In this connexion it is noteworthy that with the potash-glycerol accelerator in which the glycerol merely forms the solvent, the indication of any such arrest in the progress of vulcanisation with a small proportion of zinc oxide is almost entirely wanting; the behaviour of potassium hydroxide therefore provides an almost pure example of the "hydrosulphide-polysulphide type" (Fig. 15); the same statement can be applied in perhaps a somewhat more moderate degree to sodium phenoxide and magnesium oxide which in the proportion of 1% with 1% of zinc oxide in a 90:10 rubber-sulphur mixing give rise to an extensibility curve diverging but little from that of a similar mixing without the zinc oxide.

Fig. 15.

It is possible indeed that the degree of dependence of an accelerator on zinc oxide for the development of its full activity and its behaviour in the presence of a small proportion, *e.g.*, 1%, of zinc oxide may be of value in enabling a decision to be reached as to the extent to which an accelerator is to be assigned to the "carbosulphhydryl" and "hydrosulphide" class respectively.

Communications.

THE THERMAL DECOMPOSITION OF SUCROSE UNDER REDUCED PRESSURE.

BY JOSEPH REILLY, M.A., D.SC., F.I.C.

The recent work of A. Pictet and the Geneva School of Chemists on the thermal decomposition under reduced pressure of various types of organic substances such as cellulose, starch,[1] methylated celluloses,[2] various glucosides, inulin, gelatin,[3] albumins,[4] sodium stearate etc.[5] and oils[6, 7] has given, in spite of the drastic nature of the dry distillation method generally, some remarkable and interesting results. The success obtained in the destructive distillation under reduced pressure of certain types of compounds is due in the main to two causes:—(*a*) The process takes place at a much lower temperature than when the distillation is carried out at ordinary pressure; (*b*) the greater portion of the products of decomposition is quickly removed from the sphere of action. In consequence there are factors tending to prevent or reduce the occurrence of secondary reactions, and it is often possible to obtain a good yield of definite, well-defined, intermediate products.

Cellulose when decomposed by heating under reduced pressure gave a large yield (45%) of a well-defined crystalline product (*l*-glucosan). From this result, reviewed in connexion with the other properties of cellulose, Pictet put forward the view that the cellulose complex contains two β-glucose groupings and one α-glucose grouping together with a "chitose" complex, *i.e.*, a hydrofuran nucleus containing two side chains.[8] Starch on dry distillation under similar conditions to cellulose gave similar results, part of the starch molecule being transformed into *l*-glucosan and part being more drastically decomposed. This result Pictet explained by assuming that half of the molecular structure is the same in cellulose and starch, *i.e.*, a portion of the molecule is formed of similar β-glucose groups, and it is this part which breaks down to the *l*-glucosan. Other carbohydrates, however, such as the sugars, with the possible exception of β-glucose,[9] on similar treatment gave, in addition to liquids and easily volatile products of comparatively simple composition, only ill-defined syrups. The latter are obtained moreover in poor yield, and can only result from drastic decomposition of the original sugar. In consequence, the sugars offer less attraction in this direction, and their systematic study by this method has been practically neglected.

From the products obtained by the dry distillation of glucose in presence of lime at atmospheric pressure in iron retorts, earlier workers[10] have isolated acetone, propyl aldehyde, certain higher aldehydes and ketones, furfuran and its higher homologues, such as 2.5-dimethylfurfuran and trimethylfurfuran, and also phenols. From the products of the destructive distillation of glucose Völckel[11] isolated among other compounds acetic acid, acetone, a trace of aldehyde, furfuraldehyde, and phenols; the gaseous products consisted of a mixture of carbon dioxide, carbon monoxide, and methane. In the formation of the caramels of Gelis by the partial decomposition of sucrose at 190° C., in addition to the above volatile products such compounds as acrolein and certain benzene derivatives, *e.g.*, benzaldehyde, are also formed. Kaiser[12] has studied the distillation products of sucrose and regards the product which redistils between 60° and 80° C. as an isomer of acetone. There appears to be generally a close resemblance between the liquid and gaseous distillation products from various types of carbohydrate.

Trillat[13] has analysed the volatile products obtained when sucrose is heated to the point at which it begins to char; he obtained various aldehydes including formaldehyde, and also acetone, methyl alcohol, acetic acid, and phenol derivatives.

The destructive distillation of sucrose, starch, and cellulose has been carried out by Bantlin[14] under similar conditions, at ordinary pressure in an electrically-heated iron retort. The temperature varied between 100° and 500° C., and the process took 7—8 hours to complete. The resulting products in percentages by weight on the dry substance were:—

	Sucrose.	Starch.	Cellulose.
	%	%	%
Coke	12·2	28·6	32·9
Water	6·3	29·7	31·7
Tar	55·0	2·7	3·2
Acetic acid	8·8	5·3	3·3
Aldehydes and ketones..	6·5	6·7	5·9
Total gases	6·0	22·7	17·3

The gases in each case consisted of mixtures of carbon dioxide, ethylene, hydrogen, carbon monoxide, methane, and ethane.

By dry distillation of a mixture of equal parts of sucrose and sodium carbonate, Berthelot[15] detected ethylene, propylene, and butylene in the gaseous products.

The present paper describes a study of the dry distillation of sucrose under similar conditions to those already employed with cellulose or starch. A comparatively small distillate was collected in the receiver kept at 60° C. On an average the yield was about one quarter that obtained in comparative experiments with cellulose or starch. It is also less than that previously obtained from β-glucose or certain β-glucosides. The distillate after purification still appears to be a mixture, and contains substances closely related to the sugars. The presence of *l*-glucosan in this mixture was established through the formation of tribenzoyl-*l*-glucosan. The amount of *l*-glucosan present, however, could only represent a small proportion of the original sucrose molecule. On the assumption that the breakdown of sucrose on heating under reduced pressure follows similar lines to the breakdown of cellulose, the result obtained would indicate the absence of the β-glucose structure as a main grouping in sucrose structure. The presence of a second compound in the distillate was suspected on account of the isolation, in small quantities, of a nitrate with a higher melting point than *l*-glucosan trinitrate, from the products of nitration of the purified distillate.

The interest in this work was mainly in connexion with the ether-insoluble portion of the less volatile distillate and possibly in the gases evolved. In consequence the ether extract of the distillate collected at 60° C. and also the whole of the distillate collected in the cooled receiver were only briefly examined. The gas evolved (99 c.c. from 1 g.) was collected in three fractions, which were analysed separately. The results as given in the table would indicate that the nature of the decomposition is changing as the heating proceeds and as the amount of combined oxygen diminishes.

Experimental.

The apparatus employed in the present work consisted of a Jena flask of 300 c.c. capacity to which was fixed a small glass receptacle which was maintained at 60° C. during the distillation by immersing in a water bath kept at this temperature. This receptacle was of such a nature that the distillate could be collected in three separate fractions. To this vessel was fitted a large U-tube kept in a mixture of ice and salt so as to retain the volatile products of the distillate in this receiver. Only 40 g. of sucrose was placed in the flask, as the sugar swells considerably during the heating. The pressure employed during the experiment was maintained between 10 and 15 mm. of mercury. In the initial heating a water pump was sufficient to maintain this pressure, but towards the later stages it was found expedient to employ a Geryk pump. The flask was placed over a heated bath containing a mixture of approximately equal molecular proportions of potassium and sodium nitrates. It was only necessary to immerse the flask in the fusion mixture towards the later stages of the heating, *i.e.*, after about 1½ hours. The temperature of the outside bath varied between 150° and 380° C. The temperature of the vapours as measured in the neck of the flask varied between 100° and 280° C. The vapour which distilled at 105° condensed to a light yellow liquid; the vapours at 190°—220° condensed to a viscous yellowish-brown liquid, while those at 235°—240° gave a dark brown, very viscous distillate. A considerable amount of carbon in a very light and porous form remained in the flask. In the following table the figures in column A give the highest yield over a series of distillations, and those in column B represent the average results from six distillations carried out under somewhat varying conditions of time of distillation and of the pressure during the process.

	A %	B %
Viscous distillate collected at 60° C.	15·3	11·6
Aqueous distillate in the U-tubes	41·6	37·2
Residue in flask (carbon)	26·4	30 6
Gas and loss	16·7	20·6

It is apparent that in the dry distillation under reduced pressure of sucrose there is much decomposition. The distillate collected at 60° C. was of a brown colour, and on keeping it soon became quite black, with the formation of a tar-like material. On the addition of a small quantity of water to the distillate a cloudy solution was formed, but on the further addition of water the solution became clear. The distillate was practically all soluble in water immediately after distillation. The resulting solution is of a light amber colour and is acid to litmus. The distillate, even in a dry condition, gradually oxidised and became practically insoluble in water with the formation of tarry products. The unoxidised distillate was soluble in acetone, but insoluble in ether. The distillate at 60° C. was generally inactive; in some experiments, however, it showed a very small negative rotation after purification (3rd fraction).

The distillate collected at 60° C. was dissolved in water and filtered, the clear solution repeatedly extracted with ether, the remaining aqueous solution evaporated to dryness under reduced pressure, and the residue dissolved in acetone and fractionally precipitated with ether. The last two operations were repeated several times. The main fraction was obtained, after drying, as a syrup, and contained C 47·3%; H 6·3% ($C_{12}H_{18}O_9$ requires C 47·1; H 5·9%).

This result corresponds with that for an anhydride of a hexose in which water is lost according to the equation:—

$$2C_6H_{12}O_6 = C_{12}H_{18}O_9 + 3H_2O.$$

Indications were obtained, however, that the material analysed was probably a mixture. An aqueous solution of the product was acid to litmus. This solution readily reduced alkaline potassium permanganate solution in the cold.

Part of the ether-insoluble portion of the distillate collected at 60° was treated in aqueous solution with benzoyl chloride and dilute sodium hyroxide solution, when a benzoyl derivative was obtained. On recrystallisation three times from acetic acid, a small quantity of a crystalline compound was obtained, of m.p. 198·5°—200° C. A mixture with the benzoyl derivative of *l*-glucosan from another source also melted at 198°—199° C. The derivative obtained is therefore probably tribenzoyl-*l*-glucosan. This conclusion is supported by the result of analysis of this benzoyl derivative (Found: C 68·3%; H 4·9%, $C_{27}H_{22}O_8$ requires C 68·4%; H 4·6%). In the acetic acid mother liquors from the benzoyl compound there was probably another benzoyl compound which melted at a lower temperature, but the pure compound was not isolated. An indication of the presence of a second compound was also given by the results of nitration experiments. The last fraction of the distillate condensed at 60° C. was dissolved in water and extracted with ether, and the aqueous solution evaporated to dryness in a current of carbon dioxide to prevent oxidation. On nitration with a mixture of nitric acid and fuming sulphuric acid, and pouring the resulting product into water, a flocculent precipitate was formed which, after repeatedly crystallising from absolute alcohol, yielded a white, crystalline product melting indefinitely between 138° and 145° C. This compound was found to differ from *l*-glucosan trinitrate and also from lævulosan trinitrate in some respects. The amount of compound available represented only a very small proportion of the original sucrose and it was not submitted to any further examination.

The ether extract of the distillate collected at 60° C. gave in a pronounced manner the test for furfuraldehyde or its derivatives. After repeated ether-extraction the furfuraldehyde reaction on the aqueous layer became faint. A part of the ether extract was washed with sodium carbonate solution, the ethereal layer evaporated, and the resulting product dried and fractionated. A portion of the liquid distilled between 155° and 165° C., and there was also a small higher-boiling fraction. On redistillation of this fraction (155°—165°) the main fraction came over between 160° and 162° C.; this fraction when treated with concentrated aqueous ammonia gave furfuramide (m.p. 117° C. after recrystallisation). On warming part of the 160°—162° fraction with acetone and dilute sodium hydroxide solution it yielded furfuracetone which on recrystallisation had m.p. 39°—40° C. With *p*-nitrophenylhydrazine in acetic acid solution it gave a red crystalline solid which after recrystallisation from benzene melted at 136°—137° C. This fraction therefore contained furfuraldehyde. The ether extract also contained derivatives of furfuraldehyde, but these have only been qualitatively studied.

The wash liquor which was used to remove acid from the ether extract was briefly examined. A calcium salt, prepared from the acid liquors, was recrystallised. This salt was decomposed by sulphuric acid, and a volatile acid removed by distillation in a current of steam. From the "distillation constant" of the distillate, determined as previously described by the author,[16] it was shown that acetic acid was the principal acid present.

When the aqueous layer from the original ether extraction was distilled in a current of steam the condensate gave only a faint furfuraldehyde reaction. The residue after this distillation was heated under a reflux condenser, with a 12% solution of hydrochloric acid, and then redistilled in a current of steam. The condensate after this treatment gave a definite furfuraldehyde reaction when tested with aniline acetate and also with acid phloroglucinol. The indication was more pronounced than that obtained from the distillation in a current of steam before the acid treatment, and considerably less faint than that obtained from the initial distillation in a current of steam of the above ether extract. The distillate from the sucrose therefore also contained furfuraldehyde derivatives and probably a small proportion of substances, probably of a pentosan constitution, which changed into furfuraldehyde or to derivatives of this compound under the action of acids.

The distillate obtained in the second flask (cooled by ice and salt mixture) was redistilled, using a fractionating column. A few drops of liquid (fraction A) passed over below 70° C. A small second fraction (B) was collected between 70° and 97° C., and a third large fraction (C) between 97° and 103° C.; this latter fraction contained the greater portion of the total liquid. Some liquid still remained in the flask, but it was not quantitatively examined. Fraction A gave the iodoform test and contained acetone. Fraction B was cloudy on distillation; it separated into two layers, the top layer separating in oily globules; both layers reduced an ammoniacal solution of silver nitrate on warming, giving a silver mirror; they also reduced Fehling's solution on warming. This fraction gave a small quantity of iodoform in the test for acetone, while it restored the colour to a decolorised solution of magenta. Mixed with a solution of sodium nitroprusside followed by sodium hydroxide solution, a red colour was formed which soon faded; the colour was restored by acetic acid. Fraction C was distinctly acid, due mainly to the presence of acetic acid. This fraction, as well as the residue in the flask, gave the reactions of furfuraldehyde.

During the thermal decomposition of the sucrose under reduced pressure, gases and vapour are continuously evolved. By the aid of various washers the presence of several products was indicated. In one experiment sodium bisulphite liquor was employed in the first washer, and the presence of formaldehyde could readily be detected in the bisulphite liquor; this occurred even when the second empty receiver was cooled to −20° C. This cooling was not sufficient to condense all the formaldehyde vapours under the condition of the experiment before it reached the sulphite liquors. In other experiments the presence of carbon dioxide, carbon monoxide, and an unsaturated hydrocarbon and also a saturated hydrocarbon was detected. In the latter experiments the vacuum was produced by the aid of a Sprengel pump, and the gases evolved were collected over mercury.

The following table gives the data obtained in one experiment in which 1 g. of pure sucrose was decomposed and the vacuum kept between 1 and 5 mm. during the greater part of the heating. At the later stage the pressure rose somewhat higher, but at no period was it greater than 10 mm. of mercury. The sugar was heated in a small distilling flask (10 c.c.) connected with a bulb which was attached to a second bulb. The whole apparatus contained no rubber connexions, but was made entirely of glass and the exit tube was fused to the connexion of the Sprengel pump. The apparatus was thoroughly evacuated and then heated to 100° C. for some time before any gas was collected. The flask containing the sugar was placed over a heated bath containing a fusion mixture of equal molecular proportions of potassium and sodium nitrates. It was slowly lowered into the bath as the reaction proceeded, the rate of heating being controlled by the variation in the pressure gauge. The first receiver, which was cooled by flowing water (at 10°), received the less volatile distillation products, while the second receiver, which was cooled in a mixture of ice and salt, retained the more volatile liquid products. The evolution of gas continued for about 4 hours. The total volume of gas collected was 99 c.c. measured at 20° C. and 753 mm. pressure. The gas was collected in three fractions in order and amounts as given in the following table of their analyses:—

Fraction.	Carbon. dioxide. %	Carbon monoxide. %	Saturated hydrocarbons %	Unsaturated gases. %
a. 34·5 c.c	68·3	23·2	4·2	3·0
b. 48 c.c.	35·3	43·0	16·6	4·2
c. 16·5 c.c.	12·5	35·3	48·2	3·9

In the distillation at the very low pressure employed it is evident that, even with cooling of the distillate to −10° C., a small amount of volatile products which are liquid at ordinary temperature and pressure may not be completely condensed under the conditions of the experiment. These will affect slightly the analyses so far as the figures in the first column are concerned; they may also show in the last column. On the other hand, if the mercury in the Sprengel pump becomes slightly moist a small amount of the vapours such as that of formaldehyde etc. may be removed with the moist mercury and not be collected in the gas tube. In these experiments, when allowance is made for residue (coke), condensate, and collected gases, there is still a loss of about 2—4% which would be mostly accounted for by the volatile products removed in the mercury and by the vapour or liquid retained in the connecting glass tube. The residual gas in tube *a*, remaining after the removal of carbon dioxide, unsaturated gas, and carbon monoxide respectively, was exploded with oxygen in presence of electrolytic gas. It behaved like pure methane judging from the ratio of the contraction on explosion to absorption by potassium hydroxide solution. Also when the gas remaining after the absorption of carbon dioxide and unsaturated gas from a portion of the gas in tube *a* was exploded with oxygen and electrolytic gas, the results obtained from the absorption and contraction agreed with that of a mixture of carbon monoxide and methane in the proportions stated. The saturated gas in tubes *b* and *c* contained in addition to methane some higher members of the paraffin series.

THE STRESS-ELONGATION CURVE OF VULCANISED INDIA-RUBBER.

BY EMIL HATSCHEK, F.INST.P.

The behaviour of vulcanised rubber under tensile stress has been very generally illustrated by means of graphs (sometimes traced directly by the testing machine) in which the elongation is plotted against the load, referred to square millimetres of the original cross-section. The general appearance of the curves thus obtained is now familiar (*cf.* Fig. 1, dotted line); they show an inflexion approximately at 100% elongation, followed first by a steep rise and then by a much slighter slope against the axis of loads. It has been shown by Goldsbrough and the author that these curves can be represented with considerable accuracy as linear transformations of conchoids, the abscissæ being reduced in constant ratio.[*]

A more rational method of representation seems, however, desirable and happens to be quite simple, viz., plotting the actual stress per unit area of the *cross-section corresponding with the elongation* rather than per unit area of the original cross-section. As the volume of rubber is generally taken to remain constant, within wide limits, during deformation, the actual stress can easily be deduced from the load as registered by the testing machine. At 100% elongation the length of the test piece is double, and the cross-section half the original value; the stress per unit area of actual cross-section is therefore double the load per unit area of original cross-section. Generally, the actual stress (to be plotted as abscissa) is given by the expression

$$x' = x(y/100+1)$$

where x is the load per sq. mm. of original section, and y the elongation in per cent. corresponding to it. The true stress-elongation curve can therefore be deduced from the load-elongation curve traced, *e.g.*, by the Schopper machine simply by multiplication of the abscissæ by the appropriate factors; the abscissa corresponding with 100% elongation by 2, that corresponding with 200% by 3, and so forth. The curve thus obtained is shown in Fig. 1 in full line.

It will be noticed at once that this curve has no inflexion and that the change in curvature and in slope is quite gradual. The striking character of the usual load-elongation curve therefore appears to be due primarily to the choice of co-ordinates without direct physical connexion.

Since the original curve can be constructed by purely geometrical operations such as are involved in drawing and transforming a conchoid, it seemed of interest to ascertain whether the true stress-elongation curve could also be traced by purely geometrical methods. This can be done easily, and with considerable accuracy, as follows: a straight line, AA′, is drawn parallel to the axis of stress and, as near as can be judged, asymptotic to the curve. A tangent to the curve is then laid through the origin, which cuts off the length AB on the asymptote. To obtain points of the curve, radii vectores are drawn through A, abscissæ projected from their intersection with OB, and ordinates erected on their points of intersection with the axis of stress; the intersections of abscissæ and ordinates thus obtained are points of the curve. The correct choice of the asymptote and the tangent is checked by the construction, and can be found by trial and error in a few minutes.

The analytical expression of the construction just described leads to the following equation for the curve:

$$y = \frac{ax}{b+x}$$

where a=OA, the distance of the asymptote from the axis, and b=AB, the intercept cut off by the tangent on the asymptote. The equation is that of a rectangular hyperbola, passing through the origin and having for asymptotes parallels to the axes with the equations: $y=a$, and $x=-b$. If the equation is transformed so as to make the asymptotes the axes, we obtain:

$$x'y' = -ab,$$

the familiar form, except for the negative sign on the right hand, which indicates, as is clear from the figure, that the two branches lie in the second and fourth quadrants. The product, ab, therefore determines the size or scale of the hyperbola, while the relative values of a and b determine what portion of the curve lies above the stress axis, this portion alone having a physical meaning.

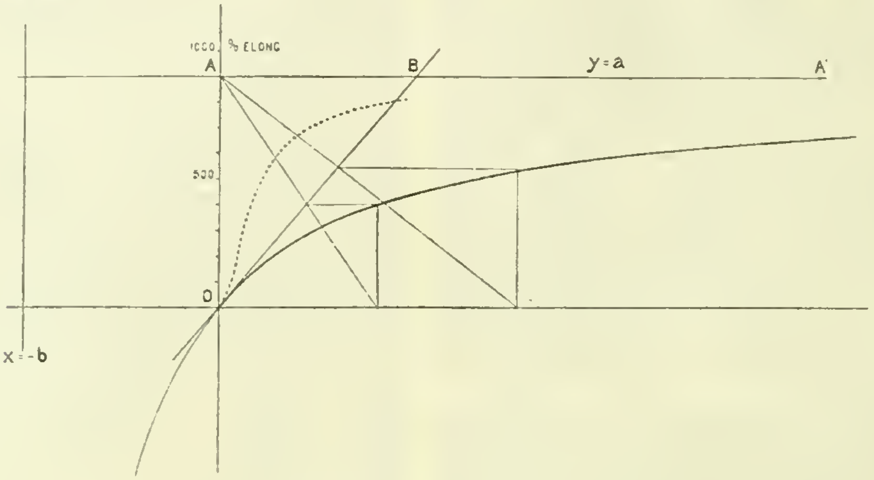

Fig. 1.

It is of interest to compare the stress-elongation curves for samples of a definite rubber-sulphur mixture cured for different lengths of time, as has been done for the load-elongation curve by Schidrowitz and Goldsbrough in the paper quoted above. Two sets of curves are shown in Figs. 2 and 3, the former being the true stress-elongation curves deduced from three curves in Fig. 1 of that paper, while the latter represents three stress-elongation curves deduced from Schopper diagrams supplied by Dr. H. P. Stevens. In both cases the curves are very exactly of the hyperbolic type. The values of a and b, as well as of the product, ab, are given below:—

	Fig. 2.				Fig. 3.		
	a	*b*	*ab*		*a*	*b*	*ab*
Curve I. ..	10·5	58	609	..	9·8	83	813
Curve II. ..	9·3	65	610	..	9·0	89	801
Curve III. ..	8·0	81	648	..	8·5	104	856

It will be noticed that, while the ratio $a{:}b$ varies considerably with the time of cure, the product ab remains fairly constant. It is therefore possible that the parameter ab is characteristic of the rubber (or mixture) and the ratio $a{:}b$ characteristic of the time of cure. A very much larger amount of experimental material would, how-

---

[*] Schidrowitz and Goldsbrough, J., 1919, 347 T.

ever, have to be examined to establish these relations definitely and generally. In Figures 2 and 3, a is expressed in terms of the original length, *i.e.*, 100% elongation = 1, while b is stated in arbitrary units.

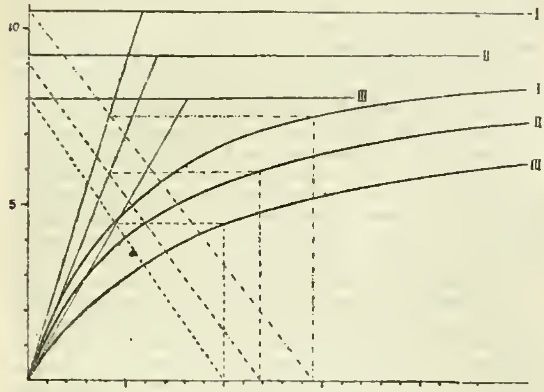

Fig. 2.

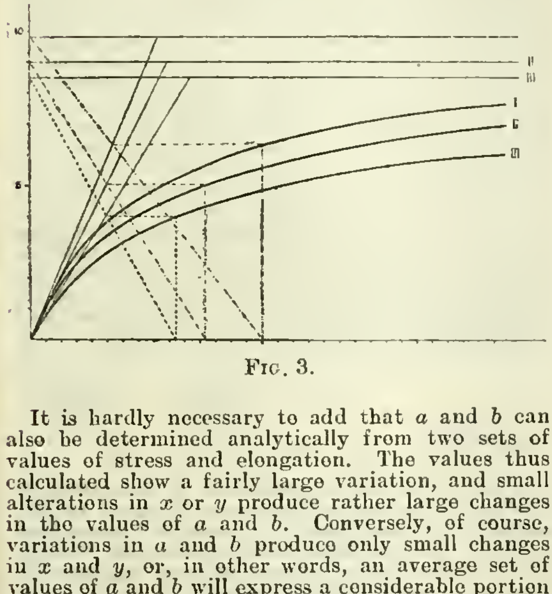

Fig. 3.

It is hardly necessary to add that a and b can also be determined analytically from two sets of values of stress and elongation. The values thus calculated show a fairly large variation, and small alterations in x or y produce rather large changes in the values of a and b. Conversely, of course, variations in a and b produce only small changes in x and y, or, in other words, an average set of values of a and b will express a considerable portion of the curve with great accuracy, this being, indeed, evident from the closeness of the graphic method of construction. It must also be borne in mind that the first portion of the Schopper diagram hardly conforms to the simple conditions assumed, as the elongation recorded is not that of a prismatic test-piece subject to pure tensile stress, but is in part due to the complicated deformation of the annular test-piece employed.

Apart from this point it is obvious that the method of representing the true stress-elongation curve by the formula given is only an interpolation method, as the asymptote cannot have a strict physical meaning. It is always risky to attempt a physical interpretation of the parameters of an equation thus found, and it is therefore not proposed to do so here. At the same time it is possible that certain properties of the curve may be co-ordinated empirically with qualities of the material; the most likely ones appear to be the slope corresponding with a given elongation, *i.e.*, the trigonometrical tangent of the angle α enclosed by the tangent to the curve at that point and the stress axis, and the area A enclosed by the curve, the stress axis, and a selected ordinate. The expressions for these quantities are accordingly given below:—

$$\tan \alpha = \frac{(a - y)^2}{ab} \qquad A = ax - ab \log_e \left(\frac{x + b}{b} \right)$$

in which a, b, y, and x are to be expressed in the same units, *e.g.*, in millimetres.

CHLORO-CELLULOSE ESTERS, AND THE ACTION OF CHLORO-ACYL CHLORIDES ON CELLULOSE.

BY W. LEIGH BARNETT, B.A., B.SC., A.I.C.

The object of this investigation was to prepare cellulose esters in which the acyl radicles would possess molecular weights greater than those of acyl groups in the lower members of the fatty acid series. It was considered that such esters would probably possess more definite characteristics than cellulose acetates of relatively high molecular complexity, for the nature of the reactions involved would necessarily give rise to esters of a lesser magnitude as regards the number of cellulose units left in the product, owing to partial resolution occurring by reason of the hydrolytic effect exerted by free hydrochloric acid liberated during the course of the reaction. At the same time the relative size of the acyl radicles, in which hydrogen is replaced by chlorine, should result in an increase in physical characteristics such as would be indicated by more definite melting points, setting points, and solubility. For this series of investigations it was considered that halogenated acetyl esters of cellulose would serve to indicate some steps towards the elucidation of the nature of the cellulose complex, and at the same time determine the suitability of methods of graduated dissection of the complex into similar compounds possessing more characteristic properties than the relatively inert parent colloid.

Attempts were made to prepare the cellulose esters of chloro-substituted acetic acids by various methods such as:—(1) Treating cellulose with αβ-dichlorovinyl ethyl ether. (2) Acting on cellulose with mono- and dichloro-acetyl chlorides in presence of either bases or acids. (3) By the use of mixed anhydrides of acetic and chloroacetic acids.

Little or no esterification was found to occur when the dichlorovinyl ethyl ether was allowed to remain in contact with cellulose, either in the cold or on heating. Hydrogen chloride was evolved, whilst the cellulose became discoloured, and was degraded to "hydrocellulose" with the simultaneous formation of water-soluble carbohydrates, which, after warming at 100° C. for half an hour, amounted to 11—14% of the weight of the cellulose.

Chloroacetyl chloride.

When chloroacetyl chloride is allowed to react with cellulose in presence of alkalis, or organic bases such as pyridine, a violent reaction occurs provided that little or no water be present; the cellulose chars and the decomposition is too complex for the progress of the reaction to be followed. When inert diluents, such as benzene or toluene, are used in conjunction with pyridine the reaction can be controlled. With aqueous solutions of alkalis, such as 50% potassium hydroxide, in the presence of benzene, the cellulose retains its original fibrous appearance, but becomes dark in colour and loses weight to the extent of 2·5%. If the benzene be omitted, then on treating cellulose in 50% potassium hydroxide with chloroacetyl chloride (with water-cooling of the mixture) the cellulose disintegrates, and after half an hour is found to have lost 10·5% of its weight. On warming the residue with acetic acid and chloroacetyl chloride it gelatinises and is esterified, increasing in weight by 50%.

Over fifty preparations were made from cellulose and chloroacetyl chloride under different conditions. For the sake of brevity only typical examples will be described. In a large number of cases the reaction could not be checked in time to isolate solid esters insoluble in water, for in general it was found that rapid degradation of the complex accompanied esterification resulting in the formation of water-soluble esterified carbohydrates.

1. The following description is typical of a preparation in which pyridine was used. One gram of cellulose was moistened with acetic acid (which had immediately previously been coloured by the passage of chlorine gas) and the excess liquid was pressed out; 10 c.c. of a mixture of one part of pyridine with two parts of toluene was added, followed by 8 c.c. of chloroacetyl chloride containing a trace of sulphur dioxide, this latter addition being made slowly, with stirring. The cellulose gelatinised gradually, and the solution became very dark, clearing somewhat on warming in a water-bath. On cooling, the toluene tended to separate, leaving a gelatinous mass, which was filtered off, washed with water, pressed, and finally treated with alcohol and ether. A portion of the product was soluble in alcohol, from which it was precipitated by ether. After the alcoholic extraction had been carried out in a Soxhlet extractor, the residue was dried, and subsequently was exhausted by chloroform in another extractor. A white powder was finally isolated from the chloroform solution after treatment according to the method described for cellulose acetate (J., 1921, 8 T). Examination of this product, after drying *in vacuo*, showed that it contained very little chlorine, and the chlorine that remained in the compound was easily split off by hydrolysis with caustic soda solution, for after acidification with dilute nitric acid, filtration from re-precipitated cellulose, and addition of silver nitrate solution to the filtrate, a precipitate of silver chloride was obtained, which is indicative either that the chlorine is present as hydrochloride or that the chlorine is associated with the cellulose residue in the form of a chlorocellulose ester. It is probable that a cellulose chloroacetate is first formed, which gives rise to an hydroxy-ester on hydrolysis, resulting in the formation of a glycollic ester of cellulose:

$$ClCH_2.CO_2R + HOH = HO.CH_2.CO_2R + HCl.$$

At the same time the cellulose has become degraded and has acquired the power of fixing a small but definite amount of chlorine. This product retained moisture persistently, which could not be entirely removed even by drying at 90° C. *in vacuo*, for decomposition slowly ensued. It had m.p. 237°—238° C., and contained C 42·28%, H 5·03%, Cl 1·50%. Calculated for $[C_6H_7O_2(CH_2OHCO_2)_3]_7HCl$, C 42·16%, H 4·76%, Cl 1·49%. The analytical results, together with the definite melting point and the fact that the compound is more soluble in dilute acetone than in dry acetone, all indicate that a resolution of the cellulose complex has taken place, whilst at the same time a definite amount of halogen has entered into combination with the cellulosic portion of the product independently of the esterified hydroxyl groups.

The alcohol-soluble, ether-insoluble product was purified and examined. It contained no halogen, and on combustion gave C 49·06%, H 5·68%. The calculated amounts for $C_{13}H_{18}O_9$ are C 49·06%, H 5·66%. Cellobiose hepta-acetate, $C_{26}H_{26}O_{18}$, corresponds with this compound.

The glycollic esters of cellulose were investigated further, and a large number of mixed esters, possessing definite melting points and great solubility in aqueous acetone, were obtained. One preparation was carried out as follows:—

2. Five c.c. of acetic acid, which was coloured with chlorine, was poured on to 2 g. of cellulose, allowed to soak for a few minutes, and the excess pressed out; 10 c.c. of a mixture of pyridine and benzene was added in small portions alternately with 8 c.c. of chloroacetyl chloride containing a trace of sulphur dioxide. A vigorous reaction took place and the cellulose gelatinised, whereupon the mixture was warmed to complete the reaction. A dark brown jelly resulted, which was mixed with excess of water, filtered, and washed copiously with water. After drying it was extracted with alcohol in a Soxhlet extractor; 0·275 g. (= 13%) of extract was obtained, which consisted of esterified sugars. The residue from the alcohol extraction was exhausted with chloroform, and the cellulose ester separated. A white powder was obtained having m.p. 256° C., and weighing 0·4417 g. (=22·08%). The chlorine was estimated by Carius' method in the usual manner. Hydrolysis of an acetone solution gave the amount of alkali equivalent to the total saponifiable acid radicles in the ester, whilst the regenerated "cellulose" was estimated. The glycollyl radicle content was estimated by hydrolysis with excess of 50% potassium hydroxide solution, dilution, and acidification of the yellow solution with dilute sulphuric acid, filtration of the precipitated cellulose through asbestos in a tared Gooch crucible, and titration of the hydroxy-acid in the filtrate with *N*/10 permanganate. Duplicate estimations using the same quantities of reagents and observing the same conditions throughout, but with half the quantity of ester, made it possible to correct for any difference due to interference caused by oxidation of soluble products of degradation of the cellulose. Hydrolysis of the ester and examination of the products indicated that the ester was a mixed ester, for acetic acid, and also an acid which on partial oxidation gave oxalic acid, and hence was presumably glycollic acid, were found. The chlorine is hydrolysed by alkali, and hence is reckoned in with the total acid radicles. It is thus a simple matter to calculate from the analytical results the respective number of acetyl and glycollyl groups in the ester. These were found to correspond with the composition indicated by $[(C_6H_7O_2)_3(CH_2OHCO_2)_7(CH_3CO_2)_2]_{12}Cl_{10}H_{10}$.

	Found.		Calculated.
Chlorine	2·99%	..	2·94%
Cellulose recovered	47·8%	..	48·3%
Glycollyl	56·05%	..	52·17%
Hydrolysis (1 g, = mg. NaOH) ..	379		391

In considering the mechanism of the reactions involved the effects of interference caused by the reactivity of side products must be taken into account. For example, the regenerated "cellulose" is liberated in a lower state of aggregation than the parent complex, because it is degraded with simultaneous formation of water-soluble products, hence lowering the yield of recovered cellulose. Similarly the degraded soluble products of hydrolysis are slowly oxidised by permanganate in sulphuric acid solution, and hence tend to make the figure for the hydroxy-acyl radical appear higher than theory. There is no doubt, however, that these reactions give rise to chlorinated mixed esters of cellulose which contain both acetyl and hydroxy-acyl radicles. These esters differ from cellulose acetates in their greater solubility, melting points, and physical properties, *e.g.*, low viscosity of solutions and the non-formation of films.

Dichloroacetyl chloride.

The action of this acyl chloride on cellulose in presence of pyridine, diluted with benzene, is more vigorous than in the case of the monochloroacetyl chloride. The products are not uniform, but consist of mixtures of cellulose acetates with chlorinated esters which are difficult to separate and identify. Even in acetic acid (in place of basic substances), although there is a more vigorous initial reaction, yet analysis of the products appears to indicate that degradation and chlorination of the cellulose has taken place, and not esterification. Frequently the products show small solubility in the usual solvents for esters of cellulose. In one case the following results were obtained:—20 c.c. of acetic acid, containing a trace of chlorine, was poured on to 5 g. of cellulose and allowed to soak in; 14 g. of dichloroacetyl chloride, containing a trace of sulphur dioxide, was added gradually. When the evolution of hydrogen chloride slackened the mixture was warmed on a water-bath, whereupon the cellulose disintegrated, swelled, and absorbed all the liquid, leaving a white, friable mass, which developed a faint purplish tint, became pasty, and finally went into solution. The ester was isolated by means of chloroform and water. In this way a white powder was obtained which weighed 5·5 g. and had no definite melting point. Analysis gave C 43·95%, H 5·82%, Cl 2·67, 2·69%. This corresponds with $(C_6H_{10}O_5)_6Cl-OH$, which requires C 43·82%, H 6·01%, Cl 2·70%.

Chloroacetyl chloride in acetic acid solution.

If no basic substances be present when cellulose is treated with chloroacetyl chloride, then the reaction proceeds differently to the cases already described. Thus, if neither extra acid nor base be present, the cellulose is only attacked slowly, and a series of complex decompositions occur which are difficult to follow. In presence of glacial acetic acid, however, together with traces of chlorine and sulphur dioxide (these traces are not essential, but assist in the promotion of the initial esterification), the esterification of the cellulose proceeds smoothly, and the products can be isolated as required. The solution of the cellulose is accompanied by evolution of hydrochloric acid, and the colour of the mass darkens, sometimes to light yellow, brown, or even purple, according to the conditions. The products all correspond with the general formula given by $(C_{14}H_{20}O_{10})$ ClH, and are powders which possess definite melting points; when melted they form transparent liquids which set to almost colourless resins on cooling. The melting points decrease with diminution in the value of "n," whilst the chlorine content increases as shown by the appended table:—

Cl %	0·54	0·74	0·84	0·91	1·20	2·47
m.p.	222°	224–5°	225–6°	202°	202°	143° C.

It was observed that the carbon, hydrogen, and oxygen atoms in these products were present in the ratio 14:20:10, which is that expected from a hydrated cellulose tetra-acetate,

$$C_6H_6O(CH_3CO_2)_4,H_2O.$$

Examination of the products, however, showed that this was not the case, for the saponification values were lower than theory for esters of the type of tetra-acetate, but higher than that required by a tri-ester, although the agreement here was better. The chlorine, however, is hydrolysable, and in a large number of cases is sufficient to account for the slight difference. In addition, careful hydrolysis and examination of the products showed that the cellulose derivatives are esters of a higher hydroxy-acid than glycollic acid, and they appear to be mixed esters of acetic and hydracrylic acids. The formation of cellulose hydracrylate is therefore assumed to result from a complex reaction between chloroacetic acid and chloroacetyl chloride. The yield of these esters is small owing to the rapid degradation of the cellulose complex to form water-soluble esterified carbohydrates.

The methods of examination of these esters will be dealt with under the examples quoted.

Examples.

1. Fifty g. of chlorinated acetic acid was poured on to 20 g. of cellulose (prepared from Swedish filter paper), and 63 g. of chloroacetyl chloride, containing a trace of sulphur dioxide, was gradually added. The reaction was facilitated by slight warming in a water bath. At 45° C. a rapid evolution of hydrogen chloride occurred, and when this slackened the temperature was increased. After two hours all the liquid was absorbed, whereupon 80 g. of acetic acid and 21 g. of the acid chloride were added. The mass became semi-gelatinous and it was necessary to add 60 c.c. more acetic acid to complete the solution of the products. Finally a brown syrup resulted from which the ester was separated by means of chloroform and water. After removal of the chloroform it was necessary to centrifuge the aqueous suspension, the precipitate was separated by decantation, stirred with more water, and re-centrifuged. With water this product forms emulsions which cannot be completely clarified by centrifuging, shaking with solutions of electrolytes, or shaking with chloroform and distilling out the chloroform in presence of excess water. On drying a light brownish resinous powder was obtained having m.p. 225°—226° C. Analysis gave 46·99—47·20% C, 5·66—5·67% H, 0·83% Cl. The ratio of the C:H:O atoms is 14:20:10, and the analysis corresponds with the formula $(C_{14}H_{20}O_{10})_{12}HCl$ which requires C 47·85%, H 5·72%, Cl 0·84%.

2. Another preparation, which was made by using 8 g. of acetic acid, 1 g. of cellulose, and 5 g. of chloroacetyl chloride, separated as a heavy liquid from the chloroform water treatment, and solidified to a waxy solid which gradually became hard and brittle. This product was purified by precipitation from acetone solution and was finally obtained in the form of a resin, which softened at 163° C. and melted at 172° C. to a clear liquid, which set to an almost colourless resin on cooling. This product contained 0·85% Cl.

3. Five grams of cellulose was treated with 40 c.c. of chlorinated acetic acid followed by 20 g. of chloroacetyl chloride. On warming in a water-bath a dark brown syrup was formed after an hour. Chlorine gas was passed into the mixture until the solution was lighter in colour. After three hours from the start the liquid was filtered through asbestos in a tared Gooch crucible, the residue being washed with acetic acid, and finally with chloroform. The dried residue amounted to 2·2% of the weight of cellulose taken. The ester was isolated from the filtrate and weighed 4·64 g., that is 92·8% of the weight of cellulose employed. It was a white powder, easily soluble in acetone, from which solution it was purified by re-precipitation. It had m.p. 222° C. Analysis gave C 47·87%, H 5·91%, Cl 0·54%. $(C_{14}H_{20}O_{10})_{18}HCl$ requires C 48·00%, H 5·77%, Cl 0·56%. Hydrolysis gave 348 mg. NaOH per g. of ester against 349 mg. calculated. This compound contained a C=O grouping (aldehyde or ketone), for it gave a *p*-bromophenylhydrazone, in the form of a dark red powder, m.p. with decomposition 196° C.

4. Substitution of bromine in place of the trace of chlorine in experiments carried out similarly to No. 3 gave similar products which, however, contained no bromine but 0·53—0·54% of chlorine, and which also corresponded with the formula

$$(C_{14}H_{20}O_{10})_{18}HCl.$$

Examination of the products of hydrolysis led to the conclusion that these esters contain one acetyl and two hydracryl radicles for each cellulose unit, $[C_6H_7O_2(CH_2OH.CH_2CO_2)_2(CH_3CO_2)]_{18}HCl$.

5. In cases where the amount of bromine used as catalyst was much in excess of the customary trace used in preparations No. 4, together with small quantities of sulphur dioxide, products were obtained in which the value of "n" was lower, and which also possessed lower melting points. One product which had m.p. 202° C. gave C 47·67%,

H 5·94%, Cl 0·91%, corresponding with the compound in which "n" is 11, which requires C 47·81%, H 5·76%, Cl 0·92%.

6. Five grams of cellulose was treated with 30 c.c. of chlorinated acetic acid followed by 15 g. of chloroacetyl chloride. After warming for nearly two hours in a water-bath the resulting syrup was filtered through asbestos, and the ester separated from the filtrate. A 37% yield of a white powder was obtained having m.p. 224°—225° C. The hydracryl radicle was estimated by oxidation with permanganate in sulphuric acid solution after hydrolysis and separation of the regenerated cellulose in the same manner as the glycollyl radicle. The analytical results agree with the formula

$$(C_{14}H_{20}O_{10})_{13}HCl.$$

Found: C 47·70%, H 5·75%, Cl 0·74%, hydracryl 51·0%, hydrolysis 347 mg. NaOH. Calculated: C 47·87%, H 5·76%, Cl 0·78%, hydracryl 50·7%, hydrolysis 351 mg. NaOH. When this compound was benzoylated in pyridine solution by means of benzoyl chloride, a benzoate was obtained as a light yellow powder of m.p. 230° C.

7. Attempts were made to isolate the products of reaction eliminating the presence of water as far as possible. The following description is typical of the procedure and results. Six grams of cellulose was treated with 30 g. of glacial acetic acid containing a trace of chlorine. Subsequently 12 g. of chloroacetyl chloride containing a trace of sulphur dioxide was gradually introduced. The mixture was warmed at 70° C. for some time and the dark, purplish-brown syrup which resulted was filtered through asbestos and washed with acetic acid. Weight of residue = 0·11 g., or 1·9%. The filtrate and acid washings were stirred into a large excess of ether, until no more precipitate was obtained. The precipitate was rapidly filtered and washed with ether to free it from acid (unless washed rapidly it absorbs moisture from the atmosphere, which causes it to form a sticky and unworkable mass). The product was dried *in vacuo*, the yield being 7·6 g., or 127%. This product dissolved easily in acetone to a pale brown, thin solution from which water gives a very finely divided precipitate. It possessed no definite melting point; at 143° C. and above it shrinks in bulk until at 156° C. a transparent brown resin is formed, and this darkens in colour and gradually melts, until at 168° C. it is a clear brown syrup. Found, C 46·62%; H 5·66%; Cl 2·47%. $(C_{14}H_{20}O_{10})_4HCl$ requires C 47·03%; H 5·71%; Cl 2·49%. The cellulose liberated after hydrolysis of an acetone solution was very sticky and could not be dried satisfactorily. The hydrolysis figures were much higher than usual, probably due to the nature of the highly degraded cellulosic portion, being 410 and 411 mg. of NaOH per gram of ester, instead of 364 mg. as required by theory.

8. Another preparation carried out in a manner similar to No. 7, but isolated after about one hour, instead of two hours from the start, was obtained as a white powder, which softened at 190° C. and melted at 202° C., with decomposition at higher temperatures. It contained 1·20% of chlorine, and gave a hydrolysis figure of 362, compared with 1·26% Cl, and 355 mg. NaOH for the compound $(C_{14}H_{20}O_{10})_8HCl$.

Mixed acetic-chloroacetic anhydride.

In view of the foregoing results, attempts were made to arrive at a similar series of products by using the mixed anhydride $CH_3CO.O.COCH_2Cl$. In the cases investigated, however, the reaction appears to be one of acetylation together with resolution of the complex, whilst at the same time the simplification of the cellulose complex is accompanied by chlorination in a similar manner to the cases in which chloroacetyl chloride is employed. Products having the general formula

$$[C_6H_7O_2(CH_3CO_2)_3]_nHCl$$

were obtained.

Example.—Cellulose was dissolved in the heated mixed anhydride, to which a little sulphuryl chloride had been added. Hydrochloric acid was evolved, whilst the cellulose solution increased in viscosity and gradually darkened in colour. On pouring the reaction mass into water a pasty solid was formed, which set to a brittle mass on cooling. This was dissolved in acetone, filtered, and the ester re-precipitated, after which it was extracted with chloroform, and the ester isolated from the extract. The purified product was a light yellow powder, having m.p. 165°—169° C. Found, C 47·45, 47·99%; H 5·43, 5·43%; Cl 2·97, 2·97%. Hydrolysis gave 406, 407 mg. NaOH per gram of ester. Calculated for $[C_6H_7O_2(CH_3CO_2)_3]_4HCl$, C 48·47%; H 5·47%; Cl 2·98%; hydrolysis, 404 if 12 acyl groups are hydrolysed.

Owing to the extensive resolution undergone by the cellulose complex in these products from the mixed acetic-chloroacetic anhydride due to the elevated temperature which is required for their formation, caution is required in the interpretation of the experimental results. In this particular example the hydrolysis figure corresponds with only twelve acyl groups, whereas the approximate formula demands thirteen acyl radicles. Hence in this case the chlorine is probably present as chloroacetyl, when the formula assumes the form

$$[(C_6H_7O_2)_4(CH_3CO_2)_{11}(CH_2ClCO_2)]H_2O.$$

This assumption agrees better with the observed facts, for the calculated values give C 47·81%; H 5·43%; Cl 2·95%; hydrolysis value 399.

Conclusions.

The action of chloroacetyl chloride and also of mixed chloroacetic-acetic anhydride on cellulose is one of esterification accompained by resolution of the cellulose complex with partial hydration of the cellulosic residue. This explains the ability of the products from chloroacetyl chloride and cellulose to act as if they contained an easily hydrolysed chlorine atom, and in addition the increased solubility of the products in aqueous acetone points to an increase in the number of hydroxylic groups in the esters formed. The hydration occurs during the treatment of the ester with water whilst it is being freed from acidic impurities, which thus accounts for the non-esterification of the newly-formed OH groups. The fact that these compounds possess definite melting points is also in agreement with simplification of the cellulose complex, tending to give esterified sugars on complete resolution and hydration.

Graduated dissection of the cellulose complex by such methods as the ones outlined above should help us to formulate a more definite conception of the nature of the cellulose molecule, which, although clearly of large magnitude, is obviously built up according to a simple regular scheme in the plant development. It is not proposed at this stage to enter into a discussion of the possible constitutional structure of the cellulose complex, but it will suffice to point out that at no stage in any of the series of cellulose esters, or derivatives therefrom, is there an abrupt change in properties, but throughout as the magnitude of the cellulose complex diminishes so the physical constants such as solubility and melting point become more clearly defined, and also follow a general order, the solubilities increasing and the melting points decreasing with diminution of the number of cellulose units left in the esters.

My thanks are due to the Department of Scientific and Industrial Research for permission to publish these results.

THE CONCENTRATION OF SULPHURIC ACID.

BY JOHN WILFRID PARKES, M.SC., A.I.C., AND EDWIN GILLARD COLEMAN.

Until the year 1906 the concentration of sulphuric acid was carried out in porcelain or glass beakers, in platinum stills, or in a Kessler apparatus. The liability of the beakers to break through contact with the hot fire gases made this process generally troublesome and the loss of acid high, while the platinum stills were very expensive. Many attempts were made, therefore, to effect the concentration by bringing the hot fire gases in direct contact with the acid, but the Kessler plant alone achieved any industrial success. In this plant hot gases from a coke producer are drawn over the surface of a shallow layer of acid in a flat volvic stone dish (the saturex), and then through a series of superimposed trays luted with acid (the recuperator). The weak acid to be concentrated is introduced into the top tray, and, passing downwards through the trays to the bottom dish or saturex, meets the hot gases on its way. The concentration of the acid takes place in a regular manner throughout the system, and it leaves the saturex in a highly concentrated condition. The system has been adopted universally, and is excellent for small outputs, but its capacity is limited, and both the Kessler and the cascade systems are very troublesome with dirty acid.

Such was the position of the problem when Gaillard took out his first patent in 1906. Up to this date all the attempts to make use of the direct contact between the hot fire gases and the acid depended on specially designed plant aiming at producing thin films of acid. Gaillard introduced an entirely new principle in the atomising of the acid in the form of a fine mist down an empty tower up which hot gases from a coke producer are ascending. Under these conditions contact between the acid and the hot gases is as intimate as possible, and the concentration takes place regularly throughout the tower, so that the acid arrives at the bottom of the apparatus in a highly concentrated condition, and the gases which enter the base at a red heat are reduced considerably in temperature when they leave the top of the tower. The concentration takes place quite independently of any special design of the plant, the tower acting merely as a sort of passage or flue for the hot gases and acid fumes to traverse. There is, therefore, very little to break or get out of order, and the life of the tower depends entirely on the acid-resisting qualities of the material of which it is constructed.

The earliest plants which Gaillard erected consisted essentially of a gas producer, a tower, a scrubber, and a fan, but it was soon realised that some form of recuperator was necessary, and a small tower, similar in shape to the main tower, was introduced into the system in front of the scrubber. Weak acid was atomised down this tower in the same way as in the main tower, and a slight preliminary concentration of the acid effected. At the same time the temperature of the gases leaving the recuperator was reduced very considerably, so that they could be forwarded safely to the coke scrubber.

A plant of the above design was erected in the Chemical Works of Messrs. Kynoch, Ltd., Arklow, Co. Wicklow, during the year 1908. The main tower was composed of 15 tiers, each comprising eight blocks of volvic lava, 1 metre in height and varying in thickness from 45 cm. at the base of the tower to 15 cm. at the top. The top of the tower was formed of four volvic plates jointed together and pierced with an inlet for the spray nozzles and an outlet for the gases. The tower, having an internal diameter of 2 m. (except for the first four metres, which was 1·70 m. in diameter), stood on a volvic base 10 cm. thick, inside a 30-lb. lead dish, which rested on a solid concrete block 2 ft. 6 in. above the foundation. The lead basin was 3 m. in diameter and contained lead water pipes for cooling the hot strong acid, which flowed from the bottom of the tower through a series of port-holes into the basin. The fume from the hot acid in the basin was an objectionable feature of the plant, and the cooling system was difficult to maintain in an efficient condition, as the pipes became covered rapidly with mud. The port-holes for the outlet of the acid into the basin silted up frequently, and when the inside of the tower base became choked with sludge, it was necessary to close down the entire plant and clean out the mud from the inside of the tower, the only entrance to which was through the gas flue from the producer.

The type of gas producer originally arranged by Gaillard for this plant gave considerable trouble through the fusing of the walls of the flue connecting with the combustion chamber, and was replaced by a simple, non-continuous coke producer, similar in design to that used with the Kessler plant. The recuperator, 4 ft. 6 in. × 29 ft. high, was comprised of a leaden shell lined with "obsidianite" acid-proof tiles 3 in. thick, a material which previous experience in acid plants had proved entirel satisfactory.

The draught through the system was produced by a 12-in. Kestner high-pressure fan running at 700—800 revs. per minute, and the weekly output averaged 50—60 tons of 94% sulphuric acid from a feed acid of 68—70%, with a fuel consumption of approximately 14—15%.

Natal.—The next stage in the development of the Gaillard plant was carried out by the staff of Messrs. Kynoch, Ltd., Umbogintwini, Natal, who had erected eight Gaillard towers in 1909–10. These towers were worked more intensively than the one at Arklow, and this, together with the climatic conditions, produced a rapid disintegration in the volvic stone, so that the upper course had to be renewed at frequent intervals. The experience gained of the satisfactory resistance of "obsidianite" to hot acid, suggested a likely substitute, and finally led to its adoption for the complete construction of the main tower. The first Gaillard tower built entirely of "obsidianite" was erected in Natal in 1911, and was followed soon by several others. A most important improvement was carried out also at this time by the installation of a sloping base inside the tower, and the introduction of a sealed mud-settling tank and cooler. By this means fume from the base of the tower was prevented, and the sludge deposited was trapped by the mud-catcher and washed out through the sludge pipe fixed in the bottom, while any collecting in the tower bottom was removed readily by means of a rake, through an opening provided for the purpose in the wall of the tower. By improvements in the method of atomising the acid, and by careful attention to details of plant working, the capacity of the plant was raised to 100 tons per week of 94% H_2SO_4 with a fuel consumption of 13—14%.

General.—Immediately after the outbreak of the war in August, 1914, extensions for the manufacture of cordite pulp on a large scale were commenced at Arklow. To deal with the greatly increased volume of sulphuric acid to be concentrated, it was decided to erect four Gaillard towers and to incorporate all improvements in the construction of these towers made by the Natal factory.

The lay-out of the plant shown in Figs. 1—2 was influenced very largely by considerations of the site, which was the only convenient space available at the time when the erection of the plant was undertaken. The four towers are identical in structure, and it will be necessary to describe only one of them. In order to follow clearly the working of the plant, it will be an advantage to trace the course of the gas through it.

Fig. 1.

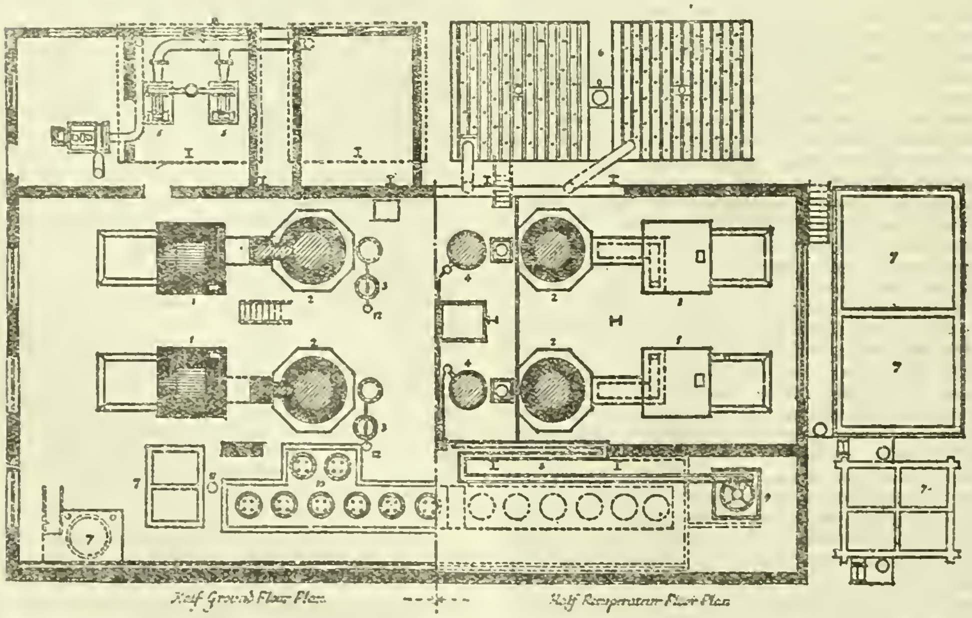

Fig. 2.

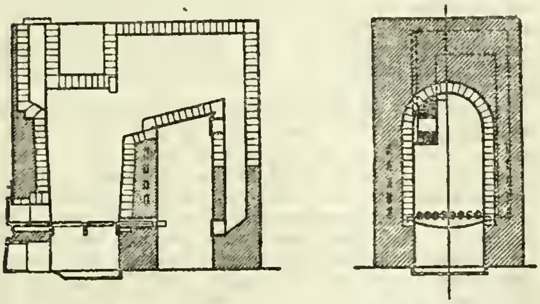
Gas producer.

The furnace for producing the hot gases, which are drawn through the plant, is shown at 1 in Figs. 1 and 2, and in detail in Fig. 3. The shell is built of ordinary red brick (20 in. thick) on a concrete foundation and braced with iron buckstaves. It is lined 9 in. thick with a suitable quality firebrick, and in this way a combustion chamber is formed 4 ft. 3 in. square × 7 ft. 6 in. high above the fire-bars. The grate is formed of 15 wrought-iron bars $1\frac{5}{8}$ in. square, which are rounded to rest and turn on grooved cast iron bearer bars, and extend through the back wall of the furnace to facilitate the turning of the bars by means of a key. The ashpit, which contains a water trough 4 ft. 3 in. square × 4 in. deep, is provided at the front with a cast iron door frame, having an opening 1 ft. 7½ in. square, closed by two sliding doors. Above this frame is fixed a cast iron plate, 4 ft. × 3 ft. 6 in., having a door opening 15 in. × 12 in. at such a height that the bottom of it is on a level with the grate bars. A hinged door fitted with a latch closes the opening. In the ashpit, about 14 in. underneath the firebars, are fixed two ⅛-in. steam jets controlled by a valve placed in a convenient position outside the furnace.



Longitudinal section of furnace.

Cross-section of furnace.

FIG. 3.

The furnace is charged from the top through an opening 14 in. × 12 in. communicating with the producer chamber, and is sealed by means of a heavy firebrick slab. The producer gas leaves the furnace through an aperture in the back wall approximately 18 in. wide, and passes into a mixing chamber (1 ft. 9 in. wide × 4 ft. deep × 5 ft. 6 in. long) where the secondary air is introduced. The shell of the furnace is pierced by a series of horizontal channels 6 in. × 3 in. passing from the front of the furnace on both sides and uniting in a common flue 21 in. × 9 in. at the back of the furnace. This flue rises vertically until it meets another one at the top of the furnace (21 in. square in section) extending in a horizontal direction to enter the mixing chamber at a point adjoining the gas outlet from the furnace. A sliding damper is fitted in the vertical flue immediately above the last horizontal channel to regulate the volume of secondary air admitted to the mixing chamber.

From the mixing chamber the hot gases pass down a flue and enter the main tower at a height of 5 ft. 6 in. from the base through an "adamantine" firebrick pipe 18 in. in diameter, built up in curved sections jointed in acid-resisting cement and securely held with iron bands. An inspection door is fitted in the downtake flue, under the mixing chamber and directly opposite the flue pipe to the main tower, which facilitates the cleaning out of the flue pipe.

Working of the furnace.—The coke is filled into wire baskets, each holding approximately 1 cwt., and, after weighing, is elevated to the top of the furnace by means of a pneumatic hoist and allowed to dry. When the furnace is ready for charging, the firebrick slab is removed from the charging hole, and the coke is tipped into the combustion chamber and the slab replaced. As soon as the coke is thoroughly ignited, the ashpit and clinkering doors are closed tightly, as sufficient primary air leaks into the plant to provide the requisite volume of oxygen for the combustion. When the coke has been burning for several hours, and the combustion shows signs of slowing down, the ashpit doors are gradually opened.

To secure the optimum results in working the producer, it is essential to restrict the supply of air passing through the combustion chamber, so that a large proportion of carbon monoxide is formed, and is carried forward and burned to carbon dioxide by the admission of an excess of secondary air in the mixing chamber immediately in front of the entrance to the main tower. The volume of secondary air admitted limits the amount of primary air passing through the combustion chamber.

The secondary air passing from the front of the furnace on both sides to the back, through the series of horizontal channels described above, is raised in temperature by the heat radiated from the furnace walls, and by this means the lining of the combustion chamber is cooled. The reduction in temperature tends to preserve the brickwork and to lengthen the life of the furnace.

To avoid clinkering troubles the firebars are made movable, so that they can be turned at regular intervals, and two steam jets underneath the firebars also assist by rendering the clinkers brittle. In addition, a clinkering door is provided in the front of the furnace on a level with the firebars through which a heavy rod can be introduced to break up any large clinkers.

During the first year the furnace was worked as a non-continuous producer with fixed firebars, and the usual charge was 20 cwt. of coke. This was allowed to burn off in 18—20 hours, and, after clinkering the fire, a fresh charge was added. This method of working was not efficient, and, when certain alterations were made to increase the output of the plant, movable firebars were introduced and the method of working changed. The furnace was charged every six hours with 12 cwt. of coke, and the firebars were turned every two hours to remove the ash and to shake up the fire. The furnace was shut down for a short time once a week for clinkering, but otherwise ran continuously, so that the whole plant was worked more steadily, and its output was increased very considerably.

Anthracite.—In the third year of the war the price of coke had risen to nearly three times its pre-war value, and the use of anthracite, which had not increased in price to the same extent, was suggested. The anthracite when used in large lumps, to avoid the formation of excessive dust, was found to give very satisfactory results. A charge consisting of 75% of anthracite and 25% of coke has been used regularly from that date. With a charge consisting entirely of anthracite, the furnace takes longer to attain its maximum heat after charging, more dust is formed, and a considerable amount of unburnt anthracite falls through the bars. The acid leaving the plant is much darker in colour when using anthracite, as the unburnt products of the distillation of the fuel, together with the dust, are caught by the acid falling down the main tower. Since the bulk of these products are produced in the course of the first two hours after charging, the acid made during this time was run away for use in decomposing sodium nitrate in the nitric acid house. As soon as the fire attains a good red heat, the colour of the acid becomes lighter, and compares favourably with that obtained by the use of coke alone.

Twin furnace.—In the latest plant erected at Arklow, a producer has been adopted having two combustion chambers charged alternately, as a similar type of furnace in Natal has given very satisfactory results.

Composition of firebrick.—In spite of careful working, deterioration of the firebrick lining occurs, and is often accelerated by the nature of the fuel employed.

When the plant was erected the combustion chamber of the furnace was lined with a very high-class silica firebrick (94—95% SiO_2). These firebricks proved fairly satisfactory until the alterations, which doubled the output, were made to the plant. It was found then that the life of the firebrick lining was shortened very considerably by the fusing of the surface of the brick. In particular, the main arch was attacked, and soon collapsed through the bricks melting away.

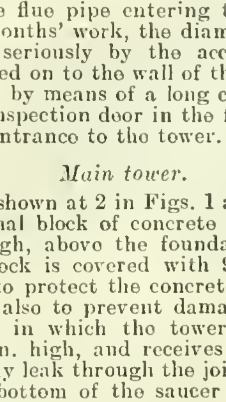
The coke used on the furnace varied considerably from time to time, but the following is a typical analysis:—Volatile matter 2·4%, ash 15·1%, carbon 82·5%. When the ash of this coke (dried at 109° C.) was analysed, it was found to have a very high iron content:—SiO_2 38·19, TiO_2 0·86, Al_2O_3 22·30, Fe_2O_3 27·26, MgO 1·54, CaO 5·43, K_2O 2·26, Na_2O 0·82, loss over 109° C. 1·42%.

It has been shown by Mellor ("Clay and Pottery Industry," p. 347) that a highly ferruginous ash has a marked action in increasing the fusibility of a silicious refractory. For this reason an aluminous firebrick was recommended, and a brick of the following composition was used, with very satisfactory results:—SiO_2 55·06, TiO_2 1·86, Al_2O_3 38·01, Fe_2O_3 2·38, MgO 0·24, CaO 0·90, K_2O 1·26, Na_2O 0·20, loss over 109° C. 0·24%.

The fusibility of the ash of the coke also gave trouble in the flue pipe entering the main tower. After a few months' work, the diameter of the pipe was reduced seriously by the accretion of dust, which was fused on to the wall of the pipe, and had to be removed by means of a long chisel introduced through the inspection door in the flue immediately opposite the entrance to the tower.

Main tower.

The tower (shown at 2 in Figs. 1 and 2) is erected on an octagonal block of concrete 11 ft. wide and 3 ft. 3 in. high, above the foundation slab. The top of the block is covered with 9-lb. sheet lead, which serves to protect the concrete from any acid splashes, and also to prevent damage to the 30-lb. leaden saucer in which the tower is built. The saucer is 22 in. high, and receives any slight acid drip which may leak through the joints of the tower blocks. The bottom of the saucer is covered with a layer of obsidianite tiles (4 in. thick, and forming a circle 8 ft. 9 in. in diameter), set in acid-resisting cement. On this base the blocks forming the shell of the tower are erected. The blocks are each 3¼ in. thick × 24 in. high, but vary in width (18, 20, 22, 24, 26 in.) according to the particular ring to which they belong, the arrangement of which is shown in Fig. 4.



Construction of concentrating tower.

FIG. 4.

Owing to slight irregularities in the size and shape of the blocks, it is advisable to assemble a few tiers of the blocks in their relative rings before commencing to erect them *in situ*. The outer ring of each tier of the tower is erected first, and the inner rings follow.

The blocks having been arranged so that the joints between them are as small as possible, the erection of the first tier is commenced, and when this has been secured by means of an iron band, the four inner rings of the tier are built in. The cavities formed between the blocks are filled in with acid-resisting cement. The blocks, which are made with a groove in the vertical joint faces, are bedded and jointed in acid-resisting cement; to form a key in the joint, additional cement is placed in the grooves and rammed with an iron rod until a perfectly solid core is obtained. In laying the different blocks in position, the jointing surfaces are washed with sodium silicate, and care is taken that they are placed so that the joints of any ring should not coincide with those of the adjoining rings, and should break joint to the extent of at least a quarter of the slab (see Fig.).

As each tier is erected it is secured with a stout iron band. In the lower part of the tower 3 in. × ⅝ in. mild steel bands, and in the upper section 3 in. × ½ in. mild steel bands are used. After several tiers have been erected, the horizontal joints are well caulked with acid-resisting cement, by means of a caulking-iron. To prevent the bands from being corroded and destroyed by acid which may sweat through the tower wall, especially if the tower is idle for any length of time, it is advisable to cover them with lead.

The inner ring is built so as to leave a space of ¾ in. between it and the next ring, to allow for the expansion of the blocks when the hot furnace gas strikes it. This ring is carried up to a height of about 10½ ft. from the base, and can be renewed readily. Its principal advantage is to protect the main tower blocks from damage at this point, where the greatest heat and strength of acid are found.

At a height of 24 ft. from the base, the outer ring of the blocks is discontinued, and the shell is built three blocks thick for a further height of 12 ft. 6 in. It is then reduced to two blocks in thickness, and continued for a height of 11 ft. 5 in. to the top of the tower in this manner. At each point at which the tower walls are reduced in thickness, and at intervals between them, a ring of horizontal bonding tiles is introduced.

The base of the tower is built up inside, so as to form an incline from a point 6 in. below the producer-gas inlet to the level of the base tiles at the exit from the tower. The slope is formed of rebated obsidianite tiles laid on a foundation of well-jointed obsidianite bricks, and the whole is set in acid-resisting cement.

At a height of 5 ft. 6 in. above the base, the gas flue from the furnace is built into the tower at a slight angle, so that any acid which may find its way into the pipe, will tend to drain back again into the main tower.

The tower is covered with a volvic stone top made in four rebated pieces jointed together and held by an iron band round the circumference. The top makes a rebated joint with the uppermost two rings of the tower wall. The volvic stone is 9 in. in thickness, and is pierced with six apertures for the atomisers and for an 18-in. gas outlet pipe.

The acid-resisting cement used in the erection of the tower is a mixture of finely-ground obsidianite and sodium silicate. The obsidianite is powdered in a disintegrator until it will pass through a 60-mesh sieve, and is then mixed with a solution of sodium silicate, which is prepared by dissolving three parts of 140° Tw. silicate (sp. gr. 1·7) in five parts of hot water, to give a solution of approximately 55° Tw. (sp. gr. 1·275). Sufficient finely-ground obsidianite is added to give a proper consistency for working similar to ordinary mortar. For ramming the joints between the slabs, a much denser and stiffer mixture is used. The cement is made up in small quantities at a time, as it sets very readily and cannot be used again.

During the erection of the tower it is essential that all the materials should be kept as dry as possible, and that no moisture has access to the joints. A small coke fire is lit in the tower as soon as possible, as the silicate joints set much quicker and harder under the influence of heat. When the erection of the tower is completed, the inside and outside surfaces are painted with a mixture of finely-ground obsidianite and weak silicate solution, and then washed with a weak sulphuric acid solution. This treatment hardens the silicate joints and tends to close up any slight pinholes or fire-cracks in the obsidianite slabs.

When a leak occurs in the jointing, it can be stopped by raking out the joint to a depth of half an inch and repointing and caulking with acid-resisting cement. If the leak is serious it may be necessary to take off the outer block, to get at the inner joints, and re-set it in acid-resisting cement.

Gas flue.

The gas leaves the top of the main tower through an 18-in. pipe, which connects it with the inlet at the foot of the recuperator. The bend and extension piece on the tower top is sloped back to the tower, so that any acid or mud which is deposited in the pipe will tend to fall back into the main tower. The bend at the foot of the flue is cut out of a solid block of volvic lava, and connects with the inlet to the recuperator. The block (30 in. square × 3 ft. 9 in. high) is covered with 9-lb. sheet lead, and set in a lead saucer on the recuperator floor level. The gas flue is erected on top of this volvic block, and is built up of obsidianite tiles 1½ in. thick × 12 in. high, made in three sections to form a pipe 18 in. diameter. It is built up and jointed with acid-resisting cement in sections of about 5 ft. in height, and then covered with 9-lb. sheet lead and securely held by iron bands 1½ in. × ⅜ in. fixed on the outside of the lead covering. The bands are rigidly supported by a timber framework round the flue, so that the weight of the flue is carried by the woodwork.

Recuperator.

The gas now passes to the recuperator (marked 4 in Figs. 1—2), which is similar in design to, but much smaller than, the main tower. The recuperator is erected on a platform, 15 ft. above the floor of the building, on which an apron of 7-lb. lead is laid to receive the 14-lb. lead saucer in which the tower stands. The bottom of the saucer is paved with a layer of tiles 3 in. thick, and on this the shell blocks are erected, forming a tower 4 ft. 6 in. internal diameter. The wall of the tower consists of a single block in thickness, the dimensions of which are 3¼ in. thick × 24 in. high × 15¾ in. wide. The blocks, as in the main tower, have a single groove in the vertical joint face, and are carefully jointed and set in acid-resisting cement. The tower (29 ft. high) is covered with 9-lb. lead, and securely held together by bands of 2 in. × ⅜ in. flat iron. The cover of the tower is formed from 14-lb. lead sheet burned to the lead covering of the sides, and supported by straps from two iron rails fixed across the tower top. The cover is pierced by two holes for atomisers, and by an 18-in. gas outlet pipe.

Unlike the main tower, the lead basin in which the recuperator stands is burned to the walls of the tower, and an overflow lip is provided at a height of 6 in. from the base, so that it can be observed readily from the flow, whether the sprays are choked or working normally. The acid flows from the foot of the tower at a temperature of 150°—160° C., and runs through a water-cooled trough to an open type lead cooler. In this way the temperature is reduced to 50° C., and the acid then flows to the feed tanks for use on the main tower.

Under normal conditions there are two sprays atomising the acid down the recuperator in the form of a fine mist, and approximately 50% of the volume of acid passing down the main tower is fed to the recuperator. A regular supply of acid down this tower is essential for cooling the gases, as the coke in the scrubber is liable to fire if an excessive temperature is attained.

Scrubber.

From the top of the recuperator tower, the gases pass through an 18-in. lead-covered stoneware pipe, supported on a timber framework, to the top of the scrubber (shown at 6 in Figs. 1 and 2). This consists of a lead-lined box (16 ft. 5 in. square × 13 ft. high internal dimensions) built up of 9 in. square pitchpine framework on a timber platform, which is carried on a steel structure 8 ft. above the floor level. The box is sheeted half-way up the sides with 9 in. × 3 in. planks, and lined with 14-lb. lead sheet. It is covered with 9-lb. sheet lead, supported by lead straps fastened on to 9 in. × 4 in. ceiling joists carried across the width of the box.

The bottom of the scrubber is paved with 1½ in. obsidianite bricks, on which is built a main channel (33 in. wide × 9 in. high), running across the diagonal of the tank corresponding to the points of gas inlet and outlet. The walls of the channel are formed of obsidianite bricks without jointing, spaced at regular intervals to connect with a series of subsidiary channels (6 in. × 4½ in.) running at right angles to it. The main channel is covered with obsidianite tiles (39 in. × 12 in. × 3 in.) spaced 2 in. apart, and the side channels, with tiles 10 in. × 5 in. × 2 in., spaced similarly.

The best hard steel coke, free from iron and other impurities, is used for filling the scrubbers. To protect the lead from the cutting action of the coke, the floor is covered with acid-proof tiles as above. The spaces between the channels are packed carefully with large pieces of coke, so as not to disturb the brickwork, and upon this a layer of 12 in. of coke is laid over the whole scrubber to form a foundation for the main packing. This consists of pieces of coke graded uniformly from 3 in. down to ½ in. pieces, and covered with a thin layer of very fine coke, free from dust. A clear space of 15 in. is left above the top of the packing.

The weight of the coke filling is approximately 50 tons, and if the lumps of coke are assumed to be spheres averaging 1—1½ in. in diameter, then the surface of the packing exposed to passage of gases is between 90,000 and 145,000 square ft., with a free space of 33·5%.

The resistance of the scrubber to the passage of the gases increases in time as the pores of the coke become clogged with foreign matter, and the speed of the fan is increased slowly to its maximum, in order to maintain a normal suction on the tower and furnace. The gradual rise in the resistance is noted carefully by means of manometer records, and as soon as the draught on the system begins to decrease beyond that which can be counteracted by increasing the speed of the fan, the coke in the scrubber is renewed. The foreign matter forms a slimy film on the layer of the fine coke, which constitutes the upper layer of the scrubber packing. If this is removed and replaced by a layer of clean coke, the life of the packing is prolonged, but ultimately it is necessary to renew the entire scrubber packing.

The gas outlet pipe is burned into the bottom of the scrubber, and stands up inside about 6 in. to prevent acid from being pulled over into the fan casing. A drain pipe is fixed in the opposite end on a level with the bottom of the scrubber, to take away the condensed acid, and convey it to a central receiving box, which is fitted with a cooling coil, as the temperature of the acid varies between 60° and 70° C. The acid drips from the fan also run into this box, which is connected to a Pohle air lift, so that the acid is elevated by this means to a small distributing box (18 in. diameter × 18 in. deep), 4 ft above the tops of the scrubbers. From the box a $1\frac{1}{4}$ in. lead main passes along the tops of the scrubbers, and is provided with four branches, terminating in four earthenware taps. The acid runs from the box through the pipe line to the automatic flush siphons feeding the distributors. These are attached to a series of glass observation tubes fixed into lead sockets formed on the leaden top of the scrubber, by means of $\frac{1}{2}$-in. lead piping, bent sufficiently to form a seal equal to the water-gauge pressure at that point. The siphon boxes are provided with water connexions, so that water can be supplied to reduce the temperature of the scrubber. The point at which the hot gases enter the top of the scrubber is provided with an increased number of lutes, so that the temperature of the gases can be reduced as quickly as possible.

By means of this circulation system of the scrubber acid, the coke is cooled and kept thoroughly wetted, so that the efficiency of the scrubber is assisted. At the same time the strength of the scrubber acid is raised to 80°—100° Tw. (sp. gr. 1·4—1·5), so that it can be returned to the plant in a fairly concentrated form.

The lead distributing box is fitted with an overflow plug, so that any excess of scrubber acid runs to the acid cooling trough in the recuperator floor, and is returned to the feed tanks for the eggs supplying the main tower.

Fan and exit.

The draught through the system is produced by means of a 16-in. Kestner high-pressure fan (marked 5, Figs. 1 and 2) with a lower horizontal discharge, direct coupled to a 10-B.H.P. motor with a speed control of 900—1700 revs. per minute, mounted on a common cast-iron bed plate on a concrete foundation.

The volume of gas passing through the plant depends on the speed of the fan and the resistance of the various sections of the plant. Under normal conditions, the volume of the gas passing through is approximately 20,000,000 cub. ft. (15° C.) per week, and the following manometer readings are typical of the resistance offered:—

	Manometer reading.	*Resistance.*
At inlet to main tower	— 0·6 in.	0·5 in.
At top of connexion to recuperator ..	— 1·1 in.	0·8 in.
At top of recuperator	— 1·9 in.	1·1 in.
At inlet to scrubber	— 3·0 in.	1·5 in.
At inlet to fan	— 4·5 in.	
At exit	— 0·1 in.	

Assuming the volume of gas passing through the plant to be 20,000,000 cub. ft. per week, and allowing for the increase of volume, due to rise of temperature, the time taken by the gas to pass through each section of the plant has been calculated to be as follows (in seconds):—Furnace 0·66, connexion to main tower 0·04, main tower 18·70, gas flue to recuperator 0·91, recuperator 8·60, connexion to scrubber 1·03, scrubber 37·20, connexion to fan 0·52, exit pipe 3·40, total time to pass through the plant 71·06 seconds.

The centrifugal motion imparted by the fan to the gas effects a further condensation of the acid mist escaping through the scrubber. The condensed acid (60°—70° Tw.; sp. gr. 1·3—1·35) runs from the base of the fan through a lute to a lead pipe, which carries it to the central receiving box.

The gas is expelled from the fan through an opening 10 in. wide × 13 in. deep, into an 18-in. exhaust pipe built of 7-lb. lead, which is carried up through the roof on a timber framework inside the main tower building, and discharges into the atmosphere. A small quantity of acid is condensed in the exhaust pipe, and runs back to the receiving box.

The exit gases consist chiefly of steam, with a slight trace of acid mist, the acidity of which averages 2—3 grains of SO_3 per cub. ft. A very large proportion of this mist consists of sulphuric anhydride, which has been formed by the dissociation of sulphuric acid at a high temperature in the main tower, and is present as a complex molecule, $(SO_3)_x$, which is extremely difficult to condense.

A sample of gas is drawn off continuously by means of an aspirator, and analysed twice in 24 hours to check the loss of acid by the escape, and, as a guide to the working of the plant, "bellows" spot tests are made every few hours.

Acid circulation.

The acid to be concentrated is blown into tanks, 7 (see Figs. 1 and 2), and fed to the eggs, 10, through two 2-in. lead mains, which are fitted with plug boxes, so that any egg may be fed with acid from either set of tanks. The acid is blown out of the egg through a lead pipe to the top of the main tower, 2, and, after passing through grit traps, a portion is fed to the recuperator sprays.

In falling down this tower the temperature of the acid is raised to 150°—160° C., and a slight concentration effected. From the base it flows through a water-cooled launder, 8, over a cooler, 9, and back into the feed tanks.

The remainder of the acid, passing through the grit traps, is atomised by the sprays of the main tower and descends in the form of a fine mist to the base, from which it runs to the mud-catcher and then to the cooler. The cold acid runs from the cooler to two mild steel eggs, and is blown away to the storage tanks.

Eggs.

For the four Gaillard units, there are twelve vertical cast-iron eggs, each 3 ft. 9 in. internal diameter × 5 ft. 6 in. total height, having a flanged cover with four mountings for connexions. They are connected by two 2-in. lead mains and plug boxes to the feed tanks, so that any egg may be fed from either set of tanks. Each tower is supplied by three eggs, which are connected with the atomisers at the top of the tower and its recuperator by means of a 1-in. extra heavy lead pipe, through which the acid is blown by compressed air. Each egg is worked in turn, and is not blown completely empty, so that any mud or sediment will remain at the bottom of the egg, and not tend to block the lead feed pipe and atomisers. Under normal working conditions, the eggs are changed every thirty minutes. As an additional precaution, two grit traps are inserted in the pipe line at the tower top. The trap consists of a horizontal cast-iron cylinder (15 in. long × 10 in. internal diameter) with a flanged cover, and is divided lengthways into two compartments by means of a regulus metal plate perforated with $\frac{1}{32}$-in. holes. The acid entering on the underside is forced through the perforated plate, which retains any particles exceeding $\frac{1}{32}$ in. in size. The acid leaves the cylinder through an opening in the cover, and then passes to the atomisers, of which there are six working in conjunction with the main tower, and two with the recuperator. In order that the number of atomisers working may be varied to suit the conditions prevailing in the plant at any particular moment, to facilitate the cleaning of them, and to prevent accidents, a 1-in. regulus metal valve is fixed in the branch pipe attached to each atomiser.

Atomiser.

The type of atomiser used on the plant is designed on the same principle as that of the original one supplied by Gaillard. It is made in regulus metal (about 88 parts of lead to 12 parts antimony). The general construction of the atomiser is shown on Fig. 5, and comprises three essential parts, viz., the body, A, cap, B, and turbine spiral centre, C. The cap, B, to which the acid supply pipe is attached at the boss, E, has an oval flange corresponding to that on the body, A, for the purpose of bolting the parts together. An extension to the cap terminates in a cone, making joint with the seating in the body at D. The turbine spiral centre, C, is formed with a two-start square thread of $\frac{3}{4}$ in. pitch, the stem being extended upwards to facilitate its removal from the body for cleaning or renewal. The end of the atomiser is protected by a rim, F, extending slightly below the lip of the outlet.

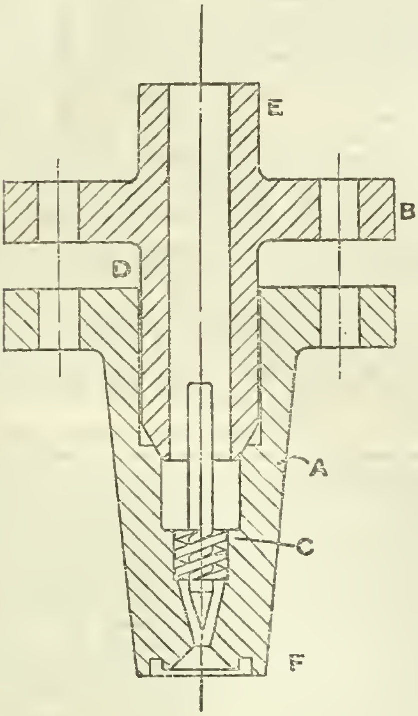


Fig. 5.

The improvements embodied in the re-designed atomiser were the introduction of flanges and bolts in place of the iron clamp and thumbscrew, which were liable to rapid corrosion, and the turbine spiral centre being made with a coarser thread to decrease the liability to clogging.

The acid is forced through the atomisers by the compressed air, and is given a rapid rotating motion by the spiral centre and expelled through the outlet in a uniform spray in the form of a hollow cone. The atomisers are made in three sizes, having outlets $\frac{3}{32}$ in., $\frac{1}{8}$ in., and $\frac{6}{32}$ in. in diameter respectively. By varying the number and size of the atomisers working on the towers, the volume of acid passing down can be adjusted at will.

Mud-catcher.

The concentrated acid falling to the base of the tower runs into a mud-catcher, and thence into a cooler.

The mud-catcher is formed by an extension of the 30-lb. lead saucer of the tower in the shape of a cylindrical tank, the wall of which is lined with obsidianite tiles 2 in. thick, set in acid-resisting cement, having an internal diameter of 3 ft. 2 in. and a depth of 3 ft. 3 in. It is fitted with a detachable steel cover for convenience of cleaning out, and a 4-in. outlet pipe with a blank flange bolted on is burned into the bottom of the tank, so that the tank can be washed out readily into the adjacent drain. The inclined base of the main tower is extended through an opening formed in the tower wall to the edge of the mud-catcher. The opening is lined with blocks to protect the joints of the tower walls, which are extended to form a connecting channel 12 in. wide from the tower to the mud-catcher. The channel is 18 in. deep at the mud-catcher end, but is diminished in depth by the slope of the base, so that it is only 6 in. deep at the inside face of the tower wall. The top of the channel is covered by blocks 6 in. thick extending to the inside of the tower wall, the underside of the inner block being chamfered off at the same angle as the inclined base. Above these blocks an opening is formed 24 in. × 16 in. deep, to facilitate the cleaning out of the tower base. When the tower is working this opening is closed by means of a special movable block of obsidianite.

At a height of 34 in. from the base of the mud-catcher a lead sleeve 4 in. long is burned on the lead wall to receive a 3-in. cast-iron outlet pipe, which is 10 in. long and flanged at the opposite end. This pipe extends to the inner face of the mud-catcher lining, and is jointed to the tiles with acid-resisting jointing, and to the lead sleeve with a jointing of red lead. An iron band clips the lead sleeve securely to the iron pipe.

To rake out the mud deposited on the inside of the tower base, the plant is shut down and the block above the outlet is removed. A rake is then inserted through the opening and the sludge pulled into the mud-catcher.

A typical analysis of this mud is as follows:—$FeSO_4$ 0·6%, $Fe_2(SO_4)_3$ 31·0%, $Al_2(SO_4)_3$ 1·6%, H_2SO_4 44·9%, insoluble in water 10·5%, moisture (by diff.) 11·4%.

Cooler.

To the flanged end of the pipe, an ironac tee pipe is connected, which dips into a cooler. This is a cast-iron cylindrical vessel (3 ft. 2 in. internal diameter × 3 ft. 11 in. deep) with a flange cast on 10 in. above the base, to carry a mild steel water-jacket. A lead outlet pipe of 2-in. bore is connected to a cored boss, cast on the cooler body at a height of 6 in. from the bottom, and carried up to such a height that the acid level is maintained at 4—5 in. from the top. The cooler wall is 1 in. thick, except for the top 8 in., where it is thickened to $1\frac{1}{2}$ in. to allow for the increased acid action at the surface of the liquid.

The acid is cooled by means of two coils, each 3 ft. 5 in. high, and made up of 16 turns of $1\frac{1}{4}$ in. × 16-lb. per yard lead pipe, one 3 ft. and the other 2 ft. 6 in. in diameter. The cooling water runs through the two coils in parallel, and then discharges into the outer jacket. The acid enters the cooler at a temperature of 250°—260° C., and leaves it at 30°—40° C. The acid is discharged into a small egg box, from which it runs to two mild steel eggs and is blown away to the store tank.

Output.

The output of the tower varies according to the strength of feed acid supplied, and to the degree of concentration of the finished acid. With a feed acid of 70% H_2SO_4 the tower will concentrate 30 tons per 24 hours up to a strength of 95·5% H_2SO_4. The output increases rapidly as the strength of the finished acid falls, and the tower is capable of producing 40 tons per 24 hours of 92—93% H_2SO_4.

When working under normal conditions (*i.e.*, producing 94—95% H_2SO_4), the approximate temperatures at the various points of the system are as follows:—Furnace 1000°—1100° C., mixing chamber 850°—900°, entering tower 750°—800°, entering recuperator 195°—205°, entering scrubber 100°—120°, entering fan 60°—70° C.

The chief guide to the working of the plant is the temperature of the gases entering the recuperator; and to facilitate the controlling of the four plants, the temperatures of the gases entering the recuperators are recorded by means of a pyrometer fixed in a convenient position on the ground level.

If the temperature rises, there are two courses to adopt: (1) increase the flow of acid down the main tower by bringing into use larger or additional atomisers; (2) increase the volume of secondary air by opening the sliding damper in the vertical flue still further. To secure the best results the volume of secondary air is adjusted to give a carbon dioxide content of 7—8% in the gases at the exit from the plant.

In case of emergency, when the temperature rises suddenly, through the choking of the atomisers, or for other reasons, such as loss of air pressure, etc., the inspection door in the flue opposite the entrance to the main tower is opened. This admits cold air direct into the tower, and at the same time reduces the pull on the furnace.

As a further guide to the working of the plant, the strength of the acid leaving the coolers is determined every hour. As the impurities present in the acid (iron sulphate etc.) tend to raise the gravity recorded by the hydrometer, it has been found advantageous to adopt the heat rise method, similar to that used for oleum.

Recent developments.

A brief outline is given below of some of the recent improvements which have been made in the Gaillard plant (1915—1918).

Gas producer.—The use of the intermittent coke producer was superseded by the installation of a central producer, which supplied the gas to several concentrating plants. The producer gas was burned in an iron-cased furnace with an excess of secondary air, and the hot gases passed into the main tower in the usual manner. By this means a very regular supply of heat was maintained, so that the plants worked steadily without fluctuations due to variations in the amount of heat entering the system, as in the intermittent coke producer. A slight defect was the presence of free hydrogen in the producer gas, which, on burning, had the effect of introducing water into the main tower, and hence lowering the thermal efficiency of the system slightly.

Main tower.—To increase the capacity of the plant the internal diameter of the main tower was increased to 10 ft. 8 in., but otherwise the tower remained the same in principle.

Several towers were built of well-known makes of acid-proof brick, which proved (so far as is known) quite as satisfactory as those built of obsidianite. Messrs. Chance and Hunt, of Oldbury, introduced an improved acid-proof cement, which has given very satisfactory service on Gaillard tower installations (*cf.* E.P. 119,966; J., 1918, 768 A). The tops of the towers were built up of brick in the form of a dome and pierced with a number of holes for the atomisers. The base of the tower was raised considerably higher above the floor level to suit the connexions from the furnace, and this in turn raised the height of the mud-catcher and cooler.

A great improvement in the working of the tower was effected by the use of eggs of very large capacity, so that the atomisers were worked for a much longer period from one egg before changing over to another.

Gas flue.—Owing to the severe conditions (due to the high temperature and acid atmosphere) to which this section of the plant is exposed, a great deal of trouble was experienced by the destruction of the lead covering and the frequent development of acid leaks. To overcome this difficulty several expedients were tried, and in some cases the length of flue was reduced to a minimum, and connected to the top of the recuperator so that the gases passed down in the same direction as the acid. In other cases the lead-covered obsidianite flue was replaced by pipes made of acid-resisting metal, with varying success. The use of a thin stoneware (ceratherm) pipe encased in a light steel shell, with the annular space between the two filled in with acid-resisting cement, was anticipated to give good results, but before any experience could be obtained the plant (Arklow) containing this flue was shut down owing to the general reduction in the output of munitions.

Recuperator.—Several interesting developments have been made in this section of the plant. In several cases the diameter was enlarged, and in others the tower has been filled with packing bricks, either partially or wholly, and worked on the principle of the ordinary packed Glover tower. From experience gained by the French works, in a great majority of cases the recuperator tower was abandoned in favour of a box form. This consisted of a lead box (6 ft. 6 in. × 4 ft. 11 in. × 4 ft. 11 in.) standing in a lead saucer and packed with chequered brickwork, over which a very large volume of acid was circulated to reduce the temperature of the hot gases passing through. This form of recuperator is very simple, and has given very satisfactory results.

Scrubber.—Very little alteration has been made in the scrubbers, but in the latest installation at Arklow the shape was altered from that of a square box (16 ft. 5 in. square × 13 ft.) to a tower form (11 ft. 6 in. × 30 ft. high), and the gases were introduced into the base of the scrubber and passed upwards through the coke packing. In this way the distance travelled by the gases through the coke packing was increased by two-and-a-half times and the air-cooled surface increased by 50%, and together with the cooled acid introduced through the lutes at the top, the temperature of the hot gases was reduced more readily and a greater condensation effected.

Fans.—Through the courtesy of the United Alkali Co., Ltd., information was received in 1916 of the working of the concentrators at the St. Gobain Co. in France. Owing to the great demand for concentrated acid they had been led to apply to the Gaillard tower the principle which had been recognised as sound in the working of the Kessler plant, namely, that for large concentrating power large volumes of moderately hot gas rather than a high temperature should be aimed at. To achieve this end they increased the freedom of the passage of the gas through the plant by enlarging the air inlets into the producer, enlarging the inlet and outlet flues of the main tower and all connexions throughout the system, and by using bigger fans. Very remarkable results were obtained from these plants, the output of 93% H_2SO_4 being increased by 200—300%.

The results were applied immediately to existing plants, and the use of larger fans became general. The standard fan up to this time was a 12 in. high-pressure fan running at 1000—1700 r.p.m. and capable of dealing with about 1000 cub. ft. per minute under working conditions. This was superseded by a 16 in. fan running at 1000—1700 r.p.m. and capable of dealing with 2000—3500 cub. ft. per minute. For larger diameter towers, producing 90—100 tons per day of 93% H_2SO_4, two 16-in. fans in parallel were used in preference to a 21-in. fan running at 1200 r.p.m. and capable of dealing with 5000—6000 cub. ft. per minute.

To avoid the gradual destruction of the fan by the corrosive action of the acid gases, plans were drawn out (Jan., 1918) for the installation at Arklow of a Sirocco fan ejector, which has been applied to the handling of acid gases with great success during the war. The apparatus is the same in principle as the steam ejector, but the motive power used is air pressure (produced by a Sirocco high-pressure fan coupled to an electric motor), which, passing through the ejector with great velocity, creates a suction and draws the gases along with the pressure air and delivers them to the atmosphere.

The authors are indebted to Messrs. Kynoch, Ltd., Witton, Birmingham, and particularly to Mr. A. T. Cocking, late Technical Director, for permission to publish this article, which was written in the spring of 1919 and printed for private circulation in the Kynoch Journal of Technical Research in June, 1919.

SOME CONSIDERATIONS ON THE DENITRATION OF WASTE ACIDS.

BY H. W. WEBB, M.SC., F.I.C.

The present paper contains an account of the examination of three sections of denitration reactions, viz.:—

(*a*) The fate of any real nitrous acid initially present in the waste acid.

(*b*) Methods of preventing the production of weak condensed acid in the process.

(*c*) The use of air in denitration.

It is well known that the nitrous acid present in most "spent" acids is not present as such, but as nitrosylsulphuric acid, $HO\cdot SO_2\cdot ONO$, since spent acid does not give many of the ordinary tests for nitrous acid unless diluted with water. The composition of a spent acid (*e.g.*, from T.N.T. manufacture) should hence be represented as H_2SO_4 63·0—65·0%; $HO\cdot SO_2\cdot ONO$ 10·8%—13·5%; HNO_3 0·1—0·5%; H_2O 21·7—24·7%, instead of the conventional method, which in the above case would be H_2SO_4 73·0—75·0%; HNO_2 4·0—5·0%; HNO_3 0·1—0·5%; H_2O 20·0—23·0%.

It is a matter of experience that such spent acids must be diluted to a concentration of 68—70% H_2SO_4, and heated to 140°—150° C., before denitration takes place.

Nitrosylsulphuric acid itself is unstable, the crystals being readily decomposed by heat. It dissolves in strong sulphuric acid, however, forming very stable solutions. Solutions of nitrosylsulphuric acid in sulphuric acids of 75—100% H_2SO_4 are comparatively stable at the boiling point. In concentrations of sulphuric acid below 70% H_2SO_4, the velocity of decomposition is much greater, increasing with temperature and dilution of the sulphuric acid; *e.g.*, in 72·8% H_2SO_4 considerable decomposition occurs at 100° C.; at 68·5% H_2SO_4 the whole of the nitrosylsulphuric acid is decomposed at the boiling point of the solution; while with acids of concentration below 64·26% H_2SO_4 (*i.e.*, below the strength of chamber acid) the crystals do not dissolve in the cold without decomposition.

These facts may be explained on the reasonable assumption that the stability of nitrosylsulphuric acid in sulphuric acid solution is dependent on the stability of the hydrates of sulphuric acid at various temperatures, *i.e.*, on the presence of "free" water in the solution. In this connexion it should be noted that the hydrate $H_2SO_4,3H_2O$ corresponds with a concentration of 64·47% H_2SO_4, the strength of solution below which nitrosylsulphuric acid decomposes in the cold. The reaction between nitrosylsulphuric acid and water may be expressed as follows:—

$$HO\cdot SO_2\cdot ONO+H_2O\rightarrow H_2SO_4+HNO_2$$

or possibly

$$2HO\cdot SO_2\cdot ONO+H_2O\rightarrow 2H_2SO_4+NO+NO_2.$$

Fate of nitric acid in spent acids.

Le Maitre (Monit. Scient., 1913, 57, 217—231) states that all nitrous compounds from waste acids in nitroglycerin manufacture tend to form nitrosylsulphuric acid, the reaction being accelerated by increase in temperature; for example, nitric acid in the presence of sulphuric acid of concentration between 70 and 90% H_2SO_4 was largely converted into nitrosylsulphuric acid by prolonged heating.

Lunge ("Sulphuric Acid and Alkali," Vol. I., part I., p. 343) gives similar results to the above. For example, he states that nitric acid in the presence of sulphuric acid containing 72—95% H_2SO_4 is reduced with loss of oxygen on heating, forming nitrosylsulphuric acid. Below a concentration of 72% H_2SO_4 the change is incomplete.

These results have an important bearing on the fate of the nitric acid in spent acid, and were consequently re-examined. A small percentage of nitric acid was added to sulphuric acids containing 75%, 85%, and 97% H_2SO_4 respectively, and the solutions heated in a flask fitted with a reflux condenser and thermometer. The results are shown in the following table:—

Analysis of original acid.	Temp. and time.	Analysis of sample.			Percentage of original HNO_3 lost.

No change in the nitrous acid content could be observed on allowing ordinary mixed acid to stand for five weeks at room temperature (20° C.).

The figures show that the conversion of nitric acid into nitrosylsulphuric acid in the presence of strong sulphuric acid, is a comparatively slow reaction, although almost quantitative with 95% H_2SO_4.

In view of the temperature and time of flow of spent acid in a denitration tower, therefore, there cannot be any appreciable conversion of nitric acid into nitrosylsulphuric acid in this way.

A more reasonable explanation of the fate of the nitric acid lies in the probable reversibility of the reaction:—

$$N_2O_4+H_2SO_4\rightleftarrows HO\cdot SO_2.ONO+HNO_3.$$

Winkler (1878) noticed that the solution obtained by mixing liquid nitrogen peroxide and strong sulphuric acid differed very much in stability from that obtained by dissolving nitrosylsulphuric acid in strong sulphuric acid. The former solution spontaneously evolved nitrogen peroxide at ordinary temperatures, and very rapidly on heating, and if the sulphuric acid initially used contained 78% H_2SO_4, the whole of the nitrogen peroxide was removable on heating, while a solution of nitrosylsulphuric acid in sulphuric acid of similar concentration was comparatively stable. The results suggest that the reaction between nitrogen peroxide and sulphuric acid is reversible. To investigate this point further, concentrated nitric acid was added to a solution of nitrosylsulphuric acid in sulphuric acid, and the mixture heated to approximately 140° C. under a reflux condenser. As an alternative method liquid nitrogen peroxide was added to strong sulphuric acid of the concentration required.

A control experiment was carried out in each case, using a solution containing 75% H_2SO_4 and 5% HNO_2 (as nitrosylsulphuric acid). Evolution of nitrogen peroxide occurred in all the above solutions and rapidly increased with rise in temperature. The results are shown in Table I.

Table I.

The sulphuric acid used in each case contained 75% H_2SO_4 before the addition of N_2O_4.

* The nitrous acid is present mainly as nitrosylsulphuric acid.

The results indicate that the reaction

$$N_2O_4 + H_2SO_4 \rightarrow HO{\cdot}SO_2{\cdot}ONO + HNO_3$$

is reversible. They also suggest that the addition of strong nitric acid to spent acid would cause more rapid denitration, but since the whole of the N_2O_4 so produced would have to be recovered in the absorption towers as dilute nitric acid the method would obviously be uneconomical, although the sulphuric acid recovered would be more concentrated. The reversibility of the reaction explains the probable fate of nitric acid in spent acid during denitration.

The reactions going on in the denitration tower are therefore:—

(1) Spent acid entering the top of the tower is heated by escaping oxides of nitrogen and any nitric acid present is decomposed as above, with formation of nitrogen peroxide.

(2) Further down the tower nitrosylsulphuric acid is decomposed by ascending steam:—

$$2HO{\cdot}SO_2{\cdot}ONO + H_2O \rightarrow H_2SO_4 + NO + NO_2.$$

(3) Any free nitrous acid would be decomposed according to one or both of the reactions

(a) $3HNO_2 \rightleftarrows HNO_3 + 2NO + H_2O$

(b) $HO{\cdot}SO_2{\cdot}ONO + HNO_2 \rightarrow H_2SO_4 + NO + NO_2$.

(4) Oxidation of traces of organic matter present also occurs with the production of carbon monoxide and dioxide, nitrous oxide and nitrogen, etc., all these gases being detectable in the exit.

Production of condensed acid.

In almost all denitration processes a weak nitric acid (15—20% HNO_3) is condensed from the cooling coil at the top of the column. It is usually separated from organic matter, and used as a feed to the absorption towers. Since the acid may amount to 30% of the nitrogen acids in the spent acid, the handling of it in bulk is a great nuisance and is expensive. A consideration of the mechanism of denitration previously outlined will show that if this explanation is correct, the weak acid must be produced by the interaction of excess of steam or water vapour and nitrogen peroxide, after leaving the tower: $N_2O_4 + H_2O \rightarrow HNO_3 + HNO_2$; $N_2O_3 + H_2O \rightarrow 2HNO_2$; etc.

Denitration ought then to be possible without the production of this weak acid. Temperature is evidently the most important factor affecting the amount of steam or water vapour carried over. Now the temperature of the gases leaving the column depends on a number of factors, such as:—Rate of feed and temperature of spent acid; temperature and quantity of steam; height of tower; nature of packing material; lagging etc. of tower and the material with which the tower is constructed.

In small denitration towers, *e.g.*, 10 ft. high and 1 ft. diam., in silica, it is a matter of experience that good denitration (*i.e.*, a minimum of nitrogen acids and high H_2SO_4 content in the resulting sulphuric acid) can only be obtained when the temperature at the top of the column is 100°—110° C., under which condition considerable quantities of steam pass over. In order to lower this temperature there are two lines of attack while utilising existent plant: (1) Increase the height of the tower; (2) use the cooling coil as a reflux condenser.

Method (1) was tried on a laboratory scale by using a silica tube 18 in. long and 1 in. diam., *i.e.*, far longer in proportion to its diameter than the ordinary towers. The tube was packed with broken quartz. It was readily shown with this apparatus that spent acid could be satisfactorily denitrated without the production of condensed acid. The principle was extended to the ordinary 10-ft. towers, which were built up to a height of 22 ft. to allow sufficient time for heat exchange between the outgoing gases and the incoming spent acid. It was found possible to denitrate 12 tons of spent acid per 24 hours containing 6% total nitrogen acids in this tower, without the production of condensed acid. As the height of the tower was decreased, the amount of spent acid which could be denitrated, without any condensed acid being produced, was reduced. The results are given in Table II.

TABLE II.

Height of tower.	Spent acid feed, tons per 24 hrs.	Period of test, hrs.	Sample No.	Denitrated acid.		Analysis of sample.					
				Tw°.	Temp. at base of tower, °F.	HNO_2 %	HNO_3 %	HNO_3 Total %	H_2SO_4 %	Organic matter collected, c.c.	Temp. gas leaving tower, °F.

16 ft.	8·2	20	Average of 4	116	296°	—	—	0·05	66·5	71	,,
14 ft.	6·4	5	Average of 4	118	288°	—	—	0·72	64·6	Condensed acid obtained.	170°
14 ft.	3·5	4	Average of 12	116	200°	—	—	0·40	66·1	A little condensed acid obtained.	60°

The results show that the denitration capacity of the tower decreased considerably with the height of the tower. With the height at 14 ft. it was very difficult to avoid the production of condensed acid even by lowering the rate of feed of spent acid to 3·5 tons per 24 hrs. The work indicated very clearly, however, that denitration was possible on a large scale without the production of condensed acid, while maintaining a relatively high concentration of denitrated sulphuric acid. There was, of course, a possibility that the nitro compound might accumulate in the tower under such conditions and ultimately cause choking. A balance-sheet of nitro compound was therefore obtained over a run of 36 hours. No sign of accumulation in the tower was obtained on dismantling. Approximately 85% of the nitro compound was carried away with the denitrated acid at the base of the tower, 2% was collected in the cooling coils, and the remainder is assumed to have been partly carried away by the nitrous gases, and partly decomposed in the denitration process. From the experimental data it is possible to obtain some idea of the requisite time of contact between spent acid and steam to secure the condition of denitration without production of condensed acid. The figures are, of course, only approximate.

Consider the optimum feed of spent acid found for each height of tower:—

(1) Tower, 22 ft. by 1 ft. Feed, 12 tons per 24 hours=629 lb. per hour (assuming sp. gr.=1·8)=10 cub. ft. per hour. Area of cross-section=$\frac{3}{4}$ sq. ft. (approx.).

Since the tower was packed with broken quartz giving approximately 40% free space, the available cross-section may be assumed to be$=\frac{40}{100}\times\frac{3}{4}=\frac{3}{10}$ sq. ft.

Hence the linear velocity of the acid down the tower$=\frac{10\times10}{3}=33\frac{1}{3}$ ft. per hour, and time of passage down tower 22 ft. high=40 mins. (approx.), assuming even distribution over the tower.

(2) Eleven tons per 24 hrs. with a tower 20 ft. high. This gives a time of passage through the tower of 39 mins.

(3) 9·7 tons per 24 hrs. with a tower 18 ft. high. Time of passage=40 mins.

(4) 8·5 tons per hr. with a tower 16 ft. high. Time of passage=41 mins.

These results indicate that for a given set of denitration conditions, without the production of condensed acid, the time of contact between acid and steam is approximately constant, and hence the capacity varies with the height of the tower. It is also evident that with a packing giving a higher "free space" than quartz, *e.g.*, ring packing or other rectilinear filling, a considerably higher tower would be required to produce the same results, and it is suggested that the heights of such towers would be approximately in the ratio of the free space of the packings, although this point has not yet been determined experimentally. The net economy in such type of operation would require careful consideration, as on the one hand there are the disadvantages with a close packing such as quartz, of great weight, side pressure, and disintegration, and on the other, of excessive heights to which the tower must be built if a symmetrical packing of high free space is used.

The second method of aiming at the elimination of condensed acid, consists in using the cooling coil at the top of the tower as a reflux condenser, to return the condensed acid into the tower.

TABLE III.

A further series of experiments was carried out in which the silica towers previously mentioned were connected at the gas outlet at the top with a 3-in. silica coil, externally water-cooled, which returned the condensed acid to the top of the tower near the spent acid inlet. The results obtained are shown in Table III. They are not so satisfactory

TABLE IV.
Effect of blowing air into base of denitrator.

as those obtained by the previous method, and indicate that a certain minimum amount of steam must not be exceeded or nitric acid is retained in the system and imperfect denitration results. Owing to lack of time the experiments could not be repeated with towers of extended height, as were the previous experiments. It is probable, however, that the method would be satisfactory if the towers were extended in height as before. The method offers the possibility of an additional economy in that weak nitric acid may be added to spent acids to replace part of the dilution water required, as it is obviously uneconomical to secure the whole of the dilution by steam.

Use of air in denitration.

In many denitration processes a mixture of air and steam is passed up the towers instead of steam alone; *e.g.*, in the Evers system a mixture of air and steam, preheated to 400° C., is used. The effects of the addition of air to the system are probably as follows:—

(*a*) By causing partial oxidation of the nitric oxide in the towers, a stronger condensed acid is produced.

(*b*) The heat evolved by the reaction $2NO+O_2 \rightarrow 2NO_2$ is an asset so far as denitration is concerned.

(*c*) More water vapour is carried over from the tower.

(*d*) The passage of an inert gas up the tower from a hot area to a cold area, causes better heat transference and increases the capacity of the tower.

(*e*) The oxygen necessary for the subsequent oxidation of the nitric oxide is added at a convenient point.

A few experiments were carried out with a brick denitrator 4 ft. 6 in. diameter and 25 ft. high, packed wth broken quartz. Air was injected at the base of the tower through a 1-in. main, with a pressure of 4 lb. per sq. in. on the delivery side. The results are shown in Table IV. It will be seen that the capacity of the tower is slightly increased by the use of air, and the sulphuric acid content of the denitrated acid is higher, but the quantity and cost of the compressed air required render the method quite uneconomical.

The author is indebted to Mr. J. Edwards, B.Sc., who carried out part of the experimental work.

Conclusions.

(1) The nitric acid in spent acid is decomposed during denitration by the nitrosylsulphuric acid present. The addition of nitric acid to spent acid before denitration enables a denitrated acid, stronger in sulphuric acid, to be obtained.

(2) Denitration may be effected without the production of condensed acid by increasing the ratio of height to diameter of the ordinary type of tower, or by working on the reflux principle.

(3) Little or no advantage is obtained from the use of air in denitration.

STUDIES IN VULCANISATION.

B.—SOME EFFECTS OF ACCELERATION ON THE RUBBER STRESS-STRAIN CURVE.

BY P. SCHIDROWITZ AND J. R. BURNAND.

The general nature of the stress-strain curve of rubber-sulphur mixings in course of normal vulcanisation (*i.e.*, in the absence of any added catalyst), has been dealt with in previous papers,[1] and it is the object of this communication to record some experiments carried out in the presence of a very

---

[1] *Cf.* Schidrowitz and Goldsbrough, J., 1919, 347–352T and *loc. cit. ibid.*

active organic "accelerator" with particular reference to the effect of the latter on the nature and course of the curve. The work hitherto published on the effect of more or less active catalysts on the mechanical properties of rubber mixings has almost invariably dealt with the behaviour of the accelerator in the presence of a comparatively large proportion (*i.e.*, 6—10%) of sulphur.[2] For the purpose of exploring certain fundamental questions the latter course is undoubtedly the proper one, but it does not, or should not, in our opinion, correspond in general to works practise. As regards the latter, particularly when a very active catalyst is employed, the effect of using a minimum of sulphur must be seriously considered, and it is with this aspect of the question, more particularly, that this paper deals.

The catalyst employed by us for this purpose was piperidyldithiocarbamate of piperidine, which, in view of its extreme activity, was evenly dispersed on a neutral carrier base, namely, a colloidal clay.[3] The quantity of the active catalyst, which was directly synthesised on the clay, was adjusted so that the mass contained 25% of the former. Except where otherwise stated, all the tests were made with the same batch of a standard thin pale crêpe rubber.

General effects.—The immediate object of the first set of experiments was to study the general effects of the use (*a*) of a comparatively large quantity of sulphur and accelerator, and (*b*) of a comparatively small quantity of each of these substances, the mixings employed being as follows:[4]

	M	N	N_1
Rubber.. ..	100	.. 100	.. As N, but special
Zinc oxide ..	2½	.. 2½	.. precautions taken
Sulphur ..	4	.. 2	.. to remove all trace
Accelerator ..	1	.. 0·5	.. of moisture from
Colloidal clay ..	3	.. 1·5	.. substances.

It will be observed that Mix M contained approximately 90·5%, Mix N 93·9% of rubber, and that while the proportion of sulphur to rubber in M was sufficient to permit of the attainment of a normal coefficient of vulcanisation (*i.e.*, 2·5 to 3·0), the proportion in N was deficient in this regard, and was markedly below the minimum quantity which would be employed in any (non-accelerated) technical mixing. In view of the work of Cranor[5] it seemed probable that, having regard to the activity of the catalyst, good cures should be effected, and this proved to be the case. All batches were mixed and sheeted in the usual way and subsequently press-cured at 40 lb. steam (268° F., 141° C.) for the time periods stated. No "rise" was given, the press plates previous to the introduction of the specimens being heated to the full temperature. Except where otherwise stated, all specimens were rested 24 hours between mixing and curing and were tested within 24 hours of the latter operation. Fig. 1 represents the general course of the curves in series M (curve II.) and for an unaccelerated rubber (curve I.), the shaded areas corresponding to the energy content, or, rather, the energy absorption in stressing the samples to the break.

Fig. 2 is a comparative representation of the various cures in the same series. For the sake of comparison there has been added to this figure a curve representing a normal (unaccelerated) 3-hour cure of a rubber-sulphur (100:8) mixing.

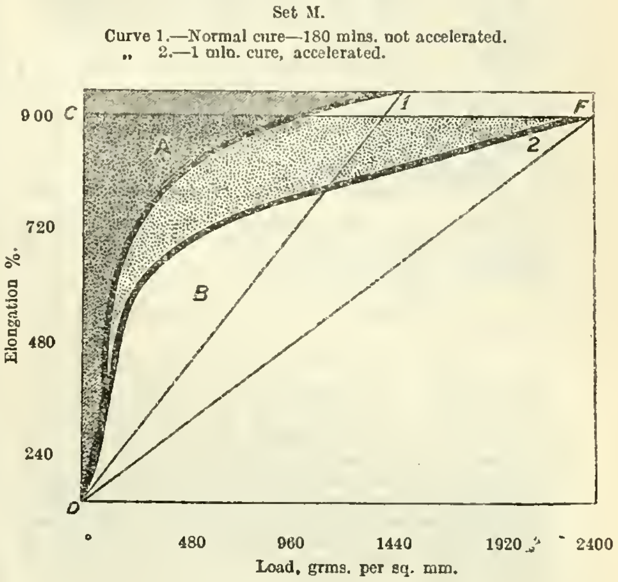

FIG. I.

Normal and accelerated cures.

Showing increased strength and improved tensile properties, also "type" of accelerated mixings.

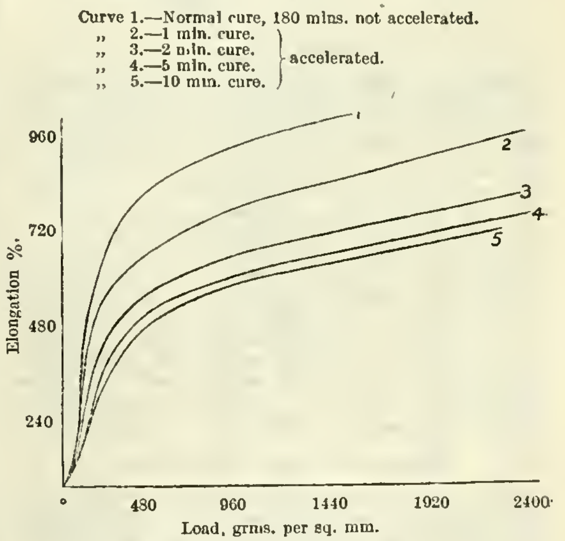

FIG. 2.

Series M.—Physical effects.

Table I. is a summary of the figures obtained in Series M. The last line in the table (in brackets) is added for comparative purposes and indicates the results obtained under similar conditions with a 100·8 non-accelerated first latex mixing. The area A was measured by means of a planimeter rule, and B obtained by calculation, subtracting A from A+B (*i.e.*, from CF×CD/2).

[3] *Cf.* E.P. Appl. No. 22491/20.

[4] Since this paper was written, G. S. Whitby (J. Ind. Eng. Chem., 1921, 816–819) has published some results obtained with a mixing containing 1% of the piperidine salt in the presence of a large quantity of sulphur—10 to 90 of rubber—but in the *absence of zinc oxide*. So far as his experiments and our own are comparable, it is to be noted that the efficiency of the accelerator when no zinc oxide is used is very greatly reduced, and that while some of the characteristics of the same are in evidence, these are less marked and to some extent dormant in the absence of the mineral "activator." In a brief addendum to his paper, Whitby refers to some further tests carried out with the same mix with the addition of 10% of zinc oxide, and finds the activity much increased, a good cure being obtainable by 4 minutes' heating at 105°. Details of these tests are to be published later.

[5] *Loc. cit.*

TABLE I.

(*Series M.*)

Curing time (min.).	E[*]	E_1[†]	Type[‡] (slope).	B[§] (lb.).	E at B[‖]	Energy absorbed.[¶]

Ordinary standard mix						
(3 hours ..	805	892	35	2046	10·4	$4·24 \times 10^3$)

[*] E=elongation % at a load corresponding to 600 g. per sq. mm. of cross section.

[†] E_1=elongation % at a load corresponding to 1040 g. per sq. mm. of cross section.

[‡] Type (slope)=$(E_1-E)/2·5$.

[§] B=breaking strain in lb. per sq. inch.

[‖] E at B=elongation at break, taking the original length as=1.

[¶] This is represented in terms of TP (the so-called "tensile-product") obtained by multiplying the breaking load by the elongation at break, as follows:—

$$\frac{TP}{2} = \frac{\text{Load} \times \text{elongation}}{2} = \text{Area CDF } (\textit{cf. } \text{Fig. 1}).$$
$$= A \text{ (shaded area)} + B.$$

$$\therefore \text{ Energy absorbed (A) in terms of } \frac{TP}{2} \text{ is } TP \times A \div (A+B)$$

Series M.—Sulphur estimations.

Estimations of "free" and "total" sulphur were made on the usual lines, and the coefficient of vulcanisation was calculated from the results. In the case of the 1-minute cure, unfortunately, the results, owing to an accident and loss of the balance of the specimens cured for this period, are not available, but to judge by the rate of curing down as shown by the stress-strain curve, and from the sulphur curve (Fig. 3), the coefficient was probably close on 0·85.

TABLE II. (*Series M*).

Coefficient of vulcanisation.

Curing time (min.).	Coefficient of vulcanisation.
1	0·85 (estimated)
2½	2·05
5	2·42
10	2·74

State of cure.

When examined within 24 hours of vulcanisation the 1-minute cure appeared to be (judged by factory standards) about correctly or very slightly under-cured. With regard to the other cures, it may be said that they were all fully cured, although the ordinary (technical) indications of over-curing were not in any way marked. Again, regarding the question from the technical point of view, it may be stated that very broadly the 1-minute cure corresponds to a 3-hours' cure of an unaccelerated mixing of a similar rubber, but of double the sulphur content. On this basis the acceleration factor is in the neighbourhood of 350. If, moreover, the stress-strain figures and the coefficient of vulcanisation of these accelerated and non-accelerated rubbers are compared, some further extremely remarkable differences are apparent.[6]

Distensibility and "toughness."

While the accelerated mixes (M above and N, N_1 below) are not absolutely comparable with a standard 100:8 rubber-sulphur mix, the differences in composition as regards non-rubber and mineral matter are so slight as to be negligible for the purpose of the comparison in view.

It will be noted that at moderate loads (*e.g.*, at 600 g. per sq. mm.) distensibility at reasonably correct cures is reduced by something like 25% (approximately 800 for the "pure," as against 600 for the accelerated mix), but that the elongation at break is barely 5% less in the case of the accelerated mixing. Again, as curing proceeds a diminution of approximately 15% in the elongation at break (comparing, say, the 2½-minute cure with the "correctly" cured non-accelerated mix) corresponds to a diminution of the order of 35% at a load of 600 g. This peculiar course of the stress-strain curve, coupled with the high breaking loads, no doubt accounts for the extraordinary toughness and "snap" of the accelerated cures compared with unaccelerated mixings.

Breaking strain.

It will be noted that while at reasonably correct technical cures, the elongation at break of the accelerated mixings is decreased by no more than 5—15%, the breaking load is increased by something like 60%. This remarkable result is probably due in part to the specific action of the accelerator, but mainly to the cutting down of the disaggregating heat effect. In the same way, if we compare the "Tensile products" (break strain × elongation at break), a figure which is favoured by other workers, it is obvious that the accelerated mixings are of the order 300×10^3 as against 200×10^3 for the non-accelerated, and, postulating a similar "type" or slope of curve, it is obvious that the work done or energy absorbed in stressing to the break is on a similarly higher plane for the accelerated specimens.[7]

"Type" or "slope."

We have elsewhere[8] shown that, at any rate within a fairly wide range of over- and under-curing, type or slope is a constant. Other workers[9], while adopting the type or slope figure as suggested by one of us (Schidrowitz) and Goldsbrough as one of the standard factors relating to "inner properties" or specific qualities of a rubber, contend that it is a variable, increasing or decreasing as curing advances. Further experience leads us to agree that up to a certain point (*i.e.*, the reversion point) this is indeed the case, but as the previously published figures by Schidrowitz and Goldsbrough (*loc. cit.*) show, the variation in the case of "pure" rubber and sulphur mixings, mixed, cured and tested according to their standard methods, is so small that it does not affect the practical value of the figure as a determinative factor in estimating state of cure or "correct" cure. In the case of accelerated mixings, as is plainly evident from the figures published in the present paper (*cf.* Series M, above, and N, N_1, etc., below), a very rapid change of type takes place, or in other words, as vulcanisation advances the rate of increase of resistance to stretching increases. Moreover, type (slope) figures are attained which are quite beyond anything known in the case of unaccelerated mixings. For example, in Series M.A. and Series H4 (below) types of 27 are recorded, and types of 28 and 29 have been frequently observed by the authors in the case of the mixing now adopted as a standard by them[10] for the purpose of testing the relative efficiency of various accelerators. These figures are remarkable when compared with the average figure of 35 and the (approximate) minimum of 31 found in connexion with standard unaccelerated mixings of first-grade plantation rubbers. Assuming, according to De Vries,[11] that there is a relationship between type

---

[6] Although Series M is not an extensive one, we are dealing with the results obtained at some length, inasmuch as further experience with scores of similar mixings have shown us that the results are typical and not specific.

[7] As a matter of fact the accelerated curves are flatter, and the disparity in favour of the accelerated mixes is therefore rather greater than it would be if the "type" were the same.

[8] *Loc. cit. supra.*

[10] Rubber 100; sulphur 2; colloidal clay 1½; zinc oxide 2½; accelerator ½.

[11] J., 1917, 1261.

and "set," it is obvious that the rational employment of an accelerator may, apart from other advantages, materially improve the resiliency and therefore the life of a commercial article.

Energy absorbed or work done.

Compared with a non-accelerated mix the figures are very high. In a sense the curve-area figure (energy absorbed) represents "toughness" perhaps more correctly than any other combination devised from the "tensile" figures or the stress-strain curve as a whole. Thus rubbers which show a high breaking load but a low elongation at break and a poorish type may be strong, but they are rigid rather than "tough." Over-curing may produce apparent toughness, as is evident in the case of Series M. Comparing the freshly vulcanised specimens in the latter, the 1-minute cure appeared very slightly under-cured and not quite so tough as the others. This possibly may be explained by the fact that while the "energy absorbed" or curve area figure decreases as curing advances, the type (up to the reversion or over-heating point) improves. That is to say, for any given increment of load the resistance to stretching on the flat part of the curve increases. Comparing the 1-minute accelerated cure with the 3-hour unaccelerated we obtain the remarkable result that the cutting down of the heat effect and the specific action of the accelerator increase the capacity for work of the rubber by about 60%.

Combined sulphur.

It will be noted that the combination of sulphur is extremely rapid and the cure is practically linear, up to 2½ minutes. From 2½ to 5 minutes the rate of combination is roughly one-fifth of the initial rate, and from 5 to 10 minutes roughly one-tenth. If we compare Series M with N (below) it will be noted that while the 5-minute cure of N is scarcely as advanced (mechanically) as the 1-minute cure of M, the former shows a coefficient of 1·41 as against, approximately, 0·85 for the latter. Very roughly, then, it would appear that mix M will give a satisfactory (technical) cure with a coefficient of 0·8, or not much more than one-half of that requisite in the case of N. In view of the small number of sulphur estimations made, it is hoped to deal with this aspect of the subject in a further communication.

TABLE III.

Series N and N_1 (cf. supra).

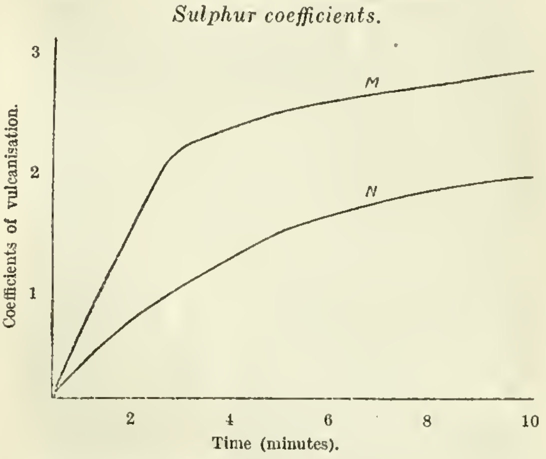
Coefficient of vulcanisation N— 5″, 1·41 (*cf.* Fig. 3).
" 10″, 1·86

a Tested 5 days after curing.
b Tested 1 day after curing.

Comparing Series M (sulphur 4, accelerator 1, to 100 rubber) with Series N and N_1 (sulphur 2, accelerator 0·5, to 100 rubber), it will be noted that (*a*) the curing effect is rapid up to about 2—2½ mins. in M and up to about 5—6 mins. in N and N_1; (*b*) the absolute curing down in the case of M is much greater than in N or N_1. Thus, while M can be cured down to an elongation corresponding to a load of 600 g. per sq. mm. at only 450%, the maximum curing down for N or N_1 corresponds to about 600%. In other words, it would appear that there is a certain minimum quantity of the accelerator (or of sulphur, or of both) which is requisite for the production of a given maximum state of vulcanisation. Thus, while, say, $x\%$ of an accelerator will yield a correct (technical) cure with a corresponding sulphur coefficient of, say, 0·8 and a maximum curing-down effect corresponding to 450% on the elongation scale for a load of 600 g., x/n will not produce a correct (technical) cure even if the coefficient is as high as, say, 2·0, nor an *absolute* curing-down effect lower than, say, 700%. The above speculations have been confirmed in the case of the accelerator mentioned, mainly as regards variation of the quantity of the latter (*cf. infra*).



Sulphur coefficients.

FIG. 3.

Effect of ageing.

Specimens of the (press-cured) accelerated rubbers described above were stored in a stout cardboard box at ordinary room temperature, and tested at intervals between November, 1920, and August, 1921. During this period the room temperature frequently rose above 80°, and on a few occasions above 90° F. The figures obtained were as follows (*cf.* Table IV.):—

a Indication of deterioration, *i.e.*, hardening.

With regard to the ageing results the following observations may be made:—

(*a*) At the end of 37 (36) weeks none of the specimens—excepting the 5-minute cure in Series M, which appeared somewhat leathery, but not brittle—showed any visible signs of perishing or deterioration.

(*b*) It will be noted, particularly in the case of Series M, but also in the others, that after-curing or ageing causes the curve to cure down to approximately the same position, irrespective of the original curing time. Thus in Series M, taking elongations at 600 and 1040 g. as the criteria, the differences between the freshly cured (one-day) specimens of the 2-minute and 5-minute cures are 79 and 84 points, but the same specimens after 37 weeks are within 13 and 4 points of one another.

(*c*) Up to a certain point the type improves and subsequently falls off, but whereas the improvement is more marked at the end of the curve—*i.e.*, at the higher load—the recession, when it takes place, also affects the far end of the curve more markedly than the beginning. This type of reversion phenomenon has frequently been observed by one of us in the case of mixings of the most diverse character, as the result of over-heating.

(*d*) In the case of the (Series M) 2-minute cure at nine weeks' age the type is remarkably low (good) and the breaking strain extraordinarily high. Taking Wormley's[12] data as to the difference between ring and rod test pieces, the breaking strain corresponds to roughly 4600 lb per sq. inch for a rod-shaped body, which, for a mixing containing rather more than 90% of rubber and rather less than 5% of minerals (other than sulphur), is, within my experience, unique.

(*e*) It is recognised that further ageing experiments, particularly on short cures of mixings containing small quantities of the accelerator and of sulphur, are desirable, and it is our intention to carry out work in this direction.

originally judged as being slightly under-cured; all the other cures in both sets were either well- or over-cured or over-heated. At the end of the exposure period all samples were, considering the severe test, in remarkably good condition. In no case was serious hardening observed, and surface hardening or cracks were not apparent on any specimen. Subject to quantitative confirmation and checks by means of non-accelerated mixes, it would appear that the cutting down of the original heat effect, as expected, tends to prolong the "life" of the rubber appreciably.

Effect of varying the quantity of the accelerator.

In order to examine the effect of varying the quantity of the accelerator the following mixes were made:—

	Pale crêpe.	Sulphur	Zinc oxide.	Accelerator.	% Accelerator to rubber.
1	200	4	5	0·5	0·25
2	200	4	5	1·0	0·50
3	200	4	5	1·5	0·75
4	200	4	5	2·0	1·00

(*Note.*—The accelerator, as in previous mixings, was dispersed on colloidal clay in the ratio of 1 to 4.)

It will be observed that the percentage of sulphur to rubber was in all cases below that necessary for adequate normal (*i.e.*, unaccelerated) vulcanisation, one object being to ascertain the minimum quantity of accelerator capable of producing adequate curing under the conditions stated.[13]

The results (*cf.* Table V. and Fig. 4) were as set forth below:—

Sunlight ageing.

Some preliminary observations, however, regarding the behaviour on exposure to sunlight may now be recorded. Two sets of cures of mixings corresponding to N (above), vulcanised at 5, 10, and 15 minutes in the press at the beginning of March, 1921, carried out with a view of controlling certain points in manufacture, were tested and then hung in a window exposed to the full force of the mid-day and afternoon sun up till the end of August (about 5½ months). In one set the 5-minute cure was

Apart from slight irregularities[14] (due to variation of time elapsed between curing and testing, as indicated), certain clear-cut deductions can be made from this table:—(*a*) In the first place it is obvious that for a given minimum of sulphur (2%

to the rubber in all the above mixings) a minimum of accelerator is required to produce the full curing effect. In other words, as was anticipated from theoretical considerations, the attainment of "full" curing with a coefficient below the normal (*i.e.*, of unaccelerated mixings) is dependent on the presence of a critical minimum of accelerator. In the case in point this minimum obviously lies between 0·25 and 0·50%. Thus in the series with 0·25% all the cures are poor; there is very little further curing down after the first (5-minute) cure, and after 10—15 minutes the reversion, or over-heating, effect is plainly visible. (*b*) While 0·25% of the accelerator produces no distinct maximum of curing effect, the mixing with 0·5% attains a maximum at approximately 6—7 minutes, and those with 0·75% and 1·0% respectively at 2½—3 minutes. (*c*) The maximum "curing down" is approximately the same for the 0·50% and 0·75% mixings, but is distinctly lower in the case of the 1·0% mix, approximately as 580 to 510 for E. (*d*) Reversion takes place in each series.

Effect of varying the quantity of accelerator.

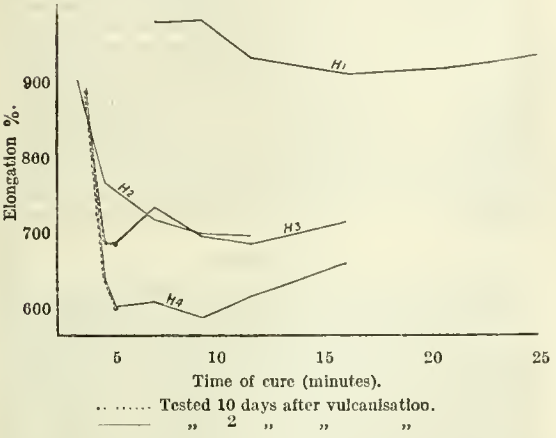

FIG. 4.

Ageing.

Quantitative ageing experiments in the above series were not carried out, but after five months' storage in a cardboard box (March to August, 1921) at room temperature, in no case was hardening, surface cracking, tackiness, or "checking" observable. In fact, all specimens, including the 15-minute cures in the series with 0·75 and 1·0% of the accelerator, were in excellent condition and all tough and lively, excepting the 0·25% specimens, which still appeared somewhat lifeless and under-cured.

Experience has shown that with ordinary (unaccelerated) mixings, cured within so wide a range of over- and under-cure, very serious deterioration will set it. The tolerance or margin of safety when using an accelerator of the type mentioned above, with a minimum of sulphur, is extremely wide. Even with double the quantity of sulphur (*cf.* Series M) this phenomenon is still very clear. The explanation, no doubt, may be sought in the following considerations:—

(1) The absolute heat effect (*i.e.*, of cure) is very small when compared with unaccelerated mixings.

(2) The small quantity of sulphur which is "free" after the cure renders any further activity on the part of the accelerator difficult.

(3) Probably the bulk of the accelerator, as such, or its transformation products are "destroyed" or rendered inactive by secondary reactions either during or after the vulcanisation process.

Vulcanisation at low temperatures (steam).

With a view of controlling certain technical points a number of cures have been run from time to time on the standard mixing (*cf.* N, above) in screw moulds in open steam. In this way some information was obtained as to the behaviour of various types of rubber (standard pale crêpe, smoked sheet, light brown crêpe—first scrap grade—and brown crêpe), as to the relative effect of press and steam cures, and the effect of varying the method of preparing the catalyst, but principally some data regarding the lowest (steam) cure at which a comparatively well-cured vulcanisation—suitable for testing—could be expected. With this end in view the moulds containing the specimens were placed in a vulcaniser (previously heated to the temperature of boiling water), the latter closed, except for the top blow-off valve, heated until the thermometer marked 100° C. and steam issued from the valve, and then, shutting off the valve, giving a rise to the desired temperature. Immediately the latter was attained the vulcaniser was blown off. In this way "rises" as follows were regularly obtained without difficulty:—(1) 6 minutes' rise to 120° C. (14·5 lb.); (2) 8 minutes to 134° C. (29·8 lb.); (3) 10 minutes to 141° C. (40 lb). Preliminary tests showed (*a*) that allowing for the variation displayed by different grades of rubber, the rise of 6 minutes to 120° C. was sufficient to produce a reasonably well-cured rubber, and that the 10-minute rise to 141° C. represented an approximate maximum of vulcanisation. The latter point was elucidated by giving in a number of sets a cure of 2 minutes and 15 minutes additional to the maximum rise. Selecting, in illustration, two sets tested, and taking as a criterion the elongation per cent. at 1040 g. per sq. mm., the following figures were obtained:—

TABLE VI.

	Elongation % at 1040 g.

4. Average results(15).
(Standard mix and standard accelerator.)

	Rise to 120°	Rise to 134°	Rise to 141°	1'	2½'	5'	7½'	10'
Steam cure ..	790	675	660	—	—	—	—	—
Press cure ..	—	—	—	830	720	680	660	665

Broadly, therefore, for standard conditions we have the following:—1-minute press curing at 141° C. is slightly less effective than a 6-minute rise (steam) to 120° C.; 5-minute press curing at 141° C. is about equal to a 6-minute rise (steam) to 134° C.; 2½-minute press curing is slightly more effective than a 6-minute rise to 120° C. As the latter represents the minimum of technical curing, according to the experience of many tests, it is fairly safe to suggest that 2-minute to 2½-minute press curing represents a correct to slightly under technical cure, 3 to 3½ minutes a full to over-cure of the standard mixing.

Part of the work described in this paper was carried out at the Northern Polytechnic Institute, N. 7, and we are indebted to the Governors for the facilities afforded. We also desire to record our thanks to Mr. L. Hubble for collaboration in part of the work described above.

DETERMINATION OF THE MELTING AND BOILING POINTS OF ANTHRACENE, PHENANTHRENE, AND CARBAZOLE.

BY W. KIRBY, B.SC., A.I.C.

In the course of an investigation on the constituents of crude anthracene it was observed that determinations of the melting and boiling points of some of these substances did not agree with the results obtained by earlier investigators. It was accordingly decided to undertake a series of determinations of these two constants in the case of three constituents of crude anthracene, namely, anthracene, phenanthrene, and carbazole.

For the purpose of this investigations these substances, after extraction from crude anthracene, were subjected to various purifying processes until all traces of impurities were removed. The determinations of the melting and boiling points were made by means of standardised thermometers of short range in order to reduce as far as possible the stem corrections.

The method of purification employed, and the results obtained, are as follows:—

Anthracene.

Anthracene, testing 97% by the Höchst test, was crystallised several times from pyridine and then dissolved in excess of toluene. In order to remove basic and phenolic impurities this solution was agitated with 30% sulphuric acid, then with weak caustic soda solution and finally with water. The anthracene, recovered from the solution, was subjected to a final recrystallisation from benzene, the resulting crystals being white with a strong violet fluorescence. The anthracene thus prepared was found to melt at 218° C. and to boil at 340° C.

Examination of a sample of Kahlbaum's anthracene, which was of a slightly yellowish colour and less strongly fluorescent, gave similar results for melting and boiling points. The following figures are given in the literature: m.p.: Graebe and Liebermann (Ann. Chem. Pharm., Suppl. Bd. 7, 264) 213° C., Fritzsche (J. prakt. Chem., 73, 286) and Berthelot (Ann. Chim. et Phys., 12, 207) 210°, Reissert (Ber., 1890, 23, 2245) 216·5°. B.p., Schweitzer (Annalen, 264, 195) 351°, Graebe and Liebermann (*loc. cit.*) 360°, Berthelot (*loc. cit.*) 360° C.

Phenanthrene.

This hydrocarbon was freed from basic and phenolic impurities in the same way as anthracene, and recrystallised several times from alcohol, combined with picric acid, recovered from the picrate, and again recrystallised from alcohol. The melting point of the phenanthrene prepared in this way was found to be 101° C. and the boiling point 332° C.

A sample of Kahlbaum's "pure" phenanthrene was found to have melting point 105·5° C. and boiling point 328°—334° C. Weger (Z. angew. Chem., 1909, 22, 342) gives the m.p. as 96° and b.p. 340° C., and Kraemer (Ber., 1890, 23, 85), m.p. 99°—100°, b.p. 302°—322° C.

Carbazole.

This substance, after several recrystallisations, was purified from the basic and phenolic impurities in the same way as the hydrocarbons, and finally recrystallised from alcohol. The carbazole so prepared was found to be entirely free from anthracene, and to possess a very faint purple fluorescence. It was completely soluble in pure sulphuric acid, the solution being of a very pale yellowish brown colour; the melting point was found to be 247° C., and the boiling point 351·5° C.

A sample of Kahlbaum's "pure" carbazole was found to melt at 245° C. Graebe and Glaser (Ber., 5, 12) give the melting point as 238°, and the boiling point (Ann. Chem. Phys., 163, 343) as 351·5° and 354°—355° C. Taüber (Ber., 1891, 24, 2597) also gives 238° C. as the m.p.

THE DETERMINATION OF AVAILABLE SULPHUR IN GOLDEN SULPHIDE OF ANTIMONY.[1]

BY B. D. W. LUFF, F.I.C., AND B. D. PORRITT, M.SC., F.I.C.

Golden sulphide of antimony, the *sulphur auratum* of the alchemists, is first met with in the writings of Basil Valentine in the 15th century. Some 200 years later, in common with a number of antimony compounds, it was in general use as a medicine. To-day it is utilised chiefly as a pigment, but is also employed to a less extent for such purposes as pyrotechny.

The name was originally given to a mixture of the sulphides of antimony and at the present time is applied indiscriminately to the tri- or penta-sulphide or to a mixture of both.

It would appear that manufacturers of golden sulphide intended for use in the rubber industry have endeavoured to produce a material containing as high a proportion of pentasulphide as is possible.

The preparation of antimony pentasulphide, by precipitating an antimonic solution with hydrogen sulphide, is beset with difficulty and, as Bosek[2] has shown, a pure pentasulphide is obtained only by careful regulation of the experimental conditions.[3] Any departure from the prescribed method results in the formation of a proportion of antimony trisulphide, free sulphur being deposited.

The technical preparation, however, is based on the fact that solutions of thioantimonates are decomposed by acids with precipitation of antimony pentasulphide, in most cases accompanied by the trisulphide and sulphur. A typical method of preparing the thioantimonate consists in adding a mixture of antimony trisulphide (stibnite) and sulphur to the melt obtained by heating together salt-cake and charcoal. The first reaction results in the formation of sodium sulphide: this then combines with the antimony sulphide and sulphur to form sodium thioantimonate, which in the commercially pure form ($Na_3SbS_4,9H_2O$) is known as "Schlippe's salt." A solution of the latter is decomposed by acid with formation of antimony pentasulphide and liberation of hydrogen sulphide. This reaction is usually accompanied by a secondary one involving the formation of antimony trisulphide and sulphur.

Various modifications of this process are in use, the general principle being the same in most cases. One method deserving mention is that in which calcium thioantimonate is an intermediate product. Decomposition with sulphuric acid results in the simultaneous precipitation of antimony sulphide and calcium sulphate; consequently the latter is often found as a constituent of the commercial product. If, in preparing the thioantimonate, insufficient sulphur is used, a greater or less proportion of thioantimonite is formed and this, on treatment with acid, will yield antimony trisulphide. Conversely, a considerable excess of sulphur will lead to the formation of polysulphides from which sulphur is precipitated together with the antimony sulphide on acidification.

The term "Golden sulphide of antimony," then, is applied to a fairly wide range of products varying in shade from a golden yellow to a deep orange, and in composition from a nearly pure antimony trisulphide to a compound containing a relatively high percentage of the pentasulphide, while calcium sulphate and free sulphur may be present to a greater or less extent according to the method of preparation.

There seems to be no valid reason, however, for the belief that golden sulphide should consist of, or at least contain an appreciable proportion of, antimony pentasulphide. The pigmentary value of the pure trisulphide is certainly equal to that of samples containing pentasulphide, and the fact that the latter may itself act as a vulcanising agent (to which reference will be made later), merely introduces a complication inasmuch as there is some doubt as to the extent to which this may occur.

It may be mentioned that certain "antimony vermilions," as they are called, prepared by the interaction of sodium thiosulphate and antimony trichloride,[4] consist of Sb_2S_3 either alone or mixed with oxide, the pentasulphide, however, being absent. It is not proposed to consider the properties of these in the present communication.

The use of golden sulphide as a pigment is almost entirely confined to the rubber industry, in which it is extensively employed for the production of articles having the familiar orange-red shade. At first sight it may appear strange that a compound of this nature should be chosen while so many other, and relatively more accessible, colouring matters are available. It must be borne in mind, however, that the conditions which obtain during hot vulcanisation, namely, the subjection to a temperature of 130° C. or thereabouts, in the presence of sulphur, would be fatal to many pigments which would serve quite well for most technical purposes.

While antimony sulphide usually[5] preserves its colour under these circumstances, its continued use may to some extent be due to conservatism on the part of the manufacturer, who in the early days of the rubber industry had no organic lakes to supplement the limited range of pigments then available. Moreover, as a result of habitual use, the consumer has come to associate the characteristic tint thus obtained with goods of the highest quality.

The pigment, as usually put on the market, contains free sulphur in varying proportions, the percentage content of each particular brand being stated by the maker. Obviously, when this colour is used for preparing rubber "mixings" the manufacturer, when calculating the amount of sulphur to be incorporated in order to give the correct proportion required for vulcanisation, must take this free sulphur into account. Thus, in addition to the tests usually carried out for the evaluation of pigments in general, *e.g.*, shade, colouring power, permanency, etc., a determination of free sulphur is necessary.

The most obvious method which suggests itself is to submit the sample to extraction with carbon bisulphide and to determine the sulphur so removed either by ascertaining the loss in weight of the sample taken or by direct weighing of the residue obtained on evaporation of the solvent.

Objection was first raised to this procedure in 1891 by Wilm,[6] who asserted that under these conditions decomposition of any pentasulphide present took place with formation of antimony trisulphide and free sulphur.

Later Klenker[7] opposed this view, stating that hot carbon bisulphide and other solvents boiling below 100° C. brought about no perceptible decomposition of the pentasulphide. Subsequently,

---

[1] Based on a paper read before the Edinburgh Section of the Society on December 12th, 1916 (J., 1916, p. 69 Supplement), and not hitherto published.

[3] See, however, Kirchhof (J., 1920, 721A), who states that antimony pentasulphide does not exist.

[4] Long, J., 1896, 363.

[5] As is well known, however, superficial blackening sometimes occurs when certain impurities are present in the material.

[6] Wilm, J., 1891, 1035.

[7] Klenker, J., 1899, 693.

Weber [8] asserted that in the determination of free sulphur acetone was preferable to carbon bisulphide and, further,[9] that the latter solvent could not be employed owing to the more or less pronounced decomposition of the pentasulphide brought about by its use.

Esch and Balla,[10] however, qualified this by declaring that decomposition occurred only when impure carbon bisulphide was employed.

Ditmar,[11] in discussing methods of analysis of this pigment, contends that carbon bisulphide at high temperatures extracts some of the combined sulphur from Sb_2S_5 forming Sb_2S_3, but mentions that this does not take place to any appreciable extent when the extraction is of short duration and is carefully performed.

Again, Hutin [12] definitely states that, although in the cold carbon bisulphide is without action on the pentasulphide, at the relatively high temperature of extraction there is a tendency for a lower sulphide to be formed with liberation of free sulphur; this author recommends the adoption of acetone as solvent, a liquid, be it noted, having a boiling point higher than that of carbon bisulphide.

The general assumption of those workers who have condemned the method of hot extraction is that the antimony pentasulphide decomposes at the temperature of the boiling solvent into the trisulphide and free sulphur. If this were the case, it is obviously illogical to suggest the use of solvents such as acetone, benzene, etc., having boiling points higher than carbon bisulphide. There is a possibility that the decomposition may be due to chemical rather than thermal influence, but no evidence had been adduced in favour of this explanation.

It has long been known that at temperatures of about 250° C. decomposition takes place quantitatively, with formation of black antimony trisulphide. If, however, liberation of sulphur takes place at all at the temperature of boiling carbon bisulphide, then by prolonging the extraction sufficiently, the reaction should proceed until all the pentasulphide has been decomposed; there is, however, no record of this having been observed.

It has even been stated that washing with cold carbon bisulphide causes reduction to trisulphide.[13] Bunsen,[14] however, recommends this treatment for the precipitate of antimony pentasulphide obtained in the separation of antimony and arsenic.

The question of the stability of antimony pentasulphide has an important practical aspect as, if there is a tendency for sulphur to be eliminated at temperatures below 100° C., there will be a greater likelihood of this occurring at a higher temperature, *e.g.*, 130° C. In this case the sulphur so liberated will be available for effecting vulcanisation, and must therefore be taken into account. Hitherto much difference of opinion has existed regarding the possibility of antimony pentasulphide itself furnishing the sulphur necessary for vulcanisation. Weber's attitude to this question is curiously inconsistent. Although he considered that carbon bisulphide extraction resulted in decomposition of the pentasulphide, he nevertheless strongly opposed the view that the latter could of itself bring about vulcanisation.[15] On the other hand, Dubosc [16] states that at the temperature of boiling carbon bisulphide there is little likelihood of decomposition occurring, but at 130°—135° C. the pentasulphide is reduced to trisulphide, the sulphur set free bringing about vulcanisation. That this may occur is indeed quite conceivable.

In this case a determination of the sulphur extractable with carbon bisulphide, in the absence of other data, would not furnish accurate information regarding the proportion of sulphur available for vulcanisation at the temperature employed for this purpose.

If the decomposition of antimony pentasulphide by heat be considered quantitatively it will be seen that 16% of sulphur is liberated if the reaction is carried to completion. Thus in a mixing containing 80 parts of rubber and 20 parts of pure antimony pentasulphide, the latter would yield 3·2 parts of sulphur if total decomposition were effected. This proportion of sulphur would be sufficient for vulcanisation purposes and under these hypothetical conditions the addition of sulphur as such would be unnecessary. This is, however, an extreme case, for, as a general rule, a much lower proportion of pigment would be employed, and, further, it is exceptional to find on the market samples containing more than about 60% of the pentasulphide.

However, it is conceivable that pentasulphide might be present to such an extent that, in the event of decomposition taking place to a marked degree, the free sulphur thus disengaged would contribute appreciably to the vulcanisation effect, or might be the cause of an inferior appearance due to "sulphuring up" subsequently taking place.

Under these circumstances it would evidently be desirable to determine not merely the proportion of sulphur soluble in carbon bisulphide at the temperature of the boiling solvent, but rather that which is in the free state at temperatures commonly employed for vulcanisation. We propose to designate this by the term "available sulphur" and to describe experiments carried out with a view to its estimation.

Previous workers have failed to take into account the possibility of the presence of amorphous sulphur, which, as is well known, is a satisfactory vulcanising agent.[17] This omission is perhaps surprising in view of the statement occasionally met with that, in order to make the percentage conform to the various standards in common use, the manufacturers sometimes add sulphur [18] which may be in the form of "flowers." This latter may contain as much as 34% of the amorphous variety which is insoluble in carbon bisulphide.[19]

Where this is present, therefore, extraction with carbon bisulphide in the usual manner will only partially remove the sulphur and an alternative procedure must be adopted in order to obtain the true value.

Experimental.

Method of extraction.—Of the two methods for determining the proportion of sulphur extracted from a sample of antimony sulphide, namely, (1) direct weighing of sulphur after removal of solvent, (2) difference in weight of sample before and after extraction, the former was considered generally preferable. It was thought, however, that objection might be raised owing to the possible loss of sulphur during the evaporation of the solvent. From a consideration of its vapour pressure even at moderately high temperatures (at 132° C. V.P.=0·08 mm.)[20] this possibility appeared somewhat remote, an inference which was confirmed by heating a sample of pure recrystallised sulphur in a CO_2 flask at 100° C. for one hour, when no appreciable loss could be detected.[21]

[21] See, however, Jones, J., 1912, 815.

A trial was then carried out to determine whether heating for this period was sufficient to remove quantitatively the traces of carbon bisulphide remaining after evaporation of a solution of sulphur in this solvent. For this purpose a sample of the latter as supplied for laboratory use was redistilled from an ordinary flask and 25 c.c. added to each of two weighed CO_2 flasks containing known weights of dry recrystallised sulphur. The added solvent was then carefully distilled off, the residue dried in a steam oven, and the flasks weighed at regular intervals of one hour. It was found that a period of between three and four hours was necessary before the flasks and contents approximated to their initial weights, and that even then the residue of sulphur possessed a disagreeable odour indicating the retention of traces of some high-boiling impurity contained in the solvent. It was therefore apparent that some additional rectification of the carbon bisulphide was necessary before it could be regarded as satisfactory.

Various methods have been employed previously for the purification of this solvent, such, for example, as one involving successive treatments with lime, potassium permanganate, mercury and mercuric sulphate, followed by distillation from fat.[22]

Following the above observation, however, it was found that a solvent of satisfactory purity could be obtained by distillation, over sulphur, from a flask fitted with a rod-and-disc fractionating column.[23] A solution of sulphur in a solvent so purified yielded on evaporation a residue which became constant in weight and odourless after heating at 100° C. for one hour.

On exposure to daylight either during extraction or storage, it was noticed that a dark deposit developed on the sides of the containing vessel, even in the case of purified solvent. This occurrence has been noted previously by various workers,[24] and is regarded as being due to the formation of a polymer of carbon monosulphide. The extent to which this takes place during the extraction, however, is not such as to impair the accuracy of the results.

This preliminary investigation suggested that no objection could be raised to the use of purified carbon bisulphide for the determination of free sulphur in antimony sulphide, except on the ground that it might fail to indicate the true sulphur content in the event of a proportion of the "insoluble" variety being present.

Insoluble sulphur.—The free sulphur in a sample of antimony sulphide might be introduced in either or both of two ways, namely, by simultaneous precipitation with the pigment, or by subsequent addition. The latter and simpler case was first considered with special reference to the possible presence of the insoluble variety. The technical product known as "flowers of sulphur" is prepared by rapidly cooling sulphur vapour in large chambers, and consists of opaque spherical particles which present a very characteristic appearance under the microscope. There should be no difficulty, therefore, in recognising the presence of this form of insoluble sulphur.

The detection of any insoluble sulphur formed during the precipitation of the pigment presents a problem much more difficult than might at first sight appear to be the case. The free sulphur, always present to a greater or less extent in antimony sulphide, if not subsequently added, must be formed during the preparation of the pigment as a result of the acid decomposition of any calcium or sodium polysulphide or thiosulphate which may be present with the thioantimonate,[25] or by the decomposition of antimony pentasulphide itself. The nature of the sulphur which results from the decomposition of polysulphide solutions has been the subject of a careful investigation[26] which has established the fact that the amorphous modification is produced in appreciable quantity only when the reactions take place in strongly acid solution.

It is evident that the acidification of the thioantimonate-polysulphide solution in the preparation of antimony sulphide may be carried out in one of two ways—either by the addition of acid to the thioantimonate solution or *vice versâ*. The latter procedure would involve precipitation of sulphur under acid conditions and would consequently render the presence of the insoluble amorphous variety a possibility in pigment so prepared.

As such sulphur could not be characterised microscopically some other means for its detection was sought.

According to the results of previous investigators, "insoluble" sulphur is actually sparingly soluble in the usual sulphur solvents of low boiling point.[27] It was thought that this characteristic would afford a means of detecting the presence of this variety.

A sample of amorphous sulphur was therefore submitted to successive 5-hour extractions with carbon bisulphide in a continuous extractor, when the following proportions of sulphur were dissolved out:—First extraction 2·24%; second 2·32%; third 1·76%; fourth 1·32%. In each instance a considerable proportion of the sulphur separated out in the boiling solvent in the "insoluble" form, and this deposit, which can readily be distinguished from the soluble variety, would serve to indicate the presence of the amorphous modification.

"Insoluble" sulphur can be converted into the soluble variety by heating to 100° C. in presence of ammonia,[28] and an attempt was made to utilise this property as the basis of a method for its quantitative estimation.

Samples of "flowers" of sulphur, containing 23% insoluble in carbon bisulphide, were therefore heated to 100° C. in an atmosphere containing ammonia for 2 hours and 5 hours respectively and thereafter extracted in the usual manner. In the former case 91·8% of the whole passed into solution, whilst in the latter instance 99·2% of the soluble variety was obtained, approximately equal to the whole sulphur content of the slightly impure sample.

It is therefore evident that in cases where the presence of amorphous sulphur is indicated, a relatively simple modification of the usual procedure will ensure that the whole of the sulphur present in the free state at ordinary temperatures is extracted.

Liberation of sulphur by heating.—It now remained to consider, in the case of the golden sulphide, the possibility of liberation of chemically combined sulphur taking place at the temperatures employed for vulcanisation. With this end in view, five samples of technical antimony sulphide were selected, which, on analysis, gave the following results.

Sample	Source.	Shade.	Antimony. %	Total sulphur. %	*Non-volatile. %	Moisture. %
1	British	Golden	66·05	28·77	0·76	0·10
2	,,	,,	46·52	50·20	0·84	0·47
3	French	Crimson	64·17	28·47	3·17	1·70
4	German	,,	64·50	32·28	1·28	1·36
5	,,	Golden	57·64	40·01	1·14	0·90

* Residue left after repeated heating with ammonium chloride. (Jacobsohn, Chem.-Zeit., 1908, **32**, 984.)

In carrying out the determination of the soluble sulphur on the foregoing, it was decided to investigate whether any evidence could be obtained of slow liberation of sulphur such as might be expected from the gradual decomposition of penta-

sulphide. For this purpose samples were subjected to two successive 5-hour extractions with carbon bisulphide at its boiling point in a Schidrowitz extractor.[29] The following results were obtained.

Sample.	First extract.	Second extract.
	%	%
1	3·70	0·33
2	31·21	0·33
3	1·02	0·13
4	4·64	0·17
5	9·14	0·63

The sulphur extracted in the second period was weighed in a separate flask and was obtained as a small crystalline globule after evaporation of solvent.

There was thus in all cases a comparatively small proportion of sulphur extractable even after the sample had been treated with solvent for a period of 5 hours. The sulphur so removed from the antimony sulphide was in every instance readily and completely redissolved in carbon bisulphide, and it may be inferred from this that amorphous sulphur was absent in the samples examined.

In this case the slight but continued extraction of sulphur observable on treating for a second period might be attributed either to mechanical causes, such as the formation of "pockets" in the sample while being extracted, or to some partial decomposition of antimony pentasulphide occurring at the temperature of the boiling solvent.

It may be said at once that the comparatively small proportion of sulphur extracted during the second treatment indicates that any decomposition caused by the boiling solvent is almost negligible unless, indeed, it is completed during the first period. That pentasulphide still remained even after the second extraction was, however, demonstrated by heating the residues at 230° C., when in nearly all cases sulphur was liberated.

As has been pointed out, however, the question whether there is any pronounced decomposition at the temperature of extraction is relatively of less importance than the knowledge of the total amount of sulphur available at vulcanisation temperatures.

In order to determine the effect of heating on the percentage of sulphur extractable with carbon bisulphide, three weighed portions of each of the samples under examination were sealed up in glass test tubes containing in the upper portions a small wad of asbestos fibre wetted with a drop of ammonia solution. The lower extremities of the tubes were then immersed in an oil bath and heated for 5 hours, a complete set of samples being submitted to temperatures of 125°, 150°, and 230° C. respectively. During this heating sulphur sublimed on to the walls of the tube immediately above the level of the oil.

After cooling, the tubes were broken and the contents, together with the portions of glass, transferred to an extraction thimble and extracted with carbon bisulphide for 5 hours, the sulphur thus removed being determined as described above. The percentage of sulphur extracted in each case is given in the following table, the results obtained from the unheated samples being included for comparison.

Sulphur extracted in 5 hours.

Sample No.	Unheated.	Heated at:		
		125°C.	150°C.	230°C.
	%	%	%	%
1	3·70	2·99	4·88	6·94
2	31·21	29·75	32·19	32·71
3	1·02	0·95	1·01	0·98
4	4·64	1·56	1·86	4·90
5	9·14	8·90	13·74	15·38

From the above figures it will be seen that the amount of sulphur in the free state varies at different temperatures. The percentage of free sulphur present after heating to 125° and 150° C., respectively, will represent the limits of variation which may be expected to be met with in works practice, as these may be regarded as maximum and minimum vulcanising temperatures. The increase in the free sulphur after heating to 230° C. compared with that found in the original sample should be a measure of the content of antimony pentasulphide present. It will be seen that only in the case of Sample No. 5, and to a less extent No. 1, was such increase at all marked. Attention may be directed to the fact that the proportion of sulphur extractable after heating to 125° C. is in all cases lower than that obtained with the unheated sample. This reduction was noticed in each instance but was most marked in the case of Sample No. 4. The experiment has been repeated several times, but always with the same result. No satisfactory explanation has yet been arrived at as to the cause of this reduction. It was at first thought that the presence of antimony oxide in the sample might result in combination with a portion of the free sulphur, but an experiment carried out with antimony oxide has shown that this is not the case. Neither can it be attributed to the conversion of the sulphur into the "insoluble" form, as the presence of the trace of ammonia would prevent this.

Heating beyond 125° C., however, results in the liberation of sulphur, the amount increasing with the temperature employed.

These experiments indicate that in golden sulphide the percentage of sulphur available for vulcanisation varies with the temperature, and that the amount of variation will depend on the percentage of antimony pentasulphide in the sample.

In each of the above instances the samples were heated for 5 hours as being a maximum vulcanising period, and it was thought desirable to determine to what extent the liberation of sulphur was dependent on time of heating.

For this purpose Sample No. 5 was chosen as containing an appreciable proportion of pentasulphide, and weighed portions were heated at 145°—150° C. in closed tubes for 1, 2, 3, and 4 hours respectively, the extraction being subsequently carried out as described above.

The following percentages of free sulphur were obtained:—After heating for 1 hour, 8·66%; 2 hrs., 9·55%; 3 hrs., 10·46%; 4 hrs., 11·81%. It will thus be seen that there is a gradual liberation of sulphur when samples containing pentasulphide are heated, the proportion of free sulphur available increasing with time of heating.

Summary.

(1) Carbon bisulphide, provided it be subjected to previous purification, is a satisfactory solvent for the removal of sulphur.

(2) The accepted method of determining free sulphur in antimony sulphide by extracting the original sample with carbon bisulphide fails to take account of (*a*) any decomposition of the higher sulphide which occurs under the conditions employed for the vulcanisation of rubber, (*b*) any sulphur present in the amorphous form, or (*c*) the pronounced fixation of free sulphur shown by certain samples of pigment between 120° and 150° C.

(3) It is suggested that the "available sulphur" should be determined by extracting with carbon bisulphide after the pigment has been heated to 150° C. for five hours in a slightly alkaline atmosphere.

In conclusion, the authors have to acknowledge their indebtedness to The North British Rubber Co., Ltd., for permission to publish the results of this investigation, which was carried out in their laboratories.

HYDROMETALLURGY OF LOW-GRADE ZINC ORES.

BY MOTOHIRO NAMBA.

The amount of zinc ore mined annually in Japan is between 35,000 and 40,000 tons; there is in addition a considerable quantity of low-grade ore containing 20—30% of zinc, which it has not up to the present time been considered possible to concentrate economically, either because the quantity in any particular instance is too small, or because the condition is unsuitable. Low-grade ores of this kind, and more especially those containing notable quantities of precious metals, may be most economically treated by a wet process of extraction.

One of the principal factors regarding the usual zinc smelting operation is the preparation of retorts suitable for its distillation. To obtain these at a reasonable cost compared with the market value of the metal, it would seem necessary to have an establishment with a productive capacity of about 20,000 tons of zinc per year, when the market price of metal is, say, £23 per ton.

In the case of Japan, where the annual demand for zinc is only 10,000—15,000 tons, it would thus seem most desirable to concentrate the smelting of zinc in one district. Against this, however, it must be remembered that whilst the total output of zinc ores in Japan is sufficient to meet this, they are obtained from many localities separated by considerable distances, and it would be very costly to transport them to one place. On this basis it would, therefore, seem that Japan is not in a favourable position for zinc smelting on a large scale.

With the object of solving the problem of extracting the zinc from the ores mined in Japan, an investigation on the hydrometallurgy of zinc was undertaken by the author at Sakai, near Osaka, in 1910.

After many trials of wet and dry processes, the wet process to be described in the present paper was finally adopted by the Takachiho-Seirensho in Yamaguchiken.

The ore used in the author's experiments was that from Wanibuchi, and had the following composition:—Zn, 32—35%; Cu, 1·5—2·5%; Pb 7%; S, 22—25%; Ba, 3%; Ag, 0·0323%.

The object was to extract the maximum possible quantity of zinc, and leave a residue in a convenient form for the recovery of the copper, lead, and silver.

The more important preliminary factors relating to the hydrometallurgy of zinc are:—(1) A high lixiviation yield of zinc from the ore itself, and (2) the almost complete purification of the liquor thus obtained by the removal of such impurities as lead, copper, iron, manganese, silica, etc. The success of the former operation depends to a very large extent upon the degree to which the zinc sulphide is converted into the oxide during the roasting process, but as this is equally important for the recovery of metal by dry distillation methods, it calls for no special comment in the present instance. It is, however, necessary to deal in some detail with the latter operation, because it is peculiar to the wet extraction process, and has very considerable influence upon its success.

Höpfner process.

In the Höpfner process for the wet extraction of zinc from its ores hydrochloric acid is used as the solvent, but unless there are special reasons for using this reagent, it is generally considered that treatment with dilute sulphuric acid is more economical.

Purification of mother liquor.—The impurities contained in the crude liquor after treating the roasted ore, when sulphuric acid is used as the solvent, are silica and the metals of the second and third groups. The metals belonging to the second group can be readily removed from solution by the addition of zinc dust. Cadmium, however, is so closely allied to zinc as to render the removal of the last trace in this way somewhat difficult. Nevertheless, it has been found that the small amount of cadmium which escapes precipitation by zinc dust does not materially influence the subsequent treatment of the solution.

The usual method for removing metals of the third group is by adding small quantities of bleaching powder and milk of lime, or precipitated calcium carbonate. In this connexion, however, the author has observed that with some solutions it is not possible to effect a complete removal of iron and manganese with the above reagents without the precipitation of a substantial quantity of zinc. In the case of such solutions, it is necessary to add a considerable quantity of milk of lime in excess of that which would normally be required for the removal of iron and manganese, and this, of course, causes the precipitation of notable quantities of zinc, which cannot afterwards be conveniently recovered. There are, therefore, two kinds of solutions, namely, those from which the iron and manganese can be readily removed by the necessary amount of bleaching powder and milk of lime, and those from which this separation is incomplete without loss of zinc. As a result of many experiments, the author has found that there is a distinct difference between those solutions which can be easily purified from iron and manganese and those which cannot. This difference is traceable to the character of the zinc ores themselves.

Action of dissolved silica.—Broadly speaking, zinc ores may be divided into two groups, one of which gives considerable quantities of dissolved silica on being treated with sulphuric acid, and the other giving only small amounts of silica in solution. The author has found that solutions containing much dissolved silica can be easily purified from iron and manganese by adding the necessary quantity of bleaching powder and milk of lime, but with those containing very little silica the iron and manganese can only be removed by using considerable excess of alkali. In the acid solutions after treating the zinc ores, the iron, manganese, and silica exist in the colloidal state, and the milk of lime or calcium carbonate first acts upon the colloidal sol of silica and converts it into colloidal gel, thus facilitating the separation of iron and manganese as a colloidal precipitate. This colloidal precipitate can be easily filtered, and after its removal the solution is clear and free from iron and manganese. This solution can then be used for the production of high-grade zinc white by precipitation of zinc hydroxide and subsequent conversion into the oxide, or for the preparation of pure zinc by electrolytic deposition.

Sodium bisulphate as solvent.—As sodium sulphate is one of the best catalysts for the coagulation of the colloidal solutions of iron and manganese, the author prefers to use sodium bisulphate in place of sulphuric acid as the solvent for roasted zinc ores. Sodium sulphate not only assists in the removal of iron and manganese, but it also gives a much more satisfactory solution for electrolytic purposes. The details of the operation are as follows:—

The pulverised roasted ore is mixed with a quantity of a 20% solution of sodium bisulphate, sufficient to dissolve the copper and zinc compounds, and the mixture is heated to 100° C. for about 30 minutes, diluted with warm water, and filtered. The solution containing the copper, zinc, etc. is then freed from the heavy metals by means of zinc sheets or zinc dust and subsequent filtration. The filtrate is neutralised by adding alkali, and a suitable oxidising agent is introduced; nearly all the iron and manganese is thus precipitated. To remove the remaining iron and manganese, the solution is boiled with a solution of sodium silicate rendered neutral to litmus by adding an acid; the strength of the sodium silicate solution and the quantity added are not of vital importance provided there is a distinct precipitate of gelatinous silica in the boiling liquid.

If the solution is to be used for the electrolytic deposition of zinc, traces of copper and cadmium which are only sufficient to give a slight yellowish or brown coloration with hydrogen sulphide do not materially influence the compactness of the deposited zinc. Iron, on the other hand, has the serious effect of giving a spongy deposit of zinc; this is manifest even when the solution shows only a slight red tint on testing with potassium thiocyanate.

The effect of manganese on the character of the deposited zinc is not so pronounced as that of iron—in fact it tends to neutralise the action of iron in producing a spongy deposit. The presence of manganese in the ore during the roasting process facilitates the oxidation of ferrous iron to ferric, and thus gives a solution which is more easily purified.

Preparation of zinc white.

Caustic soda would be too costly for use in precipitating zinc from the purified solutions. The cheapest precipitant for the separation of zinc from zinc sulphate solutions is milk of lime, but in this case the precipitate obtained is a mixture of zinc hydroxide and calcium sulphate, in which the maximum percentage of zinc oxide is 50%, even when an allowance is made for the fact that calcium sulphate is slightly soluble in water; the solubility may be taken as about 0·2%. The following figures are given in Seidell's table:—

Solubility of calcium sulphate in water.

Percentage in solution.	Temperature. ° C.
0·1759	0
0·1928	10
0·2016	18
0·2080	25
0·2090	30
0·2096	35
0·2097	40
0·2009	55
0·1932	65·3
0·1847	75
0·1619	100

The subjoined table gives the theoretical percentages of zinc oxide that would be present in the mixed precipitates of zinc hydroxide and calcium sulphate prepared by precipitating all the zinc from sulphate solutions containing varying percentages of zinc by adding the chemically equivalent amount of milk of lime.

Percentage of zinc in mixed solutions. %	Highest possible percentage of ZnO in the mixed ppt. %
10	37·59
8	37·68
6	37·8
4	38·02
2	38·76
1	40·18
0·8	41·17
0·7	41·8
0·6	42·8
0·5	43·9
0·4	45·88
0·3	49·66

Although calcium sulphate is slightly soluble in water once it has been precipitated from zinc sulphate solutions by means of lime, it is impossible to separate it from the zinc hydroxide by washing with water, as is proved by the following experiment:—

A portion of the purified zinc sulphate solution was diluted with water so as to contain 0·7% of zinc and then decomposed by milk of lime at the room temperature (10° C.), using phenolphthalein as indicator, separate portions of the mixed solutions being allowed to stand for 30 minutes, 2 hours, and 24 hours, and then filtered and lightly washed with water. The precipitates were found to contain: after 30 mins., 74·4% ZnO; 2 hrs., 46·6%; 24 hrs., 39·4%.

To test whether the calcium sulphate could be extracted by washing with water, portions of the precipitates after standing for 2 hours and 24 hours were washed with distilled water until the washings gave no turbidity on testing with barium chloride. The precipitates were found to contain 55·0 and 51·5% of zinc oxide respectively. Whilst this experiment indicates that the amount of calcium sulphate contained in the precipitate can be reduced, it shows the impracticability of using such a method for eliminating the greater proportion of it.

On comparing the results obtained after allowing the precipitate to stand in the mother liquor for different times, it is evident that immediately after the decomposition of the zinc sulphate solution the calcium sulphate exists in the mother liquor as a supersaturated solution and that it gradually separates on standing.

In view of the foregoing considerations it was at first thought to be impossible to develop a process for the manufacture of zinc oxide from purified zinc sulphate solutions, prepared from roasted zinc ores, by direct precipitation with milk of lime. Further, all attempts to obtain zinc from the mixed precipitate consisting of zinc oxide and calcium sulphate by distillation with carbon were unsuccessful. Possibly this failure was due (1) to the relatively low zinc content of the double precipitate, and (2) to the possible formation of zinc sulphide in the presence of such large quantities of calcium sulphate.

Taquet (G.P. 124,847) proposes to convert the greater part of the sulphate into chloride by adding alkaline-earth chloride and then precipitate the zinc as oxide by means of lime, but in this case also the oxide is contaminated with much calcium sulphate, although it could be used for making lithopone zinc sulphide. After numerous experiments the author found that Taquet's process was impracticable, because the reaction between zinc sulphate and the chloride is not complete, and it is exceedingly difficult to determine when the end point of the reaction has been reached. Further, as the precipitate of calcium sulphate is voluminous, it is impossible to recover the zinc chloride completely. This causes a very substantial loss of zinc.

Lance (F.P. 463,614, 1912) has proposed to separate zinc oxide from zinc sulphate solution by bringing calcium bisulphite, either produced separately or in the solution itself, into reaction with the zinc sulphate in presence of an excess of sulphurous acid. After filtering off the calcium sulphate the zinc sulphite is precipitated by neutralising the acid solution with zinc oxide. The zinc sulphite thus obtained is then converted into the oxide by calcination.

Later Lance improved this process by using barium oxide instead of lime (U.S.P. 1,198,241, 1916). The following is a brief outline of the modified process:—Sulphur dioxide is passed through the zinc sulphate solution under pressure, and at the same time barium oxide is added. The amount of barium oxide used should be less than half that required to combine with the sulphurous acid in the solution as barium sulphite. In this way barium sulphate is precipitated and an acid solution of zinc sulphite obtained. On removing the excess of sulphurous acid in the solution zinc sulphite is precipitated, and can be converted into the oxide by calcination, with the regeneration of sulphurous acid. Barium oxide is regenerated in the usual manner, and thus a working cycle is obtained. Lance's process is very complicated and requires skilful devices and trained labour to carry it out on a manufacturing scale.

However, as will be seen later, it was found possible to prepare zinc hydroxide in a comparatively high state of purity by precipitating the zinc directly by lime. This became possible by utilising the marked tendency which calcium sulphate possesses to form relatively stable supersaturated solutions.

Before proceeding to describe the author's process, it will be useful at this stage to refer to and discuss the literature bearing on the subject of supersaturated solutions of calcium sulphate.

Supersaturated solutions of calcium sulphate.

As the action between water and calcium sulphate is extremely slow, the solubility of this salt has formed the subject of investigation by numerous workers. Cameron (J. Phys. Chem., 1901, 5, 556) examines the results of previous workers and suggests that the discrepancies were due to the exceptionally slow rate at which calcium sulphate is dissolved by water, or, in other words, the long time it requires to reach a normal state of equilibrium.

Marignac (Ann. Chim. Phys., 5e ser., **1**, 274) explains the discordant data on the basis that calcium sulphate forms supersaturated solutions, which has a considerable influence upon the apparent solubility of the salt. He also points out that considerable time is required before normal equilibrium is reached even when particles of the solid salt are in contact with the solution. He observed that, on neutralising dilute sulphuric acid with calcium carbonate, the solution contained $\frac{1}{114}$ of calcium sulphate, and on allowing this solution to stand for 24 hours, crystals of calcium sulphate were formed, but $\frac{1}{313}$ of calcium sulphate still remained in solution. Crystals of $CaSO_4$ separated quickly from supersaturated solutions containing $\frac{1}{110}$—$\frac{1}{150}$ $CaSO_4$, but crystallisation did not take place freely from solutions containing $\frac{1}{350}$ $CaSO_4$; solutions containing $\frac{1}{285}$ $CaSO_4$ gave noticeable crystals after standing for 14 days, but they still contained $\frac{1}{312}$ $CaSO_4$ after standing for one month, $\frac{1}{414}$ $CaSO_4$ after two months, and $\frac{1}{446}$ $CaSO_4$ after three months, even though the solutions had been occasionally shaken. Marignac explained these facts by supposing that no marked change of density occurs during the passage of a supersaturated solution to its normal condition, and in consequence no inner currents are set up which would bring the precipitated crystals into contact with all parts of the solution.

Hulett (Chem. Centr., 1901, II., 161) noticed that the solubility of gypsum in water increased with its degree of fineness. This was attributed to the increase of the surface of contact between the solid and liquid.

Hulett and Allen (J. Amer. Chem. Soc., 1902, 667) made a careful study of the solubility of calcium sulphate in water, and as their results are considered to be the most reliable they are given in Seidell's solubility tables (*cf. ante*).

Cavazzi (Chem. Centr., 1905, I., 1693) obtained a supersaturated solution of calcium sulphate containing 9·49 g. of $CaSO_4$ per litre by shaking gypsum with water for 5 minutes at the ordinary temperature. Cavazzi (Z. Chem. Ind. Kolloide, 1913, 12, 196) also proved the existence of gelatinous calcium sulphate and showed that the formation of transparent particles when calcined gypsum and water are brought into contact is due to the production of a supersaturated solution of this gelatinous calcium sulphate, which is converted into stable calcium sulphate and crystallises out after allowing to stand for a short time. He readily obtained gelatinous calcium sulphate by mixing 0·5 g. of plaster of Paris with 25 c.c. of cold water, filtering, and adding to the filtrate an equal volume of alcohol. Gelatinous calcium sulphate contains more water than gypsum and is more soluble in water than $CaSO_4,2H_2O$. In this way he explained the strongly supersaturated solutions of calcium sulphate which had previously been observed by Marignac, and in his own previous investigation.

In the present author's experiment described on page 282 T, the precipitate of calcium sulphate obtained by adding alcohol to the solution was no doubt of the same nature as Cavazzi's gelatinous calcium sulphate. In that experiment the precipitate formed after either boiling the solution or allowing it to stand was in an extremely fine crystalline form, but that produced when alcohol was used possessed a distinctly gelatinous character, and it is for this reason that it is described as a voluminous precipitate.

Jones and Partington (Phil. Mag., 1915, [6], **29**, 35) have put forward a theory of supersaturation, according to which the solubility of a substance depends on the radius of the solid particles as well as on the temperature and pressure. They describe the radius of a particle which is in equilibrium with a supersaturated solution of a given concentration and at a given temperature and pressure, as the equilibrium size. The introduction into the solution of particles having a greater radius than the equilibrium size will produce crystallisation, but if smaller particles are added they will dissolve.

When heat is absorbed on dissolving a solid in a nearly saturated solution, the temperature value corresponding with the equilibrium size will decrease if the radius of the solid particles is reduced. On the contrary, if heat is evolved, the corresponding temperature increases when the radius of the particles is diminished.

In ordinary supersaturated solutions belonging to the first type spontaneous crystallisation would occur on introducing small particles when cooled below a certain temperature; the size of particle required to induce crystallisation is smaller the lower the temperature. With solutions of the second class spontaneous crystallisation would be brought about by heating above a certain temperature. An ordinary saturated solution of gypsum is an example of the second group.

The above theory is in complete agreement with the experimental data obtained by the author in connexion with the decomposition of zinc sulphate by milk of lime. Although the mother liquor is highly supersaturated with calcium sulphate it is relatively stable in the cold, but spontaneous crystallisation occurs on boiling.

Jones and Partington (J. Chem. Soc., 1915, **107**, 1019) have further proved the existence of supersaturated solutions of the second type, directly in the case of calcium butyrate and calcium acetate, and indirectly in the case of calcium sulphate (gypsum).

On calculating the degree of supersaturation into terms of percentage from Marignac's figures given above, the following results are obtained:—Marignac: 0·877 immediately after decomposition; 0·319 after standing 24 hours; 0·320 after one month; 0·242 after two months; 0·224 after three months. Cavazzi: 0·949.

Although working with quite a different object in view, namely, for the recovery of zinc from zinc sulphate solutions by means of milk of lime, the author has obtained similar results to those referred to above and found that the supersaturated solutions of calcium sulphate are sufficiently stable to permit complete filtration of the precipitated zinc hydroxide without appreciable crystallisation of calcium sulphate.

The fact that these calcium sulphate solutions are comparatively stable, even when they are in contact with solid particles of the salt, puts them in a class apart from the majority of supersaturated solutions. Further, just as the solubilities of the so-called practically insoluble substances vary within considerable limits, so the velocities at which they are precipitated also vary, though in many instances the actual rates cannot be measured.

With the solutions under consideration the calcium sulphate present in excess of the normal saturation possibly exists as a suspensoid, and the influence of the colloidal precipitate in the direction of destroying the supersaturated condition is very feeble, even though it may slowly act as nucleus of crystallisation.

Influence of other salts.—The solubility of calcium sulphate in water is affected by the presence of other salts. The salts usually found in industrial water are the chlorides and sulphates of sodium, calcium, and magnesium.

The more important publications dealing with the effect of other salts on the solubility of calcium sulphate in water are:—Trommsdorf (J. der Pharmacie, **18**, 1, 234); Wackenroder (Ann. Chem. u. Pharm., **41**, 316); Droeze (Ber., **10**, 338); Lunge (J., 1885, **4**, 31); Cameron and Seidell (J. Phys. Chem., **5**, 643); Evans (Chem. News, **86**, 4); Orlow (Chem. Centr., 1903, 1., 497); Cameron and Breazeale (J. Phys. Chem., **8**, 335); Cameron and Brown (*ibid.*, **9**, 210).

From the present point of view the chief conclusions to be drawn from the results of these investigations are that the solubility of calcium sulphate is increased by the presence of sodium chloride and sulphate, and decreased by the chlorides of calcium and magnesium.

The author has found that the mother liquor obtained on filtering the zinc hydroxide precipitated by means of lime from purified solutions of zinc sulphate, prepared by lixiviating roasted zinc ore with aqueous solutions of sodium bisulphate (nitre cake), contained higher percentages of calcium sulphate than could be accounted for by the normal increase in the solubility due to the presence of sodium sulphate. From this it must be concluded that sodium sulphate not only increases the normal solubility of calcium sulphate in water, but also increases the degree of supersaturation of solutions prepared in the above manner.

The author's French Patent 479,614 for the manufacture of zinc white, relates to a process for the preparation of zinc oxide by utilising the supersaturation of calcium sulphate in the presence of sodium chloride and sodium sulphate.

Experimental.

Many experiments were conducted with a view of determining any differences in the physical behaviour of zinc hydroxide and calcium sulphate during or after their precipitation, which might render it possible to effect a satisfactory separation of the two.

Perhaps the more important features in this connexion are that the precipitate of zinc hydroxide from cold dilute solutions is very light, voluminous, and flocculent, whilst that of calcium sulphate when precipitated under similar conditions is decidedly heavier, it being compact and crystalline. Hence it would seem that the former should settle out much more slowly than the latter when formed in the same mother liquor. To test this the author endeavoured to separate the two compounds by utilising the differences in the rates at which they settle in the liquid. The solution used was very dilute, and it was observed that the upper portion of the mixed precipitate contained a considerably higher percentage of zinc than the lower. Another significant fact noticed was that when the mother liquor was filtered off immediately after the addition of the milk of lime, a considerable amount of crystalline calcium sulphate separated out from what was at first a clear filtrate; this must have been held in solution, in a supersaturated form, owing to the extremely slow rate at which it crystallises from the mother liquor. To obtain additional confirmation that calcium sulphate can exist in this form after the precipitation of zinc hydroxide from the sulphate solution by means of lime, the amount of SO_3 was determined in the mother solution after immediate filtration following the decomposition of zinc sulphate by milk of lime both in cold and in boiling solutions. The original mixed solutions for this purpose contained 1·0, 0·8, 0·6, 0·4, and 0·2% of zinc. Solutions containing more than 1·0% of zinc proved unsatisfactory, owing to the extremely voluminous precipitate of zinc hydroxide preventing its ready settlement. The results obtained are given in terms of SO_3 and $CaSO_4$ in the following table:—

Zinc in the mixed solutions.	A. Cold solutions.		B. Boiling solutions.	
	SO_3.	$CaSO_4$.	SO_3.	$CaSO_4$.
%	%	%	%	%
1·0	0·475	0·808	0·109	0·186
0·8	0·491	0·835	0·111	0·189
0·6	0·518	0·881	0·107	0·184
0·4	0·309	0·526	0·107	0·181
0·2	0·229	0·389	0·116	0·197

It then appeared desirable to determine whether the whole of the zinc contained in dilute solutions could be completely precipitated by lime, and none escape in the filtrate in the same way as calcium sulphate. The zinc solution used for this purpose was the ordinary sulphate purified in the manner already described. This solution contained 5·8% of zinc, but to make the conditions really drastic, 81·9 c.c. was diluted with water to 1900 c.c., thus making a solution containing 0·25% of zinc. The whole of this dilute solution was treated in the cold, with freshly prepared milk of lime, using phenolphthalein as indicator. The solution was filtered through filter paper, and the precipitate washed five times with water by decantation. The precipitated zinc hydroxide was redissolved in dilute hydrochloric acid and the zinc determined with the following result:—Zinc in original solution, 4·750 g.; zinc in precipitate, 4·756 g. The 0·006 g. in excess of that which was known to be present is well within the range of experimental error. The result is sufficient to demonstrate that the zinc is, for all practical purposes, completely precipitated even when present in such extremely dilute solutions.

By means of the electrical conductivity method, Dupré and Bialas (Z. anorg. Chem., 1903, 55) have shown that one litre of water dissolves 0·0042 g. of zinc oxide at 18° C.

From the figures given in the above table, it will be seen that the percentage of calcium sulphate in the mother liquor after boiling is virtually constant, as would be expected, and corresponds to the figure for the maximum solubility of the salt in water.

On comparing the results tabulated in Column A with those in Column B, it will be noted that after cold precipitation and filtration, the filtrate contains considerably greater quantities of calcium sulphate. The extra calcium sulphate retained in the filtrate under these conditions can only be present in virtue of the solution being supersaturated, or because the salt is in such an exceedingly fine state of dispersion as to correspond with a suspension colloid, which enables it to pass through the filter in the same manner as if it were truly in solution. It is, however, a matter of no great importance for the present purpose which of these views is correct, the essential feature being that the sulphate is carried through with the filtrate.

On allowing these filtered supersaturated solutions to stand for a few hours, the excess of calcium sulphate gradually separates in the form of minute crystals, or by adding a little ethyl alcohol, a voluminous precipitate of calcium sulphate separates instantly from the solution. As is well known, the separation of a crystalline precipitate of this kind from its solution is accelerated by the addition of solid particles, which act as nuclei upon which crystallisation can more readily occur, or by continuously agitating the solution. In the present instance it was found that the separation of calcium sulphate occurred more slowly when large decomposing tanks were used than in smaller tanks. In consequence the percentage of zinc oxide in the precipitate was much higher from the former than from the latter. In the small-scale commercial plant controlled by the author the decomposing tanks were elliptical in shape, 8 feet wide, 17 feet long, and 7 feet deep; they were made of reinforced concrete and had two agitators. The amount of zinc oxide in the dried precipitate was never below 85% and was almost invariably above 90%; the amount of calcium sulphate present was 10—15%.

Separation of water from zinc hydroxide.

The freshly precipitated zinc hydroxide produced in the above manner being of a colloidal character and extremely voluminous, it is difficult to get a filter cake containing less than about 90% of water by means of the ordinary filter press. In order to eliminate the greater part of this water, the cake from the filter press was heated by means of steam. At temperatures above 80° C. zinc hydroxide decomposes into zinc oxide and water, and therefore by once more filtering the steam-heated filter cake the water content was reduced to 20%. This last portion of water was removed at a comparatively low temperature by heating in a direct gas-fired drying furnace.

The zinc oxide produced in this way may be used as a white pigment in the same way as the zinc white made by the usual process of burning metallic zinc. In some cases, however, it may be more profitable to use this oxide for making very pure zinc by distillation with carbon, or it may be used for making exceptionally pure zinc oxide or zinc dust free from heavy metals. Very pure zinc of this kind is difficult to make by the direct distillation of ordinary ores.

Zinc oxide for good quality rubber and zinc dust for the dyeing industry should be free from heavy metals. The composition of the distilled zinc oxide produced in the present work was:—ZnO, 99·0—99·5%; impurities, 0·5—0·7%; moisture, 0·15—0·3%; and the composition of the zinc dust Zn, 90%; ZnO, 10%.

Electrolytic zinc.

When pure metallic zinc is required the author prefers to use the purified zinc sulphate solution already referred to, for the direct electrolytic deposition of the metal. The most objectionable impurity is iron, and in order to obtain satisfactory results it must be removed completely. As previously indicated, this can be accomplished if the mother liquor contains sufficient colloidal silicic acid, which may come from the original roasted ore, or may be added later. It was stated (*cf. supra*) that it is difficult to remove the last traces of copper and cadmium from the sulphate solution by means of zinc sheets or dust. Although they do not prevent the formation of a compact deposit of cathode zinc, it has been found that practically the whole of these impurities are deposited along with the cathode zinc formed in the first vats which the fresh electrolyte enters. In view of this, these particular cathodes can be kept separate from the purer quality if it is desired. The difference between the copper and cadmium contents of the cathodes from the first and last vats will be seen from the following figures:—

	Pb %	Cu %	Cd %	Zn by diff. %
Cathodes from first vats	0·022	0·04	0·024	99·914
Cathodes from last vats	0·035	0·01	0·000	99·955

The increase in the percentage of lead indicated by these figures is probably accidental, and probably that amount could be decreased, if it were considered necessary, by introducing a cloth diaphragm between the anodes and cathodes.

The following is given as an example of the normal working conditions of a four days' run of the electrolytic plant managed by the author:—

The electrolytic baths, which were 2·5 ft. wide, 6·0 ft. long, and 2·5 ft. deep, were wooden tanks 1 in. thick, lined with best quality asphalt; 32 of these were arranged in four rows, with eight in each row, and all the baths were connected in series. Fresh electrolyte was run into each of the first four baths of each series, and then from these to the next in the respective series, and so on, flowing out at the eighth. Seven cathodes and eight anodes were used in each bath. The number of electrodes varied with the current used, but the current density was always between 10 and 11 amps. The cathodes were double sheets of electrolytic zinc, 8 in. × 2 ft. The cathodes from the eight baths in each row were taken out when they became sufficiently heavy, every four days, and replaced by new ones. The new cathodes were prepared by depositing thin layers of zinc on the surface of rolled zinc or aluminium and then stripping the deposit from the original sheet.

The electrolyte flowing from the last baths in each series contains about one third of the zinc content of the original electrolyte, and a corresponding increase in the sulphuric acid acidity occurs. This solution is of course used over and over again as a solvent for roasted zinc ores, either as it is, or with the addition of a little fresh acid.

	1st day.	2nd day.	3rd day.	4th day.
Average current density for each row, amps. per sq. ft.	10·8	10·70	10·67	10·66
Terminal voltage, average per bath	3·41	3·34	3·38	3·38

Average current efficiency ..	76·6	74·7	78·6	74·6
Kw.-h. required per ton of zinc	3550	3720	3550	3830

The above is a general description of the author's process, which may be subdivided under three heads according to the product desired, viz.:—(1) Electrolytic process. (2) Production of zinc oxide suitable for white pigments. (3) Production of specially pure zinc oxide by redistillation.

With regard to No. 1, which is the usual means of extracting metallic zinc by the wet process, the solution for electrolysis should contain between 7 and 10% of zinc if the most economical results are to be obtained. With Nos. 2 and 3 there is no restriction on the concentration of the solution. With process No. 2, however, very pure lime is required, because any impurity it contains reduces the quality of the zinc oxide produced; this does not apply to the third process.

Other things being equal, the higher the lixiviation yield of zinc the greater is the volume of the liquor. Hence, as the value of the zinc in solution decreases, for electrolytic extraction, with an increase in the degree of dilution, there must be a certain economic limit in this respect; as, however, there are virtually no limits of dilution for the successful working of processes Nos. 2 and 3, the author is of the opinion that it is most economical to use these processes in combination with each other when dealing with low-grade zinc ores and zinc ashes etc.

From data of materials used and produced monthly the following ratios have been calculated; they may be regarded as a summary of the results obtained:—

Date.	I. Ore lixiviated : ore roasted.	II. Coal : ore roasted.	III. Sulphuric acid : ZnO in products.	IV. Lime : ZnO in products.	V. Kw.-h. required per ton of zinc.

Average mean	0·90	2·70	2·38	0·85	4361

Ratio I expresses the loss in weight of ore during roasting, which was 10% of the raw ore on the average.

Ratio II gives the coal consumption for roasting, distilling, drying, steam raising, etc.; the average works out at 2·7 times the raw ore.

Ratio III—Theoretically 81 parts of zinc oxide corresponds to 98 parts of H_2SO_4, and taking the composition of 50° B. sulphuric acid as 62% H_2SO_4, 98 parts of H_2SO_4 is equal to 158 parts of 50° B. sulphuric acid. Therefore, the theoretical ratio of 50° B. sulphuric acid and zinc oxide is approximately 2·0. In the author's work the average ratio was 2·38, and the difference of 19% is due to the fact that iron, manganese, copper, cadmium, etc., were dissolved and also to the final liquor containing free acid.

Ratio IV—Theoretically the ratio of zinc oxide to lime is 81 to 56 or 1:0·7. The difference between 0·85 and 0·7 (0·15, or 21% of lime in excess) may be regarded as due partly to the lime necessary to neutralise the excess of acid contained in the sulphate solution, and partly to the presence of unburnt lime in the quicklime.

Ratio V—The average current required to deposit one ton of zinc was 4361 kw.–h., which is rather higher than the figure given in the previous table. In the monthly accounts, however, the current used was recorded before passing to the transformers, and if the efficiency of the transformer and motor generators be taken at 80%, the results are in good agreement.

In conclusion, the author desires to express his cordial thanks to Mr. T. Iwasaki for the considerable assistance he has given and the interest he has taken in the work.

NOTE ON THE RECOVERY OF ALCOHOL VAPOUR FROM AIR. COMPARISON OF WORKING DATA WITH THEORETICAL CONCLUSIONS.

BY ALAN A. DRUMMOND.

Masson and McEwan (J., 1921, 32 T) have pointed out the importance of vapour pressure determinations in problems connected with the recovery of solvent vapour from air, and have dealt with the recovery of ether and alcohol vapours by means of sulphuric acid and cresol. They also referred to the suitability of water for the recovery of alcohol vapour from air. The object of the present paper is to show the application of the principles developed by these authors to the absorption of alcohol vapour by water, and to present a comparison between actual data obtained at a Government factory, using the water recovery process, and the results anticipated from theoretical considerations.

The necessary vapour pressures were available from work done by Foote and Scholes (J. Amer. Chem. Soc., 1911, 33, 1323) at a temperature of 25° C.; Kablukow (Z. physikal. Chem., 1903, 46, 404) at 47·5° C.; and Wrewsky (Z. physikal. Chem., 1912, 81, 1) at 39·76°, 54·81°, and 74·39° C. Some of these results, re-calculated in terms of grams of vapour per cubic metre of air, are shown in Tables I and II.

TABLE I.

Vapour pressures. Alcohol—water.

Alcohol, g. per kg. water.	Pressure in g. of vapour per cb.m.	
	At 25°C.*	At 47·5°C.†
250	40·5	164
100	19·5	66·8
50	10·0	32·5
20	4·0	15·0

* Calculated from figures given by Foote and Scholes.
† Calculated from figures given by Kablukow.

TABLE II.

Vapour pressures. Alcohol—salt solution.

Alcohol, g. per kg. of salt solution contg. 1g.-mol. NaCl per l.	Pressure, in g. of vapour per cb. m., at 47·5°C.*
250	185
100	83
50	41·5
20	18·5

* Calculated from figures given by Kablukow.

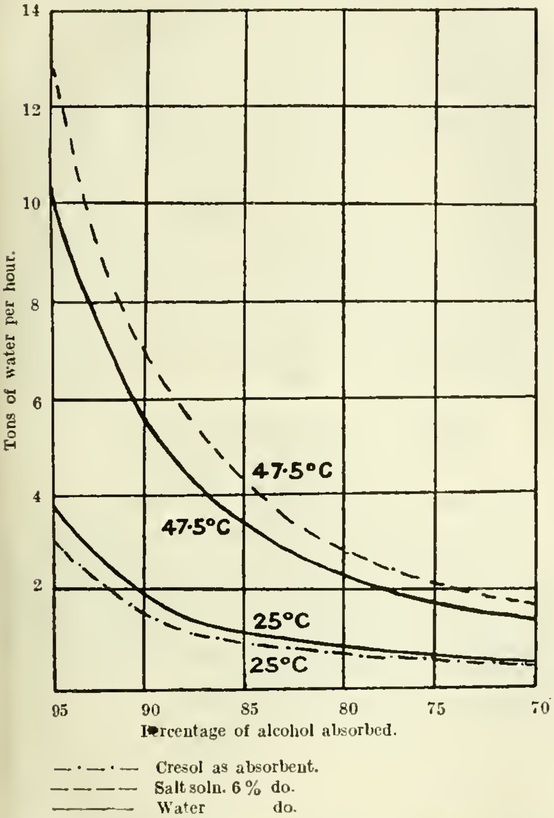
These results may be compared with similar figures for alcohol in sulphuric acid and alcohol in cresol (see Masson and McEwan, *loc. cit.*). It will be seen, for example, that the vapour pressure of a mixture of alcohol and water containing 100 g. of alcohol per kg. of absorbent at 25° C. (about 16 g. vapour per cb. m. of air) with an absorbent of 50% sulphuric acid, is not much lower than that with pure water (20 g. per cb. m.); moreover the vapour pressure of the same mixture is little more than half that with pure water when acid as strong as 64% is used. Similarly, it may be seen that the vapour pressure of the mixture considered is very little lower when cresol is the absorbent than when water is used.

Masson and McEwan have shown how it is possible to predict, for a given temperature, the amount of absorbent required to effect a stated percentage absorption independently of the concentration of the vapour in air. A specific case may be taken to illustrate the method of applying vapour pressure determinations in the case of the recovery of alcohol by water, and a comparison then made with the data obtained with cresol as absorbent. An air supply of 30,000 cb. ft. per hour (850 cb. m. per hour) contained 1% by volume of alcohol vapour (18·8 g. per cb. m.), the temperature being 25° C. It was required to determine the hourly amounts of absorbent necessary for different percentage absorptions. From the vapour pressures (Table I.) the value of the solubility coefficient (K) is found to be 5·0 for water and 5·5 for cresol.

Then by the use of values obtained as in Table IV. of Masson and McEwan's paper (*loc. cit.*), the amounts of water and cresol in kg. per cb. m. required to effect absorptions of 70—95% may be determined.

Thus an 80% absorption is effected (*a*) by water in amount 0·80 kg. per cb. m. or 680 kg. per hour (140 galls.); and (*b*) by cresol in amount 0·73 kg. per cb. m. or 620 kg. per hour (120 galls.).

Calculations for other percentage absorptions have been made similarly and the appended curves obtained, which indicate the amounts of water and cresol required for given percentage absorptions. These curves show that little benefit is to be obtained from the use of cresol as an absorbent for alcohol as compared with that of water, confirming the deductions made on examination of the vapour pressures of the mixtures.



The influence of temperature on absorption is also shown in the figure, where a curve has been drawn from results of calculations made from vapour pressures at 47·5° C. (see Table I.) on the same lines as before.

The foregoing considerations are based on the use of only one "effect." Multiple effects considerably improve the efficiency (see Table V., Masson and McEwan, *loc. cit.*).

Figures are available showing actual working practice in the recovery of alcohol vapour from air by means of water in a Government factory. Comparison of these is here made with theoretical data calculated for similar conditions by the methods outlined above. The working data are as follows:—Rate of flow of water = 300—400 galls. per hour. Sp. gr. of effluent, 0·993—0·990. Concentration of vapour, 2—3% alcohol by volume. Air supply, 180,000 cb. ft. per minute.

Taking average values:—Rate of flow of water per double tower = 350 galls. per hr. Total rate of flow per 3 sets = 1050 galls. per hr. = 4780 kg. per hr. Strength of effluent = 4·0% by wt. = 4·2 g. alcohol per 100 g. water. Concentration of vapour = 2·5% by vol. = 45·8 g. per cub. m. Air supply = 180,000 cb. ft. per hr. = 5100 cb. m. per hr.

Taking the rate of feed of water as 1 kg. per cb. m., the strength of effluent at which 100% absorption is obtained would be 4·68 g. per 100 g. water. The actual strength obtained was 4·2 g. per 100 g. water, showing an efficiency of 90%.

The rate of water feed theoretically required to give 90% absorption under the conditions named is (1) for one effect, from Table IV. of Masson and McEwan's paper (*loc. cit.*), a little less than 2 kg. per cb. m., or about 10,000 kg. per hour; (2) for two effects, 0·5 kg. per cb. m., or 2550 kg. per hour.

Now the rate of feed of water in the actual case under consideration is 4780 kg. per hour (say, 1 kg. per cb. m.), indicating that the system of three double towers is approximately equivalent to a system of 1·5 effects, where equilibrium is attained in each effect; *i.e.*, each tower works at about 50% of its maximum efficiency, regarding each double tower as one effect.

Thermal factors.—The calculations made for the hypothetical case first considered were based on the assumption that an average temperature of 25° C. was maintained inside the recovery towers. The heat liberated by the condensation of alcohol vapour and that produced on mixing alcohol with water are important factors to be considered from the point of view of absorption efficiency.

The heat of condensation of alcohol is 250 Cals. per kg., and (taking the absorption as 80%) 12·8 kg. alcohol condensed per hour will liberate 12·8 × 250 = 3200 Cals. per hour.

If the ingoing air and the water are both at a temperature of 25° C., the heat liberated by mixing alcohol and water to give a 2% solution (the strength approximately obtained in the case considered) is about 1·05 Cals. per kg. (E. Bose, Z. physikal. Chem., 1907, 58, 606, and 1907, **60**, 635), so that (12·8 + 700) × 1·05 = 748 Cals. is liberated per hour in the tower from admixture of alcohol and water. By adding the heat of condensation, 3200 + 748 = 3948 Cals. is seen to be the total heat liberated hourly in the tower, thus raising the temperature of 700 kg. of water by about 6° C.

If the temperature of the ingoing air is higher than that of the entering absorbent the temperature of the latter will necessarily be raised still further. Thus, if the temperature of the air entering were 40° C., and that of water entering 20° C., then the rise in temperature of the water due to the heated air would be about 5° C., or, adding heat due to condensation and mixing, a total rise of 10°—11° C. It may be noted that every 10° rise in temperature of the ingoing air means an addition of about 2700 Cals. per hour to the water, or a rise in temperature of the water of nearly 4° C. Obviously the entering air should be as cool as possible and refrigeration of the absorbent water would be an advantage.

Oxidation effects.—There is a tendency for alcohol to become oxidised to acetic acid by bacterial action during recovery in Robertson-Rintoul towers. In order to eliminate this trouble the addition of salt, as an anti-bacterial agent, has been suggested. The influence of the presence of salt on the absorption has been studied on the same principles as before. Vapour pressures of mixtures of alcohol and water containing salt have been measured by Kablukow (*loc. cit.*, see Table II.).

It is found that in these mixtures water has a greater affinity for salt than for alcohol, and consequently the partial pressures of alcohol over alcohol and water are greater when the mixture contains salt. The solubility coefficient at 47·5° C. is 1·5 for water alone and 1·2 for water containing 6% of sodium chloride. The figure shows comparative curves for amounts of absorbent required for different percentage absorptions with water and with salt solution. It will be seen that the presence of salt will not materially affect the conclusions arrived at for water alone as regards its absorptive capacity for alcohol.

Conclusions.

(1) A negligible advantage is shown by cresol as compared with water in its absorptive efficiency for alcohol; *e.g.*, an 80% absorption should be obtained with a feed of water of 140 galls. per hour at 25° C., where 120 galls. per hour of cresol would be necessary.

(2) A feed of water of 140 galls. per hour at 25° C. would absorb theoretically, in one effect, 80% of the alcohol contained in an air supply of 30,000 cb. ft. (850 cb. m.) per hour where the concentration of the alcohol vapour is 18·8 g. per cb. m. (1% by volume).

(3) If air and water enter at the same temperature (25° C.), the heat of mixing and condensing the absorbed alcohol raises the temperature of the absorbent by 6° C. The temperature can be kept down by introducing cooling coils between the effects.

(4) The presence of salt in the water (added to prevent bacterial action) will not markedly affect the above conclusions.

(5) A comparison has been made between factory data and the results of theoretical calculations in connexion with the recovery of alcohol vapour by water.

The author's thanks are due to the Director of Artillery for permission to publish this note and to Sir Robert Robertson for the interest he is taking in the work.

PRELIMINARY NOTE ON SYNTHESES WITH CHLORO-ACETYL CHLORIDE.

BY W. LEIGH BARNETT, B.A., B.SC., A.I.C.

The author has shown (J., 1921, 253—256 T) that when chloro-acetyl chloride reacts with cellulose in presence of acetic acid, the final products are mixed esters of cellulose containing both acetyl and hydracryl radicles. Careful examination of all gaseous products evolved during the course of the reaction, and also during the final treatment with water, revealed the fact that only hydrogen chloride is evolved during the reactions in the absence of water, but on treatment of the acetic acid solution of the dissolved cellulose esters with water formic acid is produced in large amounts.

Consideration of the conditions under which these cellulose hydracrylates are formed leads to the conclusion that the reaction proceeds in four distinct stages, viz.:—(1) The formation of chloro-acetates by elimination of hydrogen chloride: $\text{ROH}+\text{ClCO.CH}_2\text{Cl}\rightarrow\text{RCO}_2\text{.CH}_2\text{Cl}+\text{HCl}$. (2) Reaction between chloro-acetyl chloride and acetic acid to give a mixed anhydride of acetic and chloroacetic acid, with elimination of hydrogen chloride. This reaction probably occurs simultaneously with (1) owing to the catalytic nature of the large surface of the cellulose: $\text{CH}_3\text{.COOH}+\text{ClCO.CH}_2\text{Cl}\rightarrow\text{CH}_3\text{.CO·O·CO.CH}_2\text{Cl}+\text{HCl}$. (3) The cellulose chloro-acetate reacts with the mixed anhydride with elimination of hydrogen chloride and the production of a complex compound, which undergoes hydrolysis with water in the fourth stage to give the hydracrylate, formic acid, and monochloroacetic acid:

$$\text{R.CO}_2\text{.CH}_2\text{Cl}+\text{HCH}_2\text{.CO.O.CO.CH}_2\text{Cl}\rightarrow$$
$$\text{R.CO}_2\text{.CH}_2\text{.CH}_2\text{.CO.O.CO.CH}_2\text{Cl}.$$

(4) 
$$\text{R.CO}_2\text{.CH}_2\text{.}\overset{\text{HO.}}{\text{CH}_2\text{.}}\;\overset{\text{H H}}{\text{CO.O}}\;\overset{\text{OH}}{\text{.CO}}\text{.CH}_2\text{Cl}\rightarrow$$

$$\text{R.CO}_2\text{.CH}_2\text{.CH}_2\text{.OH}+\text{H.COOH}+\text{HO.CO.CH}_2\text{Cl}.$$

The author has succeeded in preparing compounds corresponding with all these stages in the case of glycerol, and it is clear that such reactions can give rise to a large variety of compounds. It is proposed to deal with the case of glycerol in a further communication shortly.

LUBRICATION AND LUBRICANTS.

BY LEONARD ARCHBUTT, F.I.C.

Theory of viscous lubrication.

During the last forty years the theory of liquid-film or viscous lubrication has become established upon a firm basis. The classical "friction experiments" made by Beauchamp Tower for the Institution of Mechanical Engineers in 1883 and 1884 established the fact that a well-lubricated journal or shaft, rotating at a fair speed, becomes separated from its bearing by a film of liquid oil, which is under pressure, and the frictional resistance is entirely due to the viscosity of the oil. The theory was worked out mathematically by Osborne Reynolds, and has been further developed for flat surfaces by Michell. In the design of bearings to-day the loads and speeds are arranged so as to ensure, as far as possible, that the surfaces do not touch when running, and that a film of liquid oil is maintained between them. In every bearing which has become bedded by wear upon a lubricated cylindrical journal the radius of curvature is slightly greater than that of the journal. The oil carried round by the journal from the pad or bath on the under side enters this narrow space, and if the speed of the journal is great enough the clearance takes the form of two curved wedges on either side of the point of nearest approach. The oil entering the wide end of the wedge on the entrant side becomes compressed in its passage through the narrower portion and lifts the brass off the journal until an oil-film is formed which completely separates the solid surfaces. So long as a complete oil-film is maintained between the bearing and the journal the friction is almost independent of the load, and would be proportional to the speed but for the fact that the heat developed lowers the viscosity of the oil, so that the friction in practice does not increase so fast as the speed, but sometimes as the square root of the speed, or at very high speeds indeed may be almost independent of the velocity.

In a thrust-bearing the friction surfaces are unable to change their relative positions, and are forced to remain parallel in the direction of motion. In such bearings, unless the pressures are very light, the oil-film does not form completely, and the friction is high. The difficulty has been overcome in the pivoted types of thrust-bearing, in which one friction surface is formed of a number of blocks pivoted so as to be capable of tilting slightly when in relative motion to the other surface. The Michell thrust-bearing is the best known of these devices. A thrust-bearing on the same principle was independently designed by Mr. R. M. Deeley in 1905, and ran successfully in a hydro-extractor. A thrust-bearing on similar lines has also been designed by Prof. Kingsbury. In these bearings the oil wedges itself between the surfaces as in the case of a cylindrical bearing, and as there are several inclined surfaces in one bearing, the number of separate oil wedges is greater than in a cylindrical bearing, which has only one, and the weight-carrying capacity is correspondingly greater.

In liquid oil-film lubrication there is no slip between the solid and liquid surfaces, and movement takes place by the intermediate planes of the liquid sliding over one another. The resistance to this shear of plane over plane is due to the viscosity of the liquid, to which the friction is entirely due. Mineral oils of similar viscosity are as efficient lubricants under these conditions as animal or vegetable oils, and as they are the more inert chemically, and are cheaper, they are very widely used.

Viscosity: Its measurement and expression.

As defined by Maxwell*, "The viscosity of a substance is measured by the tangential force on the unit area of either of two horizontal planes at the unit of distance apart, one of which is fixed, while the other moves with the unit of velocity, the space between being filled with the viscous substance." In CGS units this force can be expressed as dynes per square centimetre. The viscometers generally used for commercial purposes consist of metallic or glass pipettes having short jets of comparatively wide bore, through which the rate of flow is by no means proportional to the viscosity, except within certain limits. In using the Redwood instrument the time of outflow of 50 c.c. of the liquid in seconds is termed the "viscosity." The Saybolt viscometer is similarly used, but 60 c.c. is the standard volume. With the Engler viscometer the time of efflux of 200 c.c. is taken; this is divided by the time of outflow of the same volume of water at 20° C., and the quotient is called the "specific viscosity" or "Engler degree." None of the figures obtained with either of these instruments has any absolute significance, and to add to the confusion, individual specimens of the standard instruments do not always agree with one another.

Viscosity in centipoises.

Twenty-one years ago Mr. R. M. Deeley and the author advocated the expression of viscosity values in absolute measure, and we suggested that commercial viscometers should be calibrated with glycerol solutions of known viscosity with this object in view. Deeley and Parr in 1913 suggested that the absolute CGS unit of viscosity should be known as the "poise" (after Poiseuille), and more recently Bingham and Jackson, of the U.S. Bureau of Standards, have proposed as unit the "centipoise," designated by the letters "cp," to avoid the use of an inconveniently large unit. The generally accepted value of the viscosity of water at 20° C. is 0·01005 poise, and on the centipoise scale this becomes 1·005, and at 20·2° C. 1·000. The viscosity of oils and other liquids, if expressed as centipoises, is therefore accurately stated in terms

---

* "Theory of Heat," 9th edition (1888), p. 298.

of the viscosity of water at 20·2° C. taken as unity. The general adoption of this unit would be very desirable, and in the preceding table the approximate viscosities are given in centipoises of a few well-known lubricating and other oils at different temperatures.

Effect of pressure on the viscosity and density of lubricating oils.

A very useful piece of work carried out for the Lubrication Committee of the Department of Scientific and Industrial Research[*] had reference to the effect of high pressure on the viscosity and density of lubricating oils. No work of this kind had previously been done on lubricating oils although Prof. Faust of Göttingen in 1914 made some experiments with a few volatile liquids, including ether, alcohol, and carbon bisulphide. For the experiments on lubricating oils Dr. Stanton and Mr. Hyde of the National Physical Laboratory devised apparatus of novel design (see Hyde, Proc. Royal Soc., 1920, A. 97, 240). Viscosities were determined by measuring the rate of flow through glass capillary tubes fixed inside a closed apparatus constructed of steel into which the oil was pumped up to the required pressure. The flow took place under a small head of mercury maintained constant throughout the experiment by a very ingenious method devised by Dr. Stanton. The effect of high pressures on the densities of the oils was determined by a method devised by Mr. Hyde in which the contraction of volume of the oil was measured by gauging the distance to which a steel plunger was forced into a steel tube containing the oil when under pressure. The determinations of viscosity were made at 40° C., and it was found that all the mineral oils tested, ranging in viscosity from F.F.F. cylinder oil to "Bayonne" engine oil, were very much more susceptible to change under pressure than the animal and vegetable oils. Thus, at 6·5 tons per square inch the viscosity of "Mobiloil B.B." had increased in the ratio of nearly 27 to 1, that of Mobiloil "A." and F.F.F. cylinder oil nearly 11 to 1, and "Bayonne" oil 9½ to 1, but castor oil had only increased 4½ to 1 and the other vegetable and animal oils still less. That this difference in behaviour had no connexion with the changes in density caused by the pressure was proved by the fact that all the oils were found to be equally compressible and resembled water in this respect.

Solid contact friction.

The work of Tower and the theory of Reynolds dealt with only one aspect of lubrication, viz., that in which a film of liquid oil completely separates the solid surfaces. There are, however, many conditions and many parts of machinery in which the liquid oil-film cannot form completely and in which the friction to be overcome is due, more or less largely, to contact between solid and solid. Such a condition occurs in every bearing when starting from rest and before coming again to rest. It occurs when the bearings are new and have not become properly bedded. It also occurs whenever the speeds are so low or the pressures so high that the oil-film cannot form completely, or becomes broken. It is, in fact, inseparable from certain types of machinery, such as the various forms of gearing. Very high pressures, amounting to tons per square inch, are met with in gear, so high in fact that it is said the metallic parts may be caused to flow and change their shape, yet lubrication is possible and the loss of power in transmission may be reduced to very small dimensions. This has been proved by means of the worm-gear testing machine designed by Mr. F. W. Lanchester (Proc. Automobile Eng., 1913, 7, 212). In this machine, by direct measurement of the ratio of the torques in the worm shaft and worm wheel shaft, the efficiency of power transmission can be measured with an accuracy of 0·2%, and when transmitting as much as 50 h.p., and with a pressure between the teeth of the order of 5 tons per. square inch, an efficiency of over 97% is obtainable.

In experimenting with this machine, Mr. Lanchester noticed a remarkable difference between the lubricating values of mineral oils and vegetable oils. He states that "not only did two oils of the same, or nearly the same, viscosity often give entirely different readings, such for example as a mineral oil in which the coefficient of friction might be nearly double that of an animal or vegetable oil, but the curves given by different oils were so characteristic that with a little experience it was almost possible to say what oil was being used from an inspection of the plottings of the efficiency readings." It is, in fact, now recognised that viscosity is by no means the only important property of lubricants, but there is another equally important property which is known as "oiliness."

A series of tests of great interest was made for the Lubrication Committee with the Lanchester machine. Five mineral oils ranging in viscosity from F.F.F. cylinder oil to "Bayonne" engine oil were compared with two vegetable and two mineral oils ranging in viscosity from castor oil to sperm oil. In making a test with this machine, the temperature of the oil is rising all the time and the viscosity falling; in the case of all the mineral oils tested, it was found that when a certain temperature of the oil was reached the running of the gear became unsteady and the efficiency began to fall more or less rapidly. Experiments were continued beyond this "critical temperature" until it was considered that the test could not be carried further without risk of injury to the gear. In the case of the vegetable and animal oils no critical stage was reached at temperatures below 75° C., at which point the experiments were usually stopped. One experiment with castor oil was taken up to 100° C., but still no critical point was observed. The maximum efficiencies of the gear and the "critical temperatures" of the oils in one series of tests were as follows:—

Mean distributed load on teeth of gear 1½ tons per sq. in. Mean speed of worm-shaft, 1080 revs. per minute. Average horse-power transmitted, 33·5.

Oil.	Max. efficiency.	Critical temp.	Viscosity (approx.) in poises at the critical temp.

Aircraft castor (V.) ..	96·1		

M., Mineral oil. V., Vegetable oil. A., Animal oil.

A study of the curves[*] shows that castor oil gave the highest efficiency at the particular value of the load employed. As the temperature rose from 30° C. upwards, the efficiency of the gear when lubricated with this oil remained nearly constant at 95·6% reaching a maximum of 95·7%. A sample of aircraft castor oil gave a still higher maximum efficiency of 96·1%. Rape and trotter oils came

[*] Fig. 4 of Mr. Hyde's 1st Report to the Lubricants Committee (p. 60 of Report).

next to castor oil in order of merit. The efficiency of both these oils remained practically constant at between 95 and 95·2%. Sperm oil, although giving a high maximum efficiency at the start, showed a general decrease in efficiency as the temperature rose, but appeared to have obtained a steady value at about 65° C. The efficiency of the sperm oil at the lower temperatures was as high as that of the best lubricant used, but fell off as the temperature rose. All the mineral oils, Bayonne, Victory red, filtered cylinder, and the two Mobiloils gave lower average efficiencies than the vegetable and animal oils and, as already stated, showed the characteristic of a marked drop in efficiency when a particular temperature was reached. This was accompanied by the machine suddenly becoming unsteady, owing to the partial failure of the lubrication. Violent oscillation of the gear box occurred, and readings were very difficult to obtain. This critical temperature remained the same within 1° or 2° when the load was doubled.

Further tests made with Bayonne mineral oil[*] showed an appreciable increase in efficiency, amounting to about 2·5% when the pressure was raised from 0·5 to 1·5 tons per square inch at a speed of 1500 r.p.m. and to 2 tons per square inch at a speed of 1080 r.p.m. No explanation of this has been suggested. A small increase in efficiency also occurred when the load remained constant and the speed of the worm-shaft was increased from 500 to 1200 r.p.m. This does not seem remarkable, but it is curious to note that further increase of speed to 1500 r.p.m. did not cause any change.

The addition of rape oil to the mineral oils did not increase the efficiency very appreciably, but the critical temperature of the oil to which the rape oil was added was raised a few degrees (18° C. in the case of the F.F.F. cylinder oil and rather less with the other oils). This effect was obtained by adding as little as 2½% of rape oil, and increasing this up to 25% did not cause much further improvement. There was, however, some indication that a higher percentage of rape oil would have increased the efficiency at the higher temperatures.[†]

The particular interest in these experiments lies in the remarkable difference in behaviour between the mineral oils and the fatty oils, and as shown by the figures in the fifth column of the table, there is no connexion between the "efficiency" or the "critical temperature" and the viscosity of the oil tested. At the pressures used in these tests, the viscosity of castor oil is about six times as great as that of the trotter oil at the same temperature, and yet the frictional resistances were very nearly the same.[§] The reduction of friction must, therefore, have been due to some property of the lubricating oil other than viscosity, and the results show that this property is possessed in greater degree by animal and vegetable oils than by mineral oils. This is the property which has come to be designated by the term "oiliness."

Oiliness and its measurement.

Oiliness is not a simple physical property of lubricants, like viscosity, and it has not hitherto been easily measured. None of the oil-testing machines usually found in engineering laboratories are capable of measuring it. They are usually run at such speeds that a complete film of liquid oil forms between the friction surfaces, and they measure the friction due to the viscosity of the oil. Even at very low speeds, indeed, most of the friction is liquid friction. In the early days of the Lubrication Committee attention was called to the property of oiliness as one of the most important for investigation, and in order to provide means for measuring it, my colleague, Mr. Deeley, designed a new machine which will become, in my opinion, an indispensable instrument of the oil-testing laboratory. Its design depends upon the fact that when two lubricated surfaces are at rest and in close contact, the static friction or force required to cause movement depends upon the relative slipperiness of the surfaces. The machine comprises two opposing friction surfaces, the lower one a plane disc about 3¼ in. in diameter which can be slowly rotated, and the upper surface of the faces of three flat-ended pegs, each $\frac{6}{32}$ in. diameter, spaced in a circle on the underside of a weight-carrying frame which rests upon the lower plane disc. This lower disc lies in a circular pan in which it can be flooded with the oil to be tested. The feet of the upper disc stand in the oil upon the lower disc. Two pillars fixed in the upper disc actuate a torque-measuring device, consisting of a coiled spring and train of nearly frictionless wheels, by means of which the force required to cause the pegs to slip when the lower disc is rotated can be measured and expressed as the coefficient of the static friction between the surfaces. The lower the static friction, the greater the oiliness or friction-reducing value of the lubricant. The machine is quite portable, takes up no more room than a viscometer and can be worked by hand or by means of a small motor. The following results were obtained by Mr. Deeley with this machine:—

Description of oil.*	Mild steel on cast iron.		Mild steel on lead bronze.		Absolute viscosity at 20° C. (approx.)
	Static coefficient.	Efficiency.	Static coefficient.	Efficiency.	
H.B. clock (M.) ..	0·271	72·9	0·275	72·5	?

* A., Animal oil. V., Vegetable oil. M., Mineral oil. B., Blended oil.

The numbers representing efficiency were calculated by the formula:—

$$\text{Efficiency} = 100 - (\text{static coefficient} \times 100).$$

Three main facts emerge from a study of the figures in this table. The first is that the oils in general range themselves in the order in which practical experience would place them. Those oils, in fact, the static coefficients of which stand lowest in the list, are the oils which in practice have proved to be the best lubricants under conditions in which solid friction occurs. Thus, rape, olive, trotter, and sperm oils give the lowest friction, and the pure mineral oils the highest; castor oil gives a value intermediate between the two classes. The next point is that the static friction bears little or no relation to the viscosity, even among the oils of the same class, although the exceptionally high viscosity of the castor oil does, no doubt, account for its position in relation to the other fatty oils in the list. The third, very important, point is that the surfaces in contact have a great influence upon the friction. Thus, there is a marked difference between the friction values of most of the oils, according to whether the steel studs were resting upon the cast iron or upon the lead bronze. Rape and olive oils gave exactly the same coefficients

---

[*] Fig. 2 of Mr. Hyde's 2nd Report, following p. 70 of Report of Lubricants Committee.

[†] Figs. 3 and 4 of Mr. Hyde's 2nd Report.

[§] The viscosities given in the table are at atmospheric pressure.

between steel and cast iron, but very different values between steel and bronze, and the same is nearly true of sperm and trotter oils.

The importance of the friction surface is well known in the case of the white alloys known as "anti-friction metals." In some recent tests of a mineral lubricating oil under conditions in which there was solid as well as fluid friction, Mr. Ekins found in my laboratory with the Thurston machine that under the same conditions of load and speed, and with the same oil, bearings lined with white metal could carry double the load carried by plain bronze bearings without any increase of the friction. Professor Goodman, many years ago, noticed that the presence of traces of bismuth and other metals had a great effect in modifying the friction of a white metal surface. He found that if the added metal had a smaller atomic volume than the white alloy the friction was increased, but if it had a greater atomic volume the friction was diminished.

Mr. Deeley concludes, as the result of his experiments, that oiliness is an effect produced by the lubricant upon the metallic surfaces with which it is in contact, rather than a property of the lubricant as a liquid. He considers that the unsaturated molecules of the lubricant enter into a firm physico-chemical union with the metallic surface, forming a friction surface which is a compound of oil and metal. Even when dry, such a surface differs remarkably from a clean metallic surface. It is a common workshop experience that when the contaminated skin of a metallic surface has been removed by a file, the teeth of the file cut the metal and remove it easily, but if such a clean surface of metal be slightly oiled, or even if the hand be rubbed over it, the file will not cut anything like so freely. Thin films of matter of this kind cannot be wiped off. It is necessary to grind the surfaces in order to remove them. This view of the nature and cause of oiliness is fully in accord with other recent work, as will be shown later.

Two conditions of lubrication.

It appears from the foregoing that two entirely different conditions have to be considered in connexion with the problem of lubrication, viz.:—

(1) the condition in which the solid surfaces become completely separated by a film of liquid oil which forces itself between them, and

(2) the condition in which no such oil-film can form, and the solid surfaces come into close contact and rub against one another.

In the first condition—*liquid film lubrication*—the friction depends upon the viscosity of the lubricant.

In the second condition, which may be termed "*solid film lubrication*," the efficiency of the lubricant depends, not upon its viscosity, but upon "oiliness."

Between surfaces lubricated by a liquid film the coefficient of friction F/W is as low as 0·002 to 0·004, but between well lubricated solid surfaces, rubbing in contact, it is very much higher, say 0·1 to 0·3.

Thickness of lubricating films.

Even in liquid film or viscous lubrication, the films of lubricant between the friction surfaces are not more than a few thousandths of a millimetre thick. Thicknesses ranging from 0·005 to 0·08 mm. have been measured. Such exceedingly thin films contain, however, in their thickness many hundreds of molecules and possess the very low internal friction and other properties of true fluids. Very much thinner films than these—films of such excessive tenuity that they can no longer be regarded as fluids—can nevertheless act as lubricants. The late Lord Rayleigh in 1918 (Phil. Mag., 35, No. 206, p. 157), experimenting with a small carriage on three glass feet moving over a sheet of glass, found that the friction between the glass surfaces was extraordinarily high when the surfaces were chemically clean, but was so much reduced by merely going over the glass with the fingers that free movement ensued. He attributed the lubricating effect to an invisible film of grease derived from the fingers, and he estimated this to be probably not more than one molecule thick.

That films of mono-molecular thickness can lubricate has since been confirmed by other observers. In a recent paper by Langmuir on "The mechanism of the surface phenomena of flotation" (Trans. Faraday Soc., 1920, 15 [3], 62), the author describes a remarkable experiment in which he succeeded in transferring to glass from the surface of water a film of oleic acid of mono-molecular thickness, and he showed that whilst the friction between chemically clean and dry glass surfaces was so great that a three-legged glass slider failed to move until the glass slide was tilted to an angle of 70° or more, this molecular film of oil reduced the angle to as little as 6° or 10°. These films are very tenaciously held and cannot be wiped off. In fact, a chemically clean surface of glass soon acquires such a film spontaneously by condensation of impurities from the atmosphere, especially the air of towns. The films behave, in fact, as if they were chemically combined with the surface. The theory as to their formation is closely connected with recent developments in physical chemistry, especially in regard to the activities of surfaces, the most important papers from the point of view of lubrication being those of Langmuir and Harkins, independently communicated to the American Chemical Society in 1916 and 1917, and the more recent paper by Langmuir referred to above, also the papers by W. B. and J. K. Hardy in the "Philosophical Magazine" of July, 1919, and August, 1920, and the "Discussion on lubrication" at a meeting of the Physical Society in November, 1919.

Langmuir's earlier papers do not refer specifically to the subject of lubrication, but are chiefly concerned with the surface activities of solids and liquids, based upon the researches of Prof. W. H. Bragg and his son on the atomic structure of crystals. By means of X-rays the Braggs have been able to make out exactly how the atoms are arranged in crystals, and it follows from their work that in the surfaces as well as in the interior of all crystalline solids, including metals, the atoms are arranged in a definite pattern or lattice formation. It has been customary to consider the forces holding together the constituent particles of solids and liquids as "forces of cohesion," and to call these "physical forces" as distinguished from chemical forces. Langmuir's theory is that the atoms are held together entirely by chemical forces, and that the special surface activity of both solids and liquids is due to the "residual valency," or the "unsaturated chemical affinity" of the atoms. In the summary to one of his papers (J. Amer. Chem. Soc., 1916, 38, 2221—2295) Langmuir says, "Since energy must be expended in breaking apart a solid, the surface of solids must contain more potential energy than do the corresponding number of atoms in the interior. Since this potential energy is probably electro-magnetic energy in the field between atoms, the interatomic forces are more intense on the surface than in the interior. This intense surface field of force (unsaturated chemical affinity) is one of the causes of condensation and adsorption." In a later paper (*ibid*, 1917, 39, 1881) Langmuir gives experimental evidence showing that "the spreading of films on surfaces is determined by the shapes of molecules and the relative activities of the different portions of the molecules." The fact that vegetable oils, such as olive oil, spontaneously spread on the surface of water, whilst pure saturated hydrocarbon oils, as

Hardy has shown, do not spread, is explained by Langmuir as due to the presence of an "active group" in the molecule in the former case and its absence in the latter. In both cases the molecule consists of a chain of atoms, and in the case of the fatty oils his theory is that the glycerol ester end of the molecular chain tends to dissolve in the water, whilst the insoluble hydrocarbon end refuses to do so, with the result that the molecule stands on end, and the surface of the water is covered with a layer or film of closely packed molecules, standing erect, the thickness of the film depending upon the length of the chain of atoms forming the molecule. On the other hand, the saturated hydrocarbon oil molecules, with hydrocarbon groups at each end of the chain, have no tendency to dissolve, and refuse to spread. Langmuir applies the same theory to the spreading of films on solid surfaces. On page 1901 of the paper just quoted from he says, "Consider first the adsorption of a liquid by a plane solid surface. If the molecules of the liquid contain active groups, the molecules will become oriented and will pack into the surface layer in much the same manner as in the case of oil films spread on the surface of water."

The importance of this theory in connexion with lubrication and the problem of oiliness is obvious, especially as we know that the best lubricants do contain in their molecules "active groups," which Langmuir holds to be necessary to cause them to pack into the surface layers of the solids to be lubricated. Dunston and Thole, in a paper read before the Institution of Petroleum Technologists in 1918, laid stress upon the importance in lubricants of the unsaturated compounds, *i.e.*, those compounds whose chemical affinities being incompletely saturated possess most residual affinity. Such compounds form a large proportion of all mineral lubricating oils, and Mabery and Matthews long ago showed that viscosity increases with the degree of unsaturation of the hydrocarbons. Thus, the property of viscosity, which is of chief importance in oil-film lubrication, and "oiliness," which is the property most active in reducing solid or contact friction, may both depend, in the case of mineral oils, upon the unsaturated constituents. Fatty lubricants also contain in their molecules double bonds, and those oils rich in these constituents, such as rape oil, olive oil and castor oil, are superior in "oiliness" and viscosity to the more saturated products, such as tallow, and to the mineral lubricating oils.

Messrs. Hardy's interesting papers to which reference has been made were suggested by Lord Rayleigh's experiments in 1918. The authors show that if two chemically clean and smooth surfaces of glass are brought together until they touch, the parts which actually come into contact seize and sliding movement of one surface over the other is rendered possible only by particles being actually torn out of each surface. This, in their opinion, s the cause of static friction. If a lubricant be applied to the surfaces, in such small quantity as to form a perfectly invisible film, the resistance to sliding movement is reduced, owing to the formation of a new "composite surface" and a reduc-ion of the surface energy, the composite surface being formed by the neutralisation of chemical orces at the surface of the solid and of the lubri-ant applied to it, which is only another way of xpressing Langmuir's theory. Messrs. Hardy's xperiments were not made under conditions n which the static friction could be quantitatively measured, and the surfaces in contact were not uch as are met with in machines. All their ex-eriments have been made between similar sur-aces, either glass on glass or bismuth on bismuth, no surface being convex and the other flat, and ith pure chemical substances, their object being to ascertain the influence of chemical constitution on lubrication. The results are complex and difficult to summarise, and their papers should be consulted. They find that pure chemical substances can be divided into two groups, active and inactive, those capable of forming lubricating films on surfaces and those inert in this respect; also that the same substance may be a bad lubricant, or inert, on one kind of surface and a good lubricant on another.

The power of a lubricant to lubricate a surface depends, as we have seen, upon an interaction between the lubricant and the surface. The molecules of the liquid have freedom of movement, which the atoms or molecules of the solid have not. The surface configuration or space lattice of the atoms in the solid surface is fixed, and differs in different solid surfaces. It is conceivable that the active molecules of the liquid which interact with the solid surface, owing to variations in their size, shape, and constitution, may vary in their ability to fit into the space lattices of different solid surfaces, and so some liquids will lubricate a given surface better than other liquids. "The films on solids," says Langmuir, "are ordinarily not in stable equilibrium; many molecules are crowded into spaces too small for them, whilst others may occupy unnecessarily large areas." If this be so, it is easy to understand why a good lubricant between one pair of surfaces may be an indifferent lubricant between another pair.

It may be concluded that when a lubricating oil wets the surface of a bearing a layer, one molecule thick, becomes absorbed by the metal and forms part of the solid surface. This absorbed film entirely changes the physical character of the surface and lowers the static friction. The best lubricants are those most active in this respect, and the mineral oils which are deficient in oiliness can be improved by dissolving in them substances whose molecules are more active. This, in my opinion, is the true explanation of the remarkable effect caused by adding small quantities of fatty acids to mineral oils. I have already in the discussion on Messrs. Wells and Southcombe's paper (J., 1920, 55 T) given the results of some tests made with the Thurston machine.

Dr. Stanton was good enough to make some tests for me with the Lanchester worm-gear testing machine, comparing the behaviour of Bayonne mineral oil used alone with the same oil mixed first with 10% of commercial rape oil containing 1·86% of free fatty acid and then with 10% of the same rape oil deprived of nearly all its free fatty acid (actual percentage present 0·13%). The results show a decidedly higher efficiency with the mixture containing the acid rape oil. Bayonne oil to which 1% of rape oil fatty acids was added gave nearly as good results as the mixture containing 10% of commercial acid rape oil.

Some further tests have been made at the National Physical Laboratory with the Lanchester worm gear, comparing a straight mineral oil with a mixture of the same oil with 0·5% of free fatty acid. In these, as in the previous tests, the speed of the worm was 1100 r.p.m., and the nominal mean distributed pressure on the worm wheel teeth 1·5 tons per sq. in., the load on the actual area of contact being, of course, considerably greater. Thirty-four horse-power was transmitted. The pure mineral oil gave a constant efficiency of 95·95% up to a temperature of 100° F., at which temperature the efficiency suddenly fell off, and continued to do so as the temperature rose, as is characteristic of mineral oils. The mixed oil, containing only 0·5% of free fatty acid, gave a higher efficiency, 96·2%, and this was continued up to 120° F., and no sudden breakdown then occurred, but the efficiency gradually fell off.

These same two oils were tested by Mr. Deeley on his machine and gave the following results:—

Pressure, lb. per sq. in.	Straight mineral oil.	Same mineral oil +0·5% F.F.A.
	Static friction.	
10	8·80	6·40
20	18·80	12·40
30	27·20	21·20
40	34·80	27·10
50	45·40	31·20
60	58·00	39·10
70	61·70	42·10
80	66·50	50·00
90	89·50	57·60
100	107·10	64·70

The figures in this table under "Static friction" are the actual deflections of the needle read off on the scale, from which the coefficients of friction can be calculated. It is noteworthy that with the straight mineral oil the friction under the highest pressures increased in greater proportion than the load increased, whilst with fatty acid present this was not the case.

Further tests were carried out by Mr. Deeley with his machine on four different pale mineral oils and four red mineral oils; it was found that although the viscosities of these oils varied very considerably (63—167 cp. at 70° C. for the pale and 108—273 cp. for the red oils), the static coefficients of friction were nearly the same in the case of the four pale oils (0·223—0·239) and were also alike in the case of three out of the four red oils (0·253—0·259), showing again that the results obtained with this machine do not depend upon viscosity.

Very careful tests have been made by Mr. Hyde with the Deeley machine at the National Physical Laboratory, and the results were published in "Engineering" of June 10, 1921. Mr. Hyde found that the addition of as little as 0·1% of rape oil fatty acid to a mineral oil lowered the coefficient of static friction from 0·132 to 0·092, a reduction of 30%. He also found that 1% of oleic acid lowered the friction nearly as much as 10% and that further additions of oleic acid up to 100% did not lower it very much further. An interesting observation was made by Mr. Hyde of a "time effect" when testing mixtures containing neutral rape oil. A mineral oil to which 8% of neutral rape oil was added gave a friction coefficient of 0·117 immediately after the oil mixture had been poured on to the disc. Twenty minutes later the friction had fallen to 0·100, and the same result was obtained after 24 hours.

Tests with the Thurston machine, the Lanchester machine, and the Deeley machine are, therefore, all in agreement as to the value of free fatty acids, and there is no doubt that this discovery is one of great importance. If animal and vegetable fats and oils, which are required for food and for the manufacture of soap and glycerin, paint and varnish, and for other purposes for which their chemical composition essentially fits them, can be replaced by a little fatty acid, it is a pity they should be wasted in lubricating machinery. Not only so, but it will be a great advantage to dispense with lubricants which so readily oxidise, gum on the bearings, and develop free acids which corrode. I do not think free fatty acids will entirely replace glycerides for lubrication, but there is every reason to believe that they could replace the greater part of the glycerides at present used.

Solid lubricants.

A few minerals—mica, talc, soapstone, and graphite—act as natural lubricants. Langmuir found that the surface of freshly split mica (biotite) was as slippery as a glass surface lubricated with a film of oil, a glass or platinum slider slipping at the same angle on both. Graphite is by far the most important of solid lubricants. Natural graphite is found in the flake form and also amorphous, but the kind usually employed as a lubricant is the flake graphite. Amorphous graphite is made in the electric furnace, and by methods which have been described by Dr. Acheson is obtained by him in a colloidal form and sold, mixed with water, under the name of "Aquadag" or, mixed with oil, as "Oildag." The principal advantage of colloidal graphite is that it will remain suspended in water or oil for an indefinite period, provided the fluid medium remains neutral in reaction; natural graphite, and also artificial graphite which is not in the colloidal state, rapidly settle out and cannot, therefore, be used in admixture with oil unless the mixture is continually stirred.

In the lubrication of machinery, solid lubricants are used either dry, mixed with grease, or mixed with oil. On certain parts of lace-making machinery dry graphite is used as a lubricant to avoid staining the fabric with oil, also in chocolate-making machinery to avoid getting oil into the chocolate. Of course, the speeds of such machines are low and the pressures light. There are also instances where machines have to work at very high temperatures (bottle-making) in which only a non-combustible lubricant can be used. Another instance occurs in the production of tungsten wire filaments for electric lamps by hot drawing through diamond dies. Here "Aquadag" is used as a lubricant. The wire is passed through the "Aquadag" paste and then through a gas flame, which heats the wire to the required temperature and bakes on it a coating of the lubricant. This is said to be the chief purpose for which "Aquadag" is used at present. In all these cases the solid lubricant is used to avoid troubles arising from the use of oil. The point which the Lubrication Committee wished to determine was whether, and if so in what way, the addition of graphite to a lubricating oil was beneficial, and how the natural and colloidal forms compared with each other in efficiency. A number of tests were made with the Lanchester worm gear testing machine, "Oildag" being used in one series of tests and "Foliac" No. 100 natural graphite in the other. The results showed that in both series of tests graphite had a beneficial effect with some oils, but not with others. With some oils flake graphite gave the best results, and with others colloidal graphite. The most marked effect, an increased efficiency of 1·25%, was obtained by adding "Foliac" graphite to an animal (trotter) oil. "Oildag" added to the same oil had scarcely any effect. Bayonne (mineral) oil was improved almost equally by "Foliac" graphite and by "Oildag"; Mobiloil A.—another mineral oil—was not much affected by either. Castor oil was a little improved by "Oildag" and not improved by "Foliac." In the case of the mineral oils the graphite generally had the effect of raising the temperature at which unsteady running and a falling-off of efficiency of the gear took place. The results on the whole showed that it is worth while to add graphite to a gear oil, and best to add it in the colloidal form because, although flake graphite may give a higher efficiency, it does not remain suspended in the oil unless continually stirred, and it causes greater wear of the lubricated surfaces.

The Lubrication Committee made extensive inquiries from users of solid lubricants and published the information obtained in the "Memorandum on Solid Lubricants" issued last year. On heavily loaded bearings, and whenever the conditions are liable to cause heating, solid lubricants added to the oil have been found useful, also in cases where lubrication is apt to be neglected.

One of the most interesting instances of the successful use of graphite in steam cylinder and valve lubrication was given by E. W. Johnston in a paper read before the Birmingham Association of Mechanical Engineers in 1916. Oil carried forward in the exhaust steam from cylinders lubricated with oil is frequently the cause of a great deal of trouble when such steam is required for heating or drying, or for washing or cooking, and when the condensed water is passed back into the boilers. Oil separators such as Princep's will remove the greater part of the oil from the steam if a pure mineral oil is used for lubrication, and chemical or electrolytic separators are very efficient in removing oil from condensed water, but none of these appliances effects complete removal of the oil, their cost is considerable, and their efficiency is dependent upon the care used in working them. If, therefore, cylinders and valves can be efficiently lubricated without the use of oil, all this trouble and expense is avoided. This Johnston claims to have done on a plant including three 50 kw. high-speed vertical steam dynamos, two deep borehole pumping engines, and other small pumps working with saturated steam at 120 lb. pressure. Johnston first devised a special form of lubricator having the sight feed-glass filled with petroleum, through which the drops of "Aquadag" were arranged to fall, and which worked quite successfully. Having obtained satisfactory results for a period. one of the high-speed engines, after accurate gauging of the valves and cylinders, was put on a six months' running test. At the end of this period the greatest wear at any point was found not to exceed 0·001 in. The walls of the cylinders and the surfaces of the piston rings had a mirror-like appearance. A set of indicator cards taken on full load, compared with those taken by the makers during the official test when the engines were new, showed a difference of only 0·6% after two years' working on "Aquadag" lubrication. Micrographs taken from the surface of a piston ring showed that the graphite had filled up the pores of the cast iron and produced a smooth surface. There was no evidence that it had penetrated into the iron, except in one small place. In a letter in April last Mr. Johnston informed me that "Aquadag" has also been used successfully on horizontal engines and with heavy "D" slides with satisfactory results. In reading his paper in 1916 he exhibited a slide valve from a Worthington type feed pump, the surface of which was perfect, although, as he stated, it had been working for $2\frac{1}{2}$ years at 120 lb. pressure with no other lubricant than "Aquadag." These remarks apply to cylinders lubricated with saturated steam. In the case of cylinders using superheated steam the surfaces are drier and more difficult to lubricate owing to the higher temperatures. Graphite has been used for such purposes, mixed with cylinder oil, and the results have been sometimes successful and sometimes not. The failures with natural graphite are attributed to its being used in excess. Colloidal graphite is more likely to be successful, and no failures have been reported where it has been used. The railways are considerable users of superheated steam for locomotives, but so far as I am aware no careful trials of colloidal graphite have been made. Much trouble is experienced from carbonaceous deposits in the cylinders, and it seems worth while to try whether by the use of colloidal graphite in the cylinder oil the quantity of oil used could be reduced and the carbon deposits lessened.

Among the advantages derived from the use of graphite in lubrication are greater ease in starting, owing to the reduction of the static friction. I have no doubt that in most cases the graphite used for lubrication should be in the colloidal condition. But unfortunately this is the condition in which it is most sensitive to external influences, and great care is needed in the selection of the oils with which it is used, to use such as are quite neutral in reaction and most likely to remain so during use. When the conditions are such that the graphite and oil are mechanically churned and prevented from separating, natural flake graphite is likely to be as effective. The purity of the graphite and freedom from grit are the essential points then to be considered.

London Section.

Meeting held at Burlington House on November 7, 1921.

MR. E. V. EVANS IN THE CHAIR.

COMPARISON BETWEEN LABORATORY FUEL TESTS AND PRACTICAL WORKING RESULTS OF THE PRODUCER-GAS PROCESS.

BY N. E. RAMBUSH.

When I presented my paper on "Thermal losses in the gas-producer process" (J., 1921, 129 T), I was asked to elucidate a certain point referring to the method employed for determining in the laboratory the tar yield of fuels that might be expected under practical operating conditions. The present paper describes the apparatus used, and results obtained on the same fuel in the laboratory and on large-scale gasification.

The problem of converting a certain fuel into producer-gas introduces four points of main interest:—

(A) How much heat will be retained in the gas as potential heat?

(B) What will be the heating value of the gas?

(C) What amount of by-products is it possible to recover?

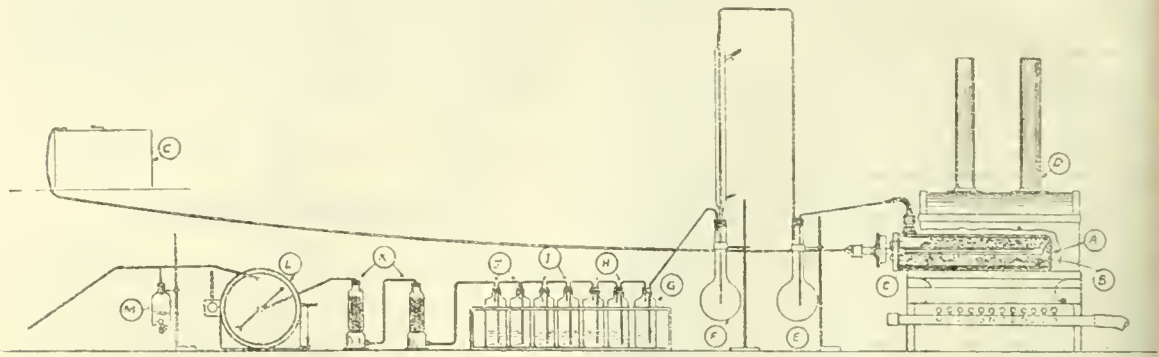
(D) What sort of plant is required?

In my previous paper I elaborated a method for dealing with item (A) above, and summarised the thermal losses as being due to:—(1) Moisture content in fuel, (2) nature of volatile matter in fuel, (3) grading of fuel, (4) soot formation, (5) ash content of fuel, (6) radiation and convection losses to atmosphere, (7) gas leakage losses, (8) losses in washing liquors, (9) moisture content of the gas, (10) the temperature of and sensible heat in the hot gases leaving the producer. The losses under items (4), (6), and (7) depend mainly on the design and working principle of the apparatus used, while items (1), (3), and (5) can be based on data obtained from the usual ultimate fuel analysis.

The ordinary fuel analysis—in particular in regard to the determination of the volatile content—is, however, insufficient to predict what products can be obtained in the gasification process; on the other hand, a distillation test carried out with a reasonably large quantity of fuel will permit the segregation of the quantities of gaseous and liquid products obtainable from the fuel, and give an idea as to their probable composition when working on a large scale.

Distillation test apparatus.

The apparatus employed is shown diagrammatically in the accompanying figure. It consists of a simple horizontal distillation retort with a condensing plant:—A is a hæmatite iron retort of about 350 cub. in. capacity, B is a protection plate to avoid "scorching" of fuel, C the pyrometer to assist control of the progress of distillation, D the gas-fired furnace, E the first condensing pot with superimposed reflux type air condenser, F the second condensing pot with superimposed down-flow water condenser. G, H, I, and J are catch bottles containing water, sulphuric acid, heavy petroleum, and pure cresylic acid respectively, K indicates two drying towers containing charcoal and/or cotton wool, L is a gas meter, and M a gas testing bottle.



This apparatus has been found to be the best for the purpose; it is made up from such apparatus as can easily be obtained and put together in a small industrial laboratory, but obviously much more elaborate and probably more scientifically correct apparatus could be made. However, the weight balances (referred to later) that have been obtained will indicate that the experimental error in the apparatus employed is of such an order that the results can be adapted to practical conditions with reasonable accuracy.

The method of procedure when testing, say, a bituminous coal is as follows:—

After grading the crude sample, the whole is crushed, sampled for analysis, and 2 kg. of screened pieces between ¼ in. and ⅛ in. is placed in the retort, and the lid carrying the pyrometer sheath closed up tightly with the aid of Permac cement. All bottles are weighed previous to coupling up, and those containing liquids are filled to give a lutage of 10 to 20 mm. The gas for heating the retort is turned on, and the temperature is gradually increased until the evolution of tar and gas commences (generally 350°—400° C. for an English or Scotch bituminous fuel)) and then adjusted to give a reasonably regular gas flow through the meter, while hourly continuous gas samples are taken. When a maximum temperature of 800° C. is reached in the retort, the heating is discontinued and the apparatus allowed to cool to atmospheric temperature. The whole heating period generally takes from 4 to 6 hours. The coke residue in the retort is weighed immediately it is removed, an average sample taken, and quickly submitted for analysis to avoid air absorption. The remainder of the coke is preserved as indicating the comparative caking property of the coal.

The various bottles are weighed, and the increases in their respective weights noted, while the tar condensate from bottles E, F, G, and H is separated and, if present in sufficient quantity, it is fractionally distilled up to 350° C. The condensate thus separated, is classified as "tar," while the increase in weight of bottles I, J, and K is classified as "volatile oils."

The average gas composition is determined from the analysis of each separate gas sample, as well as from the rate of gas evolution during each particular sampling period.

A fuel test sheet and a heat balance sheet as shown are filled up. By summarising the information contained in two such sheets a large number of data are obtained upon which it is possible to predict such results as may be anticipated on a large working scale, as well as which type of plant will be the most suitable for a particular kind of fuel.

To explain further the way in which these results can be used 20 actual results of testing various fuels in this apparatus are given in the appended table.

Tests 1, 2, and 3 were made on a fuel—for which large-scale gasification test figures were available—with a view of determining which rate of distillation would give the most useful guide for a comparison with practice. It will be seen that a slow rate of distillation gives a more volatile tar, and probably some hydrocarbons are even so volatile as not to be caught in the oil absorption bottles, and thus escape as "gas." On the other hand, a 4- to 6-hour distillation rate gives the highest tar yield, and this rate should, in my opinion, be used as a basis for "the theoretical tar yield," inasmuch as the tar is more like that obtained in practice than when distilling at a slow rate.

The average tar obtained in practice from the same fuel over a 288-hour continuous test had the following composition:—

	Sp. gr.	% by vol.	% by wt.	Appearance of fraction.	Tar acids % in fraction.

The tar yielded by the laboratory test is, as will be seen, lighter than in the large-scale test, while the actual tar yield in practice was 5·2% against the laboratory yield of 7·24%, *i.e.*, the practical tar recovery was 72% of the theoretical. The reason for the lower tar yield obtained in practice may be due to two causes: (1) Some of the tar is decomposed in the gas producer. (2) The standard type of producer-gas cooling and condensing plant is not capable of removing the lighter oils. As far as I have been able to ascertain, the cause is mainly tar decomposition in the gas producer, and we are now in Stockton carrying out large-scale experimental work with gas producers having the object of preventing such a decomposition.

Test No. 4 also refers to a fuel where a large-scale practical gasification test was carried out, where the tar yield was 7·4% and of the following composition:—0°—170° C., 1·5%; 170°—230°, 7·8%; 230°—270°, 12·6%; 270°—350°, 20·7%; above 350°, 17·3%; residue, 37·5%. The practical tar recovery efficiency was 84% of the theoretical. The reason for explaining the higher tar yield in this latter case as compared with the fuel under tests 1 to 3 is that the fuel used was of a more even grading, thus tending to a more even gasification of the fuel throughout its whole mass.

The remaining tests on bituminous fuels, (5) to (11) inclusive, are mainly given with a view of showing how varying the tar yield may be. I hope that these figures will be sufficient proof that the theory that the tar yield is a function of the content of volatile matter (either in the pure coal substance, or in the actual fuel) is incorrect. See for instance the three South African fuels (9), (10), and (11); on some of these the tar yield is double that of others, and yet all are lower than the Welsh coal (6), which has nearly the same proximate analysis.

Test (16) is the final one of the series of tests made with a fuel on which large-scale gasification tests were available, and on which there was great difficulty in obtaining a proper weight and thermal balance, until the distillation apparatus used at that time was modified to the arrangement described above. The tar yield obtained in practice was 2% by weight of the dry fuel treated and the tar analysis:—0°—170°, 1·1%; 170°—230°, 2·0%; 230°—270°, 11·2%; 270°—300°, 13·4%; 300°—350° 17·2%; above 350° C., 15·3%; residue, 35·6%. Here again less tar is recovered in practice than indicated by the laboratory tests, the recovery being 73% of the theoretical. The reason for the low tar recovery I again attribute to the very uneven grading of the material used, causing uneven gasification, and thus uneven temperatures across the producer area.

The difference in the weight balances obtained when testing the wet and the dry fuel (15 versus 16) is worthy of note, and I have come to the conclusion that when testing fuels of a high moisture content it is essential to dry the fuels previous to submitting them to the distillation test, since the moisture content cannot be sufficiently accurately estimated to avoid serious discrepancies in the weight balance.

On all the tests on fuels with high volatile content (tests 12 to 20 inclusive), it will be noticed that there is a great thermal distillation loss, even when the weight balances are reasonably accurate. I can only attribute this discrepancy to the fact that exothermal reactions take place during the distillation. Although errors may creep in in sampling and determining the calorific values of the various distillation products, and these errors are higher in percentage the lower the calorific value of the fuel, yet it will be clear that there is practically always less (in some cases very much less) heat retained in the distillation products than existed in the fuel.

I have been able to separate absorbed hydrocarbon compounds from the liquor, but never obtained these in sufficient quantities to account for more than traces of the large thermal loss. Until more light is thrown upon that unknown factor "latent heat of distillation" I am of opinion that, when heating these high volatile fuels, there is set up an exchange of oxygen linkages with a consequent exothermal reaction, say two $=C=O$ links combined to give carbon (coke) and CO_2; similarly for any $=C-O-H$ links.

As is well known, fuels of high volatile content generally also have a high moisture content, for the gasification of which heat is required to be given off by the fuel itself. The heating value of the crude fuel indicates what heat is available by burning the fuel, and any heat not retained in distillation products will, except for soluble liquid or gaseous substances, be available to evaporate the moisture in the fuel.

Taking as an example (which supports the assumption made above) the case of test No. 16, we have the following thermal balance of distillation:—

1.	Potential heat in gas in millions of B.Th.U. net per ton T.D. fuel	2·96
2.	Potential heat in tar in millions of B.Th.U. net per ton T.D. fuel	1·73
3.	Potential heat in coke in millions of B.Th.U. net per ton T.D. fuel	8·5
	Total heat in distillation products	13·19
	Net heat in 1 ton T.D. fuel, million B.Th.U.	15·7
	Distillation loss	2·51

Or the distillation loss 16%.

Now if the gasification losses are calculated on lines such as I have previously communicated (*loc. cit.*) (eliminating entirely the distillation loss obtained in the laboratory tests) we get:—Moisture loss (51% H_2O in fuel), 17%; dust and soot loss, 1·5: ash loss (12% C in ash), 5·5; radiation and leakage, 3·0; tar loss, 7·0. Total, 34·0%, or 66% of the total heat in the fuel will be retained as sensible and potential heat in the gas.

The sensible heat loss for a gas outlet temperature of 100° C. is obtained as follows:—

$$\frac{\text{Initial heat}}{\text{Total heat}} = 94\ \%$$

i.e., sensible heat loss $= 6 \times 66/100 = 4\%$. Total estimated gasification loss $= 38\%$.

Allowing, say, 2% as a safety factor, the thermal efficiency of the gas producer in practice might be expected to be 60%.

On the other hand, if an allowance is also made for the thermal distillation loss obtained in the laboratory, a gas producer efficiency of 100 less (38+16), or 46%, would be obtained.

The actual gasification efficiency obtained in practice over a week's run was however 57%, *i.e.*, in very close agreement with the calculation, which assumes that the "distillation loss" is utilised in the producer itself and thus presents no actual gasification loss.

Thermal loss due to ammonia formation.

When the heating value of a fuel is determined all nitrogen and hydrogen is burnt in the calorimeter. When gasifying the fuel under ammonia-recovery conditions, however, some of the potential heat of the fuel will be retained in the ammonia. For each 1% of nitrogen in the fuel about 35 Cals. per kg. of fuel will be retained as the potential heat of the ammonia.

In case of the fuel 16, the heat loss due to ammonia (which has not been borne in mind in making the above calculation) is about 2·5% of the the heating value of the dry fuel. In other words, this heat loss is of such an order that it should have been taken into consideration, with the result that a still closer agreement would exist between the calculated efficiency and that obtained in practice.

Heating value of gas.

To determine the heating value of the producer-gas from the distillation test figures is a point upon which I do not yet possess sufficient data. The heating value of producer-gas made from practically any commercial fuel varies, roughly speaking, from 110 to 180 B.Th.U. net. per cub. ft. at N.T.P., and although the quantity of coke produced and the volume and components of the distillation gas will give an idea of any possible characteristics of the producer-gas, yet the problem is a very complicated one.

For instance, the higher all the gasification losses (except ash and tar loss) the lower will be the calorific value of the gas, since more oxygen is required in the air blast to burn such an amount of fuel in the generator as will give enough heat to balance all the thermal losses. However, when carbon in excess is being withdrawn with the ash, then the ratio between "distillation gas" and "coke gas" is increased with a consequent increase in the heating value of the mixture "producer-gas."

At the present moment I prefer therefore to use my own practical experience when assessing the possible heating value of the producer-gas. An example of the effect of the distillation gas quality upon the producer-gas yield and heating value may be found in the cases of the fuels referred to in tests No. 4 and No. 16, for each of which large-scale operating figures are available.

No. 4 gave in practice: Producer-gas, 130,000 cub. ft. at 155 B.Th.U. net per cub. ft. at N.T.P. = 20·2 million B.Th.U. Distillation gas, 7025 cub. ft. at 560 B.Th.U. = 3·93 mill. B.Th. U. Hence coke gas, 122,975 cub. ft. at x B.Th.U. = 16·23 mill. cub. ft.

$$x = \frac{16{,}230{,}000}{122{,}975} = 132 \text{ B.Th.U. net per cub. ft. at N.T.P.}$$

The gasification efficiency on 1538 lb. of coke was

$$\frac{16{,}230{,}000}{1538 \times 12860} = 82{\cdot}2\ \%$$

No. 16 gave in practice: Producer-gas, 70,700 cub. ft. at 127·5 B.Th.U. net per cub. ft. = 9·04 mill. B.Th.U. Distillation gas, 10,500 cub. ft., at 284 B.Th.U. = 2·96 mill. B.Th.U. Coke gas, 60,200 cub. ft. at x B.Th.U. = 6·08 mill. B.Th.U. Hence $x = 101$ B.Th.U. net per cub. ft. at N.T.P., and the gasification efficiency on 1080 lb. of coke was 71·6%.

It will be clear that, except when dealing with fuels that have an exothermal distillation heat, the coke remaining after the distillation test is that which in practice has to provide the heat required to make up for the thermal losses in the gas-producer, consequently there must be a relation between the coke gasification efficiency and the gas heating value; with a few more reliable observations from large-scale practice I anticipate that it will be possible to arrive at some guide to enable the probable producer-gas analysis to be calculated given certain conditions.

In test 16 the total gasification losses were estimated at 40% on the thermal value of the dry fuel; of this 40%, 7% was allowed for tar and thus retained in the tar recovered, while 16% is set free by internal reactions in the fuel: *i.e.*, the coke will have to supply as heat 40% less (16+7), or 17% of the total heat in the crude fuel, or $17 \times 15{,}700{,}000 \div 100 = 2{\cdot}67$ mill. B.Th.U. per ton T.D. fuel. Thus $2{\cdot}67 \div 8{\cdot}5 = 31{\cdot}7\%$ of the heat in the coke is used to make up losses, which compares favourably with the 71·6% "coke gasification efficiency" calculated above from practical observations.

Obviously, if about 30% of the coke is to be burnt in the producer, the gas must be more dilute than in case 4, where only about 18% is burnt, but whether the burning is to carbon monoxide or dioxide, hydrogen, etc. is yet impossible to say, and here is the yet unsolved question.

By-products.

A guide to the determination of the quantity of tar obtainable will be found in the above quoted comparisons between laboratory results and practice. Generally I would say that 80% tar recovery is what may be termed a good yield for present-day practice. It is, of course, obvious that the higher the tar yield the better, because tar or tar oils are far more commercially valuable per heat unit than the coal from which they are made. Our latest gas-producer developments at Stockton go to show that a still higher tar yield than 80% is not impossible of achievement.

As to the ammonia yield, the laboratory test gives the volatile ammonia, which can always be recovered in full in modern gas-producers. To liberate the nitrogen in the coke as ammonia, steam is required and the ammonia yield depends upon the quantity of steam admitted. We have in Stockton lately established beyond doubt that the quantity of steam is not the only governing factor; thus by gradually modifying and improving the gas-producer design we have as an ultimate result been able to obtain the same ammonia yield from a given fuel by using 1—1¼ lb. of steam per lb. of coal gasified, instead of the 2½ lb. formerly considered necessary to obtain this recovery.

In the table figures are given covering such ammonia yields as might be expected in practice from some of the fuels; the recovery efficiency for fuel 16 was 72% in practice—a very high figure indeed, considering that only about ½ lb. of steam was introduced per lb. of T.D. fuel treated, but no different from that which could have been predicted from the laboratory test, which shows a very high volatile ammonia yield.

Type of plant.

Coming to the fourth question raised—this is difficult to answer in a general way, each purpose and plant requiring special consideration. The following may serve as a rough guide:—Fuels of fine grading generally require large gasification areas. Those of high caking power should generally be mechanically stirred, and those of high ash content require mechanical grates. Fuels giving high tar yields should be gasified at low temperatures to give the highest yield of light tar oils, and fuels of high moisture content require deep fuel beds.

Summary.

(1) By conducting a proper and thorough laboratory investigation of the behaviour of the fuel upon distillation, it is possible to predict the thermal efficiency, tar yield, and ammonia recovery obtainable in practice.

(2) A tar recovery in practice of 80% of that obtained by the distillation test should be possible with well-designed plant, and the highest possible tar yield should be aimed at.

(3) Fuels with high volatile content show thermal decomposition upon distillation; such heat would, however, not be lost for the purpose of producer-gas production.

In conclusion I wish to express my thanks to the Directors of the Power-Gas Corporation, Stockton-on-Tees, for their kindness in permitting me to publish results obtained in their laboratory.

Discussion.

Dr. H. G. **Colman** dealt with the question of the volatile matter and the tar yield from the coal, and said that he took it that the author referred more especially to producers in which it was intended to obtain a good yield of tar, and where the arrangements of that producer were such that as the tar vapours came off they were taken out of the zone of heat at the earliest opportunity. He agreed with the author that the ordinary volatile matter test was no criterion of the yield of tar obtainable from coal, whether by carbonisation in retorts or by gasification in producers. The volatile matter in coal, when tested at high temperatures, depended partly on the percentage of hydrogen in combination with the carbon, and partly on the percentage of oxygen in combination with the carbon, and, therefore, it was necessary, to get any definite yield, to make a direct experiment on the determination of the tar. The author desired, in his particular case, to get some estimate of the tar yield in a producer-gas plant. To do that he had to take the tar yield under certain conditions—which were really retort conditions and not producer conditions—and, as was pointed out in the paper, he obtained a different result; he did not reproduce on the large-scale working in the producer the results obtained on the small-scale distillation plant. Nevertheless, the relative results obtained were, he had no doubt, of great value, but he suggested that it might be possible to get a better value for the purpose—the producer purpose—by carrying out the low-temperature distillation, not by direct heating in a retort, but by the passage of hot producer-gas through the retort, distilling off the tar by means of the sensible heat of the producer-gas. In that way it would be possible to reproduce the conditions of producer manufacture, where the coal in the upper portion of the producer was actually distilled by the sensible heat of the hot producer-gas coming from the generator zone below. In the case of the Nottinghamshire coal, the large-scale producer test gave a total of 125 lb., and the small-scale retort test 162 lb. The author reckoned that he could safely say there was an 80% efficiency in both cases, but the tars were not the same in the two cases, *e.g.*, they differed in respect to the yield of fractions boiling at lower temperatures. Taking the fractions at various temperatures, the figures worked out as follows:—

	Producer. lb.	Retort. lb.
To 170° C.	1·25	6·89
170°–230° C.	8·50	36·21
230°–270° C.	13·38	20·00
270°–350° C.	30·75	36·69
Above 350° C.	70·62	60·35
Total	125·00	162·00

Thus the amount obtained by distillation in the retort of the fractions at 170° C. was vastly greater than in the producer. The same applied to the 170°—230° fractions, and there was a decidedly higher percentage of pitch from the large-scale producer than from the distillation test. That, he thought, was due to two causes. There was first the one which the author had pointed out, that they were dealing with a producer in which the tar vapours were condensed in presence of 120,000—130,000 cub. ft. of permanent gas, which retained in the form of vapour at ordinary temperature a very much larger proportion of these low-boiling constituents than the 7000—8000 cub. ft. of gas in the distillation test; as shown by these figures, the difference became greater between two tests as the volatility of the fraction increased. In addition the tar vapours given off were different in the two cases because the distillation of the volatile matter from the coal in the producer was brought about by the sensible heat of the hot producer-gas coming from the zone below, and the evidence, so far as it was available, tended to show that in the producer the original decomposition products of the bituminous matter of the coal were being approached more nearly than even in the so-called low-temperature distillation of coal in the retort. He did not think anyone had seen the original products yet; the nearest approach to it had been said to be the vacuum tar of Pictet, made by carbonising coal in a vacuum at the lowest temperature at which it would give any products, but even that, he thought, was far from being the original product formed. He thought that if a producer type of test could be arranged for determining the tar, rather than the distillation type, it would give better information for producers. On the other hand, where the test was required for distillation purposes, for determining the yield of oils from shales etc., then the distillation test, or a test as near as could be got to working conditions, would be the more favourable.

Dr. R. **Lessing** said that, as Dr. Colman had already pointed out, the atmosphere in which the heating of the coal was carried on was of the very greatest importance. Indeed, in a case like this it was the gaseous atmosphere that really determined the type of products, and particularly the type of primary products, that was obtained by the heating of coal. He asked whether, at the comparatively low temperature in Mond gas producers, the effect of the steam would be the same as that in, say, externally-heated steamed vertical retorts, or in some of the more recent producers—combined retorts and producers—for the complete gasification of coal where water-gas was made in the producer, and not the ordinary producer-gas containing the whole nitrogen of the air. That point was also of importance in connexion with the ammonia yield. He did not know whether the author could enlighten them as to the higher yields of ammonia with smaller quantities of steam. If it were merely a question of lower temperature it would be a very important step forward. With regard to the method of estimating the distillation products the author apparently discarded all the smalls obtained in the grading of the coal.

Mr. Rambush said that the whole of the coal was graded, from ⅛-in. to ¼-in., anything smaller than ⅛-in. being discarded so long as it was only about 5 or 10 .

Dr. Lessing said that that might have considerable bearing on the results of tests on certain coals, because the more friable portion of the coal would be of a different composition, especially as regards carbonaceous constituents, and particularly the volatile matter, or the ash constituents. For instance, the dust contained a considerable amount of fusain, and if that were eliminated from the average sample, then there was no doubt the resulting tar and ammonia would show very different figures to those obtained if the fusain were included in the sample. One other interesting point was the question of the exothermic losses. In ordinary bituminous coals he believed the heat balance was a fairly even one. According to the work of Euchêne and Mahler, it had been considered that the reaction was slightly endothermic. Barnum had shown that the reaction was exothermic, and his results had been corroborated by some recent work of Prof. Cobb. That related to ordinary coal, and not to peat and other highly oxygenated substances, in connexion with which there must be an exothermic heat loss, which would interfere with the heat balance of the whole fuel. The question of the atmosphere in which the test was carried out might very considerably influence the ratio of the distillation-gases to the producer-gases, and there he was afraid that Mr. Rambush's very careful calculations had been carried out on an arithmetical basis, rather than on a chemical basis.

Mr. A. H. Lymn said that he understood the author to say that steam was not essential for the production of ammonia in a gas-producer. Did not the author mean, however, that while some steam was essential to produce the ammonia, an excess was not necessary for its protection after the ammonia had been formed? With certain modifications of a gas-producer considerably more ammonia would be obtained without the steam than used to be the case, but a certain amount of steam was necessary to produce ammonia in the coke gasification zone of a producer. Dr. Colman's suggestion that producer-gas should be used for the distillation of the coal in the testing retort was correct, provided the producer-gas was made from coke, and not from coal, and that its speed and time contact were made proportionate to what they would be in the gas-producer in actual practice, but he could easily imagine that if a producer-gas made from an ordinary gas-producer using coal were passed haphazard at a certain temperature through the gas retort, erroneous results would be obtained. The author's figures demonstrated in general terms what he claimed, namely, that by means of a distillation test of this kind he could, with a fair amount of certainty, foreshadow what might be obtained in actual producer practice. The distillation thermal balance sheet showed throughout a loss which varied, in the case of coal, from 1·4 to 10%, and with other fuels, such as peat and lignite, from about 12 to 26%. Had the author also made a carbon balance sheet? In a testing apparatus such as had been described this could be comparatively easily and accurately made, whereas in a large-scale gas-producer plant treating 100 tons or more daily it was difficult. It was known as regards the old type by-product gas-producer plants that in making a carbon balance sheet the figures showed a loss varying from, say, 10 to 13%, which in those days had not been accounted for. About fifteen years ago tests had been carried out on a very large by-product producer-gas plant—two by Mr. Herbert Humphrey and one by himself. In the first two cases the unaccounted-for carbon showed 13·4% and 13·7% respectively, using Staffordshire fuels; on his own test, using Worcestershire fuels on a large scale, namely, 700 tons altogether, the figure was 13·6%. In another test of his it was 12·3% when using a smaller plant, and only 50 tons of fuel.

Mr. W. H. Patchell said that when considering what laboratory tests could show helpfully it was desirable to go further into the question of pastiness and ash. Nothing had been said in the paper about the fusibility of ash, which was highly important. The Fuel Research Board tests, which were mentioned in the Report for 1921, dealt with three different fuels, namely, Consett, Mitchell Main, and Lanarkshire. In the case of the Consett coal the ash was 10·9%, and in the case of Mitchell Main, it was 6·55%, yet Mitchell Main coal gave more trouble passing through the retorts than the Consett. If those tests had been extended to the fusibility and pastiness of the coal, they would have thrown more light on the subject.

Mr. H. Hollings said that nobody would dispute the author's hypothesis, in relation to the thermal balance, that the cause of heat evolution was due to the splitting off of carbon dioxide or of hydroxyl groups. He referred, however, to the quantity of heat involved, and pointed out that as far as bituminous coals were concerned, the quantities shown by the author were fully in accord with previous work on this subject, *i.e.*, the quantities varied from about −2% to +7% of the heat of combustion of the coal. There was one exception in the author's figures from these, namely, the South African coal, which came out at about 9·4%; that was a little difficult to understand, because the volatile matter, like the oxygen content, did not seem excessively high. Perhaps the author could offer some explanation. With regard to the higher values noted for the other fuels—lignite, peat, wood, straw, etc.—it was to be noted that all these fuels contained a much higher oxygen content, and many of them also a higher content of volatile matter, and it was quite in accord with previous work to find that these fuels gave a higher heat evolution upon carbonisation. He understood that the temperature of distillation used by the author was 800° C. Previous work had shown that exothermic reactions come to an end between 750° and 800° C., but that at higher temperatures there were endothermic reactions, and for that reason, therefore, the author would have obtained slightly lower results if he had gone further. Moreover, had he worked at 400° C. with the cellulosic materials, there would have been a still more marked effect. One important conclusion which might be drawn from the figures in the paper was that, although the heat of carbonisation was a matter mainly of academic interest, when considering the class of coal usually handled by the gas engineer or coke-oven manager, it became one of first-rate practical importance when dealing with the lower grade, highly oxygenated, cellulosic fuels which had been mentioned.
