v.3

PREFACE

IN the Preface to Volume II published in 1910 I rashly stated that it was my intention "to devote such space as is available within the limits of a text-book to the neglected subject of the geographical distribution of plants at different stages in the history of the earth," also that Volume III would be completed with as little delay as possible. Though nearly seven years have elapsed since the publication of the second volume it may fairly be said that the delay is not entirely due to causes which it was in my power to control. The subject of geographical distribution receives no connected treatment in Volumes III and IV for the simple reason that I underestimated the space required for the description of the Gymnosperms. The alternatives were either to insert a greatly compressed survey of the successive floras of the world at the end of Volume IV or to attempt a fuller and less technical treatment of the subject in a separate book. In choosing the latter course I am conscious that a further obligation is undertaken which it may not be possible to fulfil; but the risk is deliberately taken. Volume IV is in the press and will, it is hoped, be published before the end of 1917.

It is a pleasant duty to repeat my thanks to many friends who have helped me in various ways. Dr Kidston generously and without reserve allowed me access to his splendid collection of Palaeozoic plants, and the frequent occurrence of his name in the list of illustrations shows how freely I have availed myself

of his kindness. He has read some of the chapters and greatly assisted me by his friendly criticism and encouragement. By reading the proofs of this volume Dr Scott has further increased my already large debt to him. It is impossible to thank him adequately; he not only corrected many careless mistakes but by wise counsel and advice he rendered me a service which I greatly appreciate.

The exchange of views with Prof. Zeiller has been a constant source of profit and enjoyment, and it is hard to realise that the completed book will not receive his kindly criticism. He was a singularly unselfish and generous colleague, always ready to help fellow workers, and he had the faculty in an unusual degree of influencing those who had the privilege of his friendship by his sound advice and lovable personality.

The death of Count Solms-Laubach has deprived Palaeobotany of one of its most learned and strongest supporters. In common with all students of fossil plants I owe much to the critical treatment of the subject in the *Einleitung in die Paläophytologie*. Prof. Jeffrey has very kindly given me several photographs and sections which have been of great service, and I am similarly indebted to Prof. Zalessky. To Prof. Nathorst my thanks are due for the great interest he has taken in my work and for his generosity in providing drawings and showing to me many of the treasures in the famous Stockholm Museum. Prof. Bertrand and Prof. Lignier freely supplied photographs and drawings of specimens in their possession, and I am particularly grateful to them for the willingness with which they always responded to my requests.

Through the death of Prof. Lignier in March 1916 Palaeobotany has been deprived of another original thinker who devoted himself with whole-hearted enthusiasm to botanical research and for many years faithfully served the University

of Caen: he was a generous friend to whom one never appealed in vain for assistance. Through the kindness of the Director of the Indian Geological Survey I have been able to examine several fossils from the Calcutta Museum described by Oldham and Morris and by Feistmantel. With the Director's permission several photographs and drawings made for a forthcoming paper to be published by the Indian Survey are reproduced in this volume. I take this opportunity of thanking friends in Australia who recently afforded me facilities for examining fossil plants in their charge, and I would especially thank Mr A. B. Walkom of the University of Brisbane, who has recently undertaken an investigation of the rich plant-beds in the Ipswich district, for all that he did to enable me to make the most of a very short time available for palaeobotanical work.

For the loan of specimens and for other help I am indebted to Prof. Bayly Balfour, Prof. Bower, Prof. Margaret Benson, Prof. Oliver, Sir David Prain, Dr Smith Woodward, Prof. Weiss, the Director of the Geological Survey, Dr A. H. Church, Dr Arber, and other friends. I would also acknowledge a debt, by no means inconsiderable, to my Colleague Mr Hamshaw Thomas. Among younger friends in the Cambridge Botany School to whom I am indebted I wish particularly to thank Miss Ruth Holden, Miss Bancroft, Mr Sayers, Mr Dutt and others who have rendered me willing help.

In the List of Illustrations mention is made of Corporate Bodies and individuals from whom blocks have been obtained, and I am grateful to them for readily responding to my applications.

My Wife, though prevented by more urgent calls in the later stages of my task from giving as much time to the illustrations as in the two former volumes, has contributed several

drawings, and my daughter Phyllis Seward has also given me much help in preparing drawings from previously published figures.

In spite of the vigilance and wise counsel of many friends numerous blemishes remain and for these the author is alone responsible.

A. C. SEWARD.

DOWNING COLLEGE LODGE,
February 10, 1917.

NOTE. The letters A and B added to references in the footnotes indicate that the works will be found in the Bibliographies at the end of Volumes I and II.

TABLE OF CONTENTS

CHAPTER XXVIII

CYCADALES (Recent). Pp. 1—34.

CHAPTER XXIX

PTERIDOSPERMEAE (continued from Volume II.). Pp. 35—85.

	PAGE
I. LYGINOPTERIDEAE	35-85
Lyginopteris	35-70
<i>Telangium</i> 54, 55; <i>Lagenostoma</i> 55-64; <i>Lagenospermum</i> 64-66; <i>Pterispermotrobus</i> 66, 67.	
Heterangium	70-85
<i>Sphaerostoma</i> 78-81.	

CHAPTER XXX

II. MEDULLOSEAE	86-165
i. Medullosa	86-109, 156-163
<i>Myeloxylon</i> 106-110; <i>Neuropteris</i> 110-117; <i>Alethopteris</i> and <i>Linopteris</i> 113; <i>Trigonocarpus</i> 117-124; <i>Codono-</i> <i>theca</i> 124-126; <i>Schützia</i> 126-128; <i>Whittleseya</i> 128- 131; <i>Dolerophyllum</i> 132-139; <i>Ottokaria</i> 139-141; <i>Strobilites</i> 141, 142.	
ii. Colpoxylon	142-145
iii. Rhexoxylon	146-149
iv. Sutcliffia	149-156
<i>General considerations suggested by the anatomical features</i> <i>of Medullosa</i>	156-163
II. A. STELOXYLEAE	163-165
Steloxylon	163-165

CHAPTER XXXI

PTERIDOSPERMEAE. (Foliage and seeds.) Pp. 166—174.

Pecopteris Pluckenetii 166-168; *Eremopteris artemisiaefolia*
169-172; **Wardia** 172, 173; *Adiantites bellidulus* and
Lagenospermum Arberi 173, 174.

CHAPTER XXXII

CYCADOPILICES. Pp. 175—213.

	PAGE
I. MEGALOXYLEAE	175-180
Megaloxyton	175-180
II. RHETINANGIEAE	181-183
Rhetinangium	181-183
III. STENOMYELEAE	183-185
Stenomyelon	183-185
IV. CYCADOXYLEAE	185-190
Cycadoxylon	185-187
Ptychoxyton	187-190
V. CALAMOPITYEAE	190-200
Calamopitys	190-196
<i>Kalymma</i>	194-196
Eristophyton	197-200
VI. CLADOXYLEAE	200-210
Cladoxylon	201-207
Völkelia	208-210
VII. PROTOPITYEAE	210-213
Protopitys	210-213

CHAPTER XXXIII

CORDAITALES. Pp. 214—299.

A. POROXYLEAE	214-219
Poroxyton	214-219
B. CORDAITAEAE	219-284
Cordaites	219-265
<i>Noeggerathiopsis</i> 238-243; <i>Rhizozamites</i> 244, 245;	
<i>Phylladoderma</i> 244; <i>Euryphyllum</i> 245; <i>Artisia</i>	
246-248; <i>Dadoxylon</i> 248-260; <i>Metacordaites</i>	
260, 261; <i>Cordaianthus</i> 264-270; Mesoxyton	
270-275; Pelourdea 277-281; Niponophyllum	
282, 283; Titanophyllum 283, 284.	

CHAPTER XXXIV

C. PITYEAE	285-299
Pitys	285-289
Archaeopitys	290
Callixylon	291-293
Coenoxylon	293, 294
Parapitys	294, 295
Mesopitys	295, 296
Antarcticoxyton	296-299

CHAPTER XXXV

PALAEOZOIC GYMNOSPERMOUS SEEDS. Pp. 300—365.

	PAGE
I. LAGENOSTOMALES	308—318
Physostoma 309—312; Conostoma 313—316; Sphaerostoma 316; Lagenostoma 316; Gnetopsis 317, 318.	
II. TRIGONOCARPALES	318—332
Trigonocarpus 319—321; Tripterosperrum 321; Ptychotesta 321; Hexapterosperrum 321—323; Polypterosperrum 323; Pachytesta 323—326; Stephanosperrum 326—329; Polylophosperrum 329, 330; Codonosperrum 330, 331; Aetheotesta 331, 332; Eriotesta 332; Gaudrya 332.	
III. CARDIOCARPALES	332—356
Cardiocarpus 338—340; Cyclosperrum 340, 341; Cycadinocarpus 341; Rhabdocarpus and Rhabdosperrum 341—345; Mitrosperrum 345, 346; Diplootesta 346; Leptocaryon 346, 347; Taxosperrum 347; Compsotesta 347, 348; Samaropsis 348—354; Cordaicarpus 354—356.	
IV. MISCELLANEOUS SEEDS	356—365
i. Hexagonocarpus 356, 357; Decagonocarpus 357; Polypterocarpus 357, 358; Rhynchogonium 358—360; Boroviczia 360; Diplopterotesta 360, 361; Musocarpus 361; Holcosperrum 361—363.	
ii. Malacotesta 363; Thysanotesta 364; Carpolithus 364, 365; <i>Microsperrum</i> 365.	

CHAPTER XXXVI

CYCADOPHYTA (FOSSIL). Pp. 366—420.

BENNETTITALES	367—420
Cycadeoidea	367—417
Cycadella	417, 418
Amphibennettites	418
Vectia	419, 420

CHAPTER XXXVII

BENNETTITALES (<i>continued</i>)	421—477
Williamsonia	421—463
Wielandiella	463—467
Williamsoniella	467—473
Cycadocephalus	473—475
Weltrichia	475—477

CHAPTER XXXVIII

CYCADOPHYTA. Pp. 478—506.

- i. **Bucklandia** 480-490; **Cycadeomyelon** 490, 491; **Colymbetes** 491-494; **Cycadeolepis** 494-496.
- ii. **Carpolithus** 497-500; **Cycadospadix** 500, 501; **Beania** 502; **Zamiostrobus**, **Cycadeostrobus** 503-505; **Androstrobus** 505, 506.

CHAPTER XXXIX

CYCADOPHYTA (FRONDS). Pp. 507—591.

	PAGE
I. BENNETTITALES	512-566
Ptilophyllum 512-529; Zamites 529-537; Otozamites 537-545; Dictyozamites 546-548; Pterophyllum 548-558; Cycadites and Pseudocycas 558-566.	
II. NILSSONIALES	566-587
Nilssonia 566-578; Ctenis 578-583; Pseudoctenis 584-587.	
III. INCERTÆ SEDIS	587-591
Sphenozamites 587-589; Plagiozamites 589, 590; Cycadorachis 590, 591.	
LIST OF WORKS REFERRED TO IN THE TEXT (Vols. III & IV).	592-639
INDEX	640-656

LIST OF ILLUSTRATIONS

Several of the illustrations are printed from blocks for which I am indebted to learned societies or to individuals. The sources from which clichés were obtained are mentioned within square brackets. The names of donors of photographs or drawings are added after the descriptions of the figures.

FRONTISPICE. Charles René Zeiller. From a photograph given to me by Madame Zeiller.

CHAPTER XXVIII.

CYCADALES (RECENT).

AMONG the fossil genera described in the last chapter of the second volume some were spoken of as true Ferns though most of them, it was added, 'may safely be regarded as plants which will ultimately be shown to belong to some other group, in most cases that of the Pteridosperms.' Since this was written additional evidence has been obtained in favour of the inclusion of certain genera in the Pteridosperms. In the case of *Taeniopteris*, one of the genera already described, there is reason to believe that at least one species is a member of the Cycadales and not a true Fern as formerly supposed.

The Pteridosperms so far described are represented for the most part by sterile leaves preserved as impressions, the genera founded on more satisfactory material having been reserved for treatment in this volume. As these genera are founded to a large extent on anatomical characters oscillating in their essential features between recent Ferns and Cycads, it is important that the student should be in possession of the anatomical characteristics of both of these classes; and for this reason a general account of recent Cycads is intercalated between the Pteridosperms already described and those reserved for treatment in this volume.

The section of the Gymnosperms known as the Cycadales, represented by nine recent genera and less than 100 species, is of exceptional importance phylogenetically and demands special attention from palaeobotanical students. Familiarity with the morphology of recent forms is essential not only in relation to extinct cycadean plants but also to types which, though not sufficiently close

to surviving species to be included with them in one class, exhibit features regarded by many botanists as indications of an affinity either to true Cycads or to some generalised stock of which they are an offshoot. The Cycads of to-day may fairly be spoken of as anachronisms, plants appropriate to a former age but out of harmony with the present. They are confined to tropical and sub-tropical regions in both the old and new world. In habit

FIG. 377. *Cycas circinalis*. From a photograph taken by Mr A. Malins Smith at Teldeniya (Ceylon).

many of them resemble tree-ferns, but the columnar stem, which may live to a great age and attain a height of 20 metres, differs from that of ferns in its gradually tapered form consequent on the presence of one or more cambial cylinders. Though often unbranched (fig. 377) branching of the main trunk is by no means

FIG. 378. *Cycas revoluta*, as grown by Japanese horticulturalists. (After Wieland.)

FIG. 379. *Encephalartos horridus*.

unusual (fig. 378; fig. 381, B). Many Cycads are geophilous and have short tuberous stems (figs. 383, 395, 1a; 396, E): the genus *Zamia* includes a few epiphytic forms¹. The typical cycadean stem is covered with persistent petiole-bases with or without an admixture of smaller scale-leaf bases (figs. 379, 380), while in several species a transversely wrinkled or irregularly fissured periderm forms the superficial tissue (figs. 381, B; 383). The foliage-leaves are relatively large and, with the exception of the bipinnate fronds of *Bowenia* (fig. 391), they are always pinnate. The fronds usually form a terminal crown (figs. 377, 379) and

FIG. 380. *Cycas circinalis*. Stem showing alternate zones of leaf-bases (F) and scale-leaf bases (S). (From the *Encyclopaedia Britannica*.)

as many as 100 may be produced from one bud. In *Zamia pygmaea*² the fronds are only 10—12 cm. long, but in some cycads they reach a length of several metres. On both young foliage-leaves and scale-leaves long and very rarely branched³ unicellular hairs (fig. 396, N) form a characteristic feature and take the place of the ramental scales of the majority of ferns. The apex of the stem shown in fig. 386, A is covered with a mass of woolly hairs and several scale-leaves are seen on the lower part of the bud.

All recent Cycads are dioecious. The reproductive shoots, except the megasporophylls of *Cycas*—which have departed to a less extent than those of other genera from the foliage-leaf plan (fig. 381, A; fig. 392, A—C) and are borne in a terminal cluster

¹ Wieland (06) p. 190.

² *Botanical Magazine*, Tab. 1741.

³ Matte (04) Pl. XI. fig. 185 (*Microcycas*).

through which the stem subsequently pushes its way—consist of a varying number of micro- or mega-sporophylls in dense spirals on the axis of an elongated or oval strobilus (figs. 386, B, 393, 394). The microsporophylls are occasionally verticillate¹.

FIG. 381. A. *Cycas revoluta*, megasporophylls.
B. *Zamia Loddigesii*, branched stem.

The strobili are sometimes though rarely branched² and generally but by no means invariably³ terminal on the main stem which branches sympodially⁴. A striking example of

¹ Thibout (96).

² Thibout (96) PL. IV. fig. 3. A branched microstrobilus of a *Macrozamia* is exhibited in the Botanical Department of the British Museum.

³ Pearson (06).

⁴ Solms-Laubach (90); South and Compton (08); Smith, F. G. (07).

lateral strobili has recently been described by Chamberlain¹ who figures a stem of *Macrozamia Moorei* with fertile shoots wedged among the persistent petiole-bases, a condition very similar to that in the Mesozoic Bennettitales. Pearson has also described clear cases of laterally-borne cones in *Encephalartos*. *Cycas* exhibits two kinds of branching, the female plants being monopodial while in the male the branching is sympodial. The microspores are produced in sporangia grouped in more or less well defined sori (figs. 389, A; 392, E—G). There is no definite annulus, but in the occurrence of groups of thick-walled cells some microsporangia recall those of certain ferns². The ovules vary considerably in size, sometimes exceeding 5 cm. in diameter: there are usually two on each megasporophyll (figs. 393, C; 394; 395, 1*d*) but in most species of *Cycas* (fig. 392, B) and occasionally in other genera the number is larger³. A thick integument encloses the nucellus with which it is fused except in the apical region (fig. 396, A, B). Below the comparatively long micropylar tube is a well-developed pollen-chamber (fig. 396, B', *p*), a striking feature of Cycadean ovules, immediately above the megaspore; the latter is filled with prothallus-tissue and bears a small apical group of archegonia on the floor of a depression (fig. 396, A—B'). In *Microcycas*⁴ as many as 200 archegonia are recorded—a very exceptional case—and these are not confined to the apical region, though only the apical archegonia are functional. Each archegonium is characterised by a very large oval egg-cell and a much reduced neck⁵. The microspores usually produce a single prothallus-cell, a stalk-cell, and body-cell, and from the body-cell are developed two spirally ciliated spermatozooids (fig. 396, M). In this respect also the monotypic genus *Microcycas* is peculiar: it may have as many as 8 body-cells and 16 male gametes in a single pollen-tube (fig. 396, G), while in *Ceratozamia*⁶ 4 gametes have been seen in one tube. The pollen-tube grows like a fungal mycelium into the nucellar tissue and the male gametes are formed in the distended proximal end

⁶ Chamberlain (12) p. 11.

which on bursting liberates the motile sperms with the watery cell-sap. Fertilisation is succeeded by the development of a homogeneous proembryo partially or completely filling the zygote (fertilised egg): by the formation of long suspensors the embryo is brought into contact with the food-store of the prothallus. In some Cycads, e.g. *Encephalartos*, the embryogeny exhibits a close resemblance to that of *Ginkgo*¹. The embryo is dicotyledonous².

The single stele of the stem is characterised by a large pith which in some genera (e.g. *Encephalartos*, *Macrozamia*) contains an anastomosing system of collateral bundles. The vascular tissue of a cycadean stem forms a cylinder of secondary xylem and phloem, the primary xylem being represented only by a few, usually crushed, protoxylem elements on the inner margin of the reticulately pitted or scalariform tracheids. Both xylem and phloem are traversed by numerous broad and deep medullary rays³. The looser texture and more parenchymatous structure of Cycadean wood afford a ready means of distinguishing it from the wood of Conifers: for the Cycadean type the term *manoxylic* is proposed and *pycnoxylic* for the more compact coniferous wood⁴. Rims (or 'bars') of Sanio, of which much has been said in discussions on the phylogeny of Conifers, have recently been described in the petiolar xylem of *Cycas revoluta*: the rims are short and 'cling closely to the borders of the pits,' features which also characterise the rims found in the cones of the Araucarineae and in the root- and cone-wood of certain Pines⁵. In some Cycads the secondary xylem and phloem form a single cylinder, but in others (*Cycas*, *Encephalartos*, *Macrozamia*, *Bowenia*) the cambium is succeeded by one or several concentric cylinders of meristem which have their origin in the pericycle. The spasmodic occurrence of separate arcs of inversely orientated secondary xylem and phloem between the normal cylinders is a feature of importance from the point of view of comparison

¹ Saxton (10⁴).

² For an explanation of the occurrence of a single cotyledon in *Ceratozamia*, see Dorety (08).

⁵ Sifton (15).

with the Palaeozoic Medulloseae¹. The occurrence of concentric cauline strands in the cortex of *Cycas* is also a peculiarity worthy of notice. Successive bands of periderm, and occasionally a considerable amount of phelloderm², are formed in the peripheral region of the stem.

The leaf-traces in an adult stem exhibit a striking feature in their indirect or girdle-like course to the leaves (fig. 396, H, g) and in the gradual change from an endarch (fig. 396, O) to an apparently mesarch structure (fig. 400) as they pass from the perimedullary zone to the petiole: except at the base of the petiole the vascular bundles of the frond-axis consist of (i) centripetally developed xylem with a median protoxylem and a much smaller amount of centrifugal xylem (fig. 400) separated by a few parenchymatous elements from the centripetal xylem, (ii) an external arc of protophloem and within this metaphloem and parenchyma³. In the slender petiole of *Bowenia* there are a few collateral bundles arranged in the form of a circle or ellipse⁴; in *Cycas* and some other genera the more numerous bundles form a pattern like an inverted U, and in some species of *Encephalartos* the number is greater and the strands more irregularly scattered⁵. In the vegetative stems there is no centripetal xylem in the stele, but scattered centripetal tracheids occasionally occur internal to the protoxylem in the steles of the peduncles⁶.

Cycadeae. Megasporophylls each bearing 2—8 ovules, borne separately like foliage-leaves and not in strobili. Pinnae have a midrib but no lateral veins (figs. 384, 387, A). *Cycas* (fig. 377).

Zamieae. Both kinds of sporophylls form strobili. Pinnae have several dichotomously branched, more or less parallel veins. *Zamia* (figs. 388—390), *Macrozamia*, *Encephalartos* (figs. 379, 386, C), *Ceratozamia*, *Dioon* (fig. 386, B), *Microcycas*.

Stangerieae. Strobili as in Zamieae. Pinnae fern-like, numerous dichotomously branched lateral veins given off from a midrib. *Stangeria*.

Bowenieae. Leaves bipinnate (fig. 391), strobili as in Zamieae. *Bowenia*.

Distribution. The most widely spread genus, *Cycas*, occurs in Siam, India, the Nicobar Islands, Ceylon, Madagascar, and

⁶ Scott (97); Matte (04) p. 164.

Australia, in many of the islands in the Indian and Pacific oceans, in New Guinea, Borneo, New Caledonia, New Britain, China and Japan¹. *Zamia*, the most northerly genus, extends from North Mexico and Florida through Central America and some of the West Indian islands to Ecuador, Bolivia, Chile, and Peru. *Dioon* and *Ceratozamia* are confined to South Mexico, and *Microcycas* flourishes on the Cuban mountains. The continent of Africa possesses two endemic genera *Encephalartos* and *Stangeria*. *Encephalartos* extends from Cape Colony through Natal and Zululand to Zanzibar and Mombasa²: a specimen in the Kew Herbarium (probably *E. Hildebrandti*) is said to have been collected as far north as the Soudan. Two species are recorded from the Congo³ and *E. Barteri*, discovered by Barter in Central Africa, is recorded from the Gold Coast⁴. *Stangeria* has a much more limited range in S.E. Africa⁵; Australia possesses *Macrozamia*, represented by several species in Western Australia, New South Wales and Queensland, *Cycas* in Queensland and the Northern territory and the Queensland genus *Bowenia*. There are no Cycads in New Zealand. As a whole Cycads have a limited range and with the exception of *Cycas* and *Zamia* none of them extend beyond the limits of a single continent. They are as a rule not gregarious plants and play a subordinate part in the facies of the vegetation. *Macrozamia* forms dense thickets⁶ in some districts and occurs both in exposed situations and in association with Palms in damp Queensland forests. Chamberlain⁷ speaks of 100 plants of *Dioon edule* as visible in one view in South Mexico where the species forms a mountain forest. In Florida *Zamia pumila*⁸ grows in dense moist woods, a habitat in contrast to that of many Cycads. The Mexican *Ceratozamia* is associated with luxuriant vegetation, while its compatriot *Dioon*⁹ lives in blazing sunshine.

¹ The species *Cycas taiwanensis* was founded by Mr Carruthers (93) on material from Formosa, and *C. revoluta* has also been recorded from Formosa [Thiselton-Dyer (02) p. 559], but according to Mr Elwes it is very doubtful whether any native Cycad occurs on the island.

⁹ Chamberlain (09).

Sir Joseph Hooker¹ speaks of *Cycas* living in the deepest and hottest valleys in Sikkim. *Encephalartos* is essentially a xerophilous genus. *Stangeria paradoxa* is said to be confined to forests in Cape Colony, and another species grows among the grass of the Park-lands in open country². While it is true that many Cycads are characteristic of dry regions some species flourish in places where shade and moisture are abundant.

Though it is impossible in many cases to form an estimate of the age of individual plants, there are clear indications that some specimens afford notable instances of longevity. Chamberlain estimates the age of some plants of *Dioon spinulosum* as exceeding 400 years and mentions an example of *D. edule* that is probably 1000 years old. An unusually tall plant of *Encephalartos* in the Botanic Garden of Amsterdam is believed by Prof. de Vries to have reached the venerable age of 2000 years³. The restricted range and in many cases the solitary existence of recent Cycads, with their tall stems clothed with the persistent cork-covered stumps of thousands of fronds, deepens the impression of antiquity derived from a study of the geological history of this dwindling race.

Stems. The tall columnar stems of some species of *Cycas*, often branched or bearing numerous ovoid buds like enlarged bulbils⁴, are characterised by the regular alternation of large and small leaf-bases as seen in the stem of *C. circinalis* reproduced in fig. 380. In older stems of this species the leaf-bases are exfoliated and the stem is covered with wrinkled and fissured cork; but in *Cycas revoluta* the leaf-bases are even more persistent. The columnar but relatively stout stems of *Encephalartos* (figs. 379, 382, 386, A) and *Ceratozamia* are similarly encased in a covering of petiole-bases, but in these genera the differences between foliage-leaves and bud-scales is much less obvious and there is no zonal alternation. On the stems of *Macrozamia* the rhomboidal leaf-bases are more uniform in size and there are no scale-leaves. The tall and often palm-like stems of *Microcycas*

¹ Hooker, J. D. (91) A. p. 98 (footnote).

² Pearson (06).

³ Prof. de Vries kindly informed me in a letter that this estimate is not to be regarded as anything more than a rough guess.

⁴ Stopes (10).

sometimes show transverse rings on the bark marking the position of former terminal buds, and in older trunks these may disappear, leaving a fissured bark¹. In *Cycas siamensis* the tuberous stem

FIG. 382. *Encephalartos Ghellinckii*. ($\frac{1}{11}$ nat. size.)

is similarly covered with a rough bark (fig. 383) and the stems of *Zamia* are also characterised by an absence of persistent leaf-bases (figs. 381, B; 395, I a, a). It is pertinent to remind the

¹ Caldwell (07).

palaeobotanical student of the occurrence of flowering plants with stems closely simulating those of some Cycads. Prof. Bower¹ in describing *Rhynchopetalum montanum*, an Abyssinian Lobeliaceous plant, drew attention to the similarity in surface-features and to some extent in anatomical structure to cycadean stems. The resemblances are further emphasised in a more recently published account of the same species under a different name, *Lobelia Rhynchopetalum*²

FIG. 383. *Cycas siamensis*. (From the *Encyclopaedia Britannica*.)

*Fronde*s. A general acquaintance with the various types of fronds illustrated by recent Cycads is important to the student of fossils not only to enable him to compare existing and extinct forms but as affording safeguards against possible sources of error in the description and identification of impressions³. The vernation exhibits less uniformity than in Ferns: in *Cycas* the rachis is straight and the pinnae circinate (fig. 220, B, vol. II. p. 283); in *Zamia* and *Stangeria* the rachis is bent and the pinnae straight, while in *Ceratozamia* and other genera both the axis and leaflets are straight. As Braun pointed out, there is as a rule no terminal leaflet, or it may be pushed to one side giving a forked appearance to the frond apex⁴.

¹ Bower (84).

² Rosen (11).

³ Seward (95) A. pp. 15 *et seq.*

⁴ Braun, A. (75).

Cycas. The presence of a strong midrib and the absence of lateral veins are distinguishing features: the lower margin of the lamina is frequently decurrent (fig. 387, A). In *C. circinalis* the pinnae may reach 40 cm. in length with a fairly uniform breadth of 2 cm. A frond of this species in the British Museum, not quite complete, has a length of 112 cm.: on the lower part of the rachis strong spines replace the leaflets and near the apex of the leaf conrescent pinnae form a continuous lamina traversed by seven ribs and dissected at the margin into acuminate teeth (fig. 384): some of the pinnae

FIG. 384. *Cycas circinalis*, abnormal frond. (From a specimen in the British Museum.)

are forked as in *Cycas Micholitzii*¹ (fig. 385). Several years ago I noticed a similar instance of conrescence in a small plant of *C. circinalis* in the Royal Gardens, Kew (fig. 387, I). In *Cycas Micholitzii* the pinnae, reaching a length of 20 cm., are repeatedly and deeply forked (fig. 385, A, B; fig. 400): the pinnae of *C. Rumphii* var. *bifida*² are also deeply dissected. *Cycas Beddomei* has very narrow pinnae (15 cm. × 2 mm.) similar to those of the Wealden

¹ Thiselton-Dyer (65) B.; *Bot. Mag.* 1909, Tab. 8242.

² Thiselton-Dyer (02) p. 560.

species *Cycadites Saportae*, and it is noteworthy that narrow leaflets with a strongly revolute lamina would produce casts with two parallel ribs (the grooves between the midrib and the edge of the lamina) simulating the double midrib of the fossil genus *Pseudocycas*. In some fronds, e.g. *C. Cairnsiana*, the midrib is hardly visible on the upper face of a dried pinna which shows a longitudinal wrinkling simulating parallel venation.

FIG. 385. A, B, *Cycas Micholitzii*. (After Thiselton-Dyer.) C, *Zamia angustifolia*.

Encephalartos. The fronds of this genus, in *Encephalartos Laurentianus*¹ reaching the exceptional length of 7 metres, bear alternate pinnae exhibiting a considerable range in form and breadth. In *E. longifolius*, *E. Altensteinii* (fig. 386, C), *E. Lehmanni*, etc., the pinnae are for the most part linear, reaching a length of 20 cm. and a breadth of 2 cm. in *E. caffer* (fig. 387, D), *E. latifolius*, and others the pinnae are broader and shorter and often spinous. A frond of *E. longifolius* or *E. Altensteinii* may bear both entire and lobed, spinous pinnae. In *E. Frederici-Guilielmi* (fig. 387, G) and *E. Ghellinckii*² (fig. 382) the pinnae are very narrow and almost filiform, with revolute edges. The thick and leathery pinnae of some species are attached obliquely to the edge or

Zamia. In *Zamia angustifolia* (fig. 385, C) and *Z. linifolia* the pinnae are long and very narrow: the other extreme is represented by *Z. Wallisii*¹ (fig. 388) with broad ovate segments reaching a length of nearly .5 metre and attached to the rachis by a short stalk; the veins are prominent and dichotomously branched. Other forms of pinnae are represented by *Z. integrifolia*, *Z. floridana*, and *Z. Loddigesii* (figs. 389, 390, 395). The

FIG. 390. Small frond of *Zamia Loddigesii*. ($\frac{2}{3}$ nat. size.)

broad and short pinnae of *Z. furfuracea*¹ bear a close resemblance, except in the absence of an auriculate base, to those of some species of the fossil genus *Otozamites*. The broadly linear pinnae of *Z. pseudoparasitica* (45 cm. × 3 cm.) often show longitudinal wrinklings on drying which suggest comparison with the corrugated lamina of the fossil species *Nilssonia brevis*. A basal pad or callosity on the slender bases of the pinnae is characteristic of many *Zamia* fronds.

Ceratozamia. The fronds bear a fairly close resemblance to those of *Macrozamia*: in *Ceratozamia mexicana* the linear pinnae reach a length of over 30 cm. and a breadth of 2—3 cm.; the lamina tapers to a narrow apex and is more abruptly contracted at the base (fig. 387, H). The veins in *Ceratozamia* are sub-parallel and dichotomy occurs up to the middle of the lamina². A striking feature is the occurrence of two opposite stipule-like projections a short distance above the base of the petiole.

Macrozamia. A noteworthy feature in some species is the attachment of the linear pinnae along the middle line of the rachis (fig. 387, C); in others (fig. 387, B) the leaflets are attached laterally and may have a basal callosity. The parallel veins, which branch dichotomously near the base of the lamina, are often much more prominent on the lower than on the upper face. In *M. heteromera*³ (fig. 396, F, F') the narrow pinnae are deeply forked and strongly revolute. The spirally twisted rachis of *M. spiralis*, *M. heteromera*, etc., is a striking feature recalling the Rhaetic fern *Camptopteris spiralis* Nath⁴.

Dioon. The arrangement of the linear pinnae of *D. edule* (fig. 386, B), *D. spinulosum*, and *D. Purpusii*⁵ forms a ready means of distinguishing the fronds of this genus: the pinnae, often contiguous and at right-angles to the rachis, are attached in a lateral groove by an expanded and slightly decurrent base. The difference between the lower and upper face of a frond (fig. 387, E, F) affords a good illustration of a common source of error in the identification of fossil specimens. The leaflets of *D. spinulosum*, which except in their spinous margin are very similar to those of *D. edule*, may reach a length of 15 cm. and a breadth of 8 mm. The parallel veins are unbranched⁶.

*Microcycas*⁷. The pinnae of this genus, very like those of the Wealden species *Zamites Buchianus*, reach a length of 20 cm. and a breadth of 8 mm.: on falling they leave oblong scars resembling those on the rachis of *Encephalartos*.

Stangeria. This genus is particularly interesting because of its fern-like habit and venation. The large fronds of *S. paradoxa*⁸ bear broadly linear

acuminate pinnae with entire, unevenly lobed, serrate, or pinnatifid margins. Some leaflets are so deeply dissected as almost to justify the appellation pinnate. Both entire and dissected leaflets may occur on one frond and the lower ones may be stalked while the upper pinnae are sessile. The venation agrees closely with that of the genus *Taeniopteris*¹.

Bowenia. The large fronds of this genus (fig. 391) are peculiar in being bipinnate; they may reach a length of 2 metres and have a long slender petiole: the asymmetrical lamina of the segments, entire or deeply serrate, is attached by a very short stalk; the veins branch dichotomously² and

FIG. 391. *Bowenia spectabilis*, frond. (From the *Encyclopaedia Britannica*.)

diverge slightly. Both entire and serrate pinnae may occur on the same plant, but Chamberlain has revived André's specific term *serrulata* in preference to the generally adopted designation for the serrate forms, *B. spectabilis* var. *serrata*³.

*Reproductive shoots*⁴. In *Cycas circinalis*, *C. Rumphii*, and other species the megasporophylls reach a considerable length and bear several lateral ovules each of which may be as large as a

goose's egg: the sterile distal end has the form of a spear-point with an irregularly serrate edge. In *C. revoluta*, *C. pectinata*, etc., the sterile part is deeply dissected and may break off (fig. 392, A) from the fertile portion of the sporophyll. The megasporophylls

of *C. Ruminiana* exhibit a striking variation in form (fig. 392, B, C); some are 15 cm. long with several ovules, while others, reduced to 8 cm., bear only two ovules and resemble the sporophylls of *Dioon*. In all other genera the megasporophylls are

aggregated into cones, but in *Dioon* the strobili are characterised by their more ovoid form and by the looser arrangement of the sporophylls (fig. 386, B), each of which consists of a horizontal stalk expanded distally into a broadly lanceolate upturned end covered with a thick felt of hairs and bearing at its base usually 2, rarely 5—6, ovules on cushion-like swellings. In *Dioon spinulosum* the cones may be 50 cm. long. Between the cones of *Microcycas*, over 90 cm. long, and those of some *Zamias*, a few centimetres long, there are many intermediate forms. The

FIG. 394. *Macrozamia Preissii*, megastrobilus and (A) single megasporophyll; *a*, axis of cone; *p*, stalk of megasporophyll; *s*, unripe seeds. (After Rendle.)

large strobilus of an *Encephalartos* reproduced in fig. 393, D, shows the convex ends of the sporophylls with a jagged edge, and in monstrous cones the marginal lobes may be abnormally developed and assume the appearance of pinnae¹. Each megasporophyll bears two large ovules (fig. 393, B). In certain species of *Encephalartos* the swollen ends of the sporophylls have a truncate centre like the flattened umbo of some Pines (fig. 392, D). The presence of two divergent spines is a peculiarity of the mega-

ends of sporophylls (fig. 392, H) not unlike the cone-scales of *Pinus excelsa* or *P. cembra*. The megasporophylls of *Zamia* are expanded into regular cushion-like hexagons with a flat central area (figs. 389, B; 395, 1 b).

The microsporophylls (figs. 389, A; 392, E) are in all genera

aggregated into strobili which often bear a close resemblance to seed-cones (fig. 393, A). On a single sporophyll of *Cycas circinalis* there may be as many as 700 sporangia while in *Zamia floridana* there are only two microsporangia. The spore-output is large and in extreme cases, e.g. in *Dioon spinulosum*, the average number of spores in a sporangium is said to be 30,000¹.

Seeds. In the great majority of recent species the seeds may be described as large and afford a striking contrast to the small seeds of the Mesozoic Bennettitales. A feature of interest from the point of view of comparison with Palaeozoic seeds is the absence of a resting stage, germination in some cases following seed-fall without an interval. As Warming pointed out, the embryo is often undeveloped when the seeds are shed. An interesting fact is recorded by Capt. Dorrien-Smith² with regard to seed-dispersal: he describes the heavy pebble-like seeds of a *Macrozamia* as being hurled from the ripe cones a distance of 12 ft. The seeds of *Cycas* are platyspermic; the woody shell exposed on removal of the outer flesh is slightly flattened and has two prominent angles, but three-angled seeds may occur as in *Ginkgo biloba* (fig. 631, C). In other genera the seeds are radiospermic. The seed of *Encephalartos Altensteinii*³ (fig. 396, D) has a square-cut distal end with a small papilla at the summit of the unusually long micropylar canal (17 mm.). The stone of this seed (fig. 396, C) shows parallel curved ridges which mark the position of vascular strands in the inner region of the outer flesh. The large ovules of *Cycas circinalis*⁴ have an integument 1 cm. thick consisting of an outer and inner flesh and an intervening stony layer which reaches its greatest development at the base and apex. Three vascular strands enter the base of the seed, the concentric strand breaks up in the broad inner flesh into a group of bundles which embrace but do not penetrate the lower end of the nucellus. Each of the two lateral strands branches in the outer flesh near its entrance into the seed; the outer and larger collateral and mesarch bundle passes up close to the surface of the shell to the seed-apex, while the inner branch penetrates the shell and, occasionally branching, passes up the inner region of the inner

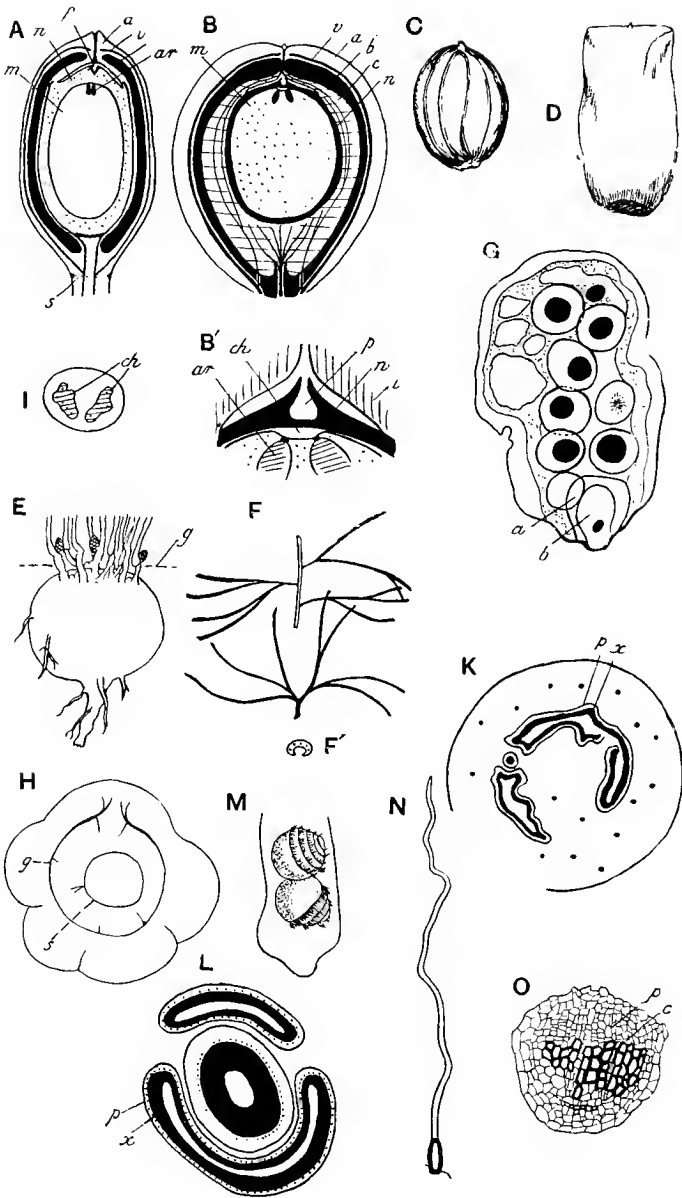

FIG. 396.

flesh as far as the micropyle. In other seeds the tracheal supply of the outer flesh consists of several bundles and not two as in *Cycas*. The inner flesh abuts on the nucellus and is connected with it except at the apex (fig. 396, B). In ripe seeds the nucellus is reduced to a thin membrane enclosing the large megaspore at the upper end of which is a depression (fig. 396, B') or sometimes two depressions (fig. 396, I) in the prothallus containing the archegonia. In the seed of *Dioon edule*¹ (fig. 396, A) the position of the absciss-layer (*s*) is indicated by a slight transverse constriction. In the seeds of *Bowenia*, constructed on the same plan, the inner series of vascular strands appears to be nucellar in position, thus differing from the strands in *Dioon*, *Cycas*, and other genera which are confined to the integument. Miss Kershaw² in describing *Bowenia* speaks of an upper and a lower pollen-chamber; the former serves as a storage-place for the microspores

prior to their further development in the lower chamber. Dr Stopes¹ regards the integument as double in origin, a view suggested by Griffith² in 1835, and as homologous with the single integument *plus* the cupule of *Lagenostoma*. This view is supported by Mrs Thoday³: on the other hand Miss Kershaw's investigation of *Bowenia* seeds leads her to regard the integument as single. Although there would seem to be a *prima facie* case in favour of the dual nature of the integument, the arguments on the other side have greater weight⁴.

Recent observations point to the probability that insects play a part in the pollination of cycadean ovules. Kraus⁵ drew attention to the strong smell emitted by the microstrobili of *Dioon edule* and noticed that small bees were attracted to the ripe strobili of *Macrozamia*, while odourless cones of a neighbouring *Ceratozamia* received no attention. Pearson⁶ and Rattray⁷ have obtained evidence that beetles and weevils act as pollinators to species of *Encephalartos*.

Anatomical features. Allusion has already been made to some of the more striking anatomical features; the large pith, the occasional occurrence of medullary vascular bundles, the presence of one or more cambiums, the large size of the medullary rays, etc. It is worthy of remark that the occurrence of an anastomosing system of medullary bundles is not a constant feature within a genus; in *Macrozamia Fraseri* such a system is present, but absent in *M. Denisoni*⁸. In the pith of stems with no medullary bundles cylinders of collateral bundles may occur in connexion with a fertile shoot. These bundles arise from the inner face of the main cylinder and pass upwards as a domical system into the base of the terminal strobilus which is eventually pushed to one side by the growth of a lateral bud⁹. The secondary xylem tracheids are usually provided with several rows of bordered pits on the radial walls and resemble those of the Araucarieae¹⁰, but in Cycads the pits are often not contiguous and less compact

in their distribution. The wood of *Stangeria* is peculiar in consisting of scalariform tracheids¹ (fig. 397). Chamberlain describes growth-rings in the wood of *Dioon*; but this is exceptional. In tangential sections of the stele leaf-trace bundles are constantly seen passing horizontally through the broad and deep medullary rays. The pith-cast of a cycadean stem reproduced in fig. 398 shows the wide meshes in the reticulum of tracheal tissue originally occupied by parenchyma, which on decay left lenticular depressions

FIG. 397. Tracheids from the stem of *Stangeria paradoxa*. (After Marsh.)

FIG. 398. Pith-cast of a *Macrozamia* stem. ($\frac{2}{3}$ nat. size.)

represented on the cast by tapered convex areas occasionally bearing the impress of an outgoing trace in the form of a narrow groove. The secondary phloem often rivals the xylem in breadth and is not always easily distinguishable from it; it consists of sieve-tubes, parenchyma, and fibres. The secondary cambial cylinders characteristic of *Cycas*, *Encephalartos*, *Macrozamia*, and *Bowenia*, to which reference was made in the summary of anatomical features, arise in the pericycle, and a few layers of

¹ Pavolini (09); Marsh (14).

pericyclic parenchyma occur between adjacent extrafascicular cylinders of xylem and phloem. In a stem of *Cycas media* 35 cm. in diameter examined by Worsdell there were 12 concentric cylinders. Matte¹ and Miss Dorety² have described partially flattened arcs of extrafascicular xylem and phloem in the hypocotyl of *Ceratozamia mexicana*. Worsdell³ first drew attention to the occasional occurrence of short tracheids on the inner edge of the secondary wood and to the spasmodic development of cambial arcs in the tissue between the extrafascicular cylinders forming strands of inversely orientated xylem and phloem. More recent work by Matte gives support to Worsdell's comparison between Medullosean stems and those of recent Cycads with inversely orientated arcs or concentric vascular cylinders. The French author draws attention to the close resemblance between the seedling stems of such species as *Encephalartos Barteri* (fig. 396, K) and *Cycas siamensis* (fig. 396, L) with their polystelic type of structure and the adult stems of *Medullosa*⁴. In the stems of *Dioon*, *Microcycas*, *Stangeria*, and *Zamia* no extrafascicular cylinders are recorded. Two main vascular bundles enter the cortex from each leaf-base and in most stems these diverge right and left and more or less completely encircle the stele before passing through the medullary rays and joining the inner portion of the xylem of the stele either as double or single bundles. These girdle-bundles (fig. 396, H) first described by Karsten and Mettenius form a very characteristic cycadean feature⁵. Adjacent girdles are joined by connecting cortical bundles and, in addition, there are cauline collateral bundles in the cortex which form an anastomosing system. In some cases, e.g. species of *Macrozamia* and occasionally in *Stangeria*, the female peduncle of a *Ceratozamia*, and in seedlings of *Bowenia* and *Cycas revoluta*⁶, the leaf-traces pursue a direct course from petiole to stele as in stems of Bennettitales. It is noteworthy that in seedlings of *Microcycas*⁷, a genus characterised by a large number of male gametes—presumably a primitive feature—the leaf-traces are of the girdle-type. The two bundles at the base of a petiole by repeated

¹ Matte (08).² Dorety (08²); (09).³ Worsdell (96).⁴ Matte (04) especially pp. 185—202. See also Worsdell (00); (06) etc.⁵ Matte (04) p. 210.⁶ Worsdell (98²).⁷ Caldwell (07).

subdivision give rise to the numerous collateral strands of the rachis. A leaf-trace in its passage to the leaf is like that of a Conifer in having the protoxylem on its inner edge, whereas in the petiole and elsewhere in the frond it is characterised by an arrangement of the xylem that has usually been described as mesarch. A typical vascular bundle from a cycadean frond is seen in fig. 399, C; by far the greater part of the xylem is centripetal, the centrifugal xylem being confined to an arc of scattered tracheids or a small strand separated by a few parenchymatous cells from the protoxylem.

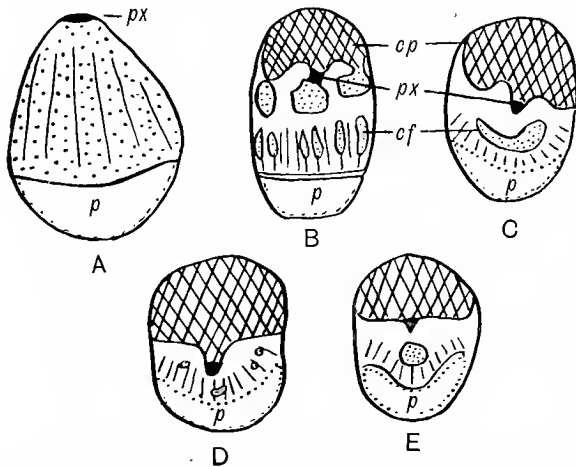

FIG. 399. Sketches illustrating the changes in the structure of Cycadean vascular bundles in their course from stem to leaf: *cp*, *cf*, centripetal and centrifugal xylem; *p*, phloem; *px*, protoxylem. (After Marsh.)

As considerable stress has been laid on the anatomical features of the cycadean foliar bundles in discussions on the affinities and phylogeny of certain Palaeozoic genera, it is important to consider the facts more closely¹. French anatomists described the cycadean bundle as diploxylic on the ground that the centripetal and centrifugal xylems are distinctly different things, the centripetal xylem being primary—a relic of a former organisation—and the centrifugal xylem secondary and homologous with the normal

¹ Carano (04); le Goc (14); Marsh (14).

wood of the cauline bundle. The term mesarch has in recent years been applied to the cycadean type of bundle. A mesarch bundle is, however, one in which centripetal and centrifugal xylem are alike in origin, both being primary structures derived from a desmogen strand. Typical mesarch bundles occur in several recent ferns; in the stele of the Osmundaceae, *Gleichenia*, and other genera; but in these plants the xylem is all produced directly from one primary desmogen region and there is no question of 'primary' and 'secondary' as in the two portions of the xylem of a cycadean bundle. Recent researches into the development of cycadean foliar bundles show that they do not conform to the mesarch type as generally understood. A leaf-trace at the base of a petiole (fig. 399, A) comprises centrifugal xylem only, and this consists of regular rows of tracheids separated by medullary rays; in the lower part of the petiole the structure is gradually modified, the centrifugal xylem is reduced and the formation of centripetal xylem is initiated. At a higher level (fig. 399, B) the centripetal xylem is in excess of the centrifugal and the latter, for a time connected with the former, eventually becomes separated by a few parenchymatous cells from the protoxylem and persists as a small strand or arc of tracheids. Fig. 399 illustrates stages in the transformation of a typical collateral bundle, at the base of a *Stangeria* petiole, into one in which the xylem is almost wholly centripetal at a higher level in the axis of the frond. A cambium is present in all: in B the centrifugal xylem is more or less clearly differentiated into two portions, loosely arranged tracheids near the phloem, and the more compact groups abutting on the centripetal xylem: figs. C—E show a further reduction in the centrifugal tracheids. The conclusion drawn from developmental study is that the two xylem portions of the bundle are independent in origin¹. Marsh has, however, shown that in *Stangeria* bundles near the base of the petiole the centrifugal xylem consists of rows of secondary tracheids and an inner portion not in rows which connects the centrifugal with the centripetal elements; this connecting portion, he adds, is 'probably primary and connects up the Cycadean foliar bundle with the truly mesarch bundle of the Cycadofilices.'

¹ Le Goc (14); Marsh (14).

In the xylem portion of the bundle from the midrib of a forked pinna of *Cycas Micholitzii* shown in fig. 400 the centrifugal xylem elements are unusually numerous: the space between the two xylems is occupied by parenchyma and the whole strand is enclosed by a sheath of crystal-containing cells, *s*, with thick inner walls. Fig. 400, 1—4, illustrates the gradual change in the form of the bundle in the region of dichotomy¹. The ground-tissue of the

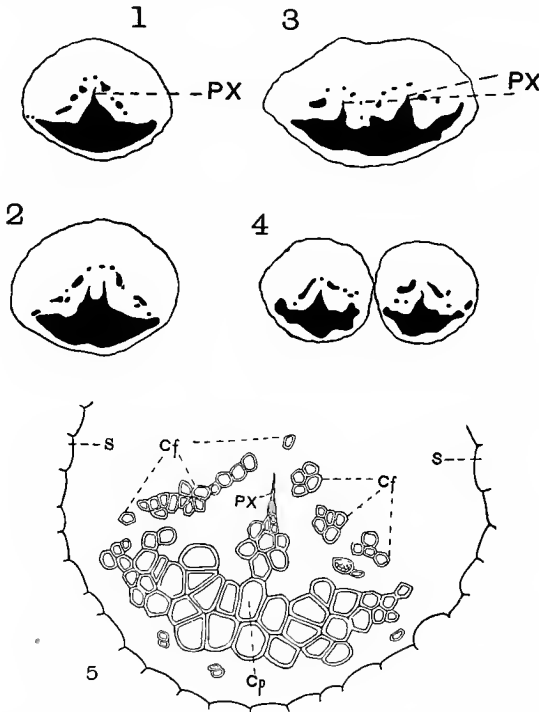

FIG. 400. *Cycas Micholitzii*. Vascular bundles in a forked] pinna; *px*, protoxylem; *s*, sheath of thick-walled cells; *cf*, *cp*, centrifugal and centripetal xylem.

petiole is abundantly supplied with secretory canals and in the hypodermal region is a cylinder of stereome. In some petioles, e.g. *Macrozamia heteromera*², the ground-tissue cells are lignified and reticulately pitted, a feature met with in some Mesozoic cycadean leaves³. In *Cycas media* Worsdell noticed a tendency

¹ Seward (06).

² Robertson (02).

³ Seward (12²).

of the leaf-trace bundles towards a concentric arrangement and similar vascular strands are recorded in the peduncle of *Dioon edule*, in various sporophylls¹ and in other cases. It is possible, as Worsdell believes, that the fairly frequent occurrence of concentric bundles in plants characterised by collateral bundles may have a phylogenetic significance.

The pinnae are dorsiventral and the veins exarch or pseudomesarch: secretory canals occur between (*Encephalartos*), above, or below the veins. The mesophyll of *Cycas* is characterised by the presence of isolated xylem-elements passing from the midrib to the edge of the lamina and, as Lignier² suggests, these may be regarded as a reduced system of lateral conducting strands.

The epidermal cells of the leaflets have straight or slightly curved walls except in *Stangeria* where they are undulate and fern-like³. The stomata, with few exceptions confined to the lower epidermis, are larger than in other gymnosperms (on the average $.075 \times .034$ mm.) and are more or less depressed below the surface; the guard-cells are usually surrounded by 4—6 subsidiary cells.

The roots exhibit no feature to which attention need be called: the pericycle is several cells broad and as in the stem there may be extrafascicular cylinders of xylem and phloem.

CHAPTER XXIX.

PTERIDOSPERMEAE.

I. LYGINOPTERIDEAE.

LYGINOPTERIS.

THE genus *Lyginopteris* is selected for the first place in this chapter simply on the ground that we have a fuller knowledge of its morphology than in the case of other types. It is not regarded as the most primitive member of its class. *Lyginopteris* may be described in a few words as a plant having the habit and to a large extent the anatomical features of a Fern, but differing from existing ferns in the possession of integumented megasporangia or seeds and in the power of secondary growth in thickness by means of a cambium in both stem and root. The seed (*Lagenostoma*) agrees with those of recent Cycads and Gnetales more closely than with the corresponding organs in Conifers or any other group, while the structure of the secondary wood is practically identical with that of Cycads. The microsporangia occur as groups of small bilocular sporangia, or synangia, at the tips of fertile pinnae of highly compound fronds.

Nomenclature and Historical Summary. In 1866 E. W. Binney¹ of Manchester published a short description of a small petrified stem from the Lower Coal Measures of Lancashire and named it *Dadoxylon oldhamium*, employing Endlicher's term *Dadoxylon* which that author substituted for *Pinites* as previously used by Witham². Three years later Williamson³ drew attention to certain features in which Binney's type differs from the genus *Dadoxylon* and substituted a new name *Dictyoxydon*, suggested by the reticulate pitting on the walls of the tracheids. In a

¹ Binney (66).

² Unger (50) A. p. 378.

³ Williamson (69).

subsequent paper Williamson¹ gave a fuller description of Binney's species and spoke of it as 'one of the most common plants in the calcareous nodules of the Lower Coal Measures' of Lancashire and Yorkshire. He connected certain casts of arborescent dimensions with Binney's type on the ground that the surface-features of the casts are such as would be produced by partially decorticated stems having a hypodermal reticulum of mechanical tissue like that preserved in the small petrified specimen described by Binney (fig. 402). Mr Carruthers called Williamson's attention to a paper by Mr Gourlie² in which the generic name *Lyginodendron* is instituted for stem-casts identical in surface-features with the fossils figured by Williamson. In spite of the much larger dimensions of the reticulum on the casts described by Gourlie as compared with that in the outer cortex of Binney's stem, Williamson concluded that *Lyginodendron* is 'undoubtedly an inorganic cast of the prosenchymatous layer of the bark of *Dictyoxyylon*.' It is but fair to add that Williamson was influenced in coming to this conclusion by a discovery by Mr Nield of a piece of a large petrified stem believed to be generically identical with Binney's type, but subsequently referred to a distinct genus³, which was comparable in size with the stems responsible for Gourlie's *Lyginodendron* casts. The type-specimen of Gourlie's *Lyginodendron Landsburgii*⁴, from Carboniferous rocks at Stevenston in Ayrshire, Scotland, is represented in fig. 401. The convex areas represent casts of depressions in a reticulum of cortical tissue, originally occupied by comparatively delicate cells, which decayed or shrunk more quickly than the enclosing framework of stronger fibrous elements that remained as a prominent reticulum and produced the depressions bounding the raised portions of the cast. Such a cast would undoubtedly be formed by the stem on which Binney founded his species: the radially disposed bands of thick-walled cells seen in the outer part of the section (fig. 402) are portions of an irregular anastomosing mechanical system, the reticulate arrangement of which is seen in the impression of a rachis of a *Lyginopteris* frond shown in fig. 405, E, and indicated in the more slender axis reproduced in fig. 404, A, b. This reticulate form of

⁴ Solms-Laubach (91) A. pp. 8, 217, 218.

cortical stereome on which Brongniart founded the genus *Dictyoxylon*¹, a term since applied by Solms-Laubach and other authors to a certain type of cortex not confined to a single genus of plants, occurs also in some Palaeozoic lycopodiaceous stems² and in itself

FIG. 401. *Lyginodendron Landsburgii*. (Kidston Coll. $\frac{3}{4}$ nat. size.)

cannot be regarded as a safe criterion of botanical affinity. The largest example of Gourlie's *Lyginodendron* that has come under my notice is an incomplete sandstone cast from Upper Carboniferous strata near Harrogate reaching a length of 100 cm. and

¹ Solms-Laubach (91) A. pp. 8, 217, 218.

² Vol. II. p. 220.

with convex areas 13 cm. long. A similar cast, 36 cm. broad, has recently been figured by Nathorst¹ from the Culm of Spitzbergen, and from the Upper Devonian of Ellesmere Land the same author has described impressions of a cortical reticulum under the name *Lyginodendron Sverdrupi*². These specimens are interesting as pointing to the former occurrence in the Arctic regions of stems—probably *Lepidodendroid*—reaching the dimensions of a fairly large tree. As Potonié³ pointed out, Gourlie's generic name serves a useful purpose for casts of stems of the type shown in fig. 401 that cannot be assigned to a definite systematic position. The genus was first used for a specimen which has nothing to do with the plant usually spoken of as *Lyginodendron oldhamium* (Binney). Though loath to give up a name by which Binney's type has long been known, in spite of its retention in the second volume of this work I feel compelled so far to conform to the recognised principles governing nomenclature as to adopt Potonié's generic term *Lyginopteris*.

Lyginopteris oldhamia (Binney).

i. *Stem.*

The petrified stem on which Binney founded the species was first figured by Dr Arber¹ from a section in the Binney collection in the Sedgwick Museum, Cambridge: this section (13 mm. in diameter) is reproduced in fig. 402. The most striking features are: (i) the pith consisting of an unusually large and irregular group of dark thick-walled parenchyma, (ii) the broad cylinder of manoxylic secondary xylem characterised by multiseriate medullary rays, (iii) the outer cortex composed of dark radially

FIG. 402. *Lyginopteris oldhamia*. Transverse section of the type-specimen in the Binney Collection, Sedgwick Museum, Cambridge. (After Arber.)

disposed and oblique bands of mechanical tissue separated from one another by partially destroyed and tangentially elongated parenchymatous elements. It is this outer cortex that Williamson aptly compared with the Roman numerals on a clock-face. In the perimedullary region and in contact with the inner edge of the secondary-xylem cylinder are six strands of primary xylem

¹ Arber, E. A. N. (02).

representing the xylem halves of collateral bundles separated from the primary phloem strands by the intervening cylinder of secondary wood. Two of the primary xylem strands in lateral contact are seen in fig. 404, C; the other four occur as separate bundles. Each primary xylem strand contains a small group of spirally thickened protoxylem elements (*px*) associated with a few parenchymatous cells. The large primary tracheids internal to the protoxylem are characterised by multiseriate bordered pits on their walls, while those external to the protoxylem, which are in contact with the innermost secondary tracheids, have scalariform pitting. The dark patch *s* (fig. 404, C) is a portion of the large group of sclerenchymatous cells, shown in figs. 402, 403. The perimedullary xylem strands of mesarch structure are the lower portions of leaf-traces and, as Scott points out, 'each of the bundles surrounding the pith is, in fact, a sympodium, composed of the united lower ends of successive adjacent leaf-traces.' The larger of the two bundles shown in fig. 404, C, is on the point of passing out to a leaf, while the smaller strand is on its way to a higher level before bending outwards through the secondary wood. Slightly beyond the middle of the secondary xylem there is an arc of narrower tracheids comparable with an incomplete annual ring. Although zones or arcs of narrow tracheids are not uncommon in the wood of *Lyginopteris* there is no satisfactory evidence of regularly recurring seasonal changes. On the outer face of the secondary wood are a few leaf-trace strands pursuing a vertical course in the pericycle region; but the structure and behaviour of these bundles are more clearly illustrated in the stem reproduced in fig. 403. The tissue between the crushed phloem and pericycle and the outer cortex (fig. 402) consists of radially compressed parenchyma with scattered secretory cells separated from the more internal tissue by a narrow band of periderm formed by a phellogen in the outer part of the pericycle.

A larger and better preserved stem, 3.7 cm. in diameter, is seen in fig. 403. In this stem the pith of parenchyma and scattered sclerenchymatous nests is larger in proportion to the stele than in Binney's type-specimen. From the inner edge of the secondary xylem several primary xylem-strands project as rounded wedges or tangentially elongated groups where two traces are laterally

FIG. 403. *Lyginopteris oldhamia*. *a—e*, foliar bundles; *f*, decurrent base of petiole; *r, r'*, roots; *s*, seed (*Lagenostoma*). ($\times 3$. Kidston Coll. 592, B.)

united in the perimedullary zone. The cylinder of secondary wood is partially interrupted at *r* by the bending outwards of the stele of an adventitious root cut across transversely as it bends down after emerging from the outer cortical region. In more or less close association with the outer surface of the secondary xylem are four pairs of leaf-trace bundles and one larger trace at *d* containing two widely separated protoxylem strands and faced externally with an arc of secondary xylem: this is a leaf-trace which shows by the slight constriction on the outer edge of its primary xylem that it is beginning to divide into a pair of equal strands. A precisely similar strand is shown on a larger scale in fig. 404, D. The twin bundles seen at *b*, fig. 403, represent a divided leaf-trace at a slightly higher level than the partially severed trace at *d*, and the arcs of secondary xylem are narrower. The appearance of the double leaf-trace at a still higher level is shown at *c*: the two strands are farther apart and the secondary xylem has almost disappeared, while those at *e*, nearer their entrance into the leaf-stalk, consist exclusively of primary xylem and phloem. At *a* the two strands of a leaf-trace, still nearer to the petiole, are inclined towards one another preparatory to reunion after reaching the leaf-stalk. A slender root is seen in transverse section at *r'* immediately outside the two leaf-bundles. As Williamson and Scott¹ have pointed out, there are always five leaf-traces beyond the xylem cylinder of a *Lyginopteris* stem as seen in transverse section, and these traces in the pericycle, separated from one another by $\frac{2}{3}$ of the circumference, alternate in position with the lower portions of leaf-traces in the perimedullary region of the same stem. The phyllotaxis is thus seen to be $\frac{2}{5}$.

The secondary wood is succeeded by a cambium of normal structure passing gradually into a narrow band of secondary phloem which in well-preserved stems is seen to consist of sieve-tubes and parenchyma with medullary rays rather broader than those in the xylem. Beyond the phloem is the comparatively broad pericycle consisting of parenchyma with nests of sclerenchyma like those in the pith and scattered secretory cells. In the outer layers of the pericycle a phellogen was formed at an

¹ Williamson and Scott (95).

early stage in the growth of the plant, producing several layers of secondary tissue, which is regarded as periderm and forms a conspicuous feature in *Lyginopteris* stems; it appears as a comparatively dark sinuous band where it bends outwards to wrap round the leaf-traces in their almost vertical course through the pericyclic region (fig. 403). The periderm is clearly seen at *p* close to the crushed secondary phloem of the dividing leaf-trace in fig. 404, D. All the leaf-traces seen in fig. 403 beyond the secondary wood are still within the deep-seated periderm and, as Williamson and Scott showed, each leaf-trace after emerging from the secondary wood remains in the pericycle-zone for a length of five internodes as it very gradually inclines outwards. Once free from this region the twin bundles bend more sharply towards the petiole. Stated briefly, the history of each leaf-trace from the perimedullary region to the leaf-base is as follows: at the outer edge of the pith a single trace consists of a mesarch xylem bundle with one protoxylem strand; it passes vertically through five internodes and then bends out through a foliar gap in the xylem-cylinder, and the primary tracheids receive additions from the cambium of the stele on their outer face. As the trace leaves the secondary xylem it bends upwards and, as seen at *d*, fig. 403, begins to divide into twin bundles. As the trace passes higher the bisection of the protoxylem and metaxylem is completed and the secondary xylem-arcs are gradually lost until the separate strands of each pair are reduced to single mesarch bundles composed wholly of primary tracheids. As the trace bends outwards through the cortex the phloem gradually encircles each xylem-strand until a concentric structure is substituted for the collateral disposition of the conducting tissue. At the same time the protoxylem strands divide and occupy a position near the inner edge of the metaxylem. On reaching the petiole or after passing some distance up the axis of the frond, the twin bundles unite and usually form a V-shaped vascular strand (figs. 404, E; 405, A). The single meristele subsequently divides into two equal portions preparatory to the bifurcation of the petiole (fig. 406).

The inner cortex, consisting of parenchymatous tissue and many secretory cells with an occasional group of sclerenchymatous elements in place of the abundant nests of this tissue in the peri-

cycle, has been invaded in the stem shown in fig. 403 by numerous rootlets of *Stigmara* and *Lyginopteris*, some of which are seen interrupting the continuity of the outer cortex. The greater width of the cortical region at *f*, fig. 403, is due to the decurrent base of a petiole the meristele of which is not included in the section. The lighter and broader bands between the cross-sections of the stereome-network in the outer cortex are occupied by remains of tangentially stretched parenchymatous cells, and beyond this zone in a younger stem there are a few layers of parenchyma forming the superficial tissue, but there appears to be no well-defined epidermal layer.

Young stems have been recognised in which there is very little secondary xylem and phloem: in these the stereome bands in the outer cortex are closer together than in the stretched hypodermal tissue of older shoots and the scattered sclerous nests are represented by unthickened cells. In addition to young stems Williamson and Scott described a distinct type of small stem in which the primary xylem forms an almost complete ring¹ comparable with the primary xylem of some adult Sigillarian stems (vol. II. p. 220) but distinguished by its mesarch structure and by the reticulate pitting of the centripetal xylem.

A characteristic feature of the stem is the occurrence of emergences from the outer cortex which have the structure either of spinous processes, broadly linear or flask-shaped, or of stalked glands². A portion of a glandular emergence is shown in fig. 405, B: the group of small cells immediately below the blunt apex is in this instance still intact though showing signs of disorganisation in the centre; but in many cases the secretory tissue has not been preserved and the head of the emergence is occupied by a space. A single stoma is seen at *s* in longitudinal section. Further reference to the emergences is made in the description of the leaf.

It occasionally happens that a meristematic layer is formed in the parenchymatous tissue immediately internal to some of the perimedullary xylem strands of a *Lyginopteris* stem from which either secondary parenchyma is produced or a zone of secondary xylem and phloem, the phloem facing the centre of the pith. An example of such internal xylem was figured by

¹ Williamson and Scott (95) p. 720.

² Williamson (90) Pl. XII. fig. 6.

Williamson¹ and similar occurrences are more fully dealt with by Williamson and Scott² who consider that the perimedullary cambium may represent an internal extension through a leaf-gap of the normal cambial cylinder. In the stem represented in fig. 403 there are two perimedullary xylem strands to the left of the bottom of the V-shaped gap in the secondary xylem-cylinder, *r*, and on the inner face of one of these, as shown in fig. 405, C, there is a narrow arc of internal secondary xylem, *c*, between the xylem-strand and the outer edge of one of the sclerous nests. The sporadic occurrence of arcs of inversely orientated secondary vascular tissue affords an interesting parallel with a similar morphological feature in some recent Dicotyledonous genera such as *Tecoma* and *Iodes*. As Williamson and Scott point out, this similarity affords 'a striking warning against the *indiscriminate* use of even conspicuous anatomical characters³.' While admitting the necessity of guarding against the danger of attaching importance to occasional and abnormal characters they may have some significance as collateral evidence in comparisons of different types of stems. It is conceivable that these anomalous arcs of secondary tissue on the inner side of the primary xylem strands may, as Worsdell⁴ maintains, be reversions to an ancestral character and in this sense comparable with the strands of inverted vascular tissue in some recent Cycadean stems. The question of relationship of *Lyginopteris* and allied types to recent Cycads and the Palaeozoic Medulloseae is considered in a later chapter.

In 1902 Lomax⁵ described two branching specimens of *Lyginopteris*, and more recently two others have been discovered at a locality near Bacup in Lancashire which have been thoroughly investigated by Miss Brenchley⁶ who constructed models from drawings of serial sections⁷. One specimen shows six leaf-bases in a length of $4\frac{3}{4}$ inches and branches spring from the axils of five of them: some of the branches show secondary ramifications. The phyllotaxis of the leaf-bases on a branch is always the reverse of that on the main stem, a divergence to which no parallel was

⁵ Lomax (02).

⁶ Brenchley (13).

⁷ For a description of the method, see Salisbury (13).

found in a selection of trees and shrubs examined by Miss Brenchley. The secondary wood of the stem swells below the point of exit of a branch and frequently a fairly large amount of wood occurs in the pith when a branch is given off: this anomalous wood may help to close the branch-gap.

ii. *Leaf.*

In his account of *Lyginopteris* stems published in 1873 Williamson¹ suggested that the vascular bundles met with outside the xylem-cylinder might be the leaf-traces of large fronds and expressed the opinion that the 'stems or petioles' previously described by him under the generic name *Edraxylon* might belong to *Lyginopteris*. A year later he substituted the name *Rachiopteris aspera* for the petioles previously referred to *Edraxylon* and inclined to the view that this type of *Rachiopteris* may be the petiole of the Carboniferous fronds known as *Sphenopteris Hoeninghausi* Brongn., an inference based to a large extent on the occurrence of emergences on *Rachiopteris aspera* (fig. 404, E) preserved as petrifications like those on impressions of *Sphenopteris Hoeninghausi* as figured by Brongniart (figs. 404, A; 405, D, D'). In 1890 Williamson was able to demonstrate the truth of the surmise that *Rachiopteris aspera* and *Lyginopteris oldhamia* are respectively the petiole and stem of the same plant, which he believed to be an arborescent fern². The petioles of *Lyginopteris* fronds, which may reach a diameter of 1 cm., are attached by a broad base to the stem, and as already suggested by the number of internodes traversed by each leaf-trace, the leaves are comparatively far apart. A transverse section of a petiole is shown diagrammatically in fig. 405 A. The hypodermal stereome is a prominent feature, but the narrow radial plates of the stem-cortex tend to be replaced in the rachis by broader and confluent masses of strengthening elements: the upper surface of the petiole is slightly grooved. Glandular and spinous emergences are often very abundant, as in the section reproduced in fig. 404, E. A glandular emergence is seen at *a* in fig. 405, A. The spinous emergences may be compared with

¹ Williamson (73) A. p. 403.

² Williamson (90).

those of *Davallia* (*Odontosoria*) *aculeata*¹, a West Indian fern of climbing habit and with the prickles on *Hemitelia* and other recent Cyatheaceous fronds², while capitate glands, though simpler than those of *Lyginopteris*, occur on the leaf-stalks of some recent Polypodiaceous species³. The concentric meristele may consist

FIG. 405. *Lyginopteris oldhamia*. A, petiole section; a, glandular emergence; r, root. B, stalked gland; s, stoma. C, inner edge of wood of a stem; c, arc of inversely orientated vascular tissue. in the lower part of the petiole of two separate and slightly curved strands like those seen in fig. 404, E, *m*: sooner or later the two strands unite to form a wide-open V or a W-shaped bundle with several slightly internal protoxylem groups close to the lower edge. The two sections represented in fig. 406, A and

¹ Vol. II. p. 299, fig. 232.

² Bower (12) Pls. xxx. xxxiii.

³ Höhlke (02).

B show the gradual divergence of the two meristeles of a petiole as they approach the level where it divides into two equal branches, a characteristic feature of *Sphenopteris Hoeninghausi* and allied fronds. At a lower level than that represented in fig. 406 the vascular strand of the petiole would have the form of a W as figured by Williamson in one of his earlier memoirs¹. The phloem with scattered secretory sacs and the adjacent tissue of the leaf-stalk are occasionally preserved in wonderful perfection². No endodermis has been recognised. Sclerous nests are scattered in the ground-tissue as are also secretory sacs (figs. 404, E; 405, A). A small root *r* has penetrated the parenchyma of the rachis shown in fig. 405, A.

FIG. 406. *Lyginopteris oldhamia*. Transverse section illustrating branching of petiole. $\times 5$. (From a drawing supplied by Prof. Oliver.)

Sphenopteris Hoeninghausi Brongn.³, founded on material from English Coal Measures, was regarded by Williamson as the foliage of *Lyginopteris* chiefly on the ground of the occurrence of emergences on the axes (figs. 404, A, B) and laminae of the impressions like those on the petrified stems, and this comparison received support from the resemblance of the fragments of pinnules associated with *Lyginopteris* and its petioles in the calcareous nodules

¹ Williamson (74) Pl. LI. fig. 1.

² Scott (09) B. fig. 139, p. 375.

³ Brongniart (28) A. p. 199, Pl. LII. For synonymy, see Kidston (11) p. 42.

to the leaflets of Brongniart's type. This identification is supported by subsequent work. The quadripinnate fronds, which attain a considerable size, resemble those of recent species of *Davallia* and other ferns, but the forking of the rachis and branches of the frond is a striking feature: the pinnae may reach a length of 15 cm.¹ The portion of carbonised rachis shown in fig. 405, E, reveals the existence of a hypodermal reticulum like that in the outer cortex of a *Lyginopteris* stem and the same feature is seen in the more slender axis represented in fig. 404, A, at *b*.² The pinnules are usually deeply lobed and the segments may be comparatively broad and blunt or narrow³ (fig. 290, C, vol. II. p. 399; fig. 404, A, *a*, B; fig. 405, D'). The lamina has a well marked dorsiventral structure: the palisade-tissue next the upper surface is separated from the epidermis by small hypodermal cells, possibly functioning as a water-storage layer, and the central part of the mesophyll consists of loose aerenchyma: the veins are collateral as in recent ferns and stomata occur in the lower epidermis. Emergences are seen both on impressions (fig. 405, D') and on petrified specimens. A striking feature of the pinnules is the rounded surface caused by the revolute edge of the lamina as seen in the section reproduced in fig. 404, B. This character coupled with the occasional occurrence of groups of short tracheal elements at the termination of the veins denotes a tendency to a xerophilous habit.

On the strength of a very close resemblance between *Sphenopteris Hoeninghausi* and *Calymmatotheca Stangeri* (fig. 408, E, F)—characterised by fertile pinnules bearing stellate groups of small linear valves, regarded by Stur as the open lobes of an indusium—Zeiller included Brongniart's type in the genus *Calymmatotheca*. The resemblance in general habit between the two species extends to the presence in their rachises of the *Dictyoxylon* form of cortex⁴. The view formerly held by some authors that the valve-like appendages to the fertile segments of *Calymmatotheca* are sporangia is incorrect: a re-examination of Stur's

¹ Zeiller (88) A. p. 82, Pl. VI.

² See also Kidston (06) B, fig. 5, p. 417; Renier (10²), Pls. 60, 70.

³ Kidston (06) B.

⁴ Stur (77) p. 257, Pls. xxv. xxvi.

specimen (fig. 408, E, F) has confirmed the original description¹. The stellate lobes are now regarded as portions of a cupular investment of a seed similar to *Lagenostoma Lomaxi*, the female reproductive apparatus of *Lyginopteris oldhamia*. The axes of the fertile pinnae bear small thorn-like emergences probably identical with those on the cupule of *Lagenostoma* and on the petioles of *Lyginopteris oldhamia*. It was stated in vol. II that the fronds known as *Sphenopteris Linkii* (Goepp.) represent, with other closely allied forms, leaves belonging to *Heterangium* stems. This statement was based on a misconception: the rachis of *Sphenopteris Linkii*, as I have satisfied myself by an examination of impressions shown to me by Dr Kidston, exhibits the reticulate pattern characteristic of *Lyginopteris* and not the transverse ribs characteristic of *Heterangium*.

It is not an easy task even for those most familiar with Carboniferous fronds to distinguish clearly between species agreeing generally with *Sphenopteris Hoeninghausi*, a species regarded by some authors as the type of a group of very similar and closely allied forms all of which were probably borne on stems referable to the genus *Lyginopteris*. The species *Lyginopteris oldhamia* as generally understood probably includes more than one specific type, and it is safe to assert that in the Carboniferous period *Lyginopteris* was represented by several forms characterised by highly compound fronds with forked rachises like *Sphenopteris Linkii*, *S. Hoeninghausi*, and others. The features characteristic of fronds included in the *Sphenopteris Hoeninghausi* group have recently been described by Gothan². Stur's generic name *Calymmatotheca* originally applied to the species *C. Stangeri* was applied to *Sphenopteris Hoeninghausi* by Zeiller, and although the fronds of the latter type have not been found with fertile appendages of the *Calymmatotheca* type there can be no doubt as to the generic identity of these, barely distinguishable, species both of which belong to stems of *Lyginopteris*. Prof. Johnson³ has recently described some impressions from the Coal Measures of Ireland, which he refers to *S. Hoeninghausi*, bearing stellate groups of lobes like those of *Calymmatotheca*, and in one case he describes a seed in the middle of the carbonised

¹ Oliver (05) fig. 6.

² Gothan (13) p. 40.

³ Johnson (11).

remains of a stellate group of cupular segments. An examination of the specimen in Dublin convinced me that there is no satisfactory evidence of the seed-nature of the appearance on the rock believed by Johnson to be an elliptical *Lagenostoma*-like seed. The actual attachment of the stellate lobes to the pinnae of the frond is not clearly demonstrated.

iii. *Microsporangia*.

In 1905 Kidston¹ announced the discovery of microsporangia on fronds of *Lyginopteris*: he described specimens from the Coal Measures of Dudley identified by him with *Sphenopteris Hoeninghausi* showing sterile and fertile pinnae in organic connexion. The fertile pinnules (fig. 407, B) are slightly expanded distally into an oval limb about 2 mm. long bearing 6 to 7 bilocular fusiform microsporangia 3 mm. long and 1.5 mm. broad: in the immature condition the sorus is hemispherical, the summit being formed of the incurved apices of the sporangia. At maturity the sporangia spread out, the sorus assuming the form of an epaulet. Fig. 408, H, shows a sorus in transverse section and in fig. 408, G, the limb and two pendulous sporangia are shown. The microspores, 50—70 μ in diameter, are studded with numerous blunt spines and each spore shows a triradiate ridge. The section reproduced in fig. 407, A, from the Coal Measures of Oldham is probably a bilocular sporangium of the same type as those described by Kidston from Dudley. Dr Kidston² describes a second type of microsporangial sorus as *Crossotheca Hughesiana* which agrees closely with *C. Hoeninghausi*, but the fertile segments are not associated with any sterile pinnae. The generic name *Crossotheca*, founded by Zeiller³ in 1883, was substituted for *Sphenopteris* on the ground that Brongniart's species *S. Hoeninghausi* is shown to possess sporangia of the *Crossotheca* type. If Kidston's specific determination is correct, his discovery demonstrates that *Lyginopteris* fronds bore microsporangia having the characters of *Crossotheca*, a type characteristic of several Carboniferous species belonging both to the form-genera *Sphenopteris* and *Pecopteris*. Reference has already been made to the difficulty of distinguishing between impressions of fronds of the *Sphenopteris*

¹ Kidston (05).

² Kidston (06) B.

³ Zeiller (83) B.

Hoeninghausi group, a difficulty that is illustrated by Dr Gothan's statement¹ that the Dudley specimens of *Crossotheca* are not identical in the character of the sterile pinnules with *Sphenopteris Hoeninghausi*. An examination of Dr Kidston's specimens led me to agree with his determination; but, it may be asked, have

FIG. 407. A, B. *Crossotheca Hoeninghausi*.
C. Pinnule with a sporangium, s.

(A, Kidston Coll. 1277; B, after Kidston; C, Camb. Botany School, 508.)

we any evidence of the association with *Lyginopteris* fronds of sporangia other than those of the *Crossotheca* type? Prof. Chodat² believes that certain petrified fragments of pinnules occasionally met with in the calcareous nodules bearing sessile and apparently annulate sporangia belong to *Lyginopteris* fronds. These sporangia appear to be identical with those named by

¹ Gothan (13) p. 49.

² Chodat (08) B.

Scott *Pteridotheca Butterworthi*¹ and regarded by him as filicean sporangia that cannot be referred to any known Carboniferous genus. The piece of lamina bearing an empty sporangium, which may or may not have possessed an annulus, reproduced in fig. 407, C, occurs in association with the larger specimen shown in fig. 404, B, and it would seem not unreasonable to regard both as parts of the same frond, namely a frond of *Lyginopteris*. As Prof. Weiss² points out, the accurate determination of small pieces of petrified pinnules is exceedingly difficult and without more decisive evidence we are hardly justified in asserting that the sporangia figured by Chodat and Scott and that shown in fig. 407 belong to the genus *Lyginopteris*. Although the available data appear to favour the view generally held that Kidston's conclusion is correct additional evidence would be welcome.

Telangium. Reference was made in vol. II.³ to the genus *Telangium* instituted by Dr Benson for some petrified sporangia from the Coal Measures regarded by her as the microsporangia of a Pteridosperm, probably *Lyginopteris*. The sporangia of *Telangium* are similar to those of *Crossotheca*. Scott points out that they are borne on a flat disc or lamina 'quite comparable to a fertile pinna of *Crossotheca*⁴,' and he concludes that these sporangia are not generically distinct from the impressions on which the genus *Crossotheca* was founded. Kidston⁵ regards *Telangium Scotti*, Benson, as the microsporangium of a Pteridosperm though not of *Lyginopteris*, on the ground that the microsporangia described by Miss Benson are not attached to a limb and that they have a single loculus in place of the double loculus (fig. 407, A) of *Crossotheca*. The presence of a limb in *Telangium* recognised by Scott removes one of these distinguishing features. There are, however, no adequate reasons for regarding *Telangium Scotti* as specifically identical with *Crossotheca Hoeninghausi*. The synangium of *Telangium Scotti*, 5 mm. in length, consists of 6—12 sporangia united basally and opening when ripe by longitudinal dehiscence. Fig. 493, E, shows eight sporangia of a synangium in transverse section: the two sporangia at the lower end of the section are less distinct than the others, some are full of spores

⁵ Kidston (06) B.

and others have shed their contents by the splitting of the thin inner walls of the loculi. The sporangial walls are composed of an outer layer of large cells with dark contents succeeded by 2—3 layers of smaller and crushed cells. The spores, $5-6 \mu \times 3.5-4 \mu$ in diameter, have a reticulately sculptured exine: Dr Benson¹ states that they agree closely with pollen-grains found in the pollen-chamber of *Lagenostoma ovoides* except in their slightly smaller size; she notes the association of *Telangium* with fragments of the vegetative organs of *Lyginopteris* and draws attention to resemblances in the structure of the tissues; but the most interesting comparison, at least in an academic sense, is with the seed *Lagenostoma*, the integumented megasporangium of *Lyginopteris*. Dr Benson points out that a transverse section of a *Lagenostoma* in the plane of the canopy, showing the nucellar apex surrounded by radially disposed chambers (fig. 409), presents a certain resemblance to a synangium of *Telangium Scotti*; and it is suggested that the chambers encircling the nucellus may represent sterilised sister-sporangia². 'The seed in fact is assumed to be a synangium in which all but one of the sporangia are sterile, and form an integument to the one fertile sporangium which has become a megasporangium with one large megaspore.' This view, though clearly incapable of confirmation in the present state of our knowledge, is not merely an ingenious hypothesis but a stimulating suggestion as to possible homologies: as an argument in favour of associating *Lagenostoma* and *Telangium* as the spore-bearing organs of the same plant it has but little weight.

iv. *The Seed. Lagenostoma Williamson.*

Lagenostoma Lomaxi, Oliver and Scott ex Williamson, ms.

In 1877 Williamson³ proposed the generic name *Lagenostoma* for some petrified seeds from the Lower Coal Measures of Lancashire and described two species, *Lagenostoma ovoides* and *L. physoides*: in his ms. Catalogue a third type is referred to as *Lagenostoma Lomaxi*. It is this third type that Prof. Oliver

¹ Benson (04) B.

² In his account of the ovule of *Stangeria* Lang (00) discusses the possibility of homologising the ovule with a sorus consisting of one sporangium.

³ Williamson (77) B. p. 234.

was the first to recognise as the megaspore-bearing organ of *Lyginopteris oldhamia*. Its structure has been thoroughly described by Oliver and Scott¹ and these authors contribute a judicial summary of the evidence on which *Lagenostoma* and *Lyginopteris* are believed to stand for one and the same plant. The evidence is based chiefly on the following considerations: an agreement in the structure of the vascular bundles in the investments of the seed with those in the leaves of *Lyginopteris*; the presence in the outer envelope of the seed of stalked glands identical with those on the stems and petioles. The evidence does not as yet amount to absolute proof, as the seeds, which occur either with or without a stalk, have not been found attached to a *Lyginopteris* frond. But 'where vegetative and reproductive organs presenting identical structural features, not known to occur in other plants, are thus found in close and constant association, the inference that the one belonged to the other appears irresistible.' While most botanists believe that a satisfactory case is established there are a few² who refuse to believe in a connexion between *Lagenostoma* and *Lyginopteris* until an actual union has been demonstrated. The discovery by Kidston³ of seeds attached to pinnae bearing *Neuropteris* pinnules and the demonstration of organic continuity between seeds and the pinnules of other Palaeozoic fern-like fronds supply abundant confirmatory evidence that leaves no doubt as to the occurrence of seeds on modified pinnae of *Sphenopteris Hoeninghausi* and of other closely allied fronds which represent the foliage of different forms of *Lyginopteris*. In this connexion it is pertinent to add that Grand'Eury⁴ has found seeds of the *Lagenostoma* type in close association with impressions of *Sphenopteris Dubuissonis* and other leaves of similar habit.

A seed of *Lagenostoma Lomaxi* reaches a length of 5.5 mm. with a maximum diameter of 4.4 mm.; it is broadly oval or barrel-like (fig. 408, C) and when immature was invested by a loose irregularly lobed glandular envelope (fig. 408, B) from which the seed eventually freed itself by a natural process of abscission. The central body or nucellus, except in the apical region, is crescent with a fairly stout integument or testa (fig. 408, C, f) the outer

portion of which is characterised by regular longitudinal rows of palisade-like cells comparable with the broad palisade-layer in the sporocarp of *Pilularia*. On the exposed surface of this palisade-tissue are small dark structureless pegs¹, possibly the remains of a mucilaginous layer such as occurs on the seed-coats of some recent Flowering plants. At the base of the nucellus the chalazal region, fig. 408, C, *ch*, is provided with sclerous elements and forms a hard investment to the axial vascular strand from the pedicel. It is at the base of this chalazal region that the seed is eventually cut off by an absciss-layer. The integument is supplied throughout its length by nine vascular bundles of

FIG. 409. *Lagenostoma*. Transverse section near the micropyle, showing the pollen-chamber, *pc*, the space, *s*, between the nucellus and integument, the fluted canopy with vascular bundles, *v*. (After Oliver.)

endarch, or approximately endarch, structure. The free portion of the integument seen from the outside (fig. 408, B) has the form of a fluted cone with a circular opening at its summit. The greater part of this domical apex, as seen in longitudinal section in fig. 408, C, appears to be hollow, but in the living state the dome, or canopy as Williamson called it, was filled with parenchyma in which the vascular bundles were embedded and, as shown in the transverse section in fig. 409, the canopy is divided into compartments by radial septa which in its basal region are replaced

¹ Oliver and Scott (04) Pl. x. fig. 28; McLean (12).

by regular and deep furrows on the inner face. Enclosed by the canopy, with its outer surface fluted as the result of the partial collapse of the outer wall of each compartment due to the decay of the filling tissue, is the flask-shaped apex of the nucellus; between the apical cone of nucellar parenchyma and the superficial layer is an annular cavity which Williamson¹ called the lagenostome. The parenchymatous core tapers to a narrow summit which slightly overtops the integument and is constricted at the broad base (fig. 493, A, B; page 311). The bottle-shaped apical tissue is separated by an annular space, *c*, fig. 493, B, from the limiting layer of the nucellus: this space is the pollen-chamber formed in the living seed by the disorganisation of the subepidermal cells of the nucellar apex. The pollen-chamber is a feature characteristic of recent cycadean ovules (see p. 6). In *Lagenostoma* the annular form of the pollen-chamber is a peculiarity distinguishing this type of seed from those of recent Gymnosperms and most other Palaeozoic seeds. As Oliver says, it marks an 'advance in precision'² over other forms as the microspores which fall into the chamber are brought direct to the surface of the underlying megaspore and presumably to the archegonia which, it is reasonable to believe, were disposed in a circle at the base of the annular crevice. Microspores frequently occur in the pollen-chamber and some have been discovered apparently in the act of liberating male gametes³.

The outer wall of the nucellus is bounded externally by a similar circular space (*d*, figs. 408, C; 493, B) which separates it from the domical canopy. In the great majority of specimens the central tissue of the seed is not preserved and an empty sac supported from the base of the nucellus-apex occupies nearly the whole of the interior: the shrunken wall of the sac is all that remains of the large megaspore. It would seem, then, that the nucellus was almost completely destroyed as a consequence of the growth of the megaspore or embryo-sac, which eventually occupied nearly the whole of the seed-body.

In an exceptionally well preserved specimen recently described and admirably illustrated by Mr McLean⁴ part of the parenchymatous tissue of the prothallus which originally filled the megaspore

¹ Williamson (76). ² Oliver (03) p. 462. ³ Benson (08). ⁴ McLean (12).

is clearly seen: its surface-layer consists of small cells succeeded by a broad band of radially elongated elements closely resembling the alveoli in the prothalli of some recent Gymnosperms, particularly certain Conifers. No archegonia have been discovered. The cupular envelope of immature seeds, compared by Oliver and Scott with the lobed and glandular husk of *Corylus colurna* L.¹, receives several vascular bundles of collateral and mesarch structure from the axial strand, and these subdivide as they ascend. The glands which occur on all parts of the cupule are sessile or stalked and identical with those on the vegetative organs of *Lyginopteris*. Assuming that pollination occurred at a comparatively early stage in the development of the seed when the cupule was still intact, it is conceivable, as Sir Joseph Hooker suggested, that the glandular secretion may have attracted insects and so aided in the transport of pollen which were perhaps drawn down the narrow pollen-chamber by exuded mucilage as in recent Conifers. The evidence obtained in recent years in favour of insect-pollination in certain Cycads and in *Welwitschia* lends support to this view: the dragon flies hovering over a fertile *Lyginopteris* frond in a recent restoration² may be a legitimate addition.

A striking feature of *Lagenostoma* as of other Palaeozoic seeds is the absence of an embryo: this and other considerations have led certain authors, notably Chodat³, to question the justification for the use of the term seed. Various suggestions have been offered in explanation of this fact. In recent Cycads, as already pointed out, the development of the embryo does not always occur before seed-fall. It may be that these older seeds had no resting-period or there may have been a period of rest after fertilisation and not as now at a stage subsequent to the formation of the embryo⁴; it is also suggested by Scott that 'the nursing of the embryo had not yet come to be one of the functions of the seed, and that the whole embryonic development was relegated to the germination stage⁵.' In this connexion

reference may be made to a statement by Miss Gibbs¹ who speaks of seeds of a *Podocarpus* picked up from the ground in apparently a mature state and with the associated bracts coloured and swollen as though ready to aid in dispersal but with no embryo: the seeds had matured before fertilisation and fell from the tree after pollination. Whatever may be the true explanation of the absence of embryos this negative character should not be allowed to outweigh the evidence furnished by morphological features as to the applicability of the term seed. As Prof. Oliver says, 'there is a long chapter in evolution to be deciphered before we can connect...the seed of *Lyginodendron* with the sporangium of any fern at present known to us'².

The cupule of *Lagenostoma* has been homologised with the outer part of the integument of a recent cycadean seed³ which, it is suggested, consists of an inner and an outer envelope that have become concrescent, and this hypothesis is supported by another author by a comparison between *Lagenostoma* and Gnetalean seeds⁴. A comparison has also been made between the collar of a *Ginkgo* seed and the much more conspicuous cupule of *Lagenostoma*⁵. Dr Benson and Miss Welsford⁶ institute a comparison between the vascular supply of the outer integument of the ovules of *Carpinus* and *Morus* and that of the cupule of *Lagenostoma*, a comparison suggested by Miss Kershaw's remarks⁷ on the similarity between the vascular system of the ovules of *Myrica Gale* and *Trigonocarpus*. In 1908 Dr Benson⁸ described some germinating microspores in the pollen-chamber of another species of *Lagenostoma*, *L. ovoides*, and recognised what she believed to be antherozoids. I am indebted to this author for allowing me to make a drawing from her section (fig. 408, D). Two microspores are seen with thick outer walls showing irregular holes probably of secondary origin and not part of a regular reticulum as Dr Benson suggests. Close to the upper microspore is a hemispherical body, *s*, described as a male gamete, and a

⁷ Kershaw (09) p. 359.

⁸ Benson (08).

similar body is seen still enclosed by the lower microspore. It is by no means improbable that these are antherozoids: they were presumably ciliate like those of *Ginkgo* and recent Cycads (fig. 396, M). The microspores are approximately $70\ \mu$ in length and the supposed antherozoids have a maximum diameter of $45\ \mu$, the latter being about $\frac{2}{3}$ the size of the sperms of *Microcycas* and $\frac{1}{6}$ the diameter of those of *Zamia*. The smaller and more delicate cells near the lower microspore (fig. 408, D) are no doubt fungal cells as Miss Benson suggests. With reference to the difficulty of determining the nature of Miss Benson's supposed gametes it is worth calling attention to some figures given by Zopf¹ of vesicular cells and sporangia of the Phycomycetous genera *Rhizophidium* and *Lagenidium* in the pollen of Flowering plants and Pines. It has been suggested by Burlingame² that the 'gametes' may be prothallial cells; but this is very improbable.

Lagenostoma ovoides Williamson.

In the memoir in which the genus was founded Williamson described two species from the Lower Coal Measures of Lancashire, *Lagenostoma ovoides* and *L. physoides*³. The seeds described under the latter name had previously been assigned by him to another new genus, *Physostoma*, and named *P. elegans*⁴. *Lagenostoma physoides* was afterwards figured by Butterworth⁵ who recognised some new features. For this species Prof. Oliver⁶ has adopted Williamson's earlier name, *Physostoma elegans*. The former species, which has recently received exhaustive treatment by Miss Pranker⁷, agrees generally in its morphological characters with *L. Lomaxi*, but differs in the structure of the surface-tissue of the integument and in some anatomical features. Moreover no cupules have been found and there is 'very little trace of a layer of separation' such as occurs in *L. Lomaxi*. Over the surface of the integument is a layer of prismatic cells, much shorter and less palisade-like than those in *L. Lomaxi*, and there are none of the pegs which are a constant feature in that species. There

are, however, indications that mucilage was poured out by the rupture of the distended cells. Some microspores were found in the pollen-chamber with an average size of $72 \times 53 \mu$; they may be as much as 90μ long. None were observed with sperm-like contents like those described by Dr Benson. Miss Pranker discusses the morphology of the integument in relation to that of cycadean seeds and makes an instructive comparison between the lagenostome (that is the modified nucellar apex) and such fern sporangia as those of *Angiopteris*, *Osmunda*, and *Schizaea*, but especially the sporangia of *Senftenbergia*¹ with their multiseriate annulus.

An interesting feature is shown in the longitudinal section reproduced in fig. 493, A (p. 311). The apex of the nucellar cone appears to be composed of thick-walled, dark cells and it is suggested that this may have served as a stopper blocking up the circular orifice of the pollen-chamber (seen below the apex between the nucellar cone and the thick surface-layer of the nucellus) and serving as a protection to the embryo. A comparable closing-up of the micropyle occurs in the seeds of *Gnetum Gneumon*² and in the beak of cycadean seeds. At the time of pollination, when the pollen-chamber must have extended to the apex of the lagenostome, the tip of the nucellar cone may have secreted some sticky substance to which the microspores would adhere.

Prof. Lignier³ has recently described some large megasporangia from the Westphalian Coalfield of Ostrau in Austrian Silesia which he made the type of a new genus *Mittagia*, after Herr Mittag, Director of Mines. Two sporangia, between 2 and 3 mm. in diameter, were found in close association as though belonging to a single sorus; one was empty and the other contained four megaspores. The structure of the thick wall of the sporangia is very similar to that of the testa of *Lagenostoma Lomaxi*, but it apparently split into two valves. Lignier refers the new type, *Mittagia seminiformis*, to some unknown Palaeozoic group of heterosporous Filicineae, possibly the ancestral stock of the Pteridosperms, and he thinks it probable that the sporangia resembled seeds in their facilities for dispersal. In the structure

¹ Vol. II. p. 364, fig. 270.

² Berridge (11).

³ Lignier (13²).

of the sporangial wall *Mittagia* also resembles the sporocarp of *Pilularia*.

*Seeds presented as impressions, without internal structure,
superficially resembling Lagenostoma.*

Lagenospermum Nathorst.

This generic name is adopted for seeds represented by casts or impressions agreeing in external features with *Lagenostoma* but which on the available evidence cannot be confidently assigned to that genus¹. Two types of seed were described by Arber² from the Lower Coal Measures of Scotland as *Lagenostoma Kidstoni* and *L. Sinclairi*: the former has been removed by Oliver³ to *Physostoma* and both are included by Arber⁴ in a recent paper in the genus *Radiospermum*. This new generic term is proposed by Arber for a number of small sub-cylindrical seeds founded on impressions including 'small seeds which, when the structure is preserved, are known as *Lagenostoma*, *Physostoma*, and *Conostoma*.' The question of nomenclature is invariably raised by cases in which impressions resemble in their superficial characters genera founded on anatomical characters: the seeds originally referred to *Lagenostoma Sinclairi* afford a good example of this difficulty. Nathorst has recently proposed the generic name *Lagenospermum* as preferable to *Lagenostoma* and *Radiospermum* in the case of *Lagenostoma Sinclairi* and similar seeds which afford no proof of the possession of such morphological characters as would justify their inclusion in the genus *Lagenostoma* but which may be examples of that genus. As Nathorst points out, the adoption of *Radiospermum* for *L. Sinclairi* is inadvisable on the ground that it is also applied to seeds of a different type. The type-species of *Lagenospermum* is *L. Sinclairi* and Nathorst describes additional species from Lower Carboniferous rocks in Spitzbergen.

Lagenospermum Sinclairi (Arber ex Kidston MS.).

Although it is not certain that these seeds are morphologically identical with the genus *Lagenostoma*, a brief description is inter-

¹ Nathorst (14) p. 29.

² Arber (05).

³ Oliver (09).

⁴ Arber (14) p. 102.

calated here as the habit of the seed-bearing axes supplies a probable key to the habit of the fertile fronds of *Lyginopteris*. The type-specimens were collected by Mr Sinclair from the Lower Coal Measures of Ayrshire, Scotland, and recorded by Kidston as *Lagenostoma* sp.: they were afterwards named by him in manuscript *L. Sinclairi* and handed to Dr Arber for description. The seeds are elliptical-oblong, $4.5-5 \times 1.5-3$ mm., radially symmetrical and enclosed by a loose envelope which is longitudinally ribbed and divided distally into several linear-lanceolate lobes (fig. 408, A, A'). This covering, though much longer than the cupule of *Lagenostoma Lomaxi*, is probably a homologous structure. The most interesting point is the attachment of the seeds to slender branches of a compound axis (fig. 408, A). It is probable that the seeds were borne on a frond characterised by the reduction or complete abortion of the sterile lamina or perhaps, as in the recent Fern *Thyrsopteris elegans*¹, some of the pinnae of a large compound frond were fertile. It is worthy of note that Arber recognised pinnules of *Sphenopteris obtusiloba*² in association with *L. Sinclairi*, a fact, as he says, in itself of no value but which acquires significance in view of the discovery by Carpentier³ of cupules in close proximity to the same species of frond. Specimens described by Dr Stopes from Westphalian rocks of New Brunswick as *Pterispermotrobis bifurcatus*⁴ bear a close resemblance to *L. Sinclairi*.

Lagenospermum oblongum (Kidston).

The species recently described by Dr Kidston⁵ as *Lagenostoma oblonga* from the South Staffordshire coal-field appears to be closely allied to Arber's *L. Sinclairi*: it is represented by pairs of seeds borne at the ends of forked branchlets: the seed is 2.5 mm. long by 1.5 mm. broad and is surrounded by a longer oblong cupule divided distally into 6 free lobes.

A larger type of seed, 3 cm. long and 2.5 cm. broad, is described by Kidston⁶ from the same coal-field as *Lagenostoma? urceolaris*. A characteristic feature is the truncate apex surrounded by a prominent canopy formed of the expanded apical free portion of

¹ Vol. II. pp. 294, 295.

² Vol. II. p. 529, fig. 352.

⁴ See page 66.

the integument. The lack of anatomical data in both these seeds is a reason for the substitution of some less committal term than *Lagenostoma*.

Grand'Eury¹ and Carpentier² have published accounts of impressions of seeds from the Coal Measures of France compared by them with species of *Lagenostoma* though not assigned to new species. These and similar seeds should be referred to Nathorst's genus *Lagenospermum*.

The difficulty of recognising the true nature of seed-like impressions is illustrated by some specimens in the Goldenberg collection in Stockholm described by Arber³ as *Carpolithus Nathorsti*: these consist of pieces of *Sphenopteris* pinnae probably, as Zeiller suggested, *Sphenopteris Schaumburg-Lippeana* (Stur) bearing at the ends of the segments of deeply divided pinnules what appeared to be seeds 1 mm. long, oval and longitudinally ribbed, and possibly enclosed in a cupule. Arber considered the 'seeds' to be related to *Lagenostoma*, probably belonging to some member of the Lyginopterideae. An examination of the specimens by Nathorst⁴ showed that the supposed seeds are collections of spores; but whether the spores of a true Fern or the microspores of a Pteridosperm cannot be determined.

Pterispermotrobis Stopes.

Pterispermotrobis bifurcatus Stopes.

Dr Stopes⁵ has recently called attention to a resemblance between specimens from the Westphalian of New Brunswick, described by her as *Pterispermotrobis bifurcatus*, and *Lagenospermum Sinclairi*. The New Brunswick fossil is made the type of a new genus *Pterispermotrobis*, which is employed for fructifications of Pteridosperms that cannot be associated with a known species of parent and may be either seeds or complex male organs borne on a definitely branched rachis. The type-species is represented by a slender axis bearing lateral branches divided into two widely divergent arms each of which bears a terminal body,

4 × 3 mm., characterised by 3—5 apical lobes extending 2 mm. beyond the distal end of the seed-like organ and resembling a cupule. In this as in many other cases it is impossible to determine the true nature of the reproductive bodies, whether they are small seeds or groups of microsporangia: the new generic name serves a useful purpose though it is not always possible definitely to refer doubtful fructifications of this kind to a Pteridosperm. The organs in question may also be compared with *Codonotheca*¹.

Pterispermotrobos pusillus (Nathorst).

The name, *Codonotheca pusilla*, is given by Nathorst² to some doubtful specimens from the Culm of Spitzbergen representing short stalks bearing linear-lanceolate scale-like bodies, 9—10 mm. long by 1 mm. broad, coalescent at the base. Nathorst compares them with Sellard's species, *Codonotheca caduca*, but adds that they may be cupules of some Pteridosperm and calls attention to their resemblance to some fossils figured by Carpentier as *Calymmatothea acuta*. Both Nathorst's species and the French specimens described by Carpentier³ as cupules may be referred to Dr Stopes' genus *Pterispermotrobos* as their morphological nature cannot be determined.

v. *Roots.*

In 1876 Williamson⁴ described some petrified vegetative organs from the Lower Coal Measures of Lancashire under the name *Kaloxylon Hookeri* characterised by a division of the secondary xylem into cuneate masses (fig. 415, C) like those in some recent Bignoniaceous stems. Williamson at first believed *Kaloxylon* to be a stem, but in a later memoir he expressed the opinion that 'it is difficult to believe that these organs have been other than roots'⁵. Felix⁶ had meanwhile described a specimen from the Coal Measures of Westphalia as *Kaloxylon cf. Hookeri* and suggested that it might be a waterplant. In 1894 Williamson and Scott⁷ demonstrated that *Kaloxylon Hookeri* is the root of *Lyginopteris*, a conclusion independently reached by Hick⁸.

¹ See page 124.

⁵ Williamson (87) p. 297.

⁶ Felix (86) A. p. 51.

⁷ Williamson and Scott (94).

⁸ Hick (95) p. 114.

The roots of *Lyginopteris* arise on all sides of the radially symmetrical stem in the pericycle region; they are copiously branched as is shown by the abundance of roots of various sizes in close association. No roots have been discovered exceeding 1 cm. in diameter nor have any been recorded with secondary periderm-tissue. The absence of root-hairs and the more or less lacunar structure of the cortex are indicative of swampy ground. It is seldom that the palaeobotanist has an opportunity of investigating the growing-points of Palaeozoic plants, and for this reason some well-preserved apices of *Lyginopteris* roots, attributed to that genus on the ground of constant association with fragments of stems in the calcareous nodules of Dulesgate, are of special interest. One of these specimens was figured by Dr Stopes and Mr Watson¹ in their account of plant-bearing nodules, and a description of that and other examples has since been published by Prof. Weiss². A longitudinal section of a root-tip, .21 mm. in diameter at its broadest part, shows a root-cap which suggests an origin from a single cell, but an examination of the plerome-cylinder in a slightly tangential section does not afford conclusive evidence of the occurrence of a single initial cell. Weiss on the whole inclines to the view that *Lyginopteris* possessed a single apical cell like the roots of Leptosporangiate Ferns, though he prefers to leave the decision open. Attention is drawn to the fact that the plate of tracheidal tissue in emerging lateral rootlets is vertical as in Phanerogams and not horizontal as in recent Pteridophyta.

The vascular tissue of a *Lyginopteris* root (fig. 410) consists of from three to eight alternate strands of centripetal xylem and phloem, and with the metaxylem is associated a small amount of conjunctive parenchyma which does not form a central pith. The pericycle, one to several layers broad, is succeeded by an endodermis which occasionally shows the characteristic thickenings on the radial walls. A broad cortex of thin-walled lacunar tissue with numerous secretory cells is bounded externally by a superficial cylinder of two or more layers of comparatively large and thin cells, the outermost of which are radially elongated. This

¹ Stopes and Watson (08) Pl. xvii. fig. 1.

² Weiss, F. E. (13).

superficial tissue forms a striking feature by which a *Lyginopteris* root may often be recognised at a glance. The root represented in fig. 410, approximately 2 mm. in diameter, has a heptarch stele divided into seven xylem-groups by crushed bands of parenchyma and a protoxylem strand occupies the apex of each projecting angle (fig. 410, *px*). The superficial cylinder of clear cells is seen at *a*. A very small root is seen at *r* in fig. 410.

FIG. 410. *Lyginopteris oldhamia*, young root. $\times 30$. (Kidston Coll. 403.)

Fig. 415, C, represents part of an older root in which the pent-arch primary xylem is enclosed by broad wedge-like groups of secondary xylem and phloem separated by conspicuous medullary rays opposite the protoxylem strands (*px*). Crushed primary phloem arcs, *p*, are often clearly recognisable beyond the cambium. The secondary thickening, as Williamson and Scott state, 'takes place exactly in the manner typical of roots of Dicotyledons, so that this fossil might very well be used for purposes of demonstration as illustrating the secondary growth of a root with diagrammatic clearness'¹. The young roots of *Lyginopteris* resemble in many respects those of Marattiaceous Ferns, though the presence of a single apical cell, if such occurs, is a distinguishing

¹ Williamson and Scott (95) p. 739.

feature; but in the presence of secondary conducting tissue they agree with those of Phanerogams.

Distribution of Lyginopteris.

The frequency with which petrified fragments of *Lyginopteris* stems occur in the calcareous nodules of the English coal seams shows that the genus must have been plentifully represented in the Upper Carboniferous vegetation, and the occurrence in both North American¹ and European localities of fronds identical with or closely resembling *Sphenopteris Hoeninghausi* affords evidence of wide geographical range. Petrified specimens were recorded by Felix² from Westphalia in 1886, and Zalessky³ has recently discovered *Lyginopteris* in the Donetz coal-basin of Russia. An investigation by Kubart⁴ of the calcareous nodules, to which attention was first drawn by Stur, in the Ostrau Coal Measures led to the discovery of several examples of *Lyginopteris* stems. The descriptions and figures so far published are hardly sufficient to enable us to estimate the degree of relationship to the English type, but some of the stems appear to be new species and Kubart considers them all to be specifically distinct from *Lyginopteris oldhamia*. *Lyginopteris heterangioides* contains scattered tracheids in the pith and thus affords an interesting transitional type between *Lyginopteris* and *Heterangium*. In *L. lacunosum* the inner cortex is lacunar and the primary xylem bundles pursue an independent course in the stele in contrast to the anastomosing arrangement in *L. oldhamia* and in another Hungarian species *L. tristichum*. The species recorded by Kubart occur in the Millstone grit and the Coal Measures.

The geological range of *Lyginopteris* as represented by petrified stems does not extend beyond the limits of the Carboniferous system.

HETERANGIUM.

The generic name *Heterangium* was first used by Corda⁵ for a piece of stem from the Coal Measures of Radnitz, Bohemia, represented by part of the vascular axis of a stem consisting

² Felix (86) A.

³ Zalessky (10).

⁴ Kubart (14); (11).

⁵ Corda (45) A. Pl. xvi.

of strands of large reticulately pitted tracheids intermixed with parenchyma and exhibiting structural features differing apparently from those of any known type. Corda's material has been re-examined by Kubart¹ who figures a section from it. *Heterangium* is a genus closely allied to *Lyginopteris* both in habit and in general anatomical characters. The stem is monostelic; the vascular cylinder prior to secondary thickening resembles the protostele of certain recent species of *Gleichenia* and may be compared also with *Trichomanes scandens*². It agrees with that of *Lyginopteris* in the possession of primary mesarch bundles but differs in the substitution of a cauline axial mass of metaxylem for the pith of *Lyginopteris*. The secondary vascular tissue agrees closely with that of recent Cycads and *Lyginopteris*. A characteristic feature is the occurrence of numerous horizontal bands of sclerous cells in the cortex (fig. 412) of the stem and in the ground-tissue of the rachis and larger branches of the fronds. The stem was erect and rarely branched 'giving off large foliar appendages at somewhat distant intervals and from its entire circumference'³. Our knowledge of the reproductive organs is less precise than in the case of *Lyginopteris*; but we are justified in asserting that *Heterangium* is a Pteridosperm which in all probability bore fern-like microsporangia and seeds similar in general plan to *Lagenostoma*.

The association of some seeds included in Williamson's genus *Conostoma* with *Heterangium Grievii* in the Pettycur beds and their resemblance to *Lagenostoma*, the seed of *Lyginopteris*, suggested the possibility of actual connexion: further evidence in support of this view has recently been brought forward by Dr Benson⁴ in the case of a species of *Conostoma* which she transfers to a new genus *Sphaerostoma*.

The two species *Heterangium Grievii* and *H. tiliaeoides* are described in illustration of the genus and reference is made to a few other types.

i. Stem.

At the Edinburgh meeting of the British Association Williamson¹ gave a brief account of some petrified stems from the Lower Carboniferous strata of Burntisland on the Firth of Forth which he included in the genus *Dictyoxyylon*. One of these was named *D. Grievii* after Mr Grieve the discoverer of the specimens. In a later and more complete description Williamson adopted Corda's generic name on the ground of the close resemblance of the Scotch stem to the Bohemian fragment *Heterangium paradoxum*. In 1873² Williamson added new facts in regard to *H. Grievii* and in 1890³ he described a very closely allied type from the Lower Coal Measures of Lancashire. Five years later his descriptions were considerably extended and modified in the joint memoir with Dr Scott⁴.

The great difference in age between the English Upper Carboniferous stem and the Scotch specimens from the Lower Carboniferous beds of Burntisland suggests a probable specific difference. Dr Scott has recently adopted the name *Heterangium Lomaxi*, proposed but not published by Williamson, for the English type. Though in the following account the species *Heterangium Grievii* is treated in the broader sense it should be recognised that the geologically younger stem is worthy of specific recognition; it is characterised, to quote Scott⁵, by 'the great distinctness of the primary xylem strands, by their nearly exarch structure,

¹ Williamson (72²).² Williamson (73) A.³ Williamson (90).⁴ Williamson and Scott (95).⁵ Scott (15).

with little primary centrifugal wood, by the abundant secretory sacs of the stele, and by the rather scattered leaves.'

Heterangium Grievii has a radially symmetrical stem bearing compound leaves with decurrent petioles which give to the otherwise cylindrical axis an angular outline as seen in transverse section (fig. 411, A). The phyllotaxis appears to be $\frac{3}{8}$. The

FIG. 411. *Heterangium Grievii*. *lt*, *a*, *b*, *c*, leaf-traces; *p*, pericycle with periderm; *ph*, phloem; *x*¹, *x*², primary and secondary xylem; *px*, protoxylem; *r*, root; *s*, sclerous tissue.

stem rarely exceeds 1.5 cm. in diameter: in the centre is a comparatively large stele consisting in young stems of primary xylem and phloem, but in older stems these are separated by a cylinder of secondary vascular tissue which in this species is always narrower than in *Lyginopteris oldhamia* and, as Williamson pointed out, often of unequal thickness on different radii. The medullated stele

of *Lyginopteris* is replaced by a solid xylem-cylinder consisting mainly of groups of large tracheids, reaching .3 mm. in diameter, with multiseriate bordered pits (fig. 411, D) embedded in an anastomosing parenchymatous tissue-system. In the stele reproduced in fig. 411, B, which with the exception of a very narrow zone of secondary xylem, x^2 , consists entirely of primary xylem, x^1 , the parenchyma is represented by a darker reticulum (cf. fig. 415, B) dividing the metaxylem into islands as in *Gleichenia*. In the peripheral portion of the xylem the tracheids are rather narrower and arranged in more definite groups in many of which is a single strand of narrow spiral elements (fig. 411, A', *px*) close to the outer margin. These peripheral primary bundles in which protoxylem is recognisable may be described as leaf-traces of mesarch structure consisting of centripetal xylem and, to a much less extent, of smaller centrifugal elements for the most part with dense spiral bands in place of the multiseriate pits of the rest of the metaxylem. The structure of these leaf-traces is practically identical with that of the primary bundles of *Lyginopteris*. There is, however, a difference to which attention is drawn by Williamson and Scott. While in *Lyginopteris* in any transverse section the primary bundles in the stele are equal in number to the leaf-traces in the pericycle and cortex, in *Heterangium* the peripheral groups in the stele may be as many as twenty, a number considerably in excess of the leaf-traces beyond the limits of the primary xylem of the stele. It may be that the leaf-trace of each leaf, which joins the stele at a distance of 6—10 internodes below its entrance into the cortex from the leaf-stalk, may branch in its descent in the axial region, or some of the primary groups of xylem may be confined to the axial region and independent of the leaf-traces. Portions of the peripheral region of the stele may be occupied by metaxylem groups without protoxylem and identical with those which make up the bulk of the metaxylem.

Scott¹ has recently published a note in which he states that most of the British Coal Measures *Heterangium*s were polydesmic. Two bundles, and not a single strand as in the Scotch *H. Grievii*, leave the stele for each leaf, and these divide into four, in some cases at least, before entering the petiole.

¹ Scott (15).

The secondary xylem is continuous at its inner edge with the outermost primary tracheids (fig. 411, A') and consists of rows of tracheids, 1—3 elements broad, alternating with numerous broad medullary rays of radially elongated parenchyma. Beyond a typical cambium-zone the secondary phloem consists of parenchyma and sieve-tubes bounded by crushed arcs of primary phloem. Abutting on the phloem is a pericycle composed of several layers of small parenchymatous cells (fig. 411, A, *p*) and in the outer layers of this tissue a phellogen (fig. 411, C, *p*) and some periderm are usually present though, as Williamson and Scott point out, the periderm is less regular and narrower than in *Lyginopteris*. The inner cortex, composed of short parenchymatous cells, is traversed by numerous narrow bands of dark, thick-walled cells similar in the structure of the elements, though peculiar in the horizontal elongation of the groups, to the sclerous nests in the pericycle and pith of *Lyginopteris*. These characteristic bands are chiefly seen in the oblique longitudinal section of a stem represented in fig. 412. In this section, 25 mm. in length, the lighter band, *p*, is the pericycle and in it a few obliquely cut leaf-traces are shown as dark patches. The horizontal bands are similar in structure and shape to the diaphragms of thick cells in the pith of *Abies magnifica*¹, and in both plants they probably serve as supports to the softer parenchyma. There may be as many as 46 bands in a vertical length of cortex of 1 inch (about 19 per centimetre). It was the occurrence of precisely similar transverse lines on the carbonised impressions of the rachis of *Sphenopteris elegans* that led Kidston² to suggest a connexion between that species and the stem of *Heterangium Grievii*.

The outer cortex, consisting of alternate strands of parenchyma and stereome similar to that of *Lyginopteris*, is much narrower and a less conspicuous feature than in *Heterangium*; the stereome bands do not form so regular a hypodermal network and extend much further vertically without anastomosing. The epidermis has been described as a layer of fairly thick cells showing in one case an appearance of a depressed stoma³. There are no secretory canals like those of Cycads but, as in *Lyginopteris*, scattered cells

¹ Jeffrey (05) Pl. III. fig. 21.

² Kidston (91²) B. p. 49.

³ Williamson and Scott (95) p. 753.

with dark contents in the stem-tissues probably represent secretory sacs.

The leaf-traces on leaving the stele pursue a very gradually ascending course to the petiole; they retain their collateral structure in the pericycle and cortex and have no secondary xylem, but become concentric as they enter the base of a leaf.

FIG. 412. *Heterangium Grievii*. Oblique longitudinal section of stele and part of cortex; *p*, pericycle. $\times 3$. (Kidston Coll. 529.)

Before passing to the description of the leaves, the more striking features in the stem may be summarised with reference to the diagrammatic sketches shown in fig. 411. Fig. 411, A, represents a section of *Heterangium Grievii* approximately 2 cm. in its maximum diameter; at the periphery of the primary xylem, x^1 , and close to its outer margin are several protoxylem groups, not shown in the drawing, each of which marks the position of a mesarch trace. The zone of secondary xylem, x^2 , is interrupted by the exit of leaf-traces and one of these is seen at *a* in fig. 415, A, separated from the central primary xylem by a foliar gap filled with parenchyma. The pericycle is shown at *p* in fig. 412 and

its outer boundary at *p* in fig. 411, A. Beyond the pericycle is the broad parenchymatous cortex with leaf-traces, *lt*, and some sclerenchymatous patches, *s*. The vascular strand *a* is passing into the base of a leaf-stalk. In the stem shown in fig. 411, B, 1.4 cm. × 7 mm., a decurrent petiole is seen at the upper end with its single vascular strand, *a*, and two sclerous nests; a similar though detached leaf-base occurs at the opposite end of the long diameter. Other leaf-traces are seen at *b* and *c*. From the left-hand side of the stele a curved strand of tracheids is passing out to supply a root, *r*.

ii. Root.

Adventitious roots of endogenous origin are occasionally met with in *Heterangium* stems, but we have less information as to their anatomy than in the case of *Lyginopteris*. In a specimen of *Heterangium Lomaxi* figured by Williamson and Scott¹ three roots are seen in a vertical series growing outwards through the cortex of a stem. The roots agree generally with those of *Lyginopteris* but the outermost cortical layers possess no special features.

iii. Leaf.

The large compound fronds long known as *Sphenopteris elegans* were recognised by Kidston as the leaves of *Heterangium* by the closely arranged transverse striae or narrow ribs on the rachis and pinnae which are the expression on the carbonised impressions of the horizontal plates of sclerous tissue in the petrified stems and petioles of *Heterangium*. The dichotomously branched fronds are included by Stur in his genus *Diplotmema* and that author figures several typical examples in his 'Culm Flora'². Fig. 413, A, shows a forked axis with the bases of more slender branches and the characteristic transverse bands and in fig. 413, B part of a pinna is reproduced. In general appearance, except in the bifurcating pinnae, the fronds resemble those of *Davallia tenuifolia* with which Brongniart compared the Palaeozoic species. There is little doubt that *Sphenopteris dissecta* and some other species were also borne on *Heterangium* stems. The rachis and petioles

¹ Williamson and Scott (95) Pl. xxvii. fig. 28.

² Stur (77) p. 236, Pls. xiii. xiv.

differ from those of *Lyginopteris* fronds in the absence of emergences (cf. fig. 404, E). The petioles (fig. 411, B, a) have a single concentric vascular bundle with internal protoxylem.

FIG. 413. *Sphenopteris* (*Diplomema*) *elegans*. A. Forked rachis with bases of lateral branches (Kidston Coll.); B, pinna. (After Stur.)

iv. *Reproductive organs.*

As yet no satisfactory evidence has been published with regard to the nature of the microsporangia but in all probability these were constructed on the same plan as those of *Lyginopteris*. There is a strong *prima facie* case for assigning the seed *Sphaerostoma* to *Heterangium*: absolute proof of organic connexion is still lacking though Dr Benson's recent account of the seeds

associated with *Heterangium Grievii* almost amounts to demonstration of continuity between vegetative organs and seeds.

Sphaerostoma ovale (Williamson).

In 1877 Williamson described some detached petrified seeds from the Lower Carboniferous rocks of Fifeshire, Scotland, as *Conostoma ovale* and *C. intermedium*. Dr Benson's investigation¹ of these two forms leads her to confirm Williamson's doubts as to the validity of a specific separation and she assigns the single

FIG. 414. *Sphaerostoma ovale*. A. Longitudinal section showing the cupule, *c*, integument, *e*, *f*, with vascular bundle, *v*, the upper part of the nucellus, *n*, and megaspore, *m*; *a*, archegonia. B. Transverse section through the roof of the pollen-chamber, *pc.*, and the summit of the nucellus, *n*. (After Benson.)

type to the new genus *Sphaerostoma*. The seeds are always associated with the vegetative organs of *Heterangium Grievii*. In 1909 Oliver² expressed the opinion that the Burntisland species of *Conostoma* (= *Sphaerostoma*) is probably the seed of *Heterangium*. The seed consists of a central body representing the nucellus, an inner integument, and an enveloping cupule or outer integument: most specimens have lost the cupule and in this condition they are 3.5 mm. long with a maximum breadth of 2.2 mm. In the

¹ Benson (14).

² Oliver (09) p. 111.

middle the seed is circular in transverse section and octagonal near the base and apex. The free apical part of the integument forms a frill (canopy) round the micropyle and extends beyond the nucellar apex which consists of a relatively flat plinth surmounted by a central dome or lagenostome (fig. 414). The lagenostome is surrounded by an annular pollen-chamber on to the lower surface of which abuts the large embryo-sac, and remains of archegonia were noticed below the pollen-chamber. The roof of the chamber in the young state consists of a layer of thin-walled cells extending across the flattened apex of the nucellus, *n*, but as the pollen-chamber becomes differentiated from the nucellar tissue by the disorganisation of the zone of cells its roof-cells thicken their vertical walls and assume the structure of a multiseriate annulus, which acts as a mechanism for opening the pollen-chamber by a circular dehiscence in such a way that the edge of the ruptured roof of the pollen-chamber slightly overlaps the periphery of the central column of nucellar tissue after it has returned to its original position subsequent to the entrance of the microspores. The micropylar region is surrounded by eight lobes of the integument and each is characterised by a crest of radially elongated cells, fig. 414, *f*, especially prominent on the outer side. External to this is the slightly longer cupular sheath (fig. 414, *c*) which may also have been lobed. The surface of the integument below the terminal crests consists of a layer of cells with small papillae which eventually ruptured and discharged mucilage. Both integuments have a vascular supply, that of the inner integument being represented by eight vascular bundles, some of which were found to have mesarch xylem, given off from the single strand in the pedicel. Fig. 414 shows the apical region of a seed of *Sphaerostoma*: the flat-topped nucellar cap, *n*, is surrounded by the annular pollen-chamber, *pc*, below which are indicated the archegonia: the wall of the megaspore (embryo-sac) is seen at *m* and external to this vascular bundles, *v*, run up the inner portion of the integument accompanied by some large cells (aqueous tissue). The elongated epidermal cells at the apices of the lobes of the integument form the frill, *f*, and at a lower level the cells of the same layer are much smaller and papillate (*e*): the outer integument, *c*, forms the

so-called cupule. The transverse section shown in fig. 414, B, is taken at the level of the roof of the pollen-chamber and of the nucellar cap; it illustrates the contrast between the 'multi-seriate annulus' and the central column of small parenchyma.

Sphaerostoma differs from *Lagenostoma* in the whorl of crests around the micropyle, in the nearly hemispherical form of the lagenostome and in the relatively wider pollen-chamber with its peculiar form of dehiscence. Miss Benson, while regarding *Sphaerostoma* as similar to *Lagenostoma* in general plan, believes the distinguishing features of the former to be such as are consistent with a more primitive form.

An important argument in support of connecting this seed with *Heterangium* is derived from the juxtaposition of some seeds and portions of *Heterangium* petioles, a juxtaposition that is believed to demonstrate original continuity.

Grand'Eury¹ has recorded the association of two species of leaves, *Sphenopteris elegans* and *S. dissecta*, with small seeds compared by him with *Lagenostoma*. In the absence of petrified specimens it would be practically impossible to distinguish between *Lagenostoma* and *Conostoma* or *Sphaerostoma*.

Carpentier² has described some impressions from French Westphalian beds as *Conostoma* and he records cupules without seeds on fronds of *Sphenopteris obtusifolia* which he speaks of as having transverse striations like those of *Heterangium*. Dr Kidston pointed out to me that the surface-features of the *Sphenopteris* rachis are probably due to ramental scales and not to the presence of horizontal sclerous bands. Carpentier's seeds may be compared with *Lagenospermum Sinclairi*.

Heterangium tiliaevoides Williamson, Phil. Trans. R. Soc. Vol. 178, p. 289.

This species, founded by Williamson on material from the Lower Coal Measures of Halifax, Yorkshire, while agreeing in the structure of the primary stele and in the general features of the cortex with the older *Heterangium Grievii*, is clearly distinguished by certain well-marked characters. Sclerous groups occur in the inner cortex as in *H. Grievii* but they are present also

¹ Grand'Eury (05²).

² Carpentier (11) Pl. XII. fig. 1.

FIG. 415. A, B, *Heterangium*. A, *H. Grievii*, a, leaf-traces. B, *H. tiliaeoides*.

 (A, B, Kidston Coll., 529, 294; C, Williamson Coll., 1631.)

in the pericycle. The peripheral leaf-traces in the stele show the mesarch structure rather more distinctly than in *H. Grievii*, and the secondary xylem, which forms a much broader cylinder than in the Scotch type, is divided by broad medullary rays into characteristic cuneate masses each of which rests at its base on the centrifugal tracheids of a leaf-trace strand of xylem (fig. 415, B). The most striking distinctive feature is afforded by the secondary phloem, which is often preserved in wonderful perfection; this is unusually thick and owing to the tangential expansion of the principal medullary rays the secondary phloem is divided into separate masses which decrease in breadth towards the external arcs of primary phloem. The triangular form of the phloem rays, composed of tangentially stretched parenchyma, suggested the specific name *tiliaeoides* on account of their striking resemblance to the rays of *Tilia*. The leaf-traces are nearly always in pairs as they pass out through the cortex; they subsequently divide and appear as four vascular strands in the petiole. The portion of stem reproduced in fig. 415, B, 8 mm. broad, shows clearly the separation of the secondary xylem and phloem into wedge-shaped groups: in each group there are several narrow medullary rays. The extrastelar tissues are represented by a few fragments only. Several layers of crushed periderm occur in the pericyclic region but the more external tissues have been almost completely exfoliated¹.

Reference has already been made to *Heterangium Lomaxi*, the English type originally included by Williamson in *Heterangium Grievii*. The provisional species *Heterangium cylindricum* Williamson and Scott² differs, as Scott says, in no important respect from *H. Lomaxi* and should not be retained. A new species, *H. minimum* Scott³, has been founded on a very small stem from the Coal Measures of Dulesgate in which the leaf-traces leave the stele as single bundles as in the Scotch *H. Grievii*.

The French species *Heterangium Duchartrei*⁴ Ren. from Permian rocks was originally referred by Renault to the genus *Poroxylon*: it is represented by little more than the xylem of the stele and

¹ For a fuller description, see Williamson and Scott (95).

² Scott (09) B. p. 410; (15).

³ Scott (15).

⁴ Renault (79) B. p. 276, Pl. xiv. figs. 4—8; (96) A. p. 251, Pl. lxxv. figs. 1, 2.

bears a close resemblance to *H. tiliaeoides*. *Heterangium punctatum* Ren. and *H. Renaulti*¹ (Brongn.) also from the Permian of France were originally placed in the genus *Lycopodium* and afterwards recognised as stems of *Heterangium*. A fourth French Permian species, *H. bibractense*², is peculiar in the possession of a very small primary stele encircled by deep wedges of secondary xylem, but without more information it is impossible to speak with confidence as to its systematic position. Kubart³ has recently published brief descriptions of some stems from the Ostrauer coal-basin in Moravia all of which he regards as specifically distinct from the English types. In *Heterangium Sturi* the primary xylem is almost exarch and the peripheral xylem groups are not very clearly defined: in *H. alatum*, so called from the presence of lateral wings on the petioles, the leaf-trace strands are more sharply differentiated from the rest of the stele. *H. polystichum* is a similar type, and *H. Andrei*, with a relatively larger amount of parenchyma in the stele and thicker stems forms an additional link between *Heterangium* and *Lyginopteris*⁴. Prof. Johnson⁵ has described a species of *Heterangium*, *H. hibernicum*, from Upper Devonian and Lower Carboniferous beds in Co. Cork, Ireland, based on some impressions of frond fragments without any pinnules. The occurrence of numerous transverse striae on the rachis and lateral branches suggests comparison with *Heterangium* fronds, but an examination of the specimens led me to suspect that some at least of the striae are cracks and not original features. The presence of spur-like appendages from the lower surface of the pinnae near their origin from the rachis is recorded as a peculiar character, and some obscure oval bodies, the nature of which is extremely doubtful, are considered to be seeds. The imperfection of the material hardly justifies the institution of a new species of *Heterangium*.

Heterangium ranges from the Lower Carboniferous to the Permian strata and is thus older than *Lyginopteris* which in the form of petrified stems is not recorded from the Lower beds of the Carboniferous system. *Heterangium* has been described as

¹ Renault (96) A. pp. 253, 255.

² *Ibid.* p. 252, Pl. LXV. figs. 3, 6.

³ Kubart (14).

⁴ Dr Scott who has seen sections of this species tells me that it is a striking intermediate form.

⁵ Johnson (12).

having a 'great preponderance of fern-like characters,' but having regard to the resemblance of the primary xylem of the latter to that of the Osmundaceae it would seem doubtful whether in their relation to the Ferns there is any important difference. *Heterangium* may safely be spoken of as the more primitive genus. The polydesmic character of the petioles of most species is particularly interesting as it brings the genus nearer to the Medulloseae and to *Rhetinangium*¹.

¹ Scott (15).

CHAPTER XXX.

II. MEDULLOSEAE.

THE term Medulloseae was first employed by Goeppert and Stenzel¹ for a family of Palaeozoic plants that appears to have reached its maximum development in the Permian period: the oldest representatives so far discovered are of Upper Carboniferous age. Our knowledge of the family is chiefly derived from a study of the anatomical characters of stems, and it is therefore on this basis that any grouping of genera or species should be attempted. Although there is little information with regard to the reproductive organs of *Medullosa*, the type-genus, it is certain that the Medulloseae are Pteridosperms differing from members of that group included in the Lyginopterideae in the presence of more than one stele in the stem, in the habit of the fronds, and in the structure of the rachis, as also in the structure of the seeds, though these organs bear a fairly close resemblance to the seeds of *Lyginopteris* and *Heterangium*. The fronds of the Lyginopterideae are of the *Sphenopteris* type while in the case of such species of *Medullosa* as afford evidence of connexion between stems and leaves the latter have the characters of *Neuropteris*, *Alethopteris*, *Odontopteris*, *Linopteris*, and other form-genera usually included in the Neuropterideae. Dr Lotsy² speaks of *Lyginopteris* and *Heterangium* as members of the Sphenopteridophylla and assigns species of *Medullosa* either to the Neuropteridophylla or to the Pecopteridophylla, the latter subdivision including species with fronds of the *Alethopteris* type. There is, however, little doubt that other forms of leaves, such as *Odontopteris* and possibly *Taeniopteris*, were borne on Medullosan stems. It is undesirable

¹ Goeppert and Stenzel (81).

² Lotsy (09) p. 723.

except in the absence of more trustworthy criteria to make use of so protean a feature as leaf-form as a basis of classification. The name Neuropterideae has been frequently employed for Pteridosperms other than the Lyginopterideae on the ground that the foliage of *Medullosa* is represented by species assigned to form-genera included in the Neuropterideae. It is, however, preferable to restrict the family-name Neuropterideae to fronds and to speak of the second family of Pteridosperms as the Medulloseae, including the genera *Medullosa*, *Sutcliffia*, and *Rhexoxylon*.

MEDULLOSA.

Some species of *Medullosa* probably resembled in habit *Angiopteris evecta* and the larger *Marattias*; they had short and relatively thick stems clothed with the large decurrent bases of long compound fronds superficially like those of some recent Ferns and the leaves of the Cycad *Bowenia*. It is probable that, as Zeiller¹ has pointed out, the fronds of *Medullosa* and of other Pteridosperms had a greater tendency than those of true Ferns to a dichotomy of the rachis. In other types the stems reached a considerable length and leaves and branches were separated by several feet of bare stem. The large size of the leaf-stalks in proportion to the diameter of the stem as shown by such species as *Medullosa anglica* and *M. Leuckarti* (fig. 416) suggests either a short and thick main axis or, in the case of long stems bearing scattered leaves, a plant that supported itself partially at least by a habit of growth comparable with that of tropical Aroids or other lianes. While *Medullosa anglica* with its contiguous leaf-bases affords an example of the first type, the occurrence of stems of a Permian species, *M. stellata*, 3½ metres long without branches or leaf-scars, suggests the habit of a liane; similarly a specimen of *Medullosa Leuckarti* in the Chemnitz Museum bearing a few spreading petioles but little narrower than the stem and given off at a wide angle would seem to favour the view that some species were ill adapted to be mechanically self-supporting plants. The longest piece of stem that has come under my notice is a specimen of *M. stellata* in the Chemnitz Museum reaching a length of nearly 8 metres: some species attained a diameter of about 50 centimetres.

¹ Zeiller (05) B. p. 725.

Medullosa is always polystelic: the plan of the vascular system varies considerably as regards both the number and form of the steles, but there is a uniform type of structure within the limits of each stele that recalls the single stele of *Heterangium*. The steles consist of a central region composed of primary xylem, originally surrounded by phloem, which in its mesarch or exarch structure agrees with the vascular tissue of some species of *Gleichenia* or *Lygodium*. To this central region a cambium added secondary xylem and phloem either in the form of a cylinder of uniform breadth, or more frequently the centrifugally developed xylem exceeded in amount the secondary conducting tissue added to the inner side of the primary region. Apart from anatomical details a Medullosan stem with its several steles, each with secondary tissue, embedded in parenchymatous ground-tissue resembles the stems of some Dicotyledonous climbers such as *Thinowia scandens*, species of *Serjania* and *Paullinia*¹.

Anatomically the main features of the stelar system of *Medullosa*, neglecting the secondary xylem and phloem, are in closer agreement with the stems of Ferns than with those of any other plants. It has been shown that the genus *Heterangium* bears a close resemblance to *Gleichenia* in the structure of the primary stele (fig. 418, C): one of the oldest types of *Medullosa*, *M. anglica*, may be described as a *Heterangium* with three steles and may be compared with a dictyostelic Fern in which the irregular vascular framework is made up of three main strands. In certain types of *Medullosa* (fig. 416) the ground-plan of the vascular system recalls that of a solenostelic Fern, while in others the greater complexity suggests comparison with such Ferns as *Matonia*, *Angiopteris*, *Psaronius*, or *Cyathea*; 'it is as though Nature were at the Carboniferous moment in the midst of a series of amazing engineering experiments, most of which were either buried deep in Palaeozoic oblivion, or permitted to survive only as vestigial relics and atavistic ghosts'². Though many Medullosae resemble Ferns there is an important difference between the two groups in the origin of the various plans of Medullosan stelar systems: in Ferns the leaf is the determining factor in the evolution of stelar arrangement, while in *Medullosa* the occasional interruption

¹ Schenck (93) B. Pls. I—v, etc.

² White, D. (05²) B. p. 389.

of a solenostele or the development of an apparently complex dictyostele are features independent of the leaf and leaf-traces. In the structure of the secondary xylem and phloem and in root-structure *Medullosa* agrees with recent Cycads. The genus is in short a generalised type with filicinean and cycadean affinities. In the possession of seeds borne on modified pinnae of compound fronds, *Medullosa* resembles both *Cycas* and the Lyginopterideae. The seeds exhibit a fairly close agreement with those of *Lyginopteris*, *Heterangium* and recent Cycads, but they appear to have advanced further towards the cycadean type than is the case with the closely related seeds of the Lyginopterideae. The microsporophylls are very imperfectly known but they were undoubtedly much less advanced and more fern-like than the megasporophylls.

The genus *Medullosa* is recorded from the Permian strata of Saxony, France, and Bohemia¹; also from the Coal Measures of England, and the discovery of petrified petioles of *Myeloxylon*, the type borne on Medullosan stems in European species, may be taken as evidence of the existence of the genus in North America during the Carboniferous period².

The name *Medullosa* was applied by Cotta³ to three types, *Medullosa elegans*, *M. stellata*, and *M. porosa*, from the Rothliegende of the Chemnitz district. The first of these was recognised by Brongniart⁴ as a distinct genus for which he proposed the designation *Myeloxylon* and this was afterwards identified by Renault, Williamson, and other palaeobotanists as a petiole and not a stem. Further reference is made to *Myeloxylon* on a later page. Cotta spoke of *Medullosa* as the most puzzling of the genera dealt with in his 'Dendrolithen,' and in spite of the many additions to our knowledge the position of this Palaeozoic genus is still a fertile source of speculation. The generic designation *Medullosa* is applied to stems, with or without petioles; petioles or rachises of fronds that frequently occur apart from stems are referred to the genus *Myeloxylon*. The leaves of *Medullosa* include several well-known species of Carboniferous and Permian genera such as *Alethopteris*, *Neuropteris* and others that have in

Cotta (32) B. p. 59.

² Penhallow (97).
⁴ Brongniart (49) A. p. 57.

recent years been transferred from the Filicales to the Pteridosperms. In a few instances seeds have been found in organic connexion with Medullosean foliage, and there can be no reasonable doubt that *Trigonocarpus*, some forms of *Rhabdocarpus*, *Pachytesta*, and other seeds represent the integumented megasporangia of *Medullosa* or some closely allied genus.

Before attempting to summarise the salient features of *Medullosa* a description of a few selected types will serve to place us in a better position to consider the genus as a whole. The British species are placed first on the ground that they are both geologically the oldest though, historically, the most recently described, representatives of the genus; and in the organisation of the stem they are simpler than the continental species. Their resemblance to *Heterangium* serves to some extent to bridge the gap between the majority of species of *Medullosa* and the simpler types of Pteridosperms represented by *Heterangium* and *Lyginopteris*.

Medullosa anglica Scott¹.

Prior to the discovery of this species the genus *Medullosa* had not been recorded from Britain. A section in the Williamson collection recognised by Scott as that of a *Medullosa* had been identified by Williamson as a large *Heterangium* stem. An undescribed specimen was found by Arber² in the Binney collection at Cambridge which afforded some additional information as to the structure of the roots.

The specimens on which Scott's thorough description is based were obtained by Messrs Wilde and Lomax from the Lower Coal Measures of Lancashire. The stem of this oldest species has the habit of a tree-fern and is almost completely invested by the stout decurrent bases of the petioles of large spirally disposed compound fronds with a phyllotaxis of $\frac{2}{5}$, the leaves of the same orthostichy being separated from one another by a vertical distance of approximately 10 cm.

A transverse section of a slightly flattened stem is shown in fig. 416, A, the bases of three petioles give to it an angular form. Its dimensions are approximately 10 × 4 cm. The ground-tissue

¹ Scott (99).

² Arber, E. A. N. (03).

of two of the petioles is continuous with that of the stem, while that of the third leaf-stalk is cut through near its separation from the stem and its adaxial face is already defined by a hypodermal band of stereome, *d*. The surface of the stem is characterised by fine longitudinal ribs caused by the slightly projecting stereome in the outer cortex, and from the narrow furrows between the leaf-bases adventitious roots emerge in vertical series. The position of an interfoliar furrow is shown by a small arrow in fig. 416, A. There are three steles, 2-3 cm. \times 6-10 mm. in diameter: each agrees very closely in structure with the single stele of *Heterangium*. *Medullosa anglica* may be described as a polystelic *Heterangium* and as having the same relation to *Heterangium* as regards the stelar system as *Primula auricula* bears to the monostelic *Primula*. The central core of the stele (the black patches in the diagram, fig. 416, A) consists of an anastomosing system of tracheal groups embedded in an irregular parenchymatous reticulum. The large primary tracheids reach a diameter of 150 μ and have multiseriate pitting: at the periphery of the primary xylem there is a more definite grouping of tracheids as in *Heterangium*, and the slightly internal (mesarch) protoxylem elements are associated with scalariform and densely spiral tracheids (fig. 416, B, C) narrower than the more internal reticulate elements. The secondary xylem is manoxylic as in Cycads, tracheids in 2-4 radial series alternating with medullary rays 1-3 cells broad and usually of considerable depth (fig. 416, B). The principal rays are continuous with the parenchymatous matrix of the central core. Thick-walled tubular elements, no doubt of the nature of sieve-tubes, form a conspicuous feature in the phloem.

The three steles occasionally divide and fuse with one another. The tissue between the steles is crushed and disorganised and in the living plant was probably small in amount. In the imperfectly preserved inner cortical region there is a sinuous band of secondary parenchyma (periderm; fig. 416, A, c) developed from a deep-seated phellogen; in older stems this formed the superficial tissue after the fall of the leaves. There is no definite boundary between the cortex of the stem and the petiole-bases except when the hypoderm cuts across the cortex preparatory to

FIG. 416. *Medullosa* stems. A—C, *Medullosa anglica*; A, transverse section; a, accessory vascular strand; b, accessory strand enclosed by periderm; c, band of periderm encircling steles; d, sclerenchyma between leaf and stem. the separation of a leaf-stalk. The stem-cortex and the ground-tissue of the petioles consist of parenchyma with numerous secretory canals, not sacs only as in *Heterangium*, and are abundantly supplied with scattered vascular bundles of collateral and exarch structure.

The leaf-traces are furnished by the peripheral tracheal groups at the free surface of the primary portion of each stele: each trace is at first concentric and consists of primary xylem with one or more protoxylem strands near the outer surface and is completely or partially enclosed by secondary xylem and phloem. In the course of its passage to the leaf a leaf-trace loses its secondary tissues, which were added by the cambium during the traverse of the zone of secondary wood, and divides into small collateral bundles consisting mainly of spiral and scalariform tracheids. The collateral bundles accompanied by some narrow fibres are of the *Myeloxylon* type (fig. 420), the xylem being wholly centripetal. In the behaviour of the leaf-traces and in the vascular system of the petioles *Medullosa* differs from *Heterangium* and *Lyginopteris*. Each leaf-base is supplied by sets of vascular strands which pass into it from the stem at different levels; a large leaf-base reaching 4 cm. in diameter receives as many as 70–80 bundles. The hypoderm is like that first described in the French species *Myeloxylon Landriotii*¹ and often spoken of as the *Sparganium* type of hypoderm. The branching of the rachises points to a compound frond, and the occurrence of numerous linear pinnules with revolute margins (fig. 420, D) in association with the stem suggests that the ultimate segments were of the *Alethopteris* form. This inference receives confirmation from the occurrence of petrified specimens of undoubted *Alethopteris* rachises with the structure of *Myeloxylon*. It is practically certain that the leaves borne on the stems of *Medullosa anglica* are those long known as *Alethopteris lonchitica* (Vol. II. A, p. 553, fig. 364).

An interesting feature in the stems is the occurrence of cortical vascular strands (fig. 416, A, *a*, *b*), reaching a diameter of 7 mm., containing scattered tracheids in a parenchymatous core surrounded by secondary xylem and phloem. These cauline bundles are almost identical both in structure and distribution with the

¹ Renault (76) B.

accessory steles in the stem of a recent *Cycas*, and the agreement is emphasised by the presence of short square-ended tracheids in the primary xylem.

The roots branch freely and may attain a diameter of more than 1 cm.: they are generally triarch and the triangular primary xylem is enclosed by secondary xylem except opposite the protoxylem. The cortex is like that of *Lyginopteris* roots and a conspicuous double layer of superficial tissue is another feature common to both (*cf.* fig. 410). The exceptionally well preserved specimens described by Arber¹ show very clearly the thick zone of periderm which forms the covering of older roots, and in some of the sieve-tubes groups of dark brown patches show the form and arrangement of the sieve-plates.

Reproductive organs. We have as yet no precise information in regard to the reproductive organs of *Medullosa anglica*, but there can be little or no doubt that the fronds bore seeds that have long been known under the generic name of *Trigonocarpus*. Many years ago Mr Hemingway noticed the almost constant association of the fronds of *Alethopteris lonchitica* with *Trigonocarpus*, and Dr Kidston's discovery² of seed-bearing *Neuropteris* pinnae considerably strengthened the evidence derived from mere association. The structure of *Trigonocarpus* is described later (p. 117) in a section devoted to reproductive organs attributed to *Medullosa*. Nothing is known as to the microspore-bearing organs.

While in the structure of each of the steles *Medullosa anglica* agrees very closely with *Heterangium*, it differs from that genus in the presence of three steles and in the structure of the petioles which are much less fern-like than the simpler petioles of *Heterangium* and *Lyginopteris*. From the continental species the British species is distinguished by its simpler stelar system, though there is a close correspondence as regards individual steles.

Medullosa pusilla Scott.

This species, briefly referred to by Scott in 1909³ and fully described in a recent paper⁴, is founded on material from the

¹ Arber, E. A. N. (03).

³ Scott (09) B. p. 441 (footnote).

² Kidston (05²) B.

⁴ Scott (14).

Lower Coal Measures of Colne, Lancashire. It agrees in essential features with *Medullosa anglica*, but differs in the following particulars: the linear dimensions of the stem are about one quarter those of a typical stem of the older species; the leaf-traces possess little or no secondary xylem and the relatively large decurrent leaf-bases have a narrower and simpler hypoderm. The stem has a tri-stelar vascular system enclosed in a ring of internal periderm, and each stele (3 mm. in-diameter) consists of a roughly triangular strand of reticulate tracheids and a small amount of scattered parenchyma. The protoxylem is either exarch or, as in *M. anglica*, mesarch, the exact position being difficult to determine in the available material. The secondary xylem closely resembles that of *M. anglica*.

Scott suggests the possibility that *Alethopteris decurrens* may be the foliage of *Medullosa pusilla*. It is possible that there is no specific difference between *M. pusilla* and *M. anglica*, but on the present evidence the employment of a distinctive name is desirable.

Medullosa centrofilis de Fraine.

This species was founded by Miss de Fraine¹ on a petrified stem from the Lower Coal Measures of Lancashire. The maximum diameter of the flattened stem including four decurrent leaf-bases is 5 cm. The vascular system consists of an outer group of four steles, reduced to three by fusion in the upper part of the specimen, enclosing a central smaller stele or star-ring (fig. 417). It is the presence of the star-ring that distinguishes this type from the other two British species and forms a connecting link with certain continental Medullosae. The peripheral steles agree with the steles of *M. anglica* but, as in *M. pusilla*, there is some doubt as to the exarch or mesarch position of the protoxylem. In the structure of the xylem the central stele conforms to the rest of the vascular system and a strand of protoxylem is preserved that is almost certainly exarch. There is evidence that the peripheral steles occasionally anastomose, but the central stele follows an independent course at least in the piece of stem examined. Leaf-traces are furnished by the primary xylem of the outer steles, and

¹ De Fraine (14).

they appear to be without secondary tracheids as in *M. pusilla*. A zone of secondary cortex encloses the vascular system as in the other British stems: it is pointed out by Miss de Fraine¹ that this tissue, usually described as a deep-seated periderm, must have differed from cork in that there is no sign of drying up or decay in the tissues external to it. The leaf-bases are of the usual *Myeloxylon* type. In size this species is intermediate between *Medullosa anglica* and *M. pusilla*.

FIG. 417. *Medullosa centrofilis*. Transverse section showing the deep-seated 'periderm' (broken line) surrounding four steles. (After de Fraine.)

Medullosa stellata Cotta.

Cotta² described *Medullosa stellata* as a stem characterised by the occurrence of several many-rayed stellate columns ('vielstrahlige Sternsäule') in a pith enclosed by a double cylinder of secondary xylem. The so-called pith is the central ground-tissue of the stem and the double 'striated ring' of Cotta is a cylindrical stele identical in structure with each of the steles of *Medullosa anglica* but having a tubular form instead of forming a relatively broad and short band (cf. fig. 416, D and A). Goepfert³ in his *Permian Flora* gave a detailed account of the species, some of his sections being cut from Cotta's material, and by the employment of varietal epithets emphasised the range of variation within the limits of the type. Goepfert and Stenzel⁴ and, several

¹ De Fraine (14) p. 259. See also Kisch (13).

² Cotta (32) B. p. 66, Pl. XIII. The well-preserved specimen figured by Cotta in his Pl. XIII. fig. 2 is in the Dresden Museum.

⁴ Goepfert and Stenzel (81).

years later, Weber and Sterzel¹ adopted the same plan as a convenient method of drawing attention to differences in anatomical characters. As Schenk² pointed out, there is a considerable risk in the case of small pieces of stems of attaching excessive importance to structural variations, and it is by no means improbable, as he said, that differences which are the expression of states of preservation or stages in development have been incorrectly regarded as distinguishing marks of individual plants. It is, however, convenient to recognise some of the more striking deviations from the type-species by speaking of the different forms as varieties though, as Weber and Sterzel fully admit, such varieties and even some of the species must be looked upon as provisional. Weber and Sterzel give expression to the provisional nature of their grouping by classifying the species with their varieties into form-cycles. Under the form-cycle *Medullosa stellata* five more or less well defined forms are recognised, the type-species being *Medullosa stellata* var. *typica*³.

Medullosa stellata var. *typica*.

Part of a transverse section of a cylindrical stem is represented diagrammatically in fig. 416, D. Very little of the cortex is preserved: a parenchymatous axial region with scattered secretory canals contains four oval or cylindrical vascular steles, the stellate columns of Cotta or star-rings of later authors. These are of the same nature as the small central stele in the English *Medullosa centrofilis*. The central region of the stem in this specimen is completely surrounded by a narrow cylinder of inversely orientated secondary xylem and phloem (fig. 416, D), the phloem being on the inner side of the xylem. Beyond the xylem is a parenchymatous band containing scattered groups of primary xylem tracheids with spiral, scalariform, and reticulate pitting, and this zone, which is usually designated the 'partial pith,' is succeeded by a second and broader, normally orientated, cylinder of secondary xylem and phloem. In this section the two concentric cylinders separated by the partial pith form a solenostele like that of several recent Ferns except in the presence of secondary

¹ Weber and Sterzel (96) B.

² Schenk (89).

³ Weber and Sterzel (96) B. p. 51; Schenk (89).

tissue. The term 'partial pith' applied to the tissue between the two cylinders of secondary tissue is misleading: this tissue (fig. 416, D, *p*) is the primary xylem of the stele and is homologous with the primary portion of the stele of *Heterangium* and of the steles of *M. anglica*. In many sections the continuity of the tubular stele is broken. In a section in the British Museum cut from one of Cotta's specimens¹, 6 × 3.5 cm. in diameter to the outer edge of the vascular tissue, the cylindrical stele is interrupted at two places. An example of the interrupted type of stele is shown in fig. 416, F, and in fig. 416, H: the latter belongs to a distinct species. The complete type of cylindrical stele is exceptional and occurs occasionally at different levels in the stem. An important point is that the frequent breaks in the cylinder are not connected with the exit of leaf-traces and do not, therefore, correspond to the foliar gaps in the solenostele or dictyostele of a Fern.

The secondary xylem is of the cycadean type (fig. 418, B, D) like that of *Heterangium* and *Lyginopteris* and several other stems. Each of the star-rings in the axial region consists of a parenchymatous core with scattered primary tracheids enclosed by secondary vascular tissue (fig. 418, B). The star-ring shown in fig. 418, B, from a Chemnitz stem illustrates the characteristic cycadean character of the secondary xylem with broad medullary rays: some of the innermost elements are in contact with the primary tracheids. The phloem is rendered conspicuous by the black contents in some of the elements. Both the star-rings and the larger peripheral steles are constructed on the same plan and agree with the steles of *M. anglica*. The star-rings occasionally branch and anastomose with one another and with the encircling stele. The star-ring in fig. 416, D at *a* is about to give off a small strand.

Leaf-traces are furnished by the primary xylem at the edge of the 'partial pith' of the outer stele: as a leaf-trace passes outwards through the outer cylinder of secondary xylem the cambium invests it with secondary xylem and phloem, but as it passes through the cortex of the stem it becomes reduced to its primary elements, and by successive branching gives rise to

¹ No. V. 8093.

small collateral bundles which enter the petioles. The piece of stem shown in fig. 416, G, illustrates the exit of leaf-traces from the stele and their subsequent division into several small bundles, *v*, which are scattered in the cortex with strands of sclerenchyma. In a specimen identified with *Medullosa stellata*, Schenk¹ found part of a leaf-base attached to the stem: its vascular system was of the *Myeloxylon* type, the bundles being identical with those in the cortex of the stem seen in fig. 416, G.

In some stems of *M. stellata* the outer, centrifugally developed, portion of the main stele is very much broader than in the example represented in fig. 416, D. The diagrammatic sketch reproduced in fig. 416, F, represents a section of a Chemnitz specimen in the British Museum² in which the axial region containing several star-rings is almost enclosed by an inner zone of secondary xylem, and beyond the narrow primary xylem (black in the sketch) the rest of the block consists exclusively of secondary xylem 5.5 cm. broad. This example illustrates a common tendency in *Medullosa* towards a large excess of centrifugal over centripetal secondary vascular tissue. A similar specimen of *Medullosa stellata* is figured by Mougeot³ from the Vosges showing a considerable development of centrifugal xylem comparable with that in the British Museum stem. Weber and Sterzel⁴ describe stems of *Medullosa stellata* showing slight periodic swellings which it is suggested, though there is no evidence in support of the opinion, may be connected with reproductive organs.

Medullosa stellata var. *corticata*⁵. The specimen referred to this variety, represented in fig. 416, G, has already been quoted as affording data with regard to the origin and behaviour of the leaf-traces. In this type of stem the outer portion of the main stele is narrower than in *M. stellata* var. *typica* and the stele never forms a complete tube. The star-rings in the centre of the stem are more numerous than in the type-species of the genus. In the axial region of some stems included in the form-cycle to which

¹ Schenk (82). See also Zeiller (90) B. p. 286.

² No. 13767, probably identical with *M. stellata* var. *lignosa* Weber and Sterzel.

⁴ Weber and Sterzel (96) B. p. 108.

⁵ *Ibid.* p. 56.

M. stellata belongs there may be flatter and tangentially elongated vascular strands in addition to the cylindrical star-rings; these are termed plate-rings.

In *Medullosa stellata* var. *lignosa*¹ the outer xylem reaches a breadth of 4 cm. and the star-rings are reduced to one. The form *M. stellata* var. *gigantea*² (fig. 416, K) is of special interest as an example of a stem reaching a diameter of nearly 50 cm. and having as many as 43 large and small star-rings in the axial region. A large tubular stele like that of the type-species (fig. 416, D) surrounds the central region, but in this form the cylindrical stele *a* is succeeded by concentric cylinders of normally orientated xylem and phloem (fig. 416, K, *bb*) produced by successive cambiums either cortical or pericyclic in origin. This type of stem presents a striking resemblance to stems of *Cycas* and *Macrozamia* except in the possession of a double cylindrical stele consisting of both centripetal and centrifugal secondary xylem and phloem separated by a zone of primary xylem (partial pith).

Medullosa gigas Renault.

This species was founded on a piece of stem from the Permian of Autun³, consisting almost entirely of secondary xylem, which Brongniart had previously placed in his genus *Palaeoxylon*⁴. The secondary xylem reaches a diameter of 45—50 cm. and in the portion of the central region preserved there are a few vascular strands like the star-rings of other species. The considerable development of secondary xylem indicates a form of stem similar to some forms of *M. stellata* (e.g. fig. 416, F), but as the available data are insufficient for accurate determination Renault's specific name is retained. Renault describes the internal xylem cylinder (i.e. the centripetal xylem) as very slightly developed or as hardly visible, a feature in which the French specimen shows a nearer approach to the structure of a recent Cycad.

¹ Weber and Sterzel (96) B. p. 63.

² *Ibid.* p. 66.

³ Renault (96) A. p. 297; (93) A. Pl. LXXI. figs. 1—6.

⁴ Brongniart (49) A. p. 77.

Medullosa porosa Cotta.

The second of Cotta's species¹, which has been fully investigated by Weber and Sterzel, is constructed on the same plan as that of *M. stellata*, but the stem is distinguished by the greater number of star-rings and, more especially, by the presence of an outer system of vascular strands in the axial region (fig. 416, M): these form a frequently interrupted cylinder of anastomosing strands characterised by the feeble development of secondary xylem and phloem or by the absence of this tissue on the outer face of the strands. The component parts of this outer series occasionally fuse with the internal star-rings.

Medullosa Solmsi Schenk² var. *typica* Web. and Ster.³

This type has a large axial region containing several very small star-rings enclosed by two concentric zones of separate plate-rings (fig. 416, E) each consisting of a complete flattened cylinder of secondary xylem and phloem enclosing primary xylem. As the complete cylindrical stele of the stem of *Medullosa stellata* shown in fig. 416, D, was compared with the solenostele of a Fern, so in this stem (fig. 416, E) the vascular cylinder may be compared at least superficially with a dictyostele. From the inner circle of plate-rings strands are given off in the form of star-rings and these pass through the gaps in the outer system, eventually breaking up in the cortex into numerous collateral bundles. In another form of this species, var. *lignosa* (fig. 416, L), the axial region is enclosed by a circle of plate-rings like those in the type-form, but these are succeeded by a circle of very asymmetrically developed and large steles with the outer xylem and phloem much broader than the inner. Moreover in this form additional cylinders of normally orientated vascular tissue are added as in *M. stellata* var. *gigantea* and in some recent Cycads. It is noteworthy that the secondary wood of *Medullosa Solmsi* is rather more compact than in other species, a feature in which it to some extent agrees with the South African genus *Rhexoxylon*.

² Schenk (89) p. 339.

³ Weber and Sterzel (96) B. p. 541, Pls II. III.

Medullosa Leuckarti Goeppert and Stenzel.

In this species¹, also from the Permian of Saxony, the central region including some star-rings is surrounded by sinuous flattened concentric steles (snake-rings) agreeing anatomically with the steles of other species and characterised by the comparatively small breadth of the secondary xylem and phloem (fig. 416, H). Leaf-traces are given off, as in *M. anglica* and other species, from the outer edge of the primary xylem. In some forms there is a single set of snake-rings; in others there is a double series. Fig. 418, D, shows part of the secondary xylem of a stele of this species from Chemnitz: the tracheids are in some places continuous with the primary xylem, and on the outer edge of the secondary wood is a cylinder of phloem. A section of *Medullosa Leuckarti* figured by Goeppert and Stenzel² shows some radial rows of very thick-walled elements in the secondary phloem which they describe as bast sclerenchyma, but Solms-Laubach³ believes them to be sieve-tubes. Precisely similar elements are figured by Scott⁴ in *M. anglica* and as this author suggests the thick walls are probably not an original feature. The structure of the primary xylem is more clearly seen in fig. 418, C, and the relation between primary and secondary xylem is shown in fig. 416, I, where the position of the protoxylem may be either exarch or mesarch. The protoxylem is only occasionally recognisable but some of the peripheral primary tracheal groups are undoubtedly mesarch. External to the stele, a part of which is reproduced in fig. 418, D, are strands of stereome elements and beyond them a band of radially elongated cells that may be 'periderm': still farther out there are some imperfectly preserved vascular bundles that are leaf-traces. This species is important as affording a complete demonstration of the organic connexion between the stem and petioles of the *Myeloxylon Landrioti* type which indicate that the fronds were probably Alethopteroid.

FIG. 418. A, *Myeloxylon radiatum*, part of petiole. B, *Medullosa stellata*; starring; $\times 14$. C, D, *Medullosa Leuckarti*; C, primary xylem; D, part of primary stellar tissues and secondary xylem and phloem; $\times 6$. (A—D, Kidston Coll., 1014, 1307, 1238.)

in fig. 419 is based has been investigated by Weber and Sterzel¹ and by Solms-Laubach². The figure is a slightly simplified version of that given by Weber and Sterzel; it represents the stem of *Medullosa Leuckarti* as a transparent object, the two lower transverse sections, B and C, being seen in perspective through

FIG. 419. *Medullosa Leuckarti*. Diagrammatic sketch of stem showing longitudinal and transverse sections: for explanation see text. (After Weber and Sterzel.)

the longitudinal faces. The steles are shaded obliquely in the longitudinal sections, and in the three transverse sections, A, B, C, the primary xylem (partial pith) is black and the enclosing secondary vascular tissue radially shaded. The whole block is 9 cm. in length and 6 cm. broad. Only a part of the axial region is shown internal to the peripheral snake-rings and in it are the star-rings *S, S, b, and c*. Outside the main steles is the narrow

¹ Weber and Sterzel (96) B. p. 95, Pl. ix.

² Solms-Laubach (97).

cortex *R* and portions of leaf-bases *I—IV*. The lowest section, *C*, shows part of a peripheral snake-ring with a slight swelling at *f* on its inner side which, as seen in sections *B* and *A*, foreshadows the separation of the star-ring *S* and the consequent break in the continuity of the snake-ring (*d*, *e*, sect. *B*). In section *A* the gap is closed: in the longitudinal section between *B* and *A* the star-ring *S* is seen to form two branches, *a* and *b*, the branch *a* closing the gap between *d* and *e* in section *B*. These sections demonstrate the formation of a star-ring from the main peripheral stele and the formation of additional star-rings by branching.

Numerous vascular bundles destined for the leaves are scattered in the cortex. The course of the decurrent leaf-base *I* is shown on the longitudinal faces, its boundary being marked by crowded stereome strands (of the *Myeloxylon Landriotti* type); other leaf-bases are represented by *II*, *III*, and *IV*.

In habit *Medullosa Leuckarti* differs from such a type as *M. stellata* in its relatively shorter and stouter stem and in the shorter internodes.

LEAVES AND REPRODUCTIVE ORGANS.

i. *Leaves*. It has already been stated that in some cases petioles occur in organic connexion with Medullosan stems, notably in *M. anglica* and *M. Leuckarti*: in the exceptionally rich collection in the Chemnitz Museum, which forms a fitting memorial of the work of the late Prof. Sterzel, there is a stem of *M. Leuckarti* bearing large petioles of the type known as *Myeloxylon radiatum*. The occurrence of vascular bundles in the cortex of other species of stem identical with those in the attached petioles points to a uniform type of leaf-structure so far as regards the petioles and rachises of *Medullosa*. While it is clearly unnecessary to distinguish by a special generic title the petrified portions of fronds known to belong to certain species of stems, the frequent occurrence of detached petioles necessitates some distinctive term. The name employed is *Myeloxylon*: the genus was instituted by Brongniart in 1849 for Cotta's species *Medullosa elegans* the petiolar nature of which was suspected by Binney in 1872.

Myeloxylon (Medullosan leaf-stalks).

1832. *Medullosa elegans* Cotta. 1865. *Stenzelia* Goepfert. 1876. *Myelopteris* Renault¹; 1877, *Aulacopteris* Grand'Eury².

There is a very close agreement in general anatomical structure between the numerous specimens of *Myeloxylon* from the Permian strata of Saxony and France and the Coal Measures and Millstone Grit of England³; the genus is also recorded from the Upper Carboniferous of Kansas⁴. Two well-defined types instituted by Renault are, however, readily distinguished by the form of the hypodermal stereome strands. *Myeloxylon* may be defined as follows: Oval or cylindrical branched axes, reaching a diameter of 15 cm., bearing pinnae having the characters of *Alethopteris*, *Neuropteris*, *Odontopteris*, and some other genera that were formerly classed as Ferns. Below a single-layered epidermis, in which stomata have been recognised, occur a few layers of parenchyma: this superficial tissue, which is rarely preserved, is succeeded by a hypodermal region consisting of parenchymatous tissue and numerous vertical groups of narrow thick-walled fibres arranged as radial plates or circular, oval, or reniform strands (the *Sparganium* type of cortex). In the hypoderm as in the ground-tissue generally secretory canals, often accompanied by stereome, are a characteristic feature. The vascular system is represented by a considerable number of collateral bundles scattered through the ground-tissue and especially abundant in the outer region: the bundles sometimes assume a more or less regular disposition in concentric circles. Each bundle consists of a small group of xylem tracheids, for the most part spiral or scalariform, though reticulately pitted elements are by no means rare, with a single protoxylem group on the outer face next the phloem (fig. 420, B, C). As a rule the xylem is wholly centripetal, but occasionally the exarch structure becomes mesarch by the occurrence of a few centrifugal tracheids. The phloem, rarely preserved (fig. 420, B), consists of narrow sieve-tubes with parenchyma, and the bundle as a whole is often partially enclosed by a sheath of fibres.

¹ Renault (76) B. p. 7.

² Grand'Eury (77) A. p. 122; (90) A. p. 287.

³ Seward (93).

⁴ Penhallow (97).

Superficially the anatomical structure is similar to that of the petioles of *Angiopteris* or *Marattia*, and both Williamson¹ and Renault placed *Myeloxylon* in the Ferns; but the collateral form of the vascular bundles, the position of the protoxylem, and the arrangement of the hypoderm tissues, are cycadean features.

Myeloxylon radiatum (Renault).

This type is characterised by the radially elongated stereome of the hypoderm. Prof. Zeiller², who has given a very clear and

FIG. 420. A, B, *Myeloxylon radiatum*; A, petiole $\frac{2}{3}$ nat. size; B, vascular bundle. C, *Myeloxylon* sp. vascular bundle; px, protoxylem. D, *Medullosa anglica*; section of pinnule. (A, B, after Zeiller; D, after Scott.)

concise description of *Myeloxylon*, is disposed to regard Cotta's *Medullosa elegans* as a specifically distinct form on the ground that there are two concentric zones of stereome in the hypoderm;

¹ Williamson (76) B. p. 8.

² Zeiller (90) B.

but this feature is shown only in one of Cotta's figures, and Weber and Sterzel¹ point out that a doubling of the hypoderm zone may be caused by accidental juxtaposition of two faulted pieces of peripheral tissue. The drawing reproduced in fig. 420, A, shows the structural plan of an unusually large petiole from the Permian of Autun: a portion of the outer tissue is seen in fig. 418, A. The vascular bundle, fig. 420, C, from a Millstone Grit specimen², shows the centripetal nature of the xylem and fragments of phloem in the outer half of the bundle, with imperfectly preserved fibres abutting on the xylem. The characteristic hypoderm is shown also in fig. 418, A; the double xylem strand on the left illustrates a common feature caused by the branching of vascular bundles. Several secretory canals are scattered in the ground-tissue. The pinnules of *Myeloxylon radiatum*, or at least of some specimens, have been shown by Renault to be of the *Neuropteris* type.

Myeloxylon Landrioti (Renault)³.

In this species the distinguishing feature is the occurrence of the hypodermal stereome in the form of circular, oval, or reniform strands in place of the radial plates of *M. radiatum*. It is this form of petiole that was borne by the stems of *Medullosa anglica* and *M. Leuckarti*. In *M. anglica* the pinnules (fig. 420, D) are of the *Alethopteris* type, almost certainly *A. lonchitica*. Renault and Zeiller have described French specimens of *Myeloxylon Landrioti* bearing pinnules like those of *Alethopteris aquilina* and *A. Grandini*.

Myeloxylon topekense (Penhallow).

The occurrence of *Myeloxylon* petioles in the New World was recorded by the late Prof. Penhallow⁴ who founded this species on some imperfectly petrified specimens from Upper Carboniferous strata at Topeka, Kansas. Enough material was available to show the *Myeloxylon* characters, but the preservation is too imperfect to admit of a complete diagnosis. The hypodermal stereome shows a tendency to form tangentially extended strands in place of the more circular or radially elongated groups in the European species.

¹ Weber and Sterzel (96) B. p. 102, fig. 26.

³ Renault (76) B.

² Seward (93).

⁴ Penhallow (97)

In addition to *Alethopteris*, *Neuropteris* (including *Cyclopteris*) and *Odontopteris* fronds, which are known to possess rachises with the *Myeloxylon* features, there is reason to believe that the Permian *Callipteris* fronds and possibly some of the older *Taeniopteris* leaves may also belong to *Medullosa*¹. It is, however, unsafe to assume that the occurrence of *Myeloxylon* petioles necessarily denotes the existence of *Medullosa*. The French stem *Colpoxylon aeduense* Brongn.² bore leaves with the same general anatomical features as those of a typical *Myeloxylon*, and there can be little doubt that other genera of the Medulloseae also possessed fronds constructed on the same plan as those known to have been borne by *Medullosa*. An interesting illustration of an injured organ that had produced a wound-cambium is afforded by a *Myeloxylon* petiole from the Coal Measures described by Mr Holden³.

REPRODUCTIVE ORGANS.

Reference was made in volume II. to the reasons which led to the removal of several genera of Carboniferous and Permian fronds from the Filicales to the Pteridosperms, and in Chapter XXIX. of the present volume certain species of *Sphenopteris* are described as the foliage of *Lyginopteris* and *Heterangium*. It is with such genera as *Neuropteris*, *Alethopteris*, *Linopteris* and others that we are now more especially concerned, as they represent some of the types of leaves borne by *Medullosa* and other members of the Medulloseae. The absence of any specimens among the large number of these common genera bearing undoubted sporangia aroused suspicion as to the correctness of the generally accepted view that these fern-like fossils were the leaves of Palaeozoic Ferns. Subsequently the suspicion based on negative evidence was confirmed by researches into the anatomical structure of the leaf-bases, petioles, and fragments of pinnae attached to and associated with stems of *Medullosa*. It is only in a few cases that actual organic connexion between reproductive organs and Medullosan leaves has been demonstrated, but from such facts as are established it is safe to make the general statement that stems of *Medullosa*—a generic term that undoubtedly includes plants

¹ Weber and Sterzel (96) B. p. 139.

² Page 142.

³ Holden, H. S. (10).

which, had we a fuller knowledge of them as complete individuals, would be assigned to more than one generic type—possessed fronds simulating in habit those of certain Ferns with some of the pinnae bearing seeds often of considerable size and in all cases of complex structure, agreeing in many respects with those of existing Cycads, while other fronds, or in some cases it may be other pinnae, bore microsporangia similar in form to the sporangia of Ferns.

a. *Microsporangia*.

Neuropteris. A. *Neuropteris heterophylla*¹.

Several examples of supposed fertile specimens of *Neuropteris* are recorded in palaeobotanical literature, but it was not until 1887 that any satisfactory specimen was discovered. In that year Kidston² described a specimen of *Neuropteris heterophylla* from the Lower Coal Measures of Scotland in which slender forked branchlets bear small bodies at their tips some of which appear to represent four-valved organs (fig. 421, D), though the imperfect state of preservation renders impossible any definite pronouncement as to their structure. To the specimen are attached a few sterile pinnules, showing that it is a portion of a frond of *N. heterophylla* characterised by the substitution of reproductive organs for pinnules. The subsequent discovery of seeds attached to pinnae of the same species afforded strong presumptive evidence, almost amounting to proof, of the microsporangial nature of the Scotch specimen. For this specimen, although no precise diagnosis is possible, Dr P. Bertrand³ has proposed the generic name *Neurotheca*. In 1911 the Abbé Carpentier⁴ described some small ovoid bodies, 1—1.5 mm. long, from the Coal Measures of France arranged in groups of 4 to 6 and in some cases said to be borne on a slender pedicel which he found in association with *N. heterophylla* and compared with sporangia described by Lesquereux from the Coal Measures of Arkansas as *Sorocladus stellata*⁵. These supposed microsporangia have recently been assigned by Bertrand⁶ to *Sphenophyllum*.

⁶ Bertrand, P. (13) p. 120.

B. *Neuropteris gigantea*, etc. *Potoniea*, Zeiller.

In 1899 Zeiller¹ instituted the name *Potoniea* for some peculiar fertile leaves found in the Coal Measures of Heraclea consisting of a branched axis with cuneate segments, 7—10 × 6—8 mm., bearing numerous fusiform bodies, 1—1.5 mm. long, at the upper edge (fig. 421, A). These marginal bodies he regarded as sporangia

and expressed the opinion that *Potoniea* may be the fructification of some form of *Neuropteris*, *Mariopteris* or *Alethopteris*. Carpentier² afterwards described similar though rather larger examples

¹ Zeiller (99) B. p. 52, Pl. iv. fig. 19. ² Carpentier (11) p. 12, Pls xvi. xvii.

from the Pas-de-Calais coal-field as microsporophyll fragments of some Pteridosperm: he stated that similar specimens had been found by Kidston in England. In a later work Carpentier¹ described the sporangia as crowded in groups (fig. 421, B) in the substance of the thick lamina of *Potonia*, and he connected the fertile segments with *Neuropteris gigantea*, *N. pseudogigantea* Pot. and *Linopteris obliqua* (Bunb.). Similar specimens are said to have been found in Holland and Silesia. Bertrand² also records the association of *Potonia* with *Neuropteris gigantea* and *N. pseudogigantea*: he describes some specimens as belonging to *N. gigantea* Sternb. while others, distinguished only by small differences, he attributes to *N. pseudogigantea*. Kidston³ has recently drawn attention to the inconstancy of the characters mentioned by Potonié as distinguishing features of *N. pseudogigantea*, and he shows good cause for referring the examples so named to *N. gigantea*. The fertile lamina is almost orbicular in surface-view and attached to a slightly excentric pedicel; the microsporangia are borne on the lower surface and probably in groups as described by Carpentier.

Neuropteris Carpentieri Kidston. Kidston⁴ has recently described some fertile leaflets under this name from the Westphalian series of South Staffordshire which he identifies with French examples referred by Carpentier⁵ to *Potonia adiantiformis* Zeill. The fertile pinnules are thick and sub-cyclopteroid in form; the upper surface bears densely packed, narrow and long, microsporangia, 4×0.5 mm., containing more or less spherical microspores $45-60 \mu$ in diameter; the ventral face of the lamina on the removal of the spores shows several strong veins. With these are associated sterile pinnules of the Neuropteroid type, and examples are described intermediate between the sterile and fertile leaflets. Kidston believes the specimens to be microsporophylls of some species of *Neuropteris*, but as the material does not suffice for identification with any known species a new name is proposed. It is pointed out that in some states of

⁵ Carpentier (11) p. 13, Pl. XVI. fig. 1.

preservation the leaflets resemble Goeppert's Permian species *Dictyothalamus Schrollianus*¹.

Alethopteris. Linopteris.

No specimens of *Alethopteris* fronds have so far been described that afford any information as to the nature of the microsporangia, and we have no means of knowing whether they were borne on naked pedicels as in *Neuropteris heterophylla*, or on modified pinnules as in *N. gigantea*.

Zeiller in 1888² described some fertile pinnules of *Dictyopteris Schützii* Roem. from Commeny bearing two rows of long sporangia: he subsequently transferred this species to the genus *Linopteris*³ and expressed the opinion that the sporangia occur singly and not in groups as he originally believed. Zeiller compares the fertile pinnules with the type *Crossotheca*. Bertrand⁴, as the result of examining similar specimens, has suggested that the fringe of pendulous bodies regarded by Zeiller as sporangia may be tooth-like lobes of modified pinnules which served to protect microsporangia borne on the lower surface of the lamina. The nature of the impressions is not clear, though there is little doubt that they are microsporophylls. The fertile pinnae of *Linopteris obliqua* (Bunb.) described by Carpentier⁵ and Bertrand⁶ closely resemble the microspore-bearing organs which have been referred to *Neuropteris gigantea*; they have the characters of *Potonia* and consist of oval laminae similar to the sterile pinnules but about half their size: the lamina was attached excentrically to a slender stalk (fig. 421, C, E) and traversed by numerous occasionally anastomosing veins. No actual microsporangia have been discovered in organic connexion with the lamina.

b. *Megasporangia.*

Neuropteris.

Kidston's discovery of undoubted seeds attached to pinnae of *Neuropteris*⁷ marked an important step in our more exact

¹ See page 127. ² Renault and Zeiller (88) A. p. 273, Pl. xxxi. figs. 2, 4.

knowledge of the morphology of Medullosan sporophylls. Specimens from the ironstone balls (Coal Measures) of Coseley near Dudley showed seeds attached to portions of pinnae bearing pinnules of *Neuropteris heterophylla*. The seeds are approximately 3 cm. long and from 1.10 to 1.40 cm. broad; oblong and gradually

FIG. 422. *Neuropterocarpus Kidstoni* (Arber). (After Kidston; $\times 3$.)

tapering from the middle to a slightly curved and obtuse apical snout (fig. 422). The outer surface shows numerous longitudinal ribs which no doubt represent hypodermal fibres. The preservation of the seeds, which appear to be circular in section, is not such as to render possible a description of structural features. In their asymmetrical form the seeds agree with the genus *Platyspermum* as recently defined by Arber, but Kidston's specimens are in all probability radiospermic. Kidston compares the *Neuropteris* seeds

with *Rhabdocarpus tunicatus* as figured from the Commeny coalfield¹ and with specimens from Gard named by Grand'Eury *R. subtunicatus*².

Additional proof of the occurrence of seeds on *Neuropteris* fronds is furnished by examples from the Coal Measures of Holland described by Kidston and Jongmans³: these seeds are of the same general type as those from Cosaley but nearly twice as large, and they were borne at the tips of a dichotomously branched pedicel of *Neuropteris obliqua*. Grand'Eury in 1904⁴ recorded the association of radiospermic seeds with *Neuropteris* fronds though no case of actual attachment was found. It is, however, noteworthy that he speaks of the frequent association with *Neuropteris* of seeds characterised by six or rarely twelve longitudinal keels, a feature recalling the sclerotesta of *Trigonocarpus* and allied seeds. Until petrified specimens are available it is impossible to refer the seeds of *Neuropteris* to a generic type founded on structural features: the seeds described by Kidston are, as he says, very similar in external characters to species assigned to *Rhabdocarpus*, and there can be little doubt as to the generic identity of the *Neuropteris* seeds and some of the impressions referred to *Rhabdocarpus* which are characterised by a similarity in form, an apical snout that gives an asymmetrical appearance to the specimens and the presence of numerous longitudinal striations⁵. It is, however, by no means certain that these seeds possessed the morphological features of *Rhabdocarpus* as described by Brongniart in petrified examples from St Étienne⁶.

The seeds of *Neuropteris* may, as Kidston suggests, agree anatomically more closely with *Pachytesta*⁷, a type that Grand'Eury associates with *Alethopteris* fronds. With a view to avoid the danger of incorrectly identifying petrified specimens and impressions that cannot be proved to belong to the same generic type, I have suggested the restriction of the name *Rhabdocarpus*⁸

⁸ See Chapter XXXV.

to seeds that do not furnish evidence as to internal structure, and the employment of the designation *Rhabdospermum* for seeds that conform to those described by Brongniart as *Rhabdocarpus*. The seeds of *Neuropteris* may be of the *Rhabdospermum* type or they may agree anatomically more closely with *Trigonocarpus* or *Pachytesta*; they are members of either the Trigonocarpales or the Cardiocarpales, probably the former group. Dr P. Bertrand¹ assigns to *Neuropteris gigantea* some seeds of the *Hexapterospermum* (= *Hexagonocarpus*²) type which occur in association with cupule-like organs. These supposed cupules resemble the *Potonia* leaflets with microsporangia also referred to the same species of *Neuropteris*; they are characterised by a lacinate edge and may be compared with the Indian fossil described by Zeiller as *Ottokaria bengalensis*³ (fig. 433). Dr Arber⁴ and Dr P. Bertrand⁵ have independently proposed the generic name *Neurospermum* for the seeds of *Neuropteris heterophylla* and *N. obliqua* in preference to *Rhabdocarpus*: the former author speaks of the seeds of *N. heterophylla* as *Neurospermum Kidstoni*. The generic term *Neuropterocarpus* used by Grand'Eury in 1904⁶, though not defined by him, has priority and avoids the adoption of a new designation for seeds attached to *Neuropteris* fronds. In his definition of *Neurospermum* Arber makes no reference to the obliquity of the apical snout that is clearly shown in fig. 422. There is no evidence that *Neuropterocarpus* possessed a cupular investment comparable with that of *Lagenostoma*. Additional instances of the association of seeds with *Neuropteris* fronds are recorded by Renier from the Belgian Coal Measures, also by Bertrand and Chodat from France: Renier found seeds associated with *N. Schlehani* Stur and with the same species of frond Bertrand found impressions of oval ribbed seeds. Prof. Chodat⁷ has figured some fragments of *Neuropteris* pinnules referred to *N. auriculata* Brongn. from the Stephanian of France which show small seed-like bodies apparently in organic connexion with the lamina; but the specimens are too imperfect to afford any

⁷ Chodat (08) B. p. 33, fig. 15.

satisfactory evidence as to the nature of the reproductive organs.

Lotsy¹ has expressed the opinion that the bodies attached to *Neuropteris* pinnae described by Kidston and other authors as seeds may possibly be vegetative buds, but if this were the case one would expect to find some evidence of the bud-nature in some at least of the specimens that have already been found.

It would seem that the microsporophylls of *Neuropteris* were constructed on different plans, some being of the type described by Zeiller and other observers as *Potoniea*, while others bore sporangia on pinnae without any accompanying laminae; but our knowledge of the latter form represented by Kidston's specimen of *Neuropteris heterophylla* (fig. 421, D) is very incomplete. On the other hand the seeds appear to have been characterised by features suggesting a close affinity to *Trigonocarpus* and pointing to membership of the same family.

Alethopteris.

Although no specimens have been discovered showing actual connexion between fronds and seeds, it is practically certain that *Alethopteris* leaves, or at least some species of the genus, bore seeds of the *Trigonocarpus* type. The association of *Trigonocarpus Parkinsoni* with *Alethopteris lonchitica* is too frequent to be fortuitous and there is further evidence afforded by certain anatomical resemblances. In France other species of *Alethopteris*, e.g. *Alethopteris Serlii* and *A. Grandini*, occur in association with *Pachytesta*², a large seed similar to *Trigonocarpus*, and *Trigonocarpus* is found in the Pas-de-Calais coal-field with *Alethopteris Serlii*.

TRIGONOCARPUS. Brongniart.

The generic name *Trigonocarpum* was instituted by Brongniart in 1828³ for ovoid longitudinally ribbed 'fruits' from Upper Carboniferous strata, the type-species being named *T. Parkinsoni*. The generic name is often altered to *Trigonocarpon*: Williamson⁴,

¹ Lotsy (09) p. 72.

² Grand'Enry (04); (04) B.

³ Brongniart (28) A. p. 137.

⁴ Williamson (77) B.; Scott and Maslen (07) p. 90 (footnote) also refer to *Trigonocarpon* as having been used by Brongniart in 1849.

who adopted this form, states that Brongniart substituted *Trigonocarpon* for *Trigonocarpum* in his *Tableau*¹, but in that work the original termination is used, the form *Trigonocarpon*, probably the result of a slip, appearing only in the index. In his later work on seeds Brongniart adopted the name *Trigonocarpus*, and in recent years this has been widely employed. Among other species named by Brongniart are two previously referred by Sternberg to *Palmacites*. Several examples of Brongniart's genus were described by Lindley and Hutton, and in their description of *T. Noeggerathii* the statement is made that a fractured specimen demonstrated that 'the fossil in its ordinary state is

FIG. 423. Casts of the seed-cavity of *Trigonocarpus Parkinsoni*.
(Manchester Museum. $\frac{1}{2}$ nat. size.)

an interior part divested of fleshy covering²; this suspicion of the true nature of the nut-like fossils was afterwards proved correct by the investigations of Hooker and Binney³ and by the later work of Williamson. The specimens on which the genus was founded are casts of seed-cavities and it is in this state that the seeds are usually preserved, often in large numbers, in the sandstones of the Coal Measures, as in the block shown in fig. 423 from the famous quarry at Peel near Bolton, Lancashire. Another type of preservation is represented by the seeds figured by Lindley and Hutton as *Carpolithes alata*⁴, but the generic identity of the two states was not recognised until the discovery of petrified material afforded the clue. Figs. 424, 1, 425 illustrate the appearance of *Trigonocarpus* when preserved as a carbonised impression

¹ Brongniart (49) A. p. 91.

² Lindley and Hutton (35) A. p. 172.

³ Hooker and Binney (55).

⁴ Lindley and Hutton (33) A. Pl. 87.

showing a thick fleshy envelope enclosing an oval kernel with a hard wall prolonged upwards as a longer or shorter micropyle. Casts of the seed-cavity are represented in figs. 423; 424, 2, 3. The surface of these casts occasionally shows one or more short cylindrical projections which are probably extensions of the sand or mud into holes formed in the testa by boring insects. The view that *Trigonocarpus* seeds are 'obviously Palm fruits' was not accepted by Hooker and Binney who inclined to regard them as the seeds of Conifers and compared them especially with the similar nuts of *Ginkgo* seeds (cf. fig. 631, C). It was Mr Wild¹ who was first struck by the association of *Trigonocarpus* and the petioles of *Medullosa* (*Myeloxylon*) and by some resemblances in structure between the testa and the hypoderm of the petioles; though, as Scott and Maslen² point out, the agreement is not so close as Wild believed, his view of a possible connexion between the reproductive and vegetative organs has been confirmed. Williamson extended our knowledge of the genus by his account of *Trigonocarpus olivaeformis* Lind. and Hutt., a form that is specifically identical with *T. Parkinsoni* Brongn. This author also drew attention to the close resemblance between Brongniart's three genera *Trigonocarpus*, *Hexapterospermum*, *Tripterospermum* and expressed doubts as to the possibility of founding specific differences on casts of the *Trigonocarpus* type without the evidence of anatomy. Our knowledge of the structure of *Trigonocarpus* has in recent years been considerably extended by the researches of Oliver, Scott and Maslen, and Salisbury.

*Trigonocarpus Parkinsoni*³ Brongniart.

The seeds of this species like all examples of the genus are radiospermic, that is radially symmetrical in contrast to the flattened or platyspermic seeds. The complete seed is elongate oval in form when preserved as an impression (fig. 425, A) and reaches a length of 4—5 cm.: the casts of the seed-cavity are ovoid and provided with three prominent ridges (fig. 424, 2, 3). The testa forms a thick covering differentiated into three regions, an outer flesh or sarcotesta, a sclerous shell or sclerotesta, and

¹ Wild (00).

² Scott and Maslen (07) p. 96.

³ Scott and Maslen (07).

an inner flesh. Transverse sections show that the sclerotesta has three sharp longitudinal keels with corresponding furrows on the inner face, and between each pair of main ribs are 2—3 less prominent ridges, usually 12 in all (fig. 426). The sarcotesta consists of thin-walled parenchyma passing externally into a

more lacunar tissue with a palisade-like hypoderm: the sclerotesta consists of thick cells which interlace and form an efficient protective shell. Both the sarcotesta and sclerotesta are continued into the apical region as the wall of the long micropyle, the sarcotesta being prolonged beyond the sclerotesta at the apex of

FIG. 426. *Trigonocarpus Parkinsoni*. (A, C, after Scott; B, after Wild; D, after Salisbury.)

the integument¹. The micropyle is triangular in section and may exceed in length the whole seed (figs. 425; 426, A). Its form as seen in transverse section (fig. 426, B) suggests the presence of wings: this appearance may be deceptive and due to pressure or, more probably, it represents an original feature. The seed-body, that is the portion enclosed by the integument, consists of the nucellus, represented by a few crushed layers of cells, bounded by a well-defined epidermis; the nucellus is separated from the integument from the base of the seed upwards, an important feature in which this and some other Palaeozoic seeds differ from *Lagenostoma* and the seeds of recent Cycads which are characterised by an integument adnate to the nucellus up to the level of the shoulder; the seeds of the Conifer *Phyllocladus* afford an example of separation of integument and nucellus as in *Trigonocarpus*. The innermost layer of the nucellus consists mainly of tracheal tissue investing the large megaspore (fig. 426, A, C, *m*) which is preserved as a contracted membrane detached from the nucellus after the death of the seed. At the summit of the nucellus is a relatively small pollen-chamber (fig. 426, A, *Pc*) like a broad and low cupola bearing a terminal beak which extended some distance into the micropylar tube. No microspores have been found in this species, but Oliver² records the occurrence of multicellular microspores in *Trigonocarpus pusillus*. The pedicel of the seed had a central strand of sclerous tissue penetrated by a concentric vascular bundle which gives off six strands to supply the sarcotesta (fig. 426, C, *v*) and then passes into the nucellus where it forms a tracheal sheath (fig. 426, A, *nt*) surrounding the lower part of the megaspore and at a higher level breaks up into anastomosing strands of tracheids which reach up to the plane of insertion of the pollen-chamber.

A second species described by Scott and Maslen as *Trigonocarpus Oliveri* has been further investigated by Salisbury who finds that it is an 8-angled seed which cannot be retained in the genus *Trigonocarpus*: its systematic position 'must for the present remain uncertain³.' Dr Arber has recently described a new species of *Trigonocarpus*, *T. Moyseyi*⁴, from the Nottingham Coal-field

¹ Arber, A (14).

² Oliver (04) p. 97.

³ Salisbury (14) p. 65.

⁴ Arber, E. A. N. (14) p. 95, Pl. vi. fig. 1.

(Middle Coal Measures), similar to *T. Parkinsoni* but much broader in proportion to its length: this species is founded on an impression without structure.

The species *Trigonocarpus Dawesi* Lind. and Hutt.¹, from the Middle Coal Measures of Lancashire, was founded on casts differing in their large dimensions from those of *T. Parkinsoni*: specimens referred to this species were described by Fiedler² from Saxony in 1857 and Lesquereux³ figures similar casts from the Upper Carboniferous and Permian rocks of North America.

Trigonocarpus shorensis Salisbury.

This species, founded on specimens from the Lower Coal Measures of Shore, Lancashire⁴, may exceed 4 cm. in length and has a breadth of 2.5 cm. In general plan it agrees with *T. Parkinsoni* but there are certain well-marked differences: the micropyle is much shorter; the thick sarcotesta, attaining a breadth of 6 mm. at the base of the micropyle, is characterised by the presence of six peripherally placed vascular bundles (fig. 426, D, v) in contrast to the deeply embedded bundles of *T. Parkinsoni*. Below the epidermis of the sarcotesta is a hypoderm formed of radially disposed plates of sclerous tissue similar to that of *Myeloxylon* and different from the palisade-like hypoderm of the type-species. Within the sarcotesta is a hard shell, the sclerotesta, characterised by three prominent ribs extending from base to apex and three shorter ribs which reach from the chalaza to about a third of the length of the seed. The fact that the sarcotesta and sclerotesta pass gradually into one another is a point in favour of the view that the integument is a single structure. There appears to be good evidence of the restriction of an inner flesh to the micropylar region, whereas this tissue in *T. Parkinsoni* was probably continuous over the whole inner face of the sclerotesta. The sarcotesta is lacunar in its outer part as in some other types of Palaeozoic seeds, a feature probably connected with floating efficiency. *Trigonocarpus shorensis* occurs in association with *Myeloxylon* petioles, and there is a resemblance between

¹ Lindley and Hutton (37) A. Pl. 221; Arber *loc. cit.* p. 95, Pl. VI. fig. 8.

² Fiedler (57) Pl. XXVII. fig. 39.

⁴ Salisbury (14).

the seed and the vegetative organs in the structure of the hypoderm as also in the structure of the secretory sacs which are particularly numerous in this species. Salisbury draws attention to the close resemblance between the form of *T. shorensis* and the seeds found in organic connexion with pinnae of *Neuropteris obliqua*¹.

The species *T. corrugatus* described by Renault² bears a close resemblance to *T. shorensis*.

OTHER GENERA FOUNDED IN PART ON REPRODUCTIVE ORGANS
WHICH MAY BELONG TO THE MEDULLOSEAE.

Codonotheca, *Schützia*, *Whittleseya*, *Dolerophyllum*, *Ottokaria*, *Strobilites*.

CODONOTHECA. Sellards.

Codonotheca caduca Sellards. This genus was founded on some spore-bearing bodies from the Coal Measures of Illinois³: nothing is known as to the plant which bore them, but Sellards is inclined to associate them with *Neuropteris decipiens* Lesq.⁴, a species abundant in the same coal-field. Whatever may have been the parent-plant it is probable, as the author of the genus believes, that *Codonotheca* is the microspore-bearing organ of a Pteridosperm. As shown in fig. 427, 5, the form is that of a stalked cup consisting in the basal portion of a stout axis, the peripheral tissue of which is believed to have been fleshy, containing an axial rod of conducting tissue running up to the floor of the cup, *c*, and then dividing into six vascular strands, each of which forks into two branches. The upper part is composed of six linear segments united basally to form the sloping surface of the cup. On the inner face of each segment is a more or less well-defined depression covered with large elliptical spores .29—31 mm. long by .18—19 mm. broad (fig. 427, 6, 8). The presence of a median ridge (fig. 427, 8) indicates a bilateral origin. 'There is no grouping of the spores or other indication of the location of the sporangia, which were doubtless more or less completely immersed in the tissue, the dividing wall disappearing at maturity.' The spores

¹ See page 115.

³ Sellards (03) p. 90; (07).

⁴ Lesquereux (80) A. p. 93; (84) A. p. 733, Pl. xciv. figs. 1, 2.

are seen in fig. 427, 2, 3, on the inner face of the lobes. Some of the specimens have a fairly long pedicel: in the example shown in fig. 427, 1, the fleshy part of the basal portion is not preserved, only the more resistant vascular core. In a later account of these organs Sellards speaks of several lying by the side of a central stalk to which he thinks they were originally attached by slender pedicels. In view of Dr Benson's interpretation of the morphology of *Telangium* it is permissible to suggest that if a central

FIG. 427. *Codonotheca caduca*. 1. The vascular tissue preserved as a conical base which was originally surrounded by fleshy tissue (cf. 5); I—III, VI, vascular bundles ($\times 2$). 2, 3. Segments with spores; c, floor of cup (nat. size). 4. Vascular tissue as a cone in the middle of the fleshy base (nat. size). 5. Plan of the whole organ opened out flat (nat. size). 6. Spores ($\times 28$). 8. A single spore showing median slit ($\times 84$). (After Sellards.)

sporangium in such a synangium as that of *Codonotheca* developed a megaspore and the peripheral sporogenous lobes were sterilised, the result would be an arrangement not unlike the apical region of the seed *Physostoma*, the tentacles of which have been homologised with the canopy of *Lagenostoma*. There are obvious difficulties in the way of this, perhaps strained, comparison: the larger size of the spore-bearing linear segments of *Codonotheca*

led Sellards to regard each as a synangium rather than a single sporangium. But precise information as to the structure of the American fossils is not as yet available. If the association of *Codonothea* with *Neuropteris* fronds has any significance it would favour a reference of these organs to the Medulloseae. In the absence of anatomical data it is impossible in some cases to distinguish microspore-bearing organs of the *Codonothea* type from small seeds enclosed in a lobed cupule or even seeds with a lobed integument: a case in point is the New Brunswick species *Pterispermostrobus bifurcatus* Stopes¹.

A Spitzbergen, Culm, fossil recently described by Nathorst² as *Codonothea* (?) *pusilla* is briefly referred to under the genus *Pterispermostrobus*.

SCHÜTZIA. Geinitz.

This generic name was instituted by Geinitz³ for some Permian fossils obtained by Bergmeister Schütz and regarded by the author of the genus as probably fertile branches of some Conifer. A more complete account was published by Goeppert⁴ in his 'Permian Flora,' where the name *Anthodiopsis Beinertiana* occurs on the Plates, printed before the publication of Geinitz's description, but in the text the specimens are referred to *Schützia anomala*.

Schützia anomala Geinitz.

The type-species, recorded from Bohemia and Silesia, is represented by fertile shoots consisting of a thick main axis bearing apparently two-ranked though probably spirally disposed short lateral branches, each of which terminates in a receptacle with numerous crowded linear-lanceolate bracts superficially resembling a partially expanded inflorescence of a Composite. Goeppert believed that the branches bore seeds and he refers to this species a number of detached, longitudinally striated and bluntly terminated, seeds. The same author describes other specimens from

¹ Stopes (14) p. 74. See page 66.

² Nathorst (14) p. 23. See page 67.

³ Geinitz (63) p. 525, Pl. vi.

⁴ Goeppert (65) p. 161, Pls. xxiii—iv. The specimens figured by Goeppert, which I saw some years ago in the Breslau Museum, do not show the finer characters very clearly.

the same localities associated with *Schützia anomala*, which he names *Dictyothalamus Schrollianus*¹: in habit these agree closely with *Schützia* but the receptacles, the reticulate appearance of which suggested the generic name *Dictyothalamus*, bear a large number of small bodies regarded as seeds. The preservation of the fossils is not such as to enable us to determine their true nature but it is probable that *Schützia* and *Dictyothalamus* are not generically distinct. In his description of *Dictyothalamus* Goeppert suggests that the two associated types may be the male and female shoots of one plant, but he speaks of seeds in both cases. Schimper², who unites *Dictyothalamus* with *Schützia*, regards the latter as female and the former as male.

Schützia Bennieana Kidston.

This species, described by Kidston³ from the Calciferous series of Scotland, differs from *S. anomala* in its much more slender axis and in the relatively narrower and less globular clusters of bract-like appendages. The principal axis bears three lateral branches with terminal clusters of acute and narrow linear scale-leaves. No seeds were found in association with the specimens.

Schützia permiensis (Renault).

Renault founded this Permian species as *Antholithus permiensis*⁴ on a specimen from Lodève; it consists of an incomplete inflorescence 6.4 cm. long bearing four lateral branches with stalks 1.5 to 2 cm. long terminated by clusters of small oval bracts 5 mm. long. Renault compares the fossil with the recent Conifers *Glyptostrobus* and *Tsuga*, but it exhibits a much closer resemblance to *Schützia anomala*.

The genus *Schützia*, originally described from Permian strata, is recorded also from Westphalian strata in North Africa⁵ as well as from Lower Carboniferous rocks in Scotland. The data at present available are insufficient to determine the morphological nature of the fertile branches: the evidence adduced by Goeppert in support of the occurrence of seeds is not convincing and the

⁵ Zeiller in Douvillé and Zeiller (08).

² Schimper (72) A. p. 358.

⁴ Renault (96) A. p. 379, fig. 73.

interpretation of the bract-like appendages is still an open question; they may have formed a cupular investment to seeds, but in the Scotch species the general appearance rather suggests that they may be microspore-bearing organs comparable with those of *Codonotheca*¹. There are no adequate grounds for supposing *Schützia* to belong to the Coniferales, a view advanced by some authors; it is much more likely to represent the fertile shoots of a Pteridosperm.

WHITTLESEYA. Newberry.

The genus *Whittleseya*, referred by many authors to the *Ginkgoales*, has no substantial claim to be regarded as allied to that group: its position is still uncertain, but the recent discovery of fertile specimens suggests the probability of a relationship to *Pottonia* and an identification of *Whittleseya* as another form of microsporophyll of a Pteridosperm.

FIG. 428. A, C. *Whittleseya elegans*. A, single leaflet, from Pennsylvania. (After Lesquereux; $\frac{5}{8}$ nat. size.) C, diagrammatic sketch of part of a leaflet showing the teeth, the striated texture of the carbonised layer, and the vein-like markings on a lower surface. (After Thomas; enlarged.)

B. *Whittleseya brevifolia*. (After White; the smaller figure $\frac{5}{8}$ nat. size.)

The generic name was given by Newberry² to some leaves, or possibly leaflets, originally described by C. Whittlesey from

¹ See page 124.

² Newberry (54).

the Coal Measures of Ohio. Whittleseya is represented by species from several North American localities¹ in Ohio, Pennsylvania, Arkansas, Nova Scotia, and New Brunswick²; it occurs in Silesia and has recently been found in the English Coal Measures³. The genus is confined to Upper Carboniferous strata.

The leaves are fairly thick; the lamina is oblong, cuneate, broadly triangular or linear, usually rounded and truncate (fig. 428, A, C), generally dentate at the distal end, the proximal portion being gradually or abruptly contracted and occasionally prolonged into a short pedicel. The veins or ribs are parallel to the sides of the lamina and except near the base unbranched.

Whittleseya elegans Newberry.

The type-species, from North America and Europe, is characterised by its shovel-like lamina from 3 to 6 cm. long closely resembling in shape some lepidopterous scales; the surface is ribbed, each rib corresponding to a tooth on the distal margin; on each of the parallel ridges are 4—5 longitudinal lines indicating either veins or stereome strands (fig. 428, A, C). The examination of preparations made by Dr Kidston from a leaflet of this species enables me to add a few facts with regard to the microspores. The spores, which cover almost the whole surface of the lamina, show a tendency to a more or less definite arrangement in longitudinal rows. Two types of cuticularised membrane are represented among the associated fragments: in some pieces of cuticle the cells are short and have straight walls while in others the preservation is inferior and the cells appear to be longer and narrower. One or both of these membranes probably belong to the sporangia. The oval slit, which is a striking feature on several of the spores (fig. 429), points to their bilateral nature and dehiscence along the major axis. A comparison of these spores with those obtained by Kidston from the English species *Whittleseya fertilis* reveals a very close agreement both in size and shape and confirms the identification of the Staffordshire specimens as leaflets of *Whittleseya*. The large size of the microspores and the gaping oval aperture in some of them are features

¹ Lesquereux (80) A. p. 523, Pl. iv; (84). For other references see Potonié (04).

² White, D. (01).

³ Thomas, H. H. (12); Kidston (14) p. 166.

in which they agree closely with the spores of *Dolerophyllum fertile* described by Renault¹. In both cases the spores tend to be arranged in long groups and they are practically identical in form and in the nature of the exine; those of *Dolerophyllum* are 280μ long while those of *W. fertilis* reach a length of 220μ . In some of the *Whittleseya* spores the exine has split as in the specimen shown in fig. 429, but in others there are two curved lines along which dehiscence has begun, a character in which the spores appear to be identical with those of *Dolerophyllum*

FIG. 429. Microspores of *Whittleseya elegans*. A, a group of spores; B, a single spore. (Preparations made from an American specimen, No. 2314, in Dr Kidston's Collection.)

described by Renault who speaks of dehiscence by means of an operculum. There is, I venture to think, little doubt as to the very close affinity of the two types. The systematic position of *Dolerophyllum* is not certainly established; if the generic identity of the leaves described as *D. Berthieri* Ren. and the petrified specimens named *D. fertile* is assumed, it is a legitimate inference that the genus is founded on fertile pinnules of a Pteridosperm with foliage of the *Neuropteris* or *Cyclopteris* form. It would seem probable that both *Whittleseya* and *Dolerophyllum*

¹ Renault (93) A. Pl. LXXII; (96) A. p. 268. See page 137.

fertile are microspore-bearing leaflets of Pteridosperms, possibly of some Medullosan plants. The leaflets of *Whittleseya* agree in form fairly closely with those of *Potoniea adiantiformis* Zeill. described on a previous page¹ as the male organs of a Pteridosperm.

The specimens described by Lesquereux from Pennsylvania as *W. integrifolia* and *W. undulata* are less satisfactory than *W. elegans*. The Arkansas species *W. microphylla*², characterised by the obtuse form of the lamina, is said to occur not only as detached leaflets but in loose bunches at the ends of slender axes, a circumstance favourable to the suggestion, based on the recently described English specimens, that the *Whittleseya* leaves may be fertile pinnules of a Pteridosperm frond. Among other species attributed to Newberry's genus is *W. brevifolia* Wh. from Nova Scotia³ with much smaller broadly triangular leaves 7 mm. long exclusive of the petiole and 8 mm. broad at the distal end (fig. 428, B). Dr Matthew⁴ has also described a Canadian species *W. concinna* from New Brunswick in beds assigned by Dr Stopes⁵ to the Westphalian series.

Whittleseya fertilis Kidston.

Since the discovery of *Whittleseya elegans* in the Coal Measures of Staffordshire recorded by Mr Thomas, Dr Kidston has published an account of some specimens from the same district under the name *Whittleseya* (?) *fertilis*⁶: these consist of smaller cuneate scale-leaves or leaflets 1.4—2.4 cm. long and 8—9 mm. broad; the lamina has a dentate upper margin and is longitudinally ribbed. The scales occur in superposed pairs, closely fitting but not organically connected, at least in the state in which they are preserved; each pair forms a sporangium-like case enclosing numerous spores but the actual sporangia or synangia have not been preserved. Kidston describes the spores as 210—222 μ in length, elliptical, and characterised in many cases by an oval slit; they are practically identical with the microspores of *W. elegans*.

⁶ Kidston (14) p. 166, Pl. xv. figs. 1—10.

DOLEROPHYLLUM. Saporta.

This name was proposed¹ primarily for a large ovoid petrified bud composed of rolled Cyclopteroid leaves from Permian rocks in the Ural Mountains, which had been previously described by more than one writer under different names and regarded as a young shoot of a Palm or other Monocotyledon. Eichwald², who published good drawings, called the fossil *Noeggerathia Goeperti*. Saporta connected with this species some leaf-impressions from the Permian of Bohemia described by Goepert³ as *Noeggerathia cyclopteroides*: in his family Dolerophylleae⁴ the French author included other leaves which are probably not closely related to the type-species, *Dolerophyllum Goeperti*. The Dolerophylleae are spoken of by Saporta and Marion⁵ as Progymnosperms. Before the publication of Saporta's note Grand'Eury had instituted the genus *Doleropteris*⁶ and the family Doleropteroidae; in the former he included several forms of leaves agreeing generally with Goepert's *Noeggerathia cyclopteroides*. Zeiller⁷ adopts Grand'Eury's designation for the Russian fossil in preference to '*Dolerophyllum*, a choice justified by considerations of priority; but the latter name is retained in this account as it was assigned by Saporta to the specimen of greatest botanical interest, namely *Dolerophyllum Goeperti*, and because it does not suggest affinity to Ferns.

Dolerophyllum Goeperti (Eichwald).

The type-species is from the Zechstein of Orenburg in the Urals and no specimens having precisely the same structure have been found elsewhere. Eichwald assigned it, with leaf-impressions of various kinds, to the Noeggerathieae and named it *Noeggerathia Goeperti*: it had previously been described by Kutorga⁸ as *Aroides crassispatha* and Unger⁹ included it among the Palms as *Palaeospathe aroidea*. The species has been described also by Saporta and Marion and by Renault¹⁰. The following account is

¹ Saporta (78).² Eichwald (55) Pl. xviii. fig. 18; (60) p. 252.³ Goepert (65) p. 157, Pl. xxi. fig. 4.⁴ Saporta (78*).⁵ Saporta and Marion (85) pp. 16, 68.⁶ Grand'Eury (77) A. p. 192.⁷ Zeiller (00²) B. p. 217.⁸ Kutorga (42).⁹ Unger (50) A. p. 334.¹⁰ Renault (96) A. p. 262.

based on sections cut from a specimen in the British Museum¹ which, though assigned on the label (within a query) to France and named *Dolerophyllum Berthieri*, is undoubtedly Eichwald's species from East Russia.

The specimen (fig. 430) is 9 cm. long and 4.2 cm. broad: at the slightly contracted and broken base is a piece of immature axis (fig. 430, B, *a*) 12 mm. in diameter overtopped by a mass of closely packed leaves encircling one another like the bulb-scales of an Onion (fig. 430 A, C)². Most of the leaves included in the

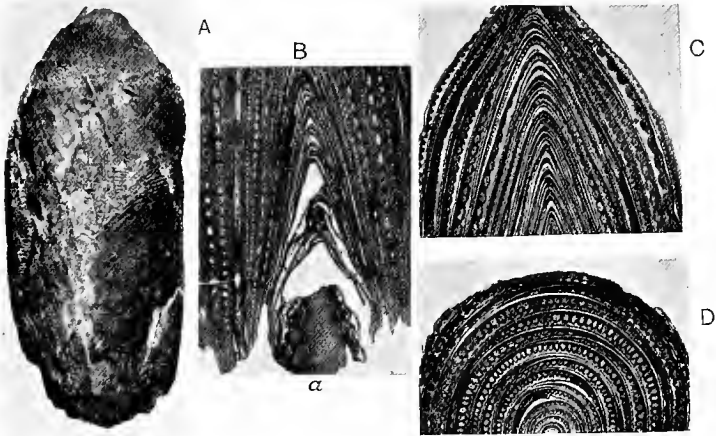

FIG. 430. *Dolerophyllum Goeperti*. Bud in surface-view, A; in longitudinal section, B, C; in transverse section, D. (British Museum; A, $\frac{2}{3}$ nat. size.)

bud were attached to the axis below the broken base. The curved, dichotomously branched, veins are seen on some of the pieces of lamina on the surface of the bud (fig. 430, A). The considerable breadth of the leaves is demonstrated by the longitudinal and transverse sections. In fig. C most of the laminae can be traced through the whole height of each of the steep-sided arches: a few overlapping margins are seen in fig. D. The veins are for the most part imperfectly preserved and appear as clear

¹ No. V. 8114.

² A specimen from Orenburg in the Dresden Museum shows the same surface-features as the British Museum specimen and agrees with the originals of Goepfert's figures which are in the Breslau University Museum.

spaces at regular intervals in the brown mesophyll. The axis of the shoot consists of homogeneous parenchyma except near the sloping sides where narrow dark bands (fig. 430, B, *a*) mark the position of desmogen-strands of thin-walled elongated elements

FIG. 431. *Dolerophyllum Goeperti*. Transverse sections of leaves. *e*, epidermis; *s*, secretory cells; *t*, transfusion-tracheids; *px*, protoxylem. (British Museum.)

representing an early stage in the development of vascular bundles some of which have already produced spiral tracheids. Short secretory cells accompany the immature conducting elements. The lamina slightly exceeds 2 mm. in thickness in the broadest part: the mesophyll is composed of large parenchymatous cells

of elliptical or spherical form often loosely attached owing to the well-developed system of intercellular spaces. The lower epidermis, assuming that the outer face of the rolled leaves is the morphologically lower surface, forms a uniform layer of palisade cells characterised by their free conical ends (fig. 431, A, B, *e*) which in some oblique sections appear as sharply pointed papillae with almost filiform apices; but while the cells were doubtless papillose like those of the epidermis of a velvety petal, the pointed form is due in part to the greater distinctness of the dark contents as compared with the lighter cell-walls. The upper epidermis is much less distinct; it consists of smaller flattened cells with occasional stomata. Renault¹ figures a specimen with stomata in a better state of preservation. The vascular bundles are rendered conspicuous by large secretory cells on the lower side, in the larger veins in the form of an arc or irregular group (fig. 432, A), but in the finer veins as single cells (fig. 431, A, B). These sacs resemble the tannin cells accompanying the veins in a leaf of *Ginkgo* (*cf.* fig. 631, G). The xylem-elements are of two kinds, (i) elongated spiral and scalariform conducting elements, forming a vertical plate of a few rows in the larger veins (figs. 431, 432) or a small compact group in the more slender veins (fig. 413, A, B); (ii) much larger isodiametric cells with reticulate or spiral thickening resembling the transfusion-tracheids of Conifers or, perhaps more closely, similar elements in the leaves of *Lepidodendron*. These short tracheids are especially abundant on the flanks of the conducting tracheids (figs. 431, *t*; 432, A, *t*), but they sometimes form a complete investment. In the obliquely cut vein reproduced in fig. 431, D, the transfusion-tracheids are abundant: a few are enlarged in fig. 431, E. In the smaller veins (fig. 431, A, B) they are represented by the larger elements, *t*, on the sides of the conducting strands. The protoxylem lies close to the upper edge in the middle line (*px*, figs. 431, A; 432, A); it is difficult to determine its precise position, but it would seem to be slightly internal, the bundle being not quite endarch. No phloem was recognised in the British Museum specimen, but it presumably occurred, if present, where the black patch is shown

¹ Renault (96) A. p. 265, fig. 43.

in fig. 432, A. Renault describes some phloem in sections which he examined.

The mesophyll next the upper surface is in most cases represented by spaces between the veins which give a crenulated outline to the parenchyma (fig. 430, C, D); in some places the spaces contain remains of very loose and crowded cells suggesting the original presence of very lacunar tissue or possibly of thin-walled storage-cells. The confinement of stomata to what is assumed to be the upper surface may, as Renault and others have suggested, indicate leaves which floated on water, an inference opposed to the view that the gaps in the mesophyll mark the position of water-tissue.

No specimens have been described which enable us to correlate with certainty mature leaves or foliage-shoots with the petrified bud. It is, however, not improbable that the impression from Mount Pelé near Epinac named by Renault *Dolerophyllum Berthieri*¹ may be correctly referred to the same genus. The type-specimen consists of an axis, whether a rachis of a compound leaf or a shoot with simple leaves cannot be determined, bearing partially overlapping more or less orbicular leaves 18—20 cm. in diameter, with a *Cyclopteris* venation. Among other leaves of unknown affinity referred to the same genus attention is drawn to *Dolerophyllum pseudopeltatum* (Grand'Eury)² with an orbicular lamina reaching in some specimens 22 × 19 cm. Specimens of *Dolerophyllum pseudopeltatum* are figured by Renault from the Commentry coal-field³, some of which reach a diameter of 12 cm. The only British specimen of a leaflet of this type which I have seen is one in Dr Kidston's collection from the Stephanian series, Glamorganshire. It is probable that some at least of the impressions assigned to *Dolerophyllum* or *Doleropteris* would be more appropriately included in *Cyclopteris* or *Cardiopteris* and may have been borne on the axis of large Pteridosperm fronds. Grand'Eury⁴ has also called attention to the difficulty of distinguishing the larger *Cyclopteris* leaflets from *Dolerophyllum*. Some

³ Renault and Zeiller (90) A. p. 556, Pl. LVII.

⁴ Grand'Eury (04).

of the Cyclopteroid leaflets figured by Roehl¹ on *Neuropteris* fronds differ but slightly from those of *D. pseudopeltatum*. The shoot showing large leaf-scars figured by Saporta and Marion² as probably the axis of a *Dolerophyllum* may well be a piece of *Cordaites*.

Microsporophylls assigned to *Dolerophyllum*.

Certain problematical fossils found in association with the sterile leaves of *Dolerophyllum Berthieri* have been described by

FIG. 432. A. *Dolerophyllum Goeperti*, section of vein. B. *Dolerophyllum Berthieri*; s, microspores. C. *Dolerophyllum fertile*. D. *Dolerophyllum fertile*, microspores. (After Renault.)

Renault as the male organs of that species. These are elliptical discs, 6×5 cm., with an excentrically placed stalk: embedded in a carbonised lamina are numerous rows of elliptical bodies,

¹ Roehl (69) B. Pl. xvii.

² Saporta and Marion (85) fig. 29.

410 μ \times 280 μ , characterised by two curved longitudinal grooves on the surface and regarded by Renault as pollen-grains. The chains of these microspores radiate outwards from the neighbourhood of the stalk and cover most of the surface of the disc (fig. 432, B). Some silicified pieces of similar spore-bearing discs from Grand' Croix named *Dolerophyllum fertile*¹ afford additional information as to these remarkable reproductive organs. The earlier account of this species by Renault is confirmed by Solms-Laubach² who examined the original sections. The peltate fleshy discs preserved as incomplete specimens consist of lacunar parenchyma 15—18 mm. thick traversed at right angles to the surface by numerous loculi (fig. 432, C), circular or oval in transverse section, containing large numbers of microspores, *s*, similar in size and form to those on the carbonised discs of the Mt Pelé specimen. Vascular strands occur between and parallel to the spore-chambers. The spores contain 8—10 cells (fig. 432, D) and Renault believes that dehiscence of the exine occurred along the two deep grooves which mark the limits of an operculum. He emphasises the peculiar structure of the microspores by speaking of them as prepollinia: in size and in the presence of internal cells (? male prothallus) they resemble the spores found in the pollen-chamber of a seed described by Renault as *Aetheotesta elliptica*³ which he thinks may belong to a member of the Dolerophylleae. It has also been suggested that *Codonospermum* may be a seed of *Dolerophyllum*⁴. An unconvincing specimen described by Saporta and Marion⁵ as a seed-bearing bract is regarded by them as referable to *Dolerophyllum*, but the evidence for any connexion is far from satisfactory.

There is nothing definite to be said with regard to the affinity of *Dolerophyllum Goeperti* or the microsporophylls represented by *D. fertile* and the specimens associated with *D. Berthieri*. Renault considers that both sterile and fertile specimens belong to the same genus, which he assigns to a position between Pteridophytes and Cycads. As Solms-Laubach says, the evidence supplied by the structure of the veins of *D. Goeperti* in favour of a

¹ Renault (96) A, p. 267, Pl. LXXII.

⁵ Saporta and Marion (85) fig. 37, p. 76.

² Solms-Laubach (91) A. p. 126.

⁴ Zeiller (06) B. p. 227.

cycadean alliance is not convincing. The type of vernation is unlike that of any known Cycad or indeed of any Gymnosperm: the large size of the leaves is another though weaker objection to this comparison, as the pinnae of *Bowenia* (fig. 391) and especially those of some species of *Zamia* (fig. 388), are of equal or larger dimensions. If, as seems probable, the xylem-strands are mesarch that is a point of contact with recent Cycads, but the bundle as a whole bears but a remote resemblance to that of a cycadean leaf and is much more like the veins of *Ginkgo*. The bud shown in fig. 430, A, is probably a young shoot and not merely a large compound leaf. If it were an unexpanded frond of *Neuropteris* bearing *Cyclopteris* pinnules we should expect to find indications of scattered desmogen-strands such as would occur in the *Myeloxylon* type of rachis. The resemblance to most forms of *Cordaites* is by no means close though a few leaves referred to that genus (e.g. *C. circularis*, fig. 468, B) are similar to those of *Dolerophyllum*¹.

The male organs are unlike those of any other plant: they may be described as sporophylls with microsporangia or perhaps synangia embedded in the mesophyll and containing microspores similar to those of some Pteridosperms or true Gymnosperms. Attention has been called to the close resemblance of the spores shown in fig. 432, C, D to those recently discovered by Kidston and referred to the genus *Whittleseya* (fig. 429), and it is very probable that the striking similarity is an index of affinity.

Ottokaria. Zeiller.

Ottokaria bengalensis Zeiller. A specimen of doubtful affinity from the Lower Gondwana (Karharbari beds) of Passerabha, India, was originally described by Zeiller² as *Feistmantelia bengalensis*, but in a postscript he substituted the name *Ottokaria* on the ground that *Feistmantelia* had previously been employed by Lester Ward. Fig. 433 is drawn from the original specimen: it consists of a stalk attached in a slightly excentric position to an almost orbicular lamina, 2.5 cm. in diameter, with subacute marginal teeth and traversed by numerous radially disposed

¹ Schmalhausen (87) Pl. v. figs. 7—9: this specimen, figured as *Dolerophyllum Goepperti*, is very similar to *Cordaites circularis* [Grand'Eury (90) A. Pl. vi. fig. 15].

² Zeiller (02) B. p. 34, Pl. iv. figs. 9, 10.

striations. Zeiller compares the fossil with *Whittleseya elegans* and *Rhipidopsis ginkgoides* and assigns it with some hesitation to the Salisburieae. An examination of the type-specimen led me to form the opinion that it may be a cupular organ of a Pteridosperm that enclosed a seed. The lamina is slightly concave and has the form of a shallow cup; moreover the surface-features resemble those of a bract rather than the regularly veined lamina

FIG. 433. *Ottokaria bengalensis*. (Nat. size; drawn from the type-specimen.)

of a foliage-leaf. The specimen bears a very close resemblance to one figured by Bertrand¹ as the cupule of *Hexapterospermum modestae* which he connects with fronds of *Neuropteris gigantea*.

Ottokaria occurs in association with fronds of *Glossopteris indica* and with the large seeds described by Zeiller² as *Cardiocarpus indicus*. I have lately obtained some evidence in favour

¹ Bertrand, P. (13) p. 131, Pl. VII. fig. 6.

² Zeiller, *loc. cit.* p. 37.

of assigning Feistmantel's seeds *Carpolithes Milleri*¹ to the genus *Glossopteris*: among several specimens from the Lower Gondwana rocks of India I found an example showing a seed partially covered by a scale-leaf in its natural position which appears to be identical with scale-leaves of *Glossopteris*. It may be that the specimen represented in fig. 433 belongs to *Cardiocarpus indicus*, though this is a mere guess: my belief is that *Ottokaria* is a cupular organ that enclosed the base of a seed borne on a Pteridosperm. There is little doubt that as additional data are obtained it will be found that Pteridosperms played no inconsiderable part in the vegetation of Gondwana Land.

Strobilites. Schimper and Mougeot.

Strobilites Milleryensis (Renault).

This species, from the Permian of France, was placed by Renault in *Cycadospadix*², but having regard to the fact that it

FIG. 434. *Strobilites Milleryensis*. (Natural size; after Renault.)

differs essentially in habit from Mesozoic examples of that genus the provisional name *Strobilites*³ is suggested. The type-specimens are long and narrow spikes or loose strobili, 8—16 cm. long and 2—2.6 cm. broad; a stout axis bears spirally disposed bracts 8—10 mm. long attached by a slender decurrent pedicel expanded distally into a fan-shaped lacinate lamina with a convex upper

¹ Feistmantel (79) B. p. 30; (81) A. p. 59, Pl. xxx. fig. 14; (82) B. p. 43, Pl. xv. figs. 5—12. Dr Arber [(05) B. p. 205] has substituted for *Carpolithes* the more appropriate designation *Cardiocarpus*.

² Renault (96) A. p. 329; (93) A. Pl. LXXIII.

³ Schimper and Mougeot (44) A. p. 31. Seward (08) B. p. 101.

face, and there are said to be two seeds attached to the sides of each pedicel (fig. 434). The oval seeds appear to be platy-spermic and resemble *Samaropsis fluitans* Daws. Two of the strobili figured by Renault are attached at right angles to a second axis, a habit suggesting comparison with that of a large compound frond. Renault is inclined to regard these fertile shoots as cycadean and suggests a possible connexion with the Permian stems *Ptychoxylon* or *Poroxyton*, both of which are known to have produced fairly numerous branches. In habit the spikes are similar to some of the longer examples of *Cordaianthus*, but their preservation is not sufficiently good to afford accurate information as to the relation of seed to sporophyll. *Strobilites Milleryensis* is, perhaps, more likely to be the fertile branch of a compound frond of a Pteridosperm, and it is significant that the seeds have been found in association with *Callipteris* leaves.

COLPOXYLON. Brongniart.

Colpoxylon aeduense Brongniart. The genus was founded by Brongniart¹ on a piece of stem 15 cm. in diameter from the Permian of the Autun district and regarded by him as a distinct type, with certain resemblances to recent Cycads. A thick section in the British Museum, 13 cm. in diameter (fig. 435, A), illustrates the main anatomical features described by Renault², to whom our knowledge of the genus is chiefly due. There are two large steles of irregular outline closely resembling those of *Medullosa Leuckarti* (cf. fig. 416, H); each consists of a band of secondary xylem with broad medullary rays and a narrow zone of phloem enclosing a central region composed of parenchyma, in which strands of primary tracheids, both reticulate and spiral, pursue a more or less horizontal course, associated with a few small groups of vertical xylem-strands at the inner edge of the secondary wood. The manoxylic nature of the wood is clearly shown in fig. 436; the continuous ink-line marks the position of the cambium and the dots show the internal protoxylem. Homogeneous parenchyma surrounds the steles and beyond this is crushed tissue containing large secretory canals and nests of stereome

¹ Brongniart (49) A. p. 60.

fibres either as separate groups or in contact with the canals (fig. 435, C). In the same peripheral tissue occur scattered collateral vascular bundles (fig. 435, D) identical with those of *Myeloxylon*. The outer cortex of the stem is marked off from the more homogeneous inner region by a fairly distinct line where there is some indication of periderm. The anatomical features are clearly shown in fig. 436, a photograph from a section in Dr Kidston's collection. At *a* is an imperfectly preserved vascular bundle with a crescentic group of secondary xylem which is probably a leaf-trace that has just emerged from the secondary cylinder. Renault speaks of these more or less circular strands as possibly connected with reproductive shoots, but it is more probable that they are homologous with the strands in the pericycle and inner cortex of *Medullosa* and represent leaf-traces before division into smaller collateral strands. Renault describes the stem as possessing seven vascular cylinders in the apical region and suggests branching of the main axis as the cause of the increase in number: there is, however, no evidence to support such correlation. The two steles seen in fig. 435, A, become merged at a lower level into a single stele of sinuous form (fig. 435, B).

Beyond the facts furnished by the leaf-trace bundles in the outer cortex and the occurrence of two large scars about 5 cm. in breadth on a stem figured by Renault, we have no positive information as to the form of the leaves or the structure of the reproductive organs. There is little doubt that the fronds were large and compound like those of most species of *Medullosa*. There is, however, some slight evidence that *Alethopteris Grandini* Brongn. and seeds of the *Pachytesta* type (fig. 497) were borne on *Colpoxylon* stems; this rests solely on the association in the Loire coal-basin¹ of *Alethopteris* fronds with stems presenting structural resemblances to *Colpoxylon aeduense*.

The striking resemblance between *Colpoxylon* and *Medullosa Leuckarti* has led certain authors² to propose the substitution of

¹ Grand'Eury (08) B. p. 1242.

² Goepfert and Stenzel (81) p. 125; Weber and Sterzel (96) B. p. 79. Solms-Laubach [(97) p. 196] draws attention to the resemblances between the leaf-scars of *Colpoxylon* and *Medullosa*.

Medullosa for *Colpoxylon*. The resemblances though close are hardly sufficient to warrant this course. In *Colpoxylon* the stelar system is simpler; there is no central region with star- or plate-rings as in *Medullosa Leuckarti* but, as in *Medullosa anglica*, the vascular tissue consists only of large steles without a medullary system. *Colpoxylon* differs from *M. anglica* in the reduction in some parts of the stem of the vascular system to a single stele and, moreover, the primary portion of the steles is much more parenchymatous in structure and contains more irregularly anastomosing tracheal strands than is the case in *M. anglica*.

The alteration in the pattern formed by the vascular system at different levels in some Medullosan stems, especially in *Colpoxylon*, may be compared with the varying disposition of the vascular strands in the thick dorsiventral rhizomes of *Polypodium heracleum* Kunz. and *P. quercifolium* L. In the rhizome of *P. heracleum* there are two vascular systems, an outer, cortical, system in the form of a hollow cylinder composed of a lattice-work with polygonal meshes from which branches are given off to the roots, and a more complex medullary system that is concerned with the emission of leaf-traces. As shown by a series of drawings reproduced in an account by Klein¹ of the anatomy of these species of *Polypodium*, the inner system of steles consists of two cylinders connected towards the upper surface of the stem by a rounded arch of vascular strands; nearer the leaf-base the two cylinders meet and eventually a larger cylinder is produced partly from the upper halves of the two cylinders of the previous section and in part from the connecting arch: the remains of the two smaller cylinders become connected with the outer vascular system. These and other changes suggest comparison with *Colpoxylon* as also with the stelar changes in the stem of *Ptychoxylon*. The comparison cannot be carried beyond the grosser features and is chiefly interesting as affording a further illustration of a similarity in plan between some recent Ferns and extinct Pteridosperms and other Palaeozoic genera.

¹ Klein (81) Pls. xxii.—xxiv.

RHEXOXYLON. Bancroft.

Rhexoxylon africanum Bancroft. The genus *Rhexoxylon* was instituted for a new type of stem represented by a single incomplete specimen from the Karroo series of South Africa: its precise geological horizon is not known but it may be referred provisionally

FIG. 437. *Rhexoxylon africanum*. Transverse section of stem showing peripheral steles and central (c) stele. (After Bancroft; $\times 2$.)

to the lower or Palaeozoic portion of the series. Though our knowledge of the morphological features of the type-species is far from complete owing in part to the method of preservation of the specimen and in part to the destruction of the outer portion

of the vascular tissue and the whole of the cortex, Miss Bancroft's careful description¹ demonstrates the existence of characters which justify the employment of a new generic name. *Rhexoxylon* is more nearly related to the Medulloseae than to any other group and is particularly interesting as the first recorded example of this group from the Southern Hemisphere.

Fig. 437 shows a transverse section (7×5 cm.) of the stem. The ground-tissue consists of fairly large-celled parenchyma with sclerous nests and a few bands of periderm. At the periphery of the stem are radially disposed groups of vascular tissue varying in size and to some extent in shape. Unfortunately the stem is incomplete and it is impossible to say how much vascular or other tissue originally existed beyond the present corroded edge. The vascular groups, or steles as they may legitimately be called, follow a vertical course through the length of the block (6.5 cm.) and afford only slight evidence of branching or anastomosing. A close examination of the steles shows that they consist of portions of two series, an inner and outer set; there is also a curved vascular band in the central ground-tissue (fig. 437, *c*) and some isolated and scattered patches of vascular elements. Each stele of the inner series is made up of two parts, an outer smaller and normally orientated group of secondary xylem and a larger inversely orientated inner group of identical structure. A single stele of the inner series is shown in fig. 438, B, C; the larger inner portion consists of slightly divergent rows of tracheids and uniseriate medullary rays and is separated from the smaller portion by a narrow space, *a*, occupied by crushed tissue which may correspond to the 'partial pith' or primary xylem of a Medullosan stele. The two groups of xylem are no doubt the products of two cambium arcs, the protoxylem of each group being situated on the flat inner face. The cambium and phloem are represented only by crushed brown cells on the curved outer edge of the xylem. The separate individuality of the two portions of each stele is indicated not only by the presence of the 'partial pith' but by the discontinuity of the tissue at the ends of the narrow space. The tracheids seen at *b*, fig. C, are in oblique longitudinal section and are probably being detached to form a leaf-trace. This type of stele may be

¹ Bancroft (13).

compared with the steles of *Medullosa Solmsi* (fig. 416, L) but those of *Rhexoxylon* differ in the lack of continuity of the secondary xylem round the narrow band of crushed primary xylem. The other steles of the inner ring exhibit the same dual nature though with local modifications. In the stele seen in fig. 438, B, there is a close approach to a continuous cylinder of secondary xylem especially on the right-hand side. External to the inner series are several portions of normally orientated secondary xylem-groups (fig. 437): these probably represent a second series of steles separated from the inner series by a narrow crushed arc of tissue on which the protoxylem strands of the outer groups abut. The xylem of the outer steles agrees in its normal orientation with

FIG. 438. *Rhexoxylon africanum*. A, radial wall of tracheid; B, C, peripheral steles; *a*, primary portion of stele; *b*, lateral strand. (After Bancroft.)

the outer and smaller part of the inner steles and, as there is no accompanying group of inversely orientated xylem corresponding to the larger mass of secondary xylem of the inner series, the outer strands are designated partial steles. The central stele consists of two curved irregular bands composed of vertically and obliquely running tracheids: the central part of this stele consists of crushed tissue that probably represents primary xylem like that between the two parts of each of the peripheral steles.

Rhexoxylon differs from the usual Medullosan type in the structure of the secondary xylem which is composed of tracheids with an Araucarian form of pitting: there are usually two alternate rows of contiguous pits (fig. 438, A) and occasionally one or three rows. The medullary rays are uniseriate and 3 to 15 cells in depth, a feature characteristic of coniferous wood and not of the wood of the Medulloseae.

In the absence of more complete information as to the anatomical structure of this stem and of all information as to the leaves or reproductive organs it is impossible to fix with precision the systematic position of the genus. It is, however, clear that *Rhexoxylon* is closely connected with *Medullosa* in certain features though in the structure of the wood it exhibits important peculiarities. The imperfectly known stem *Cladoxylon Kidstoni*¹ shows a fairly close agreement with the African plant in the form of the steles (fig. 460) but the pitting is scalariform.

SUTCLIFFIA. Scott.

Sutcliffia insignis Scott.

The generic name *Sutcliffia* was given by Dr Scott² to a peculiar type of stem from the Lower Coal Measures of Shore, Lancashire, in recognition of the valuable services rendered to Palaeobotany by the late Mr W. H. Sutcliffe, the owner of the colliery from which several new types of plants have been obtained. Two stems are recorded, the type-specimen and a more recently discovered stem, also from Shore, described by Miss de Fraine³, which differs in several particulars from Dr Scott's species. In view of the well-marked peculiarities of the second stem it is convenient to speak of it as *forma* β instead of including it without a distinctive epithet in *Sutcliffia insignis*. We know nothing of the reproductive organs of the genus.

1. *Sutcliffia insignis*, *forma* α .

This consists of a piece of stem approximately 12×7 cm. in diameter characterised by a broad cortex of parenchyma with secretory sacs and ducts and strands of mechanical tissue (fig. 439, A). Decurrent and massive leaf-bases form a prominent feature as in the stem of *Medullosa anglica*. The stele, though compressed before petrification, was probably not quite cylindrical but more or less polygonal or broadly triangular in section; it consists of groups of large primary tracheids (350μ in diameter) with numerous bordered pits (fig. 439, B, and fig. 440) embedded in an anastomosing system of parenchyma containing scattered secretory sacs, a type of protostele like that of *Heterangium* and *Medullosa*

¹ Page 205.

² Scott (06).

³ de Fraine (12).

FIG. 439. *Sutcliffia insignis* Scott. A, B, E, forma α . (After Scott.) C, D, forma β . (After de Fraine.)

- A. Transverse section of stem; a , b , double rows of leaf-trace bundles. The larger black masses are the meristeleles; the smaller patches represent bundles derived from the meristeleles.
- B. Longitudinal section of a radially symmetrical bundle from a leaf-base.
- C. The junction between the primary and secondary xylem.
- D. Vascular system in transverse section: m , m' , meristeleles; s , main stele; e , extra-fascicular strands; lt , leaf-traces; c , secondary cortex.
- E. Vascular bundle from petiole showing a ring of large sieve-tubes surrounding the xylem, and portions of stereome strands.

anglica except in the possession of exarch protoxylem strands. The metaxylem tracheids contiguous to the external protoxylem elements have a dense spiral or scalariform type of pitting. In the lower part of the stem the primary xylem is enclosed by a cambium which has added a few secondary tracheids (120μ in diameter), but in the upper part of the specimen the cambium is only partially developed and the addition of secondary xylem has hardly begun (fig. 440). A narrow band of secondary phloem was recognised in places consisting of small-celled parenchyma with some sieve-tubes and medullary rays continuous internally

FIG. 440. *Sutcliffia insignis*. Part of the primary xylem showing on the upper edge the beginning of secondary growth. (Cambridge Botany School, 560.)

with the parenchyma of the primary stele. In close association and occasionally in organic connexion with the surface of the stele are several tangentially elongated and large groups of vascular tissue associated with smaller oval strands varying considerably in size. These groups, designated meristeles (Fig. 439, A), are identical in structure with the main stele and are occasionally invested by a feebly developed zone of secondary xylem and phloem. The meristeles are detached at intervals from the parent stele around which they form by anastomoses an irregular network: the larger meristeles give off smaller strands and from these the

actual leaf-traces are produced by subdivision. It appears, however, that in this type the meristeles are not completely used up in the production of the leaf-traces, portions of them behaving as cauline vascular strands. A protoxylem of a meristele still attached to the central protostele occupies an internal position, and at a higher level, as separation of the meristele is effected, the spiral tracheids occur on the inner face. New meristeles are given off at intervals from the main stele 'to compensate for those parts of the reticulum which were used up in the formation of leaf-trace strands¹.' The meristeles form the starting-point for the leaf-traces, an intermediate system between the main stele and the actual leaf-traces; they differ, therefore, from the parent leaf-traces of *Medullosa anglica*, which are completely used up by repeated subdivision. Moreover in *Sutcliffia* the leaf-bundles are concentric and not collateral.

A conspicuous feature of the stem of *forma a* is the occurrence of two double rows of vascular strands stretching across the cortex (fig. 439, A, *a*, *b*). These are interpreted by Scott as downward continuations in the stem of the inner surface of leaf-bases. The outer cortex of the stem and leaf-bases has hypodermal strands of stereome which remain separate or rarely anastomose, and form a superficial zone exactly like that of some species of *Medullosa*.

The leaf-trace bundles may be radially symmetrical or unilateral in the arrangement of the xylem which is in all cases completely surrounded by phloem. Fig. 439, B, shows part of a longitudinal section of a large leaf-trace bundle: spiral protoxylem elements (*px*) abut on the phloem (*ph*) and are succeeded to the left by narrow scalariform and large reticulately pitted tracheids. In the larger and radially constructed traces there are several protoxylem-strands distributed over the surface of the xylem, while in the smaller unilateral traces there may be one or two protoxylem strands. A characteristic feature of the xylem of the leaf-traces is the admixture of parenchyma with the tracheids (fig. 439, B, E) and another noteworthy character is the occurrence of large thin-walled tubes in the phloem described by Scott as sieve-tubes and compared with the large sieve-tubes in Marattiaceous leaf-bundles. Immediately

¹ Scott (06) p. 53.

internal to the hypoderm is a row of leaf-bundles (fig. 439, A) each of which is accompanied by stereome strands.

The petioles, which reach a diameter of 12 cm., contain numerous, occasionally anastomosing, concentric bundles. Nothing is known of the fronds as a whole beyond the fact that they are spirally disposed and had decurrent bases of large dimensions in proportion to the stem.

Sutcliffia insignis, forma β .

This form, described by Miss de Fraine as *Sutcliffia insignis*¹, is represented by a stem rather smaller than the type-specimen described by Scott, though it is probably an older example of the same species. It is distinguished by a greater development of secondary xylem and phloem both on the main stele and the meristeles; it differs also in the absence of the greater part of the cortex and leaf-bases which have been cut off as the result of the formation of a deep-seated periderm (fig. 439, D, C). The meristeles are smaller and fewer than in the larger form and are distinguished by some other peculiarities. At *m'* in fig. 439, D, a meristele is seen attached to the main stele. In *Sutcliffia insignis forma a* the main stele is enclosed by an irregular network of subsidiary steles or meristeles and these form the points of departure of the leaf-traces, but the meristeles are not completely used up in the process of conversion into leaf-traces. In *Sutcliffia insignis forma β* the meristeles agree in structure with the main stele except in the smaller amount of secondary tissue: they do not, however, form a network as in *forma a* but occur as strands parallel to the central stele, 'giving off leaf-traces and ultimately dividing up into smaller strands, often unequal in size, the primary wood of the meristeles being entirely used up in the production of radially symmetrical or unilateral bundles.' In this respect, as Miss de Fraine points out, *forma β* agrees more closely than *forma a* with *Medullosa anglica* and supports Scott's view that *Sutcliffia* is a primitive type of Medullosan stem. The leaves were given off at fairly long intervals as in some species of *Medullosa*: the leaf-traces are exarch and similar to those of the type-species. The most striking feature of the new stem is the presence of a

¹ de Fraine (12).

vascular network (fig. 439, D, e) which encloses both the main steles and the meristeles; it consists of extrafascicular strands composed of normally orientated bands of secondary xylem and phloem often assuming a fan-like arrangement and occasionally almost concentric or inversely orientated. These strands are always accompanied by short, usually reticulate, tracheids on the inner margin of the xylem: similar isodiametric tracheids also occur in the pericyclic region. The extrafascicular strands are believed to be secondary structures phylogenetically independent of the meristeles and main stele, comparable with the successive cylinders or arcs of secondary xylem and phloem in some recent Cycads and in some species of *Medullosa*¹.

The stele is exarch and roughly triangular; except in the broader zone of secondary tissue it agrees with the protostele of *forma a*. The secondary xylem (fig. 439, C) possesses numerous medullary rays 3—4 cells broad and of considerable depth: the secondary phloem is characterised by the presence of thick-walled elements, presumably sieve-tubes, like those of *Medullosa Leuckarti* and *M. anglica*.

The ground-tissue is rich in secretory tissue and the stem-surface, from which the leaf-bases have been detached, is limited by a wide zone of secondary tissue produced by a phellogen.

Sutcliffia Williamsoni (Seward).

1876. *Mylopteris (pars)* Williamson, Phil. Trans. R. Soc. Vol. 166, Pl. II. figs. 7, 8; Pl. IV. fig. 17.
1893. *Rachiopteris Williamsoni* Seward, Ann. Bot. Vol. VII. p. 1.
1894. *Rachiopteris Williamsoni* Seward, *ibid.* Vol. VIII. p. 207, Pl. XIII.
1906. *Sutcliffia Williamsoni* Scott, Trans. Linn. Soc. Vol. VII. pt IV. p. 62.

In an account of *Mylopteris* (= *Myeloxylon*) published in 1876 Williamson included some sections of petioles from the Lower Coal Measures which I afterwards with his concurrence transferred to the genus *Rachiopteris* as *R. Williamsoni*. In *Rachiopteris Williamsoni* the vascular bundles are concentric and not collateral, and are further distinguished from those of *Myeloxylon* by the association of parenchyma with the tracheids.

¹ Reference should be made to the helpful drawings of models of the vascular system in Miss de Fraine's paper.

In the arrangement of the bundles and in the structure of the ground-tissue the petioles of *Rachiopteris Williamsoni* agree with those of *Myeloxylon*. An outstanding feature of the vascular strands of the former is the occurrence at fairly regular intervals in the peripheral part of the phloem of comparatively large tubes described by me as secretory canals on the ground that evidence was furnished of their development by the schizogenous separation of cells to form a central canal. The canals were compared with the large sieve-tubes of the Marattiaceae, but with the qualification that 'their mature form and their manner of development are strongly suggestive of small secretory canals.' Nothing was known as to the stem which bore these petioles until Scott's discovery of *Sutcliffia* with vascular bundles in the cortex and leaf-bases of the same type as those of *Rachiopteris Williamsoni*. As Scott says, there are a few distinguishing features which suggest that *R. Williamsoni* is not specifically identical with the petioles of *Sutcliffia insignis*, though the agreement is such as to justify the substitution of *Sutcliffia* for *Rachiopteris*. The tubular elements in the phloem which I considered to be secretory canals are regarded by Scott and Miss de Fraine as sieve-tubes.

Miss de Fraine gives an excellent summary of our knowledge of the genus and discusses, in the light of the additional facts furnished by the second stem, the position of *Sutcliffia* in a phylogenetic series. The new form strengthens the comparison instituted by Scott between *Sutcliffia* and *Medullosa* and gives support to a close connexion between the Medulloseae and the Cycadaceae. Scott lays stress on the fact that the Medulloseae, except *Sutcliffia*, are polystelic, while the Cycads, at least the adult stems, are monostelic. The views of Worsdell and other botanists who believe that the Medulloseae and the Cycads are intimately related are discussed on another page: in reference to these views Miss de Fraine adds a caveat as to the danger of attaching excessive importance to evidence based on seedling anatomy when we are concerned with broad phylogenetic questions. The stele of a cycadean stem may be derived from a protostelic type such as that of *Sutcliffia* by the gradual disappearance of the internal tracheids: in *Sutcliffia*, as in some Cycads and species of *Medullosa*,

extrafascicular strands and cylinders are a characteristic feature and these may well have arisen independently of the central stele in response to physiological requirements. From such a type as *Sutcliffia* evolution may have proceeded along two lines; in one direction new types were produced in which increasing complexity, as represented by a multiplication of steles, was an outstanding feature. These forms, illustrated by *Medullosa anglica* and other more elaborate species, proved inefficient and were unproductive. Along another line the protostelic condition was maintained though in some cases extrafascicular strands or cylinders and cortical steles were superadded: it was this line that led to the recent Cycads.

*General considerations suggested by the anatomical features
of Medullosa.*

A comparison of the stems described under the generic name *Medullosa* reveals a considerable range in the grosser anatomical features superadded to certain fundamental characters denoting a common origin¹ If additional data were available giving us a fuller knowledge of individual plants differences between species would be more clearly defined and would provide adequate grounds for the institution of new genera for some of the types now included in the comprehensive genus *Medullosa*. A proposal by Dr Lotsy² to adopt the names *Pecopteromedullosa* and *Neuropteromedullosa* rests primarily on the relatively unimportant difference between the fronds associated with certain Medullosan stems and, as Scott³ points out, this two-fold division if applied to such a species as *Medullosa Leuckarti* would result in its separation from species which anatomically are clearly of the same generic type. In *Medullosa anglica*, one of the oldest and simplest types, there are three steles of equal importance, and each of them is practically identical with the single stele of *Heterangium*. Each stele—as indeed all Medullosan steles—consists of a strand of primary xylem enclosed by secondary xylem and phloem, and it is obvious that the development of a constantly increasing cylinder of

¹ For additional figures of the principal types of *Medullosa*, see Miss Bancroft's paper (14).

² Lotsy (09) p. 719.

³ Scott (14) p. 998.

secondary conducting tissue about three centres would lead to serious mechanical difficulty: a stem constructed on the plan of *Medullosa anglica* or the smaller *M. pusilla* could not increase the thickness of its secondary vascular tissue beyond a certain point without detriment to its efficiency. In some types this difficulty is partially overcome by the production of complete concentric cylinders of centrifugally developed conducting tissue external to an inner system of concentric steles agreeing individually with those of *Heterangium* (fig. 415, B). *Medullosa anglica*, regarded from the point of view of the architectural efficiency of its vascular system, affords a much less promising *point d'appui* for further evolution than some of the forms described under *Medullosa stellata* in which the mechanical *impasse* is avoided by the adoption of the cycadean plan as represented by such genera as *Cycas* and *Macrozamia*. The English species *Medullosa centrofilis* (fig. 417) affords the first example of a characteristic Medullosan feature, namely the presence of a small concentric stele in the central region of the stem: this so-called star-ring differs not only in its smaller dimensions but in its more cylindrical form from the larger peripheral steles. In the later Permian species, e.g. *Medullosa porosa* and *M. Solmsi*, the single star-ring of the older *M. centrofilis* is replaced by a large number of precisely similar conducting strands. These star-rings are structurally comparable with the cortical steles of *Cycas* and, in position, with the medullary system of bundles in a *Macrozamia*; they are essentially cauline and take no part in the emission of leaf-traces. *Medullosa Leuckarti* (fig. 416, H) resembles in its vascular plan *M. centrofilis*, but in this larger stem there are several star-rings and the enlarged peripheral steles are more or less sinuous. In *Medullosa Solmsi* (fig. 416, E) the star-rings are still more numerous and the main vascular system consists of a double series of concentric steles, each agreeing with the larger peripheral steles of *M. Leuckarti*.

Some of the forms included in *Medullosa stellata* appear to be very different from *M. anglica* and *M. Leuckarti* (cf. fig. 416, F, A, H), but their similarity is apparent if we imagine *Medullosa anglica* with only one main stele (with the addition of star-rings) which is stretched tangentially until it becomes a

long and narrow plate-ring and is then rolled into a hollow cylinder like that in fig. 416, D. A modification of the tubular type of stele is seen in *Medullosa stellata* var. *corticata* (fig. 416, G) in which the vascular cylinder is broken up into two or more curved plate-rings, a change superficially similar to that by which a dictyostele is produced from a solenostele, but in *Medullosa* it is not the overlapping of leaf-gaps that is the cause of the change. A striking feature in the stem of *Medullosa stellata* represented in fig. 416, D and F (especially F), is the inequality in breadth of the centrifugal and centripetal xylem: this inequality is an expression of the difficulty caused by the presence of an internal as well as an external addition of secondary conducting tissue. A limit is set to the production of secondary centripetal xylem by the space available for extension, whereas there is unlimited room for increase in the case of the centrifugal tissue. This tendency to a greater development of xylem and phloem on the outer side of the primary portion of the steles is illustrated also in *M. Solmsi* var. *lignosa* (fig. 416, L) where the outer of the two series of peripheral steles has a much larger proportion of centrifugal xylem. In *M. anglica* the secondary xylem on the inner side of the steles is not infrequently broader than the corresponding tissue on the abaxial side¹; but this is exceptional in the genus. A further development of centrifugal conducting tissue without any corresponding development of centripetal tissue is effected in certain cases (fig. 416, K, L) by the addition of concentric cylinders of centrifugal xylem and phloem beyond the original concentric steles. The type illustrated by *Medullosa Solmsi* var. *lignosa* and *M. stellata* var. *gigantea* (fig. 416, L, K) at once suggests comparison with stems of *Cycas*, *Macrozamia*, and *Encephalartos*, the chief difference being the presence in *Medullosa* of an inner series of concentric steles and a central ground-tissue containing star-rings, though the latter may be regarded as corresponding to the medullary system of bundles in *Macrozamia*. In *Macrozamia* the central region of the stem is considered to be the pith of a monostelic stem, whereas in *Medullosa* the stem is polystelic. In recent cycadean stems it is not uncommon to find patches of inversely orientated xylem and phloem internal to one or more

¹ Scott (99) p. 89.

of the cylinders of centrifugal vascular tissue. These abnormal developments are considered by Worsdell¹ to be relics of the inner portions of concentric steles possessed by the Medullosan ancestors of recent Cycads. This interpretation affords a means of bringing into closer relationship the polystelic Medulloseae and the monostelic Cycadaceae, the apparent simplicity of the latter being the result of the progressive loss of centripetal xylem and phloem, the normal cycadean cylinder being therefore regarded as a one-sided remnant of a concentric Medullosan stele. In other words, the Cycads are descended from polystelic ancestors. As further evidence in support of this view Worsdell points to the occurrence of concentric steles in the cortex of *Cycas* and their occasional presence in the pith of other genera. Matte² has shown that in the seedling stem of *Encephalartos Barteri* (fig. 396, K) there are three concentric steles each similar to a normal Medullosan stele: at a higher level in the axis the steles become 'unrolled' and assume the form of one-sided cylinders of centrifugal xylem and phloem.

In the peduncles of some recent Cycads, e.g. *Stangeria*, there is a tendency towards a somewhat irregular orientation of the collateral bundles that constitute the vascular cylinder, and tracheids occasionally occur internal to the protoxylem of the individual bundles³. Worsdell regards these features as evidence of a Medullosan ancestry. If the sinuous plate-rings of a stem of *Medullosa Leuckarti* (fig. 416, H) were broken up into separate portions and wholly or in part deprived of the centripetal xylem, the result would be an arrangement of bundles comparable with that in a *Stangeria* peduncle⁴. The scattered centripetal tracheids discovered by Scott in *Stangeria* and other cycadean peduncles are interpreted by Scott and by Worsdell as relics of some ancestral centripetal xylem, but with this important difference in the point of view; Scott believes that they represent the almost completely aborted centripetal xylem of a single stele like that of *Lyginopteris*, while Worsdell sees in them fragmentary vestiges of the central primary xylem of two or more Medullosan steles.

¹ Worsdell (96); (98); (00); (06) etc.

² Matte (04); (08). See also Bancroft (14); Dorety (09).

³ Scott (97).

⁴ Worsdell (06).

An abnormal seedling of *Araucaria Bidwillii* described by Shaw¹ exhibits features analogous to those in some cycadean seedlings: within the normal stele a cambium forms an inversely orientated vascular cylinder which at a lower level becomes continuous with the outer centrifugal tissue, the whole vascular system being eventually represented by two concentric steles. The polystelic stage is a development of a monostelic condition, and the inner or inverted portion of each of the two concentric steles is derived from an inversely orientated cylinder in the central region of the root. This abnormal root does not, however, supply an argument in favour of the derivation of a monostelic type of stem from one that was polystelic, but it shows a close relation between the two plans in one organ. The seedling is not altogether normal in form apart from structure and it is not improbable that the anatomical abnormality is connected with some pathological cause.

It has been suggested² that Worsdell attaches too much phylogenetic significance to the irregularities in the disposition and form of the vascular bundles in the peduncle of *Stangeria*, and the criticism that insufficient allowance is made for the possible reaction on structure of the special physiological requirements of reproductive shoots is well founded. Granting an overestimate of the arguments drawn from the occasional occurrence of concentric vascular strands, a considerable body of evidence remains in favour of Worsdell's main contention.

Mrs Thoday³ has drawn attention to certain features exhibited by the inflorescence-axes of *Welwitschia*, particularly the occurrence of concentric and inversely orientated bundles, similar to those characteristic of the seedling of *Cycas siamensis*⁴ described by Matte, and to anatomical characters occasionally present in adult cycadean stems and normally represented in *Medullosa*. She is of opinion that the occurrence in *Welwitschia* of certain Medullosan features has a phylogenetic significance. The differences between the Gnetales, Medulloseae, and Cycadales are considerable, and it would seem unlikely that the anatomical resemblances described by Mrs Thoday are of great value as criteria of close relationship. The comparison of *Lagenostoma* with

¹ Shaw (09).

³ Sykes, M. G. (10²); (10).

² de Fraine (12) p. 1060.

⁴ Matte (04) Pls. xv. xvi.

gnetalean seeds is alluded to elsewhere. To the statement that the presence of concentric and inversely orientated steles in *Welwitschia* are reminiscent of the polystelic Medulloseae, Mrs Thoday adds the qualifying remark that the occurrence of four concentric groups of vascular tissue in the hypocotyl of *Welwitschia* is not sufficient to justify the conclusion that the ancestral type was polystelic. This reservation accords with the contention of Scott and other botanists, that the occasional occurrence in cycadean seedlings and adult stems of anatomical features suggestive of polystely does not in itself furnish an adequate reason for doubting that the apparent monostely of Cycads is phylogenetically what it seems to be, namely, an indication of monostelic ancestry. This brings us to the question of a possible monostelic ancestor. It may be that the Upper Carboniferous genus *Sutcliffia* affords a clue to the problem of the origin of the polystelic type illustrated in various forms by *Medullosa*. The protostele of *Sutcliffia* bears a close resemblance to each of the three steles of *Medullosa anglica*; the fact that *Sutcliffia* is exarch and that *Medullosa anglica* has mesarch xylem is of secondary importance, particularly as exarchy is represented within the genus *Medullosa*. The extrafascicular strands of xylem and phloem and the accessory strands are points in which *Sutcliffia* and *Medullosa anglica* agree and, as Miss de Fraine¹ adds, the meristeles of *Sutcliffia* may be homologous with the leaf-trace strands of *Medullosa*. Scott² gave expression to the characters shared by these two types by describing *Sutcliffia* as the most primitive of the Medulloseae. It is suggested that the protostelic axis of *Sutcliffia* may be regarded as the starting-point of the monostelic Cycads, the central mass of tracheal tissue being replaced by a parenchymatous pith, while the extrafascicular and accessory strands arose independently of the central stele in response to increased physiological demands consequent on the increase in size of the stem. From the same starting-point evolution may have progressed along another line through such a type as *Medullosa anglica* leading to the more complex Permian species of *Medullosa*. Chodat's view³ that the Medulloseae are Protocycadaceae, if we include *Sutcliffia* as well

¹ de Fraine (12).

² Scott (06) p. 64

³ Chodat (08) B. p. 38.

as *Medullosa* in the Medulloseae, is probably correct. There is clear evidence of a close bond of union between recent Cycads and the Medulloseae, and *Sutcliffia* offers a possible means of deriving complex polystelic types from a monostelic ancestor.

Worsdell's opinion¹ that the stele of *Lyginopteris* affords evidence of derivation from a polystelic ancestor and is not homologous with the true monostele of *Heterangium* is opposed to the undoubted signs of intimate connexion exhibited by these genera. The Lyginopterideae are, as Scott² says, a less advanced group than the Medulloseae and, it may be added, they are more remote from the modern representatives of the Cycadales. The Lyginopterideae and the Medulloseae are probably offshoots of a common stock, but the Medulloseae occupy a position farther removed from the filicinean ancestry than *Heterangium* and *Lyginopteris*³.

The relative meagreness of our knowledge of the reproductive organs of the Medulloseae gives precedence to anatomical data in phylogenetic considerations, but the evidence furnished by *Trigonocarpus* and other seeds that may fairly be assigned to Medullosan plants is in harmony with the conclusions based on vegetative characters with regard to a close affinity between the Medulloseae and Cycads.

The comparative examination of recent Cycads naturally suggested by any attempt to compare the group as a whole with Palaeozoic types leads to some apparently contradictory results. The habit of the megasporophyll of *Cycas* is usually quoted as a primitive attribute: the close resemblance in plan and in manner of occurrence on the stem between megasporophylls and foliage leaves recalls both Ferns and Medullosan fronds. On the other hand the production of eight body-cells in the pollen-tube of *Microcycas*⁴ in place of the usual single cell may also be regarded as a primitive character. It is perhaps possible, as Miss Dorety⁵ says, that the polyspermy may be a case of recurrence and not a direct inheritance. *Microcycas* differs from *Cycas* in having only one vascular cylinder, and if the presence of several concentric

¹ Worsdell (06) pp. 140 *et seq.*

⁴ See p. 6.

⁵ Dorety (09²) p. 144.

cylinders in *Cycas* be interpreted as an indication of a closer connexion with a Medullosan ancestry, the *Microcycas* type would represent a more advanced stage in evolution. Attempts to arrange plants according to a natural sequence are frequently frustrated by instances of unequal progress in the development of vegetative and reproductive organs; one or other set of members lags behind; some characters point to the retention of primitive traits while others indicate a marked progressive tendency. It is noteworthy that the Mesozoic Bennettitales are characterised by a greater simplicity of stem-structure than is the rule in recent Cycads, and both in their vegetative features and in the structure of the seeds they are further removed from the Medullosan type.

II. A. STELOXYLEAE.

Steloxylon. Solms-Laubach.

Steloxylon Ludwigi (Goepfert and Stenzel). The genus is founded on a piece of stem from Siberia, possibly of Permian

FIG. 441. *Steloxylon Ludwigi*. A, surface-view (longitudinal) of stem showing leaf-bases. (After Solms-Laubach.) B, longitudinal section showing anastomosing vascular strands. C, steles, the lower one showing the emission of a leaf-trace. (B, C, after Schenk.)

age though not improbably older, which was originally described as *Medullosa Ludwigi*¹. It is characterised by numerous

¹ Goepfert and Stenzel (81) p. 126, Pl. xvii.

cylindrical and band-like vascular strands forming an irregular anastomosing system (fig. 441, B) and by crowded spiral leaf-scars on the exposed face. The appearance presented by the transverse section figured by these authors, while suggesting comparison with *Medullosa*, reveals a distinctive character, namely the absence of a definite peripheral system of vascular rings such as forms a striking feature of the continental Medullosae. A more complete description was afterwards published by Schenk¹ who recognised more fully the peculiar features and hinted at the possibility that the species might more appropriately be regarded as a member of a distinct group. Solms-Laubach² went a step further and instituted the generic name *Steloxylon*, and in a later publication gave a fuller account of the anatomical characters. The complete stem must have reached a diameter of approximately 13 cm. The homogeneous ground-tissue forms a matrix enclosing an anastomosing vascular system of cylindrical or oval steles (fig. 441, C). Each strand consists of a band of secondary xylem tracheids with one or several rows of circular or oval bordered pits on the radial walls and narrow medullary rays usually 1—2 cells broad and 1—4 cells deep, though occasionally deeper. No phloem is preserved. The tissue in the centre of each stele is very imperfectly preserved, but it is clear that the secondary xylem enclosed a central region ('partial pith') like that in the steles of a *Medullosa*, doubtless consisting of primary xylem and conjunctive parenchyma.

The stem is covered with leaf-bases of oval or circular section and between them are small organs, probably multicellular hairs (fig. 441, A). A leaf-base consists of an outer zone of strengthening tissue and a parenchymatous ground-tissue traversed by two or more small vascular strands which assume various forms. These petiolar strands are simply portions of the main vascular system which bend outwards at the periphery of the anastomosing network. The more noteworthy features in which *Steloxylon* differs from *Medullosa*, particularly such species as *M. stellata* and *M. Leuckarti*, are (i) the crowded and comparatively small leaf-bases in place of the massive decurrent petioles of *Medullosa*; (ii) the supply

¹ Schenk (89) p. 525, Pl. I. figs. 1—16.

² Solms-Laubach (96) B. p. 62; (97) p. 197; (10) p. 542, Pl. III. fig. 9.

of the leaves by compact branches of the stelar network instead of the bundles detached as leaf-traces from a stem-stele of *Medullosa* (the origin of a leaf-trace in *Steloxylon* is shown in fig. 441, C); (iii) the absence of a peripheral system of vascular plate-rings and the irregular distribution of cylindrical and plate-steles in the ground-tissue. Nothing is known of the reproductive organs or leaves beyond the structure of the attached leaf-bases. The opinion expressed by P. Bertrand¹ that the fossil described by Stenzel as *Asterochlaena (Clepsydropsis) kirgisica* is the petiole of *Steloxylon* was abandoned after the additional facts published by Solms-Laubach.

As regards the affinities of *Steloxylon*: the structure of the steles agrees closely with that of the star- and plate-rings of a *Medullosa*, while the pitting of the tracheids is more like that in *Medullosa* than *Cladoxylon*. In the tendency to a more radial than tangential disposition of the band-like steles *Steloxylon* recalls *Cladoxylon* rather than *Medullosa*, but in *Cladoxylon* the vascular system does not form an irregular network as in *Steloxylon*. The information as to the structure of the primary xylem is very meagre, but it points to a closer connexion with *Medullosa* than with *Cladoxylon*. On the whole *Steloxylon* may perhaps be defined as a genus allied to the Medulloseae in the anatomical features of the stem more closely than to other genera, but sufficiently distinct to be excluded from the Medulloseae as at present understood².

¹ P. Bertrand (08); (11) p. 47 (footnote).

² In a recent note on *Steloxylon* to which Dr Scott has drawn my attention Bertrand records the genus from Saalfeld (Upper Devonian) and expresses the opinion that *Steloxylon* may be a condition of *Cladoxylon* and not a distinct type—P. Bertrand (14) p. 448.

CHAPTER XXXI.

PTERIDOSPERMS REPRESENTED BY SEED-BEARING LEAVES ONLY OR LEAVES IN CONSTANT ASSOCIATION WITH SEEDS.

BEFORE describing other genera represented by petrified vegetative organs exhibiting in their anatomical features points of contact with the Medulloseae, a short account is intercalated of some imperfectly known seed-bearing fronds and seeds belonging to the Pteridosperms but which do not afford sufficient data to admit of their reference to a more precise position in a natural classification.

Pecopteris Pluckeneti (Schlotheim).

In the section in Volume II. devoted to the genus *Pecopteris* reference was made to the species *P. Pluckeneti*¹, further treatment being deferred until other Pteridosperms had been described. The fern-like fronds originally described by Schlotheim as *Filicites Pluckeneti*² and afterwards transferred by Brongniart and other authors to *Pecopteris*³ are now recognised as the leaves of a Pteridosperm. Some doubt has been expressed as to the specific identity of the specimens figured by Schlotheim and Brongniart respectively, but Potonié's examination of the type-specimen of the earlier author convinced him that Brongniart's leaves were correctly named. The large fronds of *Pecopteris Pluckeneti* are characterised by the bifurcation of the principal axis which bears opposite pairs of bi- or tri-pinnate branches and in the angles of the bifurcations of the rachis undeveloped buds occur on prolongations of the axis, a habit recalling recent species of *Gleichenia*⁴

¹ Vol. II. p. 576.

⁴ Sterzel (83); (86²) B.; Zeiller (06) B. p. 60.

(figs. 225 and 226, vol. II.). The variation in the form of the pinnules is shown in fig. 442, A, which represents both the apical portion and parts of pinnae 10 cm. lower on the rachis of a large leaf from the Coal Measures of Radstock. The species is characteristic of the Upper Coal Measures and is recorded also from Permian strata. In 1883 Sterzel adopted for this species the generic name *Dicksonites* because of the occurrence of shallow circular cups at the end of the lowest lateral vein on some of the pinnules which he believed to be sori of the Cyatheaceous type. The cups

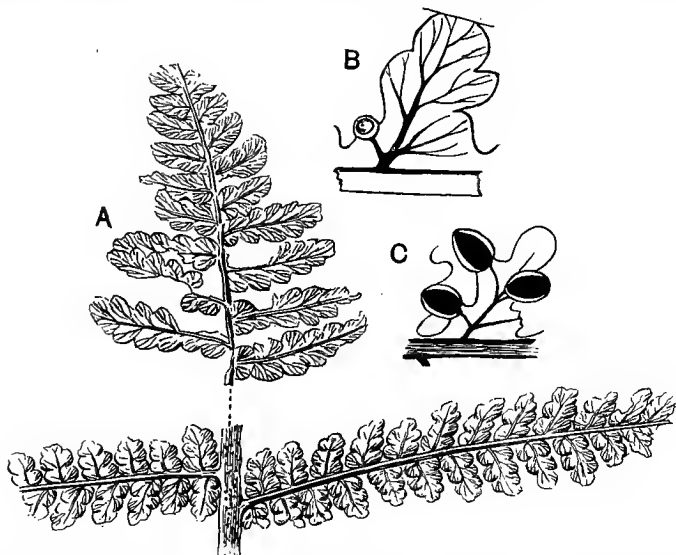

FIG. 442. *Pecopteris Pluckeneti*. A, apex and lower pinnae (Kidston Coll., 234); B, pinnule with supposed sori (after Sterzel); C, pinnule with seeds (after Zeiller).

have an involute margin and occasionally a small scar in the centre (fig. 442, B). Stur¹ declined to accept Sterzel's evidence as satisfactory and suggested a fungal origin for the sori-like impressions, a view, as Sterzel objected, that is rendered improbable by the constant position of the single cups on several pinnules. The nature of Sterzel's 'sori' has not been demonstrated: it is suggested by Grand'Eury² that they mark the position of micro-

¹ Stur (85) B. p. 293.

² Grand'Eury (05).

sporangia. Some seed-bearing specimens in Dr Kidston's collection show cups, like those figured by Sterzel, on pinnules from which the seeds have fallen, and it is not improbable that they are the scars of seeds. In 1905 Grand'Eury published a description and photographs of specimens of *P. Pluckenetii* from the St Étienne coal-field showing hundreds of well-preserved seeds, many of them attached to pinnules characterised by a very slightly reduced lamina. Some fronds were found to be entirely fertile, while others bore both sterile and fertile pinnae. The smallest seeds, 5 mm. long and 3 mm. broad, were found at the tips of unexpanded leaves: the mature seeds, only slightly larger, agree in their broadly oval form and narrow marginal 'wing' with small examples of *Samaropsis*¹. The seeds were figured by Grand'Eury² in an earlier work as *Carpolithes granulatus*. They are believed to have hung free from the lamina, a conclusion based on the position of the seeds relative to the plane of the pinnule in well-preserved examples. Prof. Zeiller informs me that he is by no means certain that Grand'Eury's seed-bearing fronds should not be referred to *Pecopteris Sterzeli*; but as that species and *P. Pluckenetii* are very closely allied forms and may well have borne the same general type of fructification, the question of specific difference does not affect the significance of Grand'Eury's discovery. A statement was made in vol. II.³, quoted from Grand'Eury, that the fronds of *P. Sterzeli* were borne on a *Psaronius* stem, but Prof. Zeiller told me that in his opinion the fronds and stem are merely in association and not in organic contact. It is probable that the *Psaronius* stem bore fronds of some species of *Pecopteris* with sori of the *Asterotheca* or *Scoleopteris* type and not seeds. *Pecopteris Pluckenetii* and *P. Sterzeli* are no doubt the fronds of a Pteridosperm⁴, but apart from the seed-impressions there is no evidence as to the nature of the reproductive organs or stem. The form of the seeds with a fairly thick sarcotesta, which gives them a winged appearance, suggests a member of the Medulloseae rather than a plant with seeds like those of *Lyginopteris* and *Heterangium*.

⁴ Zeiller (06) B. p. 63.

Eremopteris artemisaefolia Sternberg with *Samaropsis acuta* Lindley and Hutton.

The generic name *Eremopteris* was instituted by Schimper for a type of frond from the Coal Measures of Newcastle described by Sternberg as *Sphenopteris artemisaefolia*. He included also a second species, *E. Neesii*, from the Permian of Bohemia: this was removed by Zeiller to *Callipteris*. The type-species of *Eremopteris* is included in this chapter on the ground that the almost constant association with the fronds of seeds comparable with those described by White as *Aneimites (Wardia) fertilis* affords a strong argument in favour of assigning *Eremopteris artemisaefolia* to the Pteridosperms.

1826. *Sphenopteris artemisaefolia* Sternberg, Flor. Vorwelt, Fasc. iv. p. 15, Pl. LVI. fig. 1.
 1833. *Sphenopteris crithmifolia* Lindley and Hutton, Foss. Flor. Vol. I. Pl. XLVI.
 1833. *Cardiocarpon acutum*, *Ibid.* Pl. LXXVI.
 1869. *Eremopteris artemisaefolia* Schimper, Trait. Pal. Vég. Vol. I. p. 416.
 1914. *Samaropsis acuta* Kidston, Trans. R. Soc. Edinb. Vol. L. Pt. I. p. 156.

The large compound fronds of this species¹ are characterised by the regular dichotomy of the main branches, a feature frequently met with in Palaeozoic fern-like leaves: the cuneate or oval-cuneiform pinnules (fig. 443, A, C) vary considerably in breadth from the typical cuneate type of segment as figured by Brongniart² to narrow, almost linear, leaflets like those of *Sphenopteris crithmifolia*. Several spreading veins traverse the lamina. Lindley and Hutton, while admitting a very close resemblance between their species and *S. artemisaefolia*, adopted a distinctive name. The only evidence so far obtained as to the stem of the plant is furnished by some specimens in the Hutton collection (Newcastle-upon-Tyne) one of which shows a piece of rhizome bearing several petioles (fig. 443, B): there are no pinnules attached to the rachises but some occur in close association. Brongniart noticed the frequent association of *Eremopteris* fronds with small seeds, but he regarded it as accidental. Dr Kidston³ has recently

drawn attention to a note by Prof. Duns published in 1872 on the juxtaposition of seeds and fronds, and Mr Howse¹ in his Catalogue of the Hutton plants considers that the seeds were borne on the *Eremopteris* leaves; in his synonymy of *E. artemisiaefolia* he includes *Cardiocarpon acutum* Lind. and Hutt. as the 'spore-cases or sporangia.' The *Eremopteris* seeds are of the platyspermic (*Samaropsis*) type, broadly oval and about 7 mm.

FIG. 443. *Eremopteris artemisiaefolia*. A, part of a frond with associated seeds of *Samaropsis acuta*; B, rhizome with fragments of fronds; C, pinnule. (Drawn by Mr L. D. Sayers from specimens in the Hutton Collection, Newcastle. A, B, $\frac{2}{3}$ nat. size.)

long with an obtuse base and two slightly divergent acute processes at the apex (fig. 444). Some specimens in Dr Kidston's collection from the Lower Coal Measures of Midlothian, which were associated with *Eremopteris* fronds, are preserved as mummified cuticular membranes and on microscopical examination they show clearly the presence of a pollen-chamber. The seeds are of the *Samaropsis* type. The drawings reproduced in fig. 444 were made for me by Dr Kidston from two specimens, in his collection,

¹ Howse (88) p. 45.

of exceptionally well-preserved seeds from Midlothian: the seeds of this species vary considerably in size and form; some are almost orbicular and show no distinction between nucule and border (fig. 444, A) while in others (B) the impression of the flattened and longitudinally striated sarcotesta is clearly distinguished. Kidston is of opinion that in younger seeds there is a single apical point replaced in a later stage of development by two cusps, as seen in figs. A and B, formed by the opening of the micropylar tube. A ridge in the middle of the flattened surface indicates the position of the vascular bundles in the principal plane as in *Cardiocarpus*. The fully developed seeds are 8—9 mm. long. The correlation of the seeds represented in figs. 443 and 444 with *Eremopteris* fronds furnishes an additional illustration

FIG. 444. *Samaropsis acuta*. (From drawings by Dr Kidston of specimens in his collection, 3475 (A), 3316 (B); $\times 2$.)

of the impossibility of trusting to external form as a criterion of affinity, for it is known that seeds of the *Samaropsis* type were produced by Pteridosperms with foliage represented by *Eremopteris artemisaefolia* and *Pecopteris Pluckenetii*, also by some members of the Cordaitales (e.g. fig. 480). Dr Arber¹ has recently proposed a new generic name *Cornucarpus* for *Cardiocarpon acutum*, but the drawings that he gives of seeds from the Kent coal-field referred to this species suggest a type distinct from that of Lindley and Hutton. In the absence of specimens showing actual attachment it is impossible to say how the seeds were borne, but the analogy of *Wardia fertilis* and *Pecopteris Pluckenetii* lends support to the view that the seeds were attached to pinnules with a reduced lamina. *Eremopteris artemisaefolia* occurs in the Lower and Middle Coal Measures of England: a species recorded by

¹ Arber, E. A. N. (14) p. 97; (09) p. 29, Pl. I. fig. 5.

Kidston from the Calciferous sandstone of Scotland as *E. Macconochii*¹ is now believed by that author to be generically distinct². With the exception of the unsatisfactory specimen reproduced in fig. 443, B, we have no information with regard to the habit of the stem to which the *Eremopteris* leaves were attached.

WARDIA. White.

Wardia fertilis (White). Another example of a fern-like frond bearing seeds is afforded by specimens from the Lower

FIG. 445. *Wardia fertilis* (White). A, sterile portion of frond; B, D, enlarged pinnules; C, seed. (After White. A, ca, nat. size; B—D, $\times 2$.)

Pottsville series of Virginia (correlated with the Millstone grit of British geologists) described by Mr David White³ as *Aneimites* (*Wardia*) *fertilis*. The compound fronds usually referred to the

¹ Kidston (83) B. p. 540, Pl. XXXII. fig. 3.

² White refers some fronds from the Missouri Coal Measures to *Eremopteris*, but their generic identity with the type-species is open to doubt. White (99) B. p. 16.

³ White (04) B.

genus *Adiantides* or *Adiantites*¹ are characterised by cuneate pinnules with a thin lamina and forked, slightly divergent veins (fig. 445, A, D). White discards the name *Adiantides* in favour of Dawson's genus *Aneimites* on the ground that Goeppert², who instituted the former term, applied it in the first instance to leaves of *Ginkgo* which he identified as simple Fern fronds. In spite of this misapplication of the name it has been constantly used and is well established. The discovery of seeds is, however, a reason for the adoption of a new generic name, and as White proposed *Wardia* for the seeds it may appropriately be extended to the fronds in place of the provisional term *Aneimites*. The seeds which occur at the apices of slender pedicels on pinnae bearing relatively small pinnules with a reduced lamina (fig. 445, B, C) are rhomboidal in shape, 4.5 mm. long and 2.5 mm. broad. The bilaterally symmetrical seeds were probably enclosed, as White suggests, in a fleshy integument which on pressure became laterally extended as a wing-like border. In some of the seeds there is an indication of a 'slight collapse within the apex of the nutlet,' which may mean the presence of a pollen-chamber; but while the preservation is too imperfect to afford any decisive evidence as to anatomical features, there is no reason to doubt the conclusion as to the seed-nature of the organs described by White. Nothing is known of the stem, though the opinion may be hazarded that *Wardia* is a member of the Medulloseae.

Adiantites bellidulus Heer and *Lagenospermum Arberi* Nathorst.

Reference is made to the genus *Lagenospermum* in the account of *Lagenostoma*³. The species *Lagenospermum Arberi* has recently been founded by Dr Nathorst⁴ on some seeds obtained from Lower Carboniferous rocks in Spitzbergen: a brief description is intercalated here because it is probable that they were borne on fronds of the *Adiantites* type similar to those on which White found the seeds described by him as *Wardia*. The seeds of *L. Arberi*, 14—18 × 5 mm., are spindle-shaped with an obtuse apex and longitudinally ribbed with a stalk at least 7 mm. long. Nathorst considers that a cupule was probably present: the

¹ Vol. II. p. 376.

² Goeppert (36²) A. p. 216.

³ See page 64.

⁴ Nathorst (14) p. 30, Pl. xv. figs. 18, 60—68.

specimens do not convey the impression of naked seeds and in some examples there are indications of an investing envelope, though this may be the result of tearing of the testa. Nathorst regards the Spitzbergen seeds as probably specifically identical with a specimen described by Schmalhausen¹ from Carboniferous rocks in the Urals as *Rhabdocarpus orientalis* Eich., a species which agrees closely with *Lagenospermum nitidulum* as described by Heer² (under the name *Carpolithes nitidulus*) and Nathorst³ from Spitzbergen. It is also possible that Kidston's *Rhabdocarpus elongatus*⁴, from the Lanarkshire coal-field and elsewhere, recently transferred by Arber⁵ to *Platyspermum*, is an example of the same species. The chief interest of *Lagenospermum* lies in the fact, assuming Nathorst's correlation of the seeds with *Adiantites bellidulus* Heer to be correct, that it is a typical radiospermic seed, while *Wardia*, borne on foliage of the same general type, is an equally typical platyspermic seed.

CHAPTER XXXII.

CYCADOFILICES.

IN this chapter are included several types represented by stems, but which in the absence of definite information with regard to the reproductive organs cannot be assigned to the Pteridosperms.

MEGALOXYLEAE.

Megaloxylon. Seward.

This genus is represented by a single species founded on a piece of stem from the Lower Coal Measures of Lancashire discovered in the Binney Collection in the Sedgwick Museum, Cambridge¹. Nothing is known as to the leaves, reproductive organs, or roots. The type-specimen consists exclusively of primary and secondary xylem.

Megaloxylon Scotti Seward.

The type-specimen, reproduced natural size in fig. 446, A, B, consists of a fragment of stem which at first sight bears a close resemblance to *Cordaites*, but the apparent pith, 1.9 cm. in diameter, is the primary xylem of the stele and is enclosed by an incomplete cylinder of secondary xylem 2 cm. broad. The distinction between the lighter primary xylem and the darker secondary cylinder is especially well marked in the longitudinal section (fig. 446, B). The central region, shown on a larger scale in fig. 447, is occupied by groups of tracheids varying in size and shape associated with thin-walled parenchyma: the latter is represented by lighter patches in the section. The majority of the tracheids are characterised by their great breadth—in some

¹ Seward (99) B.

cases .4 mm.—and their iso-diametric or even horizontally elongated and flattened form. Some of these large metaxylem elements are seen in longitudinal section at *m* in fig. 448 where the shrinkage and partial decay of the parenchymatous tissue have resulted in the separation of transverse bands of xylem

FIG. 446. *Megaloxylon Scotti*. A, B. Transverse and longitudinal sections. x^1 , x^2 , primary and secondary xylem; *lt*, leaf-traces. Nat. size. C. Secondary xylem.

simulating the discoid pith of a *Cordaites*. The walls of these tracheal cells are covered with multiseriate pits. With the short and sometimes flattened xylem elements occur others of greater length, but these are chiefly met with in the more peripheral part of the central region where some of the tracheids are

FIG. 447. *Megaloxylon Scotti*. Transverse section of the primary portion of the stele with leaf-traces, *lt*, and the inner edge of the secondary xylem.

much narrower and have the form of ordinary water-conducting elements. On one side of the primary xylem in fig. 447 an oval and more compact group of narrow and longer tracheids is seen at *lt*; this is a leaf-trace about to enter the secondary-xylem

FIG. 448. *Megaloxylon Scotti*. A, transverse section at the junction of the primary and secondary tissues; B, longitudinal section showing the inner edge of the secondary xylem, x^2 , a leaf-trace, *lt*, and the metaxylem, *m*.

cylinder on its outward course. The same leaf-trace is shown at *lt* in fig. 446, B; as it descends the trace becomes less distinct and its elongated elements gradually merge into the general mass of metaxylem. A portion of this leaf-trace is seen in fig.

448, B, lt , close to the inner edge of the secondary xylem, x^2 , and abutting internally on the contracted tissue, m , which consists mainly of large and short tracheae with remains of associated parenchyma. The trace includes some conjunctive parenchyma interspersed with the tracheids: on its outer surface, that is on the abaxial edge of the ovate xylem strand as shown at lt^1 in fig. 447, there are six external protoxylem strands. In the peripheral region of the primary xylem of the section reproduced in fig. 447 there are several more or less well-defined leaf-traces, e.g. lt^2 , lt^3 ; these differ from that seen at lt^1 in their greater tangential breadth and in the less compact arrangement of the tracheids. As each trace is followed downwards in the primary region of the stele it tends to become broader, especially in a tangential direction; the spiral protoxylem strands are more widely separated (fig. 448, A, px) and the elongated and comparatively narrow tracheids as they spread out fan-wise are reduced in length, finally passing over into the broad and short reticulately pitted cells. Each leaf-trace can be followed through approximately four internodes before its individuality is lost in the general mass of metaxylem. The disposition of the peripheral traces is such as to justify the conclusion that the phyllotaxis of the stem is $\frac{2}{5}$.¹

The secondary xylem (fig. 446, C) resembles that of *Lyginopteris* and *Heterangium* though it is less parenchymatous. The medullary rays are numerous and vary in breadth from 1 to 5 cells, while the tracheids, with multiseriate bordered pits on their radial walls, form bands 1 to 8 elements in breadth. There are no regular rings of growth but occasional arcs of narrow tracheids interfere slightly with the otherwise uniform structure of the wood. A leaf-trace in its oblique outward course through the wood becomes completely enclosed by a cylinder of secondary xylem and thus appears to be concentric. Owing to the absence of any tissue external to the secondary xylem of the stem, statements as to the subsequent behaviour of the leaf-traces on emerging from the stele are purely hypothetical. It is, however, not improbable that each concentric trace lost its secondary tissue

¹ For additional figures, see Seward (99) B.

and broke up into several collateral strands, a suggestion based on the behaviour of the leaf-traces in *Medullosa anglica*.

The most striking characteristics of *Megaloxylon* are: (i) the structure of the primary xylem, particularly the unusual form of the majority of the metaxylem tracheids, a form obviously correlated with storage rather than with conduction of water; (ii) the gradual spreading of the leaf-traces and their absorption as they descend into the main mass of the xylem; (iii) the exarch structure of the primary xylem. Confining our attention to the primary region of the stele; a comparison is at once suggested with *Heterangium*. In *Megaloxylon* the peculiarities are the substitution of the large storage-tracheids for the normal xylem-elements; the greater irregularity in the groups of metaxylem; and an exarch instead of a mesarch structure. In these last features the primary xylem agrees with that of recent species of the Schizaeaceous Fern *Lygodium* and the external protoxylem is a character shared with *Rhetinangium*. The occurrence of short tracheids similar to those of *Megaloxylon* in the inner portion of the stele of the Osmundaceous Fern *Zaleskya gracilis* (Eich.)¹ may be quoted as an example of parallel modification but, as Scott² points out, the resemblance has no phylogenetic significance. The secondary xylem though less parenchymatous than in recent Cycads agrees more closely with the manoxylic than with the pycnoxylic type.

Megaloxylon affords an interesting example of a combination of primary stelar anatomical features, comparable in the exarch position of the protoxylem with the stele of *Lygodium*, and secondary wood similar to that of *Lyginopteris* and *Heterangium*. The large metaxylem tracheids may be regarded as derivatives of elements which in some ancestral type were structurally fitted for the rôle of water-transport and made up the xylem of a *Lygodium*-like stele with little or no secondary xylem. As the cambial activity increased and centrifugal xylem became a prominent feature, usurping the function of the centripetal xylem, the latter became modified and fitted for a new service.

¹ Vol. II. p. 326.

² Scott (09) B. p. 476.

RHETINANGIEAE.**Rhetinangium.** Gordon.*Rhetinangium Arberi* Gordon.

The stem on which this genus is founded was discovered by Dr Gordon¹ in the Calciferous Sandstone series of Pettycur: a specimen collected by Dr Kidston in Berwickshire may be specifically identical with the Pettycur plant. We know nothing of the leaves or reproductive organs of *Rhetinangium*. The stem, approximately 2 cm. in diameter, was probably cylindrical; it possesses a single stele consisting mainly of a central primary region occupied by anastomosing groups of tracheids, 130—150 μ in diameter, embedded in parenchyma containing numerous secretory sacs and ducts. In the peripheral region of the stele the groups of tracheids consist of narrower elements characterised by exarch protoxylem. Each peripheral group forms the base of a wedge of secondary xylem (fig. 450, x^2), the primary medullary rays being in direct connexion with some of the parenchyma of the primary xylem. The secondary tracheids, 45—85 μ in diameter, have multiseriate bordered pits on their radial walls and the rays are broad and deep as in *Heterangium* and *Lyginopteris*. With the exception of the external position of the protoxylem, the stele of *Rhetinangium* is practically identical with that of *Heterangium*, though in *Rhetinangium* the primary tracheids form larger and fewer groups. The inner cortex is composed of thin-walled cells with many secretory sacs: there are no stereome elements. In the outer cortex (fig. 449, *cr*) radially disposed bands of stereome form a reticulum with narrow and very long meshes like that of Medullosean petioles.

The recently recorded occurrence of polydesmic petioles² in *Heterangium* is of special interest from the point of view of the comparison of that genus with *Rhetinangium* and the Medulloseae.

The very broad decurrent petiole-bases are a striking feature, the major diameter of the pulvinus-like base of the leaf-stalk exceeding that of the stem (fig. 449, *p*). Several xylem-strands

¹ Gordon (12). The rich development of secretory tissue suggested the name *Rhetinangium* ($\rho\eta\tau\iota\nu\eta$, resinous gum): the same prefix had previously been adopted by Renault in his genus *Retinodendron* [Renault (96) A. p. 365].

² Scott (15).

from the peripheral region of the primary xylem go to form a single leaf-trace: these U-shaped strands of xylem destined for a leaf are connected laterally by parenchyma and form an irregularly corrugated band. Fig. 450 shows a petiole-trace still enclosed on each side by the secondary xylem cylinder x^2 .

FIG. 449. *Rhetinangium Arberi* Gord. Transverse section of stem with large leaf-base; *cr*, outer cortex of stem; *p*, petiole. (After Gordon; $\times 1\frac{3}{4}$.)

There are several protoxylem groups in a leaf-trace, one on the outer face of each xylem-strand. In the petiole the xylem groups are more intimately connected and the trace has the form of a flat band with abaxial protoxylem. There is no indication that a leaf-trace undergoes division into separate strands. The roots are described as tetrarch with well-developed secondary xylem.

FIG. 450. Transverse section of leaf-trace of *Rhetinangium Arberi* showing the exarch structure; x^2 , secondary xylem. (After Gordon.)

The primary xylem of *Rhetinangium* agrees in its exarch structure with the Palaeozoic genera *Sutcliffia*, *Megaloxylon* and *Stenomyelon*, also with *Lygodium* and some other recent Ferns: the secondary wood is of the manoxylic type like that of *Lyginopteris*, *Heterangium* and other genera. In the general structure of the stele *Rhetinangium* agrees with *Sutcliffia* and, except in the exarch structure of the primary xylem, with the steles of *Heterangium* and *Medullosa anglica*¹; but the structure and origin of the leaf-traces are characters which mark it off

¹ Page 90.

from *Sutcliffia*. The sclerenchymatous bands in the inner cortex of *Heterangium* are unrepresented in *Rhetinangium*, and in the latter genus the abundance of secretory sacs and ducts is a characteristic feature, moreover in *Rhetinangium*, the leaf-trace consists of several groups of primary xylem-elements. Dr Gordon regards *Megaloxylon* as the type which comes nearest to *Rhetinangium*; but the differences in the structure of the secondary wood and the marked contrast between the leaf-traces are too pronounced to justify a preference for *Megaloxylon* over *Heterangium* in the order of affinity. Gordon considers that the undivided leaf-trace of *Rhetinangium* may represent a form transitional between the simple leaf-trace of *Lyginopteris* and the much divided type in *Medullosa*. The external position of the protoxylem is a character to which too much weight may easily be attached: the difference in position between the protoxylem of *Rhetinangium* and *Heterangium* is in some examples of the latter genus hardly perceptible. Kubart¹ speaks of the stele of his species *Heterangium Sturi* as being almost exarch. The inconstancy in the position of the protoxylem in the xylem of Osmundaceous stems and in the primary bundles of *Eristophyton* and other Palaeozoic genera is worthy of consideration in this connexion.

STENOMYELEAE.

Stenomyelon. Kidston.

Stenomyelon tuedianum Kidston. The specimens on which this monotypic genus is founded² were obtained from the Lower

FIG. 451. *Stenomyelon tuedianum* Kidst. Transverse section of stem. The black patches represent leaf-traces. (After Kidston; $\times 1\frac{1}{2}$.)

Carboniferous rocks (Calcareous Sandstone series) at Norham Bridge, Berwickshire, Scotland. They consist of petrified pieces of a flattened stem, a fragment of a rachis and portions of laminae:

¹ Kubart (14).

² Kidston and Gwynne-Vaughan (12).

there is no evidence as to the nature of the reproductive organs. The original form of the stem is obscured by the destruction of a considerable part of the cortex and the consequent flattening of the whole with the production of wing-like extensions of the imperfectly preserved tissues enclosing the almost cylindrical stele (figs. 451, 452).

The stele consists of a bluntly triangular core of primary xylem, 3—4 mm. in diameter, composed almost entirely of reticulately pitted tracheids reaching a diameter of 160μ : a few parenchymatous cells occur in the peripheral region and a band of parenchyma extends from the middle of each of the three sides of the xylem to the centre of the stele, thus dividing the primary conducting tissue into three groups which are the expression of a phyllotaxis of $\frac{1}{3}$. The tracheids near the outer face of each xylem-group are narrower than the others and have scalariform pitting. The secondary xylem first appears along the slightly concave sides of the primary stele, eventually enclosing the whole: it consists of tracheids with multiseriate pits on the radial walls and numerous deep medullary rays 1—6 cells broad. No phloem is preserved though it is probable that a narrow band was originally present. A characteristic feature is afforded by a zone of thick-walled cells, regarded as periderm, encircling the stele and formed by a deep-seated phellogen. On the outer face of this band there are projecting bosses, and similar sclerous nests are scattered in the cortex. The outer cortex has a *Sparganium*¹ type of hypoderm, that is long vertical strands of fibres alternating with parenchyma. The leaf-traces are formed from the blunt angles of the primary xylem; an angle becomes nipped off as a more or less cylindrical strand enclosed by a zone of secondary tracheids which is very narrow on the adaxial side (fig. 452). Protoxylem was recognised only in the leaf-traces and not in the rest of the stele. A pair of protoxylem strands occurs on the outer edge of a prominent angle of xylem before it becomes detached from the stele, and these form a single strand at a lower level. As a leaf-trace passes outwards, the exarch xylem strand becomes mesarch and there is a single protoxylem group except at a point near the bifurcation

¹ Similar to the *Dictyoxylon* type except in the independent and not anastomosing course of the stereome strands.

of a trace. In its passage through the cortex a leaf-trace divides repeatedly, the secondary xylem on the outer face of each strand being retained for a considerable time.

Our meagre knowledge of the nature of the leaves is based on incomplete fragments found in association with the stem. The leaf is believed to have been simple and characterised by a thick lamina with a hypodermal zone of sclerous strands and several vascular bundles.

FIG. 452. *Stenomyelon tuedianum*. Transverse section of stele.
(After Kidston; $\times 7$.)

As Kidston and Gwynne-Vaughan¹ remark, *Stenomyelon* is a very distinct type; while resembling *Sutcliffia* in some respects it differs from that genus not only in the structure of the primary stele but in the absence of the system of meristeles which form so characteristic a feature of the latter genus.

CYCADOXYLEAE.

Cycadoxylon. Renault.

This generic term² is applied to a few types of Permian and Upper Carboniferous stems possessing a vascular cylinder, which

¹ Kidston and Gwynne-Vaughan (12) p. 269.

² Renault (96) A. p. 307.

may reach a considerable breadth, of secondary centrifugally developed xylem and phloem enclosing a large pith containing either a narrow, peripherally placed, and more or less continuous cylinder of inversely orientated conducting tissue or scattered bands of centripetal xylem and phloem. The secondary xylem is manoxylic, while the internal vascular tissue recalls that of *Ptychoxylon* and to a less extent the inverted arcs that are rarely met with in *Lyginopteris* stems. A brief diagnosis of two species may serve to illustrate the genus: a third species is included in *Cycadoxylon*, but it is founded on material too incomplete to admit of satisfactory diagnosis.

Cycadoxylon Fremyi Renault.

This Permian species¹ is represented by a piece of stem 2—2.5 cm. in diameter (fig. 453, B) characterised by (i) a fairly broad parenchymatous cortex with secretory canals and several hypodermal nests of sclerous tissue, (ii) a cylinder of secondary xylem and phloem nearly the whole of which is centrifugal, (iii) a large pith containing several scattered narrower bands or arcs of centripetally developed xylem and phloem. The tracheids, with 4—6 series of hexagonal pits, form radially disposed rows, 1—4 elements broad, separated by broad and deep medullary rays. Renault does not mention the occurrence of any primary xylem as distinct from the secondary centrifugal xylem, but in a section which I examined some years ago in his laboratory there appeared to be a group of primary tracheids. There are no anastomoses between the main cylinder and the internal bands of inversely orientated tissue.

Cycadoxylon robustum (Seward).

This species² is based on a piece of stem from the Lower Coal Measures of Lancashire first described by Williamson and identified as an unusually large example of *Lyginopteris*. Williamson and Scott, while recognising certain features in addition to the large size of the stem, which must have reached 14 cm. in diameter, expressed the view that 'there is a presumption that it really belonged to a *Lyginodendron*, or to some plant of the same type of structure.' The examination of additional material led me to

¹ Renault (96) A. p. 308, figs. 55, 56.

² Seward (97²).

adopt the name *Lyginodendron robustum*, though I suggested that possibly *Cycadoxylon* might be the more appropriate genus. Subsequently Scott¹ proposed the substitution of *Cycadoxylon* for *Lyginodendron*.

The type-specimen consists of secondary xylem agreeing closely in structure with *Lyginopteris* and recent Cycads: the pith, 2.9 cm. in breadth, is incompletely preserved; there is a narrow band of centripetal xylem² at the periphery of the perimedullary region and close to the inner face of the main mass of wood (fig. 453, C; the black line marks the position of the centripetal xylem). Nests of sclerous tissue and secretory canals are scattered in the medullary parenchyma and deeper in this region are arcs of secondary parenchyma, possibly periderm. In places the centripetal and centrifugal xylem are in contact and occasionally the tapered ends of the rows of centrifugal tracheids merge into groups of primary xylem elements. The preservation in the central region is far from complete, and although the occurrence of primary xylem groups is probable it cannot be said to be positively established. At the inner edge of the centrifugal xylem and in tangential longitudinal sections a few leaf-traces are seen, but nothing is known as to the nature of the leaf-traces in their course beyond the stele nor have we any data with regard to the leaves or reproductive organs.

This older species differs from *Cycadoxylon Fremyi* in the limitation of the centripetal xylem to the outer portion of the pith and in the presence of sclerous nests in the medullary region, though the latter character is probably of no great taxonomic value. *Cycadoxylon robustum* approaches more closely to *Lyginopteris*, and although the differences are sufficient to justify a distinctive generic name, there can be little doubt as to a fairly intimate relationship between this type of *Cycadoxylon* and *Lyginopteris*.

Ptychoxylon. Renault.

*Ptychoxylon*³ *Levyi* Renault. Like many Palaeozoic genera founded on anatomical features, *Ptychoxylon*⁴ is represented only

¹ Scott (00) B. p. 364.

² A second band is sometimes present. Scott (00) B. p. 484.

³ πτύξ, a fold.

⁴ Renault (89); (96) A; (93) A. Pl. LXIX.

by stems, our knowledge of the leaves being confined to the leaf-traces in the stem which appears to have a phyllotaxis of $\frac{2}{3}$. The stem of this Permian species has a diameter of 5—6 cm.: the comparatively broad cortex contains numerous secretory canals, but in place of hypodermal strands of stereome there is a superficial periderm. The vascular tissue, consisting of secondary

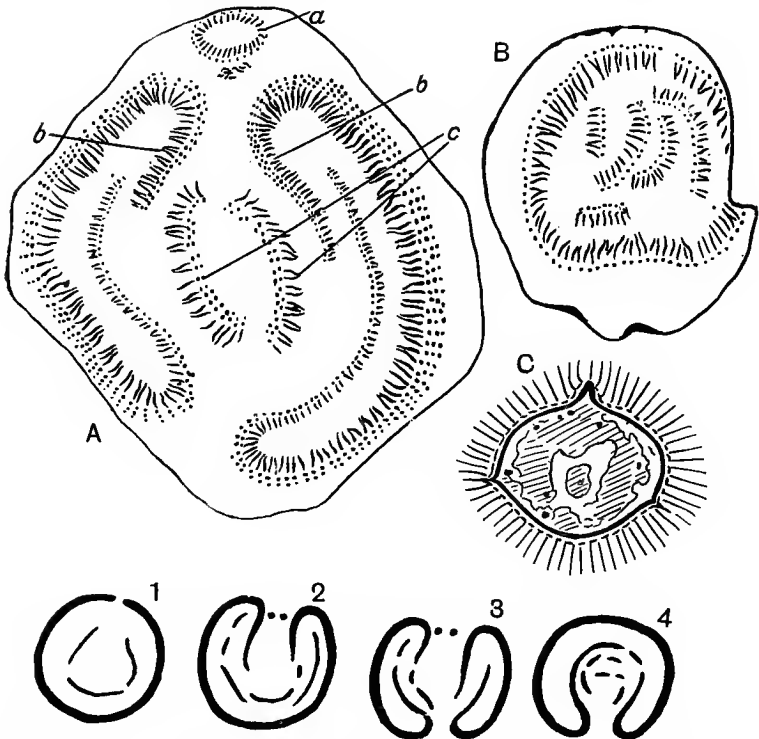

FIG. 453. A. *Ptychoxylon Levyi*; transverse section of stem; a, stele of branch. (After Renault.)
 B. *Cycadoxylon Fremyi*; transverse section of stem. (After Renault.)
 C. *Cycadoxylon robustum*; centre of stem.
 1—4, diagrams of sections of the stem of *Ptychoxylon* at different levels. (Simplified from Renault)

xylem and phloem, assumes different patterns at different levels. There is an outer vascular cylinder of centrifugally developed xylem and phloem; the xylem is manoxylic and the tracheids

have 3—5 rows of bordered pits on the radial walls. At intervals the continuity of the main stele is broken by the formation of leaf-gaps and before one gap is repaired a second may be produced, thus converting the cylinder into two crescentic and infolded bands (fig. 453, A). A striking character is the occurrence in the large parenchymatous central region of internal vascular bands or arcs varying in size and number at different levels and composed of centripetally developed secondary xylem and phloem. These internal bands differ from the outer and broader cylinder both in their inverse orientation and their limited vertical range. The connexion between the inner and outer vascular tissue and the alteration in plan of the conducting tissue at different levels are illustrated by fig. 453, 1—4, simplified from some of Renault's figures of successive sections through a vertical distance of 4—5 cm. In section 1 the main cylinder is continuous except for a small gap where a leaf-trace is about to be given off: there are three internal vascular bands similar in structure to the outer stele but inversely orientated. At a higher level (section 2) the leaf-gap is larger and in it is a double leaf-trace of two collateral strands consisting of primary centripetal xylem and a fan-like group of secondary xylem and phloem. The free edges of the outer stele of section 1 have curved inwards and united with the two lateral medullary bands, while the lower internal band of section 1 has increased in extent and forms a discontinuous arc with the upper portions enclosed by the loops formed by the infolded ends of the outer vascular tissue. In section 3 a second leaf-gap has been formed in the outer stele and its invaginated ends have fused with the internal bands. In section 4 the first leaf-gap is closed and the invaginated bands of section 3 have broken up into an irregular circle of shorter bands. The section reproduced in fig. 453, A, shows the main cylinder in the form of two curved and flattened loops, each composed partly of the centrifugally developed xylem and phloem of the main stele and in part of the inversely orientated tissue of the inner bands. At a lower level the two bands *b, b*, will become detached as the upper leaf-gap is closed and form part of an inner cylinder like the discontinuous ellipse formed by the two bands *c*. The section of a branch-stele is seen at *a*.

Ptychoxylon differs considerably from *Medullosa*, which Renault included in the *Cycadoxyleae*, in the plan of the vascular system: there is nothing corresponding to the 'partial pith' or primary region which forms the central portion of the plate- and snake-rings in *Medullosa*. The double leaf-trace and the absence of the *Medullosa* type of hypoderm are other distinguishing features. The paired leaf-bundles suggest comparison with *Lyginopteris* among other genera and, as Scott¹ points out, the internal arcs of inversely orientated tissue which sometimes occur in the peripheral region of the pith of *Lyginopteris* (fig. 405, C, c) behave like the internal bands of *Ptychoxylon* in occasionally joining the main cylinder at a leaf-gap; but the differences outweigh the resemblances. As regards the general arrangement of the vascular tissue in two irregular concentric circles and their connexions with one another, but not in the structure of the xylem and phloem, there is a similarity between this genus and such a Fern as *Matonia*. In the varying patterns formed by the vascular system at different levels in the stem *Ptychoxylon* resembles the Ferns *Polypodium quercifolium* and *P. heracleum*².

CALAMOPITYEAE.

Calamopitys. Unger.

In 1856 Unger³ described several fragmentary petrifications from Thuringian strata of Upper Devonian age, the majority of which he referred to the Calamarieae and the Rhachiopterideae. In an earlier publication⁴ he gave a list of species including two families, the Haplocalameae and the Calamoxyleae, assigned by him to the group Calamarieae: in the Haplocalameae he placed the new genera *Kalymma*, *Calamosyrinx*, *Calamopteris*, and *Haplocalamus*. These were subsequently examined by Graf Solms-Laubach and identified as portions of petioles, for the most part belonging to unknown stems. In his second family, the Calamoxyleae, Unger included the single genus *Calamopitys* represented by the type-species *C. Saturni*. The type-specimens have been thoroughly investigated by Solms-Laubach⁵ who instituted the

⁵ Solms-Laubach (96) B.

² Klein (81).

⁴ Unger (54) p. 599.

family-name *Calamopteyae* and recognised a close anatomical affinity between *Calamoptys* and *Lyginopteris*, a conclusion which led to the incorporation of Unger's genus in the Pteridosperms. Further data have been supplied by Zalesky¹ and, more recently, by Scott and Jeffrey² who have recognised *Calamoptys* in Lower Carboniferous beds in Kentucky.

Calamoptys Saturni Unger.

Our knowledge of this and other species is confined to stems and petioles. One of the largest examples of the species is a piece of stem with a diameter of 1.5 cm.: the single stele consists of a parenchymatous pith enclosed by secondary xylem made up of tracheids with 4—8 rows of bordered pits and medullary

FIG. 454. *Calamoptys Saturni*. B, stem with leaf-base; x, primary xylem and pith; black patches represent leaf-traces; C, stem with two leaf-bases; D, section of petiole. (After Solms-Laubach.)

rays more than one cell broad and of considerable depth. Between the inner edge of the wood and the pith are groups of primary xylem (fig. 454, B, x) which, like those in *Lyginopteris*, constitute the leaf-traces: each has a single internal protoxylem strand (fig. 455, B). The comparatively wide cortex consists of parenchyma with a hypoderm of the *Sparganium* type. Each primary xylem-strand passes out as a single leaf-trace through the secondary xylem and on emerging divides into two as in *Lyginopteris*: these branch in the cortex and the two are replaced by six in the leaf-base (fig. 454, B—D). As seen in figs. 454, C, 455, A, the boundary between the stem proper and the decurrent leaf-base is marked by a line of stereome strands. The petioles of *Calamo-*

¹ Zalesky (11).

² Scott and Jeffrey (14).

pitys Saturni agree generally in structure with the imperfect specimens on which Unger founded his genus *Kalymma*¹, so named in reference to the structure of the hypodermal zone. A specimen described by Solms-Laubach as a *Kalymma* petiole occurs in organic connexion with a stem of *Calamopitys* (fig. 454, C: a detached petiole is shown in fig. 454, D). The identification by White² of this attached petiole with Unger's *K. grandis* has been confirmed by Scott and Jeffrey. A fuller account of *Kalymma* (fig. 456) is given on a later page, as the petioles so named belong to more than one species of stem.

FIG. 455. *Calamopitys Saturni*. A, stem with leaf-bases; $\times 5$. B, stela showing leaf-trace after emerging from the secondary xylem; $\times 16$. (After Zalessky.)

In *Calamopitys Saturni* we have a plant agreeing with *Lyginopteris* in the possession of secondary xylem of the manoxylic type and in the structure of the common primary bundles, while it is distinguished from *Lyginopteris* by the greater number and by the structure of the bundles in the axis of the leaf.

¹ κάλυμμα, a veil or covering.

² White (05²) B. p 384.

Calamopitys annularis (Unger)¹.

This species, originally assigned to the genus *Stigmaria*, has a more strongly developed primary vascular system and there is a more decided tendency towards the formation of a continuous zone of primary xylem on the inner edge of the secondary wood; but where the protoxylem tracheids occur the metaxylem elements form definite strands, like those of *C. Saturni*. It has been pointed out by Scott and Jeffrey that there is some evidence of the occurrence of tracheids in the parenchymatous pith of this species, an important feature distinguishing it from *C. Saturni* and connecting it with *C. americana*. Information with regard to the behaviour of the leaf-traces is far from complete, but there are indications that each trace divides into two before emerging from the secondary xylem². The leaf-traces in the cortex are concentric as in *C. Saturni*.

Calamopitys americana Scott and Jeffrey.

This Lower Carboniferous species³ from the Waverley shales of Kentucky is represented by portions of stems and leaf-bases and detached petioles. The secondary wood consists of tracheids, 30—60 μ in diameter, with deep and broad rays; the small pits on the tracheids form 5—6 alternating series. Phloem and cambium are very imperfectly preserved. The outer cortex is of the same type as in other species. At the inner edge of the secondary xylem there is a ring of primary xylem strands of mesarch structure composed of rather larger tracheids, 80—120 μ in diameter, separated from one another by narrow strips of parenchyma. So far the vascular tissue agrees with that of *C. annularis*. In the American species the axial region is not a parenchymatous pith but a protostele, consisting of parenchyma and a larger or smaller number of tracheal groups, the number being less in stems with a larger central region. The peripheral strands alone are concerned with the emission of leaf-traces, as in *Heterangium*. Each primary xylem strand divides into two as it leaves the perimedullary zone and passes through the secondary xylem as two

¹ Richter and Unger (56) B. p. 174, Pl. x. figs. 1—3; Solms-Laubach (96) B. p. 73; Scott (12) p. 1027.

² Scott and Jeffrey (14) p. 326.

³ *Ibid.* p. 317, Pls. 27, 28, 30, 31.

bundles, each being accompanied by an arc of secondary tracheids which, in the cortical region, completely surrounds the primary elements. At a later stage the single protoxylem of each trace divides into two and before entering the leaf-base there is a further division. In some specimens leaf-bases of the *Kalymma* type were found attached to the stem. The occurrence of tracheids in the axial region is a distinguishing feature and suggests a comparison with *Heterangium*, while *C. Saturni* agrees more closely with *Lyginopteris*; the species *C. annularis* would appear, from the recent observations of Scott and Jeffrey, to occupy an intermediate position.

Calamopitys, as the generic designation is here employed, is confined to central Germany and Kentucky and occurs in Upper Devonian and Lower Carboniferous strata. There is, however, some doubt as to the exact geological horizon of the rocks in both countries though in neither case is there any question of an horizon higher than Lower Carboniferous. Certain specimens from the Lower Carboniferous of Scotland described by Scott¹ as species of *Calamopitys* have been made by Zalesky the type of a new genus, *Eristophyton*, and are dealt with under that name.

Kalymma. Unger.

Kalymma grandis (petiole of *Calamopitys*). Under the generic name *Kalymma* Unger described specimens from Thuringia of Upper Devonian age which he assigned to two species, *K. grandis* and *K. striatum*. Solms-Laubach has shown that *Kalymma* is not an independent stem as Unger believed but a petiole of *Calamopitys*, and this has been confirmed by Scott and Jeffrey who found a leaf-base with the *Kalymma* type of structure in connexion with a piece of *Calamopitys* stem, probably *C. americana*. An examination of a section (2.3 cm. broad) of Unger's *K. grandis* in the collection of the Geological Survey enables me to confirm the conclusions recently published by Scott and Jeffrey. The best specimens of *Kalymma*, which appear to be identical in essential features with Unger's type-species, are from Kentucky, some from the Genessee shales of Upper Devonian age and others from beds (Waverley shales) believed to be Lower Carboniferous.

¹ Scott (02).

FIG. 456. *Kalymma grandis*. (From a section in the possession of Prof. Power; $\times 4$.)

Through the kindness of Prof. Bower I have had an opportunity of examining sections from the older horizon in his possession. The transverse section reproduced in fig. 456 has a diameter of 3.8×2.2 cm.¹: on one side the radially placed plates of stereome are clearly shown, and in the outer portion of the ground-tissue is a ring of vascular bundles varying in size and shape but with a general tendency to a radially elongated form. The ground-tissue consists of homogeneous parenchyma: in one place I noticed what appeared to be a large secretory canal, but secretory tissue, generally at least, is unrepresented. The xylem is composed of imperfectly preserved elements, which appear to have scalariform pits; spiral protoxylem strands, embedded in the metaxylem as two or four groups, occur near the ends of the long axis of the bundle and in some cases also near the centre. The phloem probably surrounded the xylem, though it is not certain whether the arrangement was collateral or concentric: there are no secondary-xylem tracheids, though in some places I noticed a tendency to a radial disposition of cells at the periphery of the vascular tissue simulating an early stage of secondary growth. Unger's second species *Kalymma striata* is characterised by an arrangement of the bundles similar to that in a petiole described by Scott and Jeffrey as *Calamopteris Hippocrepis* which differs from *Kalymma* in the partial substitution of bands of vascular tissue for separate bundles and to some extent in the disposition of the bundles. The two types of petiole *Kalymma* and *Calamopteris*, as Scott and Jeffrey state, are very closely allied. Dawson and Penhallow² have also described *Kalymma grandis* from Kentucky but they, like Unger, mistook the hypodermal stereome for an outer zone of vascular bundles. The petioles from Germany and North America included under the name *Kalymma grandis*, though too similar to be referred to different species, no doubt represent petioles of stems which are unquestionably distinct types: as in the case of *Myeloxylon* in its relation to the genus *Medullosa*, *Kalymma* stands for several closely allied forms of petioles belonging to several species of *Calamopitys*.

¹ Scott and Jeffrey (14) p. 328, refer to a specimen over 6 cm. in diameter: these authors give several excellent figures of *Kalymma*.

² Dawson and Penhallow (91).

Eristophyton. Zalessky.

Eristophyton fasciculare (Scott). The generic name *Eristophyton*¹ was proposed by Zalessky² for two incomplete stems of Lower Carboniferous age provisionally³ referred by Scott to *Araucarioxylon* and subsequently to *Calamopitys*⁴. The species *E. fasciculare* was founded on material obtained by Dr Kidston from the Lower Carboniferous of Dumbarton, Scotland, and on a specimen in the Williamson collection from Northumberland. There is a small pith of parenchyma, 2—3 mm. in diameter, with eight strands of primary xylem of varying diameter (fig. 457)

FIG. 457. *Eristophyton fasciculare*. Transverse section showing the relation of primary (black) to secondary xylem. (After Scott.)

and in each a single protoxylem-group. The primary xylem elements are considerably larger than the secondary tracheids. These xylem-bundles are leaf-traces and their disposition points to a phyllotaxis of $\frac{2}{5}$. The traces attain their maximum size when about to pass out through the secondary xylem. The tracheids are reticulate and scalariform while some have an intermediate type of pitting. A leaf-trace on reaching the pith gradually moves further from the xylem-cylinder and may be separated from it by 2—6 layers of parenchyma: as it passes down the pith the protoxylem strand assumes an almost endarch position consequent on the reduction of the centripetal xylem. In Scott's words, 'each circummedullary strand branches at regular

¹ ἐρίστος, to be disputed.

³ Scott (99²).

² Zalessky (11).

⁴ Scott (02).

intervals; the one branch, that on the anodic side [turned towards the course of the genetic spiral], becomes the leaf-trace and passes out, while the other continues its course up the stem as a reparatory strand, until the next leaf of the orthostichy has to be supplied¹. The secondary xylem consists almost entirely of tracheids with 3—4 rows of pits on the radial walls and medullary rays usually one cell broad varying in depth from 1 or 2 to 16 or more cells. A characteristic feature of the secondary xylem is the occurrence on its inner face of numerous short and broad tracheae similar to the still larger tracheae in the primary stele of *Megaloxylon*². Nothing is known as to the behaviour of the leaf-trace in the extrastelar region, but the fact that an outgoing trace was found to have two protoxylems points to a subdivision similar to that of the foliar bundles of *Calamopitys Saturni*. A well-marked difference between *Eristophyton fasciculare* and *Calamopitys* and *Lyginopteris* is the more compact structure of the secondary wood; it is pycnoxylic and not manoxylic. Prof. Zalessky in criticising the use of the generic title *Calamopitys* puts forward several arguments in support of his institution of a new designation: (i) the primary xylem strands of *Eristophyton* are not confined to the periphery of the pith as is the case in *Calamopitys Saturni*, though he speaks of one leaf-trace in the latter species separated by several layers of cells from the xylem-cylinder; (ii) some of the pith-cells have thick walls and dark contents in distinction to the homogeneous parenchyma of *Calamopitys*, a feature of little importance; (iii) the difference in the structure of the secondary wood already alluded to, though this loses some of its significance by the occurrence of narrower rays, more like those of *Eristophyton*, in *C. annularis*; (iv) the more elliptical and broader pits in the secondary tracheids in place of the more regular hexagonal form in *Calamopitys*. While admitting a certain degree of relationship between the two types, Zalessky asserts that as yet we have insufficient evidence to justify their generic union. Scott³ maintains that Zalessky does not attach sufficient weight to the form and mesarch structure of the primary xylem bundles as a feature common to both genera.

 1911. *Eristophyton Beinertianum* Zalessky, Com. Geol. St Petersburg. p. 24.

The pith, 13—15 mm. in diameter, is rather larger than in *E. fasciculare* and is characterised by the occurrence of dark sclerotic nests surrounded by radially disposed rows of parenchyma. The primary xylem strands are more numerous and smaller than in *E. fasciculare* and these increase in diameter as they approach the secondary wood. In places the primary xylem elements form a more or less continuous band as in *Calamopitys annularis*.

FIG. 458. *Eristophyton Beinertianum*. A strand of primary xylem, showing the protoxylem, *px*, abutting on the secondary xylem. ($\times 35$. After Zalessky.)

The largest leaf-trace bundles at the periphery of the pith are mesarch (fig. 458), but as each trace passes down the pith the reduction in the centripetal xylem is carried further than in *E. fasciculare* until the xylem-strand becomes endarch in the lower part of its course. The secondary tracheids have usually two contiguous rows of pits and the medullary rays are one cell broad.

There can be no doubt as to the generic identity of the two

¹ Tuzson (09).

species referred to *Eristophyton*, but the question as to the degree of affinity to *Calamopitys* is more difficult to settle. There is force in Zalesky's contention that these two stems should not be retained in *Calamopitys*: the recently described American species, *C. americana* Scott and Jeffrey, gives emphasis to the view that the restriction of *Calamopitys* to the German (and American) types is the safer course. While *Calamopitys* as thus restricted is almost certainly a Pteridosperm, the inclusion of the types referred to *Eristophyton* in the same category rests on a more slender basis.

CLADOXYLEAE.

This order was founded by Unger¹ for some imperfectly preserved stems from Palaeozoic strata in Thuringia and in it he included the two genera *Cladoxylon* and *Schizoxylon*. There is some doubt as to the precise age of the Thuringian beds; they were assigned by Richter to the Devonian system and subsequently placed in the Culm: Solms-Laubach in his later reference to Unger's plants favours a Devonian horizon². Unger included the Cladoxyleae in the Lycopodiales, and though this conclusion is not accepted the position of the order is still uncertain. His genus *Schizoxylon* has no claim to generic separation from *Cladoxylon*. An inspection of the illustrations in the memoir by Richter and Unger reveals a striking resemblance in the main anatomical features between several types assigned to different genera and distributed among the Cladoxyleae and Rhachiopterideae (a term first used by Corda for petrified rachises or petioles of ferns) and other orders. Solms-Laubach³, to whom our more accurate information as to Unger's plants is chiefly due, is inclined to regard the specimens referred by Unger to the genus *Arctopodium* as young stems of *Cladoxylon*, and he draws attention to a close similarity between *Hierogramma*, another of Unger's genera, and *Cladoxylon*. Paul Bertrand⁴ goes further in considering that the following genera represent one generic type, namely *Syncardia* (fig. 459, F), *Hierogramma*, *Arctopodium*, *Cladoxylon*, and *Schizoxylon*. The same author interprets the fossils so named by

¹ Unger and Richter (56) B. p. 178.

² Scott and Jeffrey (14) p. 364.

³ Solms-Laubach (96) B.

⁴ P. Bertrand (08).

Unger as stems and does not agree with the inclusion of any of them in the Rhachiopterideae. Without losing sight of the fact that Bertrand's conclusion is not based on proof but is the expression of a view suggested by a close agreement in general anatomical plan, I venture to adopt the designation *Cladoxylon* in a wide sense primarily on the ground that Bertrand's view is probably correct and in part for the sake of convenience of description. As Unger's species of *Cladoxylon* differ from one another in features which may fairly be regarded as of minor importance, they are included under one specific name.

Cladoxylon. Unger.

Cladoxylon mirabile Unger¹. The following are regarded as specifically identical with or closely allied to *Cladoxylon mirabile*: *C. dubium*, *Schizoxylon taeniatum*, *Hierogramma mysticum*, *Syncardia pusilla*, *Arctopodium insigne* and *A. radiatum*².

i. *Stems.* The stems assigned to *Cladoxylon* are characterised by a complex system of steles, either simple or branched and occasionally anastomosing, presenting in transverse section the form of oval or cylindrical strands or narrow, straight or curved bands arranged on a more or less clearly marked radial plan (fig. 459, A, B, D). In some stems the primary vascular tissue is enclosed by secondary xylem and phloem (fig. 460, B), while in others (Unger's *Arctopodium*, *Hierogramma*³, *Syncardia*) there is no evidence of secondary thickening. The diagrammatic drawing represented in fig. 459, F, shows a section of a small axis, regarded by Unger and Solms as a petiole (3 mm. in diameter), containing four vascular strands composed exclusively of primary xylem, each with one or, in the case of a double strand, two protoxylem groups. This type may be a slender stem or branch or possibly a petiole. The other extreme, as regards complexity of vascular structure, is represented by such stems as those shown in fig. 459, A, B, D. In Unger's *Cladoxylon mirabile* (fig. 459, A; fig. 460, B) the stem reaches a diameter of 3 cm. and consists of several radially disposed plates of vascular tissue with an

¹ Unger and Richter (56) B. p. 179, Pl. XII. figs. 6, 7; Solms-Laubach (96) B. p. 52, Pl. II. figs. 11, 13 (?).

² Unger and Richter, Pl. XII. figs. 3, 4; Solms-Laubach (96) B. Pl. XI. fig. 10.

³ See footnote 3, p. 205.

occasional smaller oval or cylindrical stele embedded in a ground-tissue composed of thick-walled cells. The plates are curved like a U or sinuous and not infrequently anastomosing. In a section of this type figured by Unger the vascular plates appear to form a complex anastomosing system, but Solms¹ states that the drawing exaggerates the amount of fusion between the strands,

FIG. 459. A, *Cladoxylon mirabile*, section of stem; B, *Cladoxylon taeniatum*, section of stem; C, *Cladoxylon dubium*, section of stele; D, *C. dubium*, section of stem; E, *Cladoxylon (?) mirabile*, section of petiole; F, *Syncardia pusilla*; G, development of leaf-trace in *Cladoxylon taeniatum*. (A—E, after Solms-Laubach; F, after Unger; G, after P. Bertrand.)

and an examination of a section in the collection of the English Geological Survey cut from Unger's specimen enables me to confirm this statement. Each vascular plate consists of a narrow median region composed of primary tracheids with a scalariform type of pitting surrounded by secondary tracheids with interspersed medullary rays one cell broad. The thickness of the

¹ Solms (96) B. p. 53.

secondary xylem varies considerably in the same specimen and in places this tissue is hardly represented, a fact of importance in view of the very striking resemblance between *Arctopodium* and *Cladoxylon*, the sections referred by Unger to the former genus having steles without any secondary xylem. The occurrence of one or two elongated spaces (shown in black in fig. 459, A) near the distal end of each plate mark the position of the protoxylem tracheids. Fig. 459, C, represents a stele of a stem referred by Unger and by Solms to *Cladoxylon dubium* which shows the typical *Cladoxylon* structure, namely the central primary xylem with distally placed protoxylem and the enclosing sheath of secondary xylem. In the stem shown in fig. 459, D (*C. dubium*) there are 12 steles, each constructed on the plan already described, differing in their relatively broader and shorter form and in the greater breadth of the secondary xylem from those seen in fig. 459, A (*C. mirabile*). The black areas in fig. 459, A, show the primary xylem, and the protoxylem is seen in fig. 459, C. A stem described by Dawson¹ as *Asteropteris noveboracensis* from Devonian beds is compared by him with Unger's *Cladoxylon mirabile* and regarded as possibly allied to it. The radial plates of xylem in Dawson's plant meet in the centre like those of *Asterochlaena* and the leaf-traces are of the Clepsydropsoid type.

The type of stem for which Unger founded his genus *Schizoxylon* is represented in fig. 459, B; there are five small steles in the centre and external to these eleven radially arranged plates, with oval steles between them, in the peripheral region of the stem. Each stele consists of primary (black in the figure) and secondary xylem and agrees with the steles in the other stems.

From the type of stem illustrated by *Cladoxylon mirabile* to that on which the genera *Arctopodium*² and *Hierogramma*³ were founded is a very small step: the vascular tissue has the same characters both as regards gross and minute anatomy, but there is no evidence of cambial activity in the stems referred to the two latter genera, a difference in itself hardly worthy of generic recognition.

¹ Dawson (81) A. p. 299, Pl. XII. figs. 1—9; Solms-Laubach (91) A. pp. 173, 188

² This type is represented in the Geological Survey Collection (No. 15871).

³ For figures, see Solms-Laubach (96) B. Pl. II.

ii. *Leaves.* Before describing a second type of stem referred to *Cladoxylon* it is important to consider briefly such evidence as we have as to the vascular supply of the leaves. Nothing is known of the reproductive organs and there is no satisfactory information with regard to the form of the fronds. Solms-Laubach has described the only known example of a lateral branch of a *Cladoxylon* stem (fig. 459, E): this has a single concentric vascular strand of plate-like form with two blunt projections and there are four protoxylem-groups, two in the angle of the plate and two at the base of the projections. The structure is essentially fern-like; the xylem is wholly primary. This type of vascular strand agrees fairly closely with that of a petiole described by Unger as *Megalorhachis elliptica*, a section of which is in the Museum of the Geological Survey¹. The petiole is oval in section and laterally winged, and the meristele is tangentially elongated and has two blunt projections almost identical with those in fig. 459, F. There is no evidence as to the nature of the supporting stem, but there can be little doubt as to the close connexion with *Megalorhachis* and the section shown in fig. 459, F. In a note published in 1908 P. Bertrand stated that he had identified several of Unger's genera as stems which bore leaf-traces having the form and structure of *Clepsydropsis*, one of the types referred by Unger to the Rhachiopterideae and described in the second volume of this work² as a Coenopteridean petiole. Bertrand points out that in the oval or plate-like steles of *Cladoxylon*, *Arctopodium*, *Hierogramma*, etc., there is a single protoxylem group near the distal end of the primary xylem, and he adds that the leaf-traces were formed of strands cut off from the distal portions of the vascular plates. Similarly the hour-glass-like leaf-trace in the primary rachis of *Clepsydropsis* gives off from each end a ring of xylem to supply a secondary rachis. These laterally detached annular strands are, he believes, similar to the leaf-trace cut off from the steles in a *Cladoxylon* stem. The conclusion is that *Cladoxylon* is a fern stem and its leaf-trace represents the simplest form of the *Clepsydropsis* type, namely an oval bundle of xylem with a central protoxylem, which is

¹ No. 15870. Unger and Richter (56) B. Pl. VII. figs. 19—21.

² Page 472, fig. 324.

also the form of the trace given off from the stem of *Asterochlaena*. Solms¹, while admitting that Bertrand may be correct in uniting under one genus *Cladoxylon* and such types as *Syncardia*, *Hierogramma*, and *Arctopodium*, disagrees with the view that they are *Clepsydropsis* stems. A *Clepsydropsoid* leaf-trace has never been found in direct association with any of the stems of the *Cladoxylon* type and such evidence as there is indicates a leaf-trace of an entirely different form (fig. 459, E). In his more recent memoir on *Asterochlaena* Bertrand² draws attention to Solms' figures of a stele of *Cladoxylon* (fig. 459, C) in which the distal portion is on the point of being separated as a small annular strand. This, Bertrand considers, would gradually become converted into a *Clepsydropsis* form of stele as it passed to the petiole. Bertrand's drawings made from a section of *Cladoxylon taeniatum* (Ung.) (fig. 459, G) illustrate successive stages in the departure of a leaf-trace from one of the plate-like steles of the stem (fig. 459, B). In fig. 459, G, 1, a piece of the stele is detached and near its extremity is a group of thin-walled cells with protoxylem: a later stage is seen in fig. 2, and in fig. 3 a small ring of xylem is being detached which, Bertrand assumes, would later in its course be converted into the *Clepsydropsoid* strand (fig. 4), which consists of primary tissue. The weak point in Bertrand's contention³ is the absence of any proof of a true *Clepsydropsoid* trace in connexion with a *Cladoxylon* stem, and there is a strong probability that the leaf-trace of *Cladoxylon* has the form shown in fig. 459, E.

Cladoxylon Kidstoni Solms-Laubach⁴.

This species, founded on imperfectly preserved material in Dr Kidston's collection from Lower Carboniferous rocks in Berwickshire, is referred to *Cladoxylon* on evidence that cannot be regarded

¹ Solms-Laubach (10) p. 540.

² Bertrand, P. (11) p. 47.

³ Since this account was printed my attention has been drawn by Dr Scott to a note by Bertrand in which he considerably modifies his views. He finds that *Hierogramma* and *Syncardia* are probably different states of the petiole of *Cladoxylon* and while agreeing with Solms-Laubach's conclusions he has been able to add important new facts. Bertrand has now given up the opinion that *Clepsydropsis* is the petiole of *Cladoxylon*. For further details students should consult the preliminary note which it is hoped will be followed by a fully illustrated memoir [Bertrand, P. (14)].

⁴ Solms-Laubach (10) p. 537, Pl. III. figs. 7, 11, 13.

as convincing. The type-specimen consists of a small piece of stem about 3 cm. in breadth showing three complete oval steles and portions of two others which seem to be in their original position and probably formed part of a series of peripheral steles

FIG. 460. A, C. A single stele and tracheids of *Cladoxylon Kidstoni*. (Kidston Coll. 630 B, 630 C.)

B. *Cladoxylon mirabile*, part of a stele. (Museum of Practical Geology, 15872.)

such as those shown in fig. 459, D. Each stele consists mainly of secondary xylem (fig. 460, A) with some crushed tissue, presumably phloem, on its outer face. The secondary xylem is

narrower on the inner side of each stele where a wedge-shaped piece is partially detached. In the centre there is a narrow area parallel to the long axis of the stele containing crushed tissue which probably consists of parenchyma and primary xylem, but the preservation is very imperfect. The secondary xylem has a fairly compact structure and the rays are narrow, 1—10 cells in depth. The pits of the tracheids are described by Solms as scalariform with occasionally two rows of elliptical pits on the radial walls. A careful examination of the type-specimen leads me to describe the pits as uniseriate and transversely elongated, very like those of *Protopitys*, or biseriate and almost circular like those of Conifers, the pits of the two rows being alternate or sometimes opposite (fig. 460, C): in places three rows of bordered pits are present. There is a certain degree of resemblance between the steles of this species and those of the South African stem *Rhexoxylon*¹, but the data are inadequate for a satisfactory comparison.

There is a close similarity between the vascular systems of *Cladoxylon* and *Medullosa*, but an obvious difference is the substitution of the oval, transversely elongated, pits on the xylem elements for the multiseriate pitting of *Medullosa*. In *Cladoxylon Kidstoni* the pitting shows transitional forms between a narrow scalariform uniseriate type and a biseriate or triseriate arrangement similar to that in the Araucarineae and Cordaitales. In *Cladoxylon*, as limited by Unger, the presence of secondary wood is a generic feature, but by the inclusion of *Arctopodium* and other forms this character no longer holds good. The inclusion of these more fern-like stems without secondary xylem brings *Cladoxylon* (in the wider sense) into closer contact with *Asterochlaena*, a comparison previously suggested by more than one author. In *Medullosa* the development of secondary xylem is on a larger scale than in *Cladoxylon*, and the vascular system of the former genus assumes a more complex form. Moreover the *Myeloxylon* type of petiole, which is a distinctive feature of *Medullosa*, differs widely from any form of leaf-trace associated with *Cladoxylon*.

¹ Bancroft (13).

Völkelia. Solms-Laubach.

Völkelia refracta (Goeppert). The generic name *Völkelia*¹ was proposed by Solms-Laubach² as a substitute for *Sphenopteris*³ in the case of some petrified stems or petioles associated with fragmentary impressions of fronds from Lower Carboniferous rocks in Silesia. Both leaf-impressions and petrifications were included in the genus *Sphenopteris*: Solms, while retaining Goeppert's designation for the leaf fragments, proposed a new generic name for the petrifications on the ground that there is insufficient evidence of their connexion with the leaves. The short account of Goeppert's petrified specimen given by Graf Solms-Laubach in his 'Fossil Botany'⁴ is supplemented by a fuller description in a later paper. The fragments of highly compound fronds are characterised by very small filiform ultimate segments, but the specimens are too imperfect to afford a clear idea of the habit of the leaf. The 'stem' bears a close superficial resemblance to that described by Unger as *Cladoxylon dubium* (fig. 459, C, D) and was regarded by him as an example of that species: it contains several radially placed steles represented by fairly well-preserved xylem, but no phloem has been recognised. The steles vary in size and shape: five reach almost to the centre (fig. 461, A) and smaller xylem groups occupy a peripheral position. Each stele is excentric in structure and consists of (i) an outer zone of secondary tracheids of horse-shoe form in transverse section, but the apparent gap in the secondary xylem on the outer edge of each stele is due to the crushing of the tracheal tissue and to its smaller breadth in the distal part of each group; this is shown in fig. 461, B, where the apparent gap is seen to be occupied by distorted and crushed tracheids, *a*, identical with those which form the rest of the outer zone (fig. 461, B, *b*); (ii) a zone of tracheal tissue continuous with and originally identical in appearance—except that the elements are rather narrower—with the outer secondary xylem; (iii) an excentrically situated island composed of tracheids enclosing a small central area occupied by thin-walled parenchyma. This third region, represented by

¹ After the late Herr Völkel of Neurode.

³ Goeppert (52) Pl. XII.

⁴ Solms-Laubach (91) A. p. 164.

black patches in fig. 461, A, in all probability represents the primary part of each stele to which the rest of the tissue has been added by the cambium. A striking feature of the secondary xylem is the absence of medullary rays: the tracheids resemble those of *Cladoxylon* and *Protopitys* in the transverse elongation of the pits (fig. 461, D) which form either a single row or several irregularly distributed rows. The primary xylem consists in the peripheral region of tracheids with very narrow scalariform pitting which at first sight suggest close spiral bands (fig. 461, C),

FIG. 461. *Völkelia refracta*. A. Transverse section of a specimen in the Breslau Museum. B. Portion of a stele; *a*, the crushed xylem on the outer side; *b*, the inner side. C. Longitudinal section showing the median protoxylem. D. Tracheid from the secondary xylem. (After Solms-Laubach.)

while the inner tracheids are either annular or reticulate and associated with elongated parenchyma. The imperfectly preserved ground-tissue appears to consist of homogeneous parenchyma with radially disposed bands of stereome in the outer cortex.

Our knowledge of *Völkelia*, though far from complete, justifies its generic separation from *Cladoxylon* from which it differs in the lack of medullary rays and in the structure of the primary portion of each stele. In the form and arrangement of the pits in the secondary tracheids *Völkelia* differs from *Medullosa*, and

resembles *Cladoxylon*. The opinion expressed by P. Bertrand¹ that *Völkelia* is probably the stem of one of the *Zygoterideae* is based on the older accounts of the genus and not on the fuller description of 1910.

PROTOPITYEAE.

Protopitys. Goeppert.

The only species so far described is that for which Goeppert founded the genus in 1850, substituting *Protopitys*² for the name *Araucarites*, adopted in an earlier paper, on the ground that the structure of the xylem denoted a distinct generic type. The type-species is from the Upper Devonian rocks of Falkenberg in Silesia.

Protopitys Buchiana Goeppert.

1845. *Araucarites Buchianus* Goeppert, in Wimmer's Flor. Schlesien (edit. II.) p. 218.
 1847. *Pinites Goepperti* Unger, Chlor. Protog. p. 31.
 1847. *Dadoxylon Buchianum* Endlicher, Syn. Conif. p. 300.
 1850. *Protopitys Buchiana* Goeppert, Foss. Conif. p. 229, Pl. XXXVII. figs. 4—7; Pl. XXXVIII. figs. 1, 2.

In his Monograph of Fossil Conifers Goeppert figured a large piece of stem consisting mainly of secondary wood and described the more important anatomical features. He recognised the narrow, transversely elongated, pits on the radial walls of the tracheids as a feature of special interest indicating a type of pitting transitional between that of Ferns and Conifers. A further description was given by Kraus³ who included under Goeppert's name both the Falkenberg stem and a second specimen from Basel though the latter is Triassic in age and a distinct plant; he suggested a comparison of *Protopitys* with *Sigillaria* and *Stigmaria* rather than with Conifers. It is, however, to Graf Solms-Laubach⁴ that we owe the most thorough account of this species. Nothing is known of the leaves or reproductive organs. The largest piece of stem is nearly 1 ft in diameter and consists mainly of secondary xylem resembling that of Conifers and *Cordaites* except in the

¹ P. Bertrand (08).

² The name *Palaeopitys*, with which *Protopitys* might be confused, was used by McNab for an imperfect specimen from the Old Red Sandstone of Scotland described as *Palaeopitys Milleri*; McNab (70).

³ Kraus (92).

⁴ Solms-Laubach (93).

form of the bordered pits on the radial walls of the tracheids (fig. 462, D). The centre of the stem is occupied by a parenchymatous pith, elliptical in transverse section, enclosed by a band

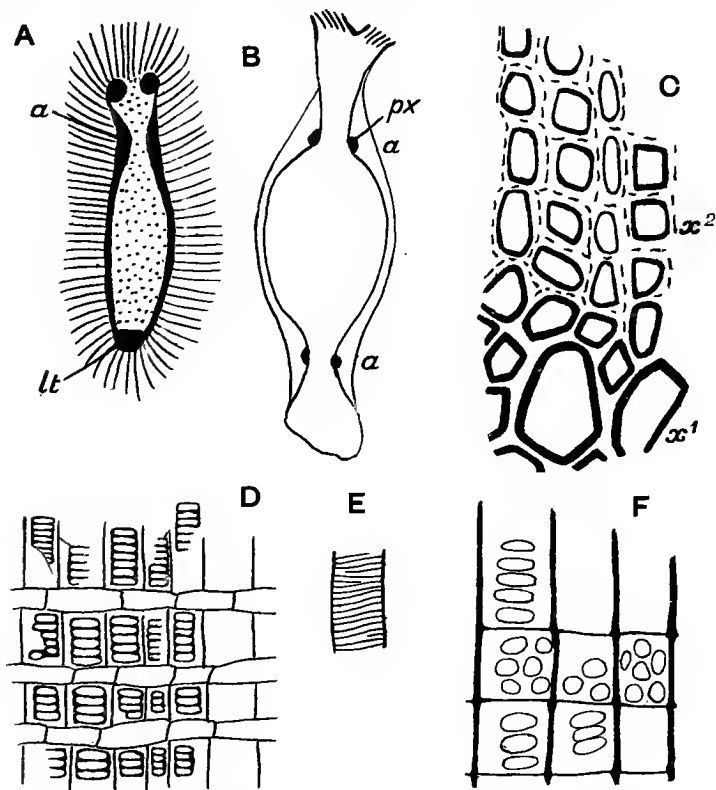

FIG. 462. *Protopytis Buchiana*. A, B. Central region of the stem showing the pith, the primary xylem (black in fig. A) and (A) the inner part of the secondary xylem; *a*, shoulders of xylem at the leaf-gaps; *lt* leaf-trace; *px* protoxylem. C. Secondary, x^2 , and primary xylem, x^1 . D. Radial longitudinal section of the secondary xylem. E. Scalariform tracheid of the primary xylem. F. Pits on the medullary-ray cells. (After Solms-Laubach.)

of primary xylem composed of large polygonal tracheids (fig. 462, C, x^1) characterised by a delicate scalariform pitting on all their walls (fig. 462, E). The primary xylem forms a narrow layer on the sides of the ellipse, 1—3 elements broad (fig. 462, A, B), but

it increases in breadth at the ends of the long axis where the tracheids are intermixed with parenchyma. The primary xylem and pith-tissue at the ends of the major axis of the central region assume different forms at different levels, owing to the detachment of leaf-traces and the consequent formation of foliar gaps as portions of the primary xylem pass obliquely outwards into the secondary xylem on the way to the distichously arranged alternate leaves. The diagram, fig. 462, A, shows the inner part of the secondary xylem (see also fig. 462, C, x^2) which at one end, *lt*, has formed an oval group about to pass out as a leaf-trace: at the opposite end the strand is detached and divided into two equal branches. The two swellings of the primary xylem ellipse shown at *a* in figs. 462, A and B, are a characteristic feature: these are clearly seen after the leaf-trace has become detached; at the inner edge of each of them there appears to be a protoxylem strand. After the formation of a foliar gap these swellings of the xylem gradually meet and so re-establish continuity below the outgoing leaf-trace. No protoxylem has been detected in the actual trace, which is believed to be concentric. The formation of the leaf-gap and the shoulders bordering it constitute interesting filicinean features, recalling corresponding characters in solenostelic Ferns. At the upper end of the diagram, fig. 462, B, the outgoing leaf-trace is undergoing dichotomy while at the opposite end the trace has passed out of view. The secondary xylem shows incomplete rings or arcs of narrower elements, which at first sight give the impression of annual rings: the occurrence of similar incomplete or pseudo-rings is a common feature in *Lepidodendron* and other Palaeozoic stems. The secondary tracheids (54.4μ in tangential diameter, 68.5μ in radial diameter) have usually a single series of broadly oval bordered pits on the radial walls with here and there two rows (fig. 462, D). In one case only were the pits of the medullary rays recognised (fig. 462, F). The rays are uniseriate, generally 1—2 cells deep, but occasionally 3 cells in depth and very rarely deeper. The cambium is of the normal type, and in some specimens secondary phloem was found consisting of bands, 4—5 layers broad, of stone-cells alternating with tubular thin-walled elements, presumably sieve-tubes.

As Solms-Laubach says, it is highly probable that each leaf-trace, which forks close to its exit from the primary xylem, became further subdivided before reaching the leaf. Morphologically, *Protopitys* is of special importance as a type possessing characters that indicate a connexion with Conifers or Cordaitean genera, notably the structure of the secondary wood, while the presence of foliar gaps is a feature reminiscent of Ferns. The primary xylem resembles that of some of the Palaeozoic arborescent Lycopodiales, but in *Protopitys* the interruptions in this tissue are due to the emission of leaf-bundles, whereas in the discontinuous primary xylem of some *Sigillarias*¹ the gaps have no connexion with leaf-traces. Moreover the distichous leaves of *Protopitys* and the larger, branched, leaf-traces are other distinguishing features. The pitting of the primary xylem is like that in the Lycopodiales and Filicales, while that of the secondary wood shows a closer approach to the coniferous type. A comparison may also be made with the transversely elongated pits of *Cladoxylon Kidstoni*².

A piece of wood agreeing anatomically with the Silesian species of *Protopitys* has been found in the Yoredale rocks of England³.

The peculiarities of the genus have been emphasised by Solms-Laubach by the institution of a family-name Protopityeae: the genus is essentially a generalised type exhibiting in the structure of its stem both Filicean and Coniferous features. The bordered pits differ from those in recent Conifers in their flatter form, but in this respect they exhibit a closer agreement with the transversely stretched pits of *Xenoxylon phyllocladoides* Goth.⁴, a Mesozoic species.

¹ Vol. II. p. 212, fig. 200, A, B.

² See page 206.

³ In the form of the pits on the tracheids and in the structure of the medullary rays the English species (as represented in Dr Kidston's Collection) agrees very closely with Goeppert's type.

⁴ Gothan (07²) p. 10.

CHAPTER XXXIII.

CORDAITALES.

A. POROXYLEAE.

Poroxyton. Renault.

In 1879 Renault¹ briefly summarised the anatomical features of some silicified vegetative shoots from the Permian of Autun for which he instituted a new family, the Poroxyleae. The more complete account contains a description of two species, *Poroxyton Boysseti* and *P. Duchartrei*: the latter was afterwards recognised as a stem of *Heterangium*. Renault considered this new genus to be closely allied to *Sigillaria* and *Sigillariopsis* and pointed out its resemblance to *Cordaites*. Additional species have since been described but as yet the genus has not been found outside France in Permo-Carboniferous strata of Autun and the St Étienne district. The results of a more detailed investigation of the anatomy of the genus were published by Bertrand and Renault in 1882 and since then² Bertrand, Renault, and Scott have added to our knowledge of this interesting type. In several respects *Poroxyton* stems present a striking resemblance to *Lyginopteris*, but the recent discovery of the genus *Mesoxylon* has given greater significance to the characters in which *Poroxyton* agrees with representatives of the Cordaitales. Our knowledge of the genus, though exceptionally full with regard to the anatomy of vegetative shoots, does not include any precise information as to the reproductive organs.

¹ Renault (79) B. p. 272, Pls. XIII. XIV.

² Bertrand and Renault (82); Bertrand, C. E. (89); Renault (96) A. p. 279, (93) A. Pls. LXXIV. LXXV; Scott (09) B. p. 500. See also Scott and Maslen (10) Maslen (11) p. 409.

The slender cylindrical stems, not exceeding 2—3 cm. in diameter in specimens so far recorded, bore large broadly linear leaves similar in form and venation to those of some species of *Cordaites* which were attached singly to slightly swollen nodes separated from one another by internodes several centimetres long. The base of the rather fleshy lamina passes imperceptibly from the narrow lower portion into a tangentially expanded petiole which forms a decurrent ridge on the stem. Axillary buds frequently occur. Little is known of the leaf-impressions, but if Grand'Eury¹ is correct in his identification of certain specimens from French Stephanian beds as the leaves of *Poroxyton*, the lamina reached a length of 1 met. and a breadth of 15—20 cm. In habit the stems probably resembled some of the larger-leaved Bamboos. The only evidence bearing on the nature of the reproductive organs is furnished by Grand'Eury who believes that some *Rhabdocarpus* seeds and bractless inflorescences associated with the leaves assigned to *Poroxyton* belong to that genus.

The single cylindrical stele has a relatively large solid pith, the perimedullary region being characterised by the occurrence of a row of primary crescentic strands of centripetal xylem of exarch type, though not improbably in some cases slightly mesarch, varying in size and shape and forming single or paired bundles. These strands represent the xylem of collateral leaf-traces similar to those of *Lyginopteris* but differing in the absence of well-defined centrifugal elements: the curved form of some of the xylem strands gives them an appearance similar to that of the leaf-traces of *Lyginopteris*. The leaf-traces, except in the lower part of their course through the pith, are double and pass through several internodes before the centripetal tracheids die out. The secondary xylem (fig. 463) is manoxylic and very similar to that of *Lyginopteris* though rather less parenchymatous. The secondary phloem and cambium are often very well preserved. No endodermis and no distinct pericycle has been recognised. The cortex is parenchymatous and, like the pith and to some extent the phloem, contains numerous secretory sacs; in the outer cortex the presence of hypodermal strands is a prominent

¹ Grand'Eury (05).

feature. At an early stage in the growth of the stem a deep-seated phellogen forms secondary tissue both externally and internally and decortication ensues.

FIG. 463. *Poroxylon Edwardsii*. A. Transverse section of stem. B. The central region of another stem of the same species. (A, $\times 9$; University College Collection; B, from a photograph supplied by Prof. Bertrand of a specimen in the Renault Collection, Paris.)

The bundle of each leaf-trace is accompanied by an arc of secondary centrifugal xylem as it passes through the secondary wood and this is retained in the leaf except in the finer veins. After entering the petiole the leaf-trace branches and an arc of

bundles is produced, the concave side facing the upper surface of the thick lamina (fig. 464, A). Further reference is made to the structure of the leaves in the description of *Poroxylon stephanense*. The specimens of roots so far described are characterised by a diarch plate of primary xylem and two masses of secondary vascular tissue separated by two medullary rays opposite the protoxylems. Bertrand mentions the occurrence of roots of *P. stephanense* with more than two protoxylem strands. The phellogen was produced in the pericycle as in the roots of recent Gymnosperms. It is suggested by Lignier¹ that some silicified rootlets from Grand' Croix (Loire) described by him as *Radiculites reticulatus* and at first compared with roots of *Sequoia* may belong to some Cordaitalean plant, possibly *Poroxylon*.

Poroxylon Edwardsii Renault.

This species² affords a good illustration of the generic characters already summarised. The strap-like leaves are fleshy and the occasionally forked, parallel or slightly divergent, veins are embedded in a homogeneous mesophyll with hypodermal strands of mechanical tissue. The pith consists of parenchyma in vertical series with scattered secretory sacs and differs from that of *Cordaites* and *Mesoxylon* in the absence of transverse discs. There are 13 primary-xylem strands close to the inner edge of the secondary wood: the centripetal tracheids are scalariform or have multiseriate pitting like that in the secondary xylem. The structure of the leaf-traces is clearly shown in fig. 464: the double trace seen in fig. 464, C, has two protoxylem-strands accompanied by some parenchyma, and these are almost enveloped by the metaxylem tracheids which abut on the secondary wood. At this stage in its course, that is just before bending outwards, the centripetal xylem reaches its maximum development and the trace forms a prominent and broad twin-strand in striking contrast to the two narrower and tangentially extended strands shown in fig. 464, E, D. Each of these strands with a single protoxylem-group would at a higher level assume the broader and more compact form and contain two protoxylems as in fig. 464, C. The tracheids of the secondary xylem have 4—7 alternate

¹ Lignier (11²).

² Renault (80).

FIG. 464. *Poroxyton*. A, B, *Poroxyton Boisseti*. A, transverse section of leaf in the region of lateral expansion of the petiole; B, portion of vascular tissue of A. C—E, *Poroxyton Edwardsii*. (From photographs supplied by Prof. Bertrand.)

rows of contiguous alternate pits on the radial walls: the medullary rays are 2—3 cells broad and may be 60 cells deep. According to Renault¹ several small oblique pits occur on the radial walls of the ray cells. The secondary phloem, separated by a normal cambium from the xylem, forms a broad band of sieve-tubes with lateral sieve-plates like those in *Medullosa anglica* alternating with tangential rows of parenchyma. The cortex is relatively narrow and in older stems is chiefly occupied by secondary tissue formed from deep-seated phellogens.

Poroxylon Boysseti Renault.

The stems of this species agree closely with those of *P. Edwardsii*, the chief difference being in the structure of the secondary phloem which does not show the regular concentric alternation of sieve-tubes and parenchyma.

Poroxylon stephanense Bertrand and Renault.

This the oldest species, from Stephanian beds at Grand' Croix, differs in no essential features from the other representatives of the genus. It is from a study of the leaves of this type that Bertrand and Renault have obtained most of the facts with regard to the anatomy of *Poroxylon* foliage. In the median region of the fleshy leaf the bundles are characterised by a comparatively large amount of centripetal xylem accompanied by a considerable development of secondary centrifugal tracheids: the bundles are connected laterally by both centripetal and centrifugal xylem and thus at certain levels in the lamina the vascular tissue has the form of a continuous plate (fig. 464, A, B). The veins become independent on branching and near the edge of the lamina they consist only of primary elements. Secretory sacs of elongated form are scattered in the homogeneous mesophyll, and thick stereome-strands underlie the epidermis. The epidermal cells are rectangular and rows of stomata occur on both surfaces.

B. CORDAITEAE.

Cordaites. Unger.

A preliminary statement with regard to nomenclature may serve to remove possible misconceptions in connexion with the

¹ Renault (93) A. Pl. LXXIV. fig. 8.

application of the generic name *Cordaites*. It has been the general practice to apply this name to certain forms of linear leaves which are particularly abundant in Carboniferous and Permian strata in Europe and North America, and in recent years a few palaeobotanists have substituted *Cordaites* for *Noeggerathiopsis* as the more suitable designation for Permo-Carboniferous specimens abundant in the rocks of Gondwana Land. It has been customary to assign to *Cordaites* certain reproductive shoots, seeds, and stems described under the generic names *Cordaianthus*, *Cordai-carpus*, *Cordai-cladus*, *Cordai-oxylon*, etc. Stems agreeing anatomically in their main features with those of recent Araucarineae have long been attributed to *Cordaites*, but a few years ago a new type of stem was discovered which, though almost identical with that of *Cordaites*, is distinguished by the character of the primary xylem. For this new type the name *Mesoxylon*¹ was proposed. Nothing is known as to the reproductive organs borne on *Mesoxylon* stems, but the leaves are externally at least indistinguishable from those referred to *Cordaites*. It is therefore obvious that when we apply the name *Cordaites* to leaves or other plant-organs, under that designation are undoubtedly included specimens belonging both to *Mesoxylon* stems and to stems with the characters of *Cordaites* (*Cordai-oxylon*). Further research may enable us to subdivide *Cordaites* into more precisely defined types distinguished by well-marked morphological characters, but at present the only course would seem to be to restrict the term *Mesoxylon* to petrified stems exhibiting the features of that genus and to retain *Cordaites* as a comprehensive designation in accordance with the general account of the genus given in the following pages. This widely distributed and mainly Palaeozoic genus is especially well represented in the coalfields of France where in some localities it contributed largely to the formation of seams of coal², and it is chiefly from the researches of French Palaeobotanists that our knowledge of its morphology is derived. *Cordaites* has shared the fate of most other abundant fossil plants in the distribution of its *disjuncta membra* among several genera and classes, but on the whole the information that

¹ See page 270.

² See Vol. I. p. 76, fig. 13.

is now available enables us to reconstruct the complete plant with a greater degree of confidence than is usually attainable.

Cordaites may be described as a forest-tree closely resembling in habit and probably in size the recent Conifer *Agathis*, more especially such species as *A. macrophyllus*, *A. vitiensis* and others with leaves considerably longer than those of the Kauri Pine (*A. australis*)¹. The main stem reached a considerable height before giving off scattered branches bearing spirally disposed, sessile, and often crowded leaves² like the foliage of *Agathis*. The absence of any evidence of a two-ranked arrangement of leaves on lateral branches suggests a general tendency towards a vertical rather than a horizontal direction of growth. The sessile and closely set leaves for the most part of leathery texture vary considerably in length and breadth in different types (figs. 466—472): in some the broadly linear lamina with its parallel veins and perfectly constructed I-shaped girders (fig. 465) reached a length of nearly 100 cm., in shape like the blade of a straight broad-sword or the leaves of a *Yucca*, torn by the wind into strips; in other forms the lamina is shorter and more obovate, while in some the leafy shoots must have looked like slender stems of the smaller-leaved Bamboos. There is no proof that young vegetative branches with their spirally rolled leaves³ were protected by bud-scales, but some oval triangular scales (fig. 468, C), occasionally found in association with larger foliage-leaves, may have served that purpose. The branches from which leaves had recently fallen at the time of fossilisation are characterised by transversely elongated oval scars, occasionally showing a slightly curved row of pits like the marks of leaf-traces on the scars of a Horse Chestnut, sometimes terminating a feebly projecting decurrent leaf-cushion (fig. 466, C). The leaves persisted for a comparatively long period as in *Araucaria imbricata*, and on older leafless branches the scars are transversely stretched; the leaf-cushion loses its individuality and eventually the develop-

¹ See Vol. iv.

² For restorations, see Grand'Eury (77) A. Pl. D; good examples of foliage-shoots are figured by Renault and Zeiller (88) A. Pls. LXVI. LXXXI.; Grand'Eury (90) A. Pl. LXIV.; Kidston (02) B. Pl. LXIV. fig. 2.

³ Renault (79) B. Pl. xvi. fig. 1; Lignier (13²). Cf. *Dolerophyllum*, p. 133.

ment of secondary cortical tissue causes the exfoliation of the superficial bark.

In the form and structure of the fertile shoots *Cordaites* parts company with *Agathis*; the trees bore no cones in the ordinary sense, but unisexual inflorescences—whether on one plant or on different individuals is uncertain—were produced in the axils or from a supra-axillary position as compound spikes or compact racemes. Both the longer female shoots and the shorter and more compact male branches are constructed on a similar plan. The ovulate inflorescence may exceed 30 cm. in length (fig. 479); a stout axis bears two-ranked linear bracts subtending short lateral bud-like shoots with one or several sessile or stalked ovules (fig. 480) between the sterile scales. The seeds are platyspermic and agree much more closely with those of Cycads and *Gingko* than with the seeds of Conifers. The male inflorescence is on a smaller scale, in habit not unlike the elongated male shoot of *Cephalotaxus pedunculata* and some other Conifers; each bract subtends a small oval bud composed of imbricate scales and highly modified microsporophylls borne singly or in clusters (figs. 481, F; 482). A microsporophyll consists of a comparatively long pedicel bearing at its apex a few long microsporangia. The term microsporophyll implies a morphological interpretation which is not accepted by all palaeobotanists, some of whom prefer to regard the microsporangia as stamens or microsporophylls reduced to their simplest terms and sessile on an elongated flower-stalk.

The stem agrees very closely in its more important features with that of an *Araucaria* or an *Agathis*: the primary xylem forms the inner surface of the thick cylinder of secondary wood, merging gradually into it as in recent Conifers; there are no separate bundles of primary centripetal xylem. The medullary rays are narrow: in other words the secondary xylem is of the pycnoxylic type. The pitting of the tracheids is Araucarian and, as in *Agathis*, the leaf-traces arise as twin-bundles. The pith is larger than in the Araucarineae and more homogeneous in structure; it shares with the pith of *Juglans* and some other recent plants an almost constant tendency to assume a discoid structure. Anatomically the leaves agree more closely in the

structure of the vascular bundles with Cycads than with Conifers though there are points of contact with both of these classes. The roots branch freely and their horizontally extended arms (figs. 468, A; 478) suggest growth in swampy ground; anatomically they conform to the recent Gymnospermous type and there is good evidence that in some cases fungal mycelia lived symbiotically in the cortex of coralline rootlets.

Sternberg¹ figured some leaves of *Cordaites* from Carboniferous rocks in Bohemia under the generic name *Flabellaria* in the belief that they belonged to a Palm. Brongniart substituted a new name *Pycnophyllum*² on the ground that Corda had disproved the supposed relationship with Monocotyledons. The name *Cordaites* was instituted by Unger³, his definition being based on leaf-form as well as on stem-anatomy. It has recently been proposed to revive the forgotten designation *Pycnophyllum*⁴, but the reasons given are hardly likely to induce botanists to discard the familiar generic name which perpetuates the memory of Corda. As already pointed out, the name *Cordaites*, even though employed in what has always been regarded a legitimate sense, is no doubt often given to specimens of some other allied member of the Cordaitales which can only be recognised as such in the case of more completely preserved material. The naming of wood of the Cordaites type, but which may equally well belong to another genus, raises a difficult question: if there is satisfactory evidence from collateral sources that the wood is that of a *Cordaites* Grand'Eury's name *Cordaixylon*⁵ or Schenk's form *Cordaioxylon*⁶ may be used, though there seems to be no adequate reason against the use of the name *Cordaites*. If there is no confirmatory evidence available and it is impossible to say whether the wood is that of a Conifer or a *Cordaites*, or some other plant with the same type of secondary xylem, Endlicher's term *Dadoxylon*⁷ is most conveniently employed. The confusion liable to follow from the use of the two generic names *Dadoxylon* and

Araucarioxylon for wood of the same type differing only in geological age is an argument in favour of extending *Dadoxylon* to all specimens having certain anatomical characters, which cannot be certainly assigned either to the Araucarineae or the Cordaitales, irrespective of geological age. The term *Cordaicladus* sometimes applied to branches is hardly necessary, but the sub-generic names *Eu-Cordaites*, *Dory-Cordaites*, and *Poa-Cordaites*, instituted by Grand'Eury for different forms of leaf, are frequently employed and serve a useful purpose as descriptive terms though the characters which they connote are of small importance and by no means always well defined or constant. For inflorescences it is customary to adopt the name *Cordaianthus* suggested by Grand'Eury as a substitute for *Antholithus* and some other terms. The same author uses *Rhizo-Cordaites* for roots.

The nomenclature of seeds is more difficult: in a few instances seeds occur in organic connexion with Cordaitan shoots, but there is no doubt that many platyspermic Palaeozoic seeds preserved as detached fossils belong to *Cordaites* or some other member of the group. The difficulty is that in the present state of knowledge we cannot definitely determine in many cases whether a seed is Cordaitan or whether it belonged to a genus of Pteridosperms. For this reason the account of several seeds that were probably borne on *Cordaites* or some allied genus is given in a later chapter devoted to Gymnospermous seeds. There is no doubt that under the generic names *Cardiocarpus*, *Cordaicarpus*, and *Samaropsis* are included true Cordaitan seeds, though it would be incorrect to say that all the seeds so named belong to members of the Cordaitales.

Cordaites reached its maximum development in the Carboniferous and Permian periods; the genus or some closely allied types persisted into the Triassic and Rhaetic periods, and there is reason to believe that the group was represented in some post-Rhaetic floras. The genus is one of many remarkable examples of the high degree of specialisation attained by Palaeozoic plants. The complex mechanisms represented by *Cordaites* and similar types give force to the conviction that we cannot hope to penetrate below the higher branches of the genealogical tree which had its roots in a period of the earth's history inaccessible to botanical

investigation. The plants of the present age are to a large extent the result of evolutionary tendencies more correctly described as the result of degeneration or simplification than as the latest phase in a series composed of a succession of types gradually growing in complexity. *Cordaites* is essentially a generalised type, a composite product of an age characterised by an activity in the elaboration of the complex from the simple. Botanical records furnished by the geological series available for investigation furnish evidence of the sorting of characters among gradually diverging races and of changes in plant-organisation tending towards simplification and increased efficiency.

Cordaites, using the generic designation in a wide sense, occurs in Carboniferous and Permian strata in Europe, North America, and China; it is recorded from several localities in Russia and Siberia for the most part from Permian rocks, from Permo-Carboniferous (Lower Gondwana) beds in India, Australia, South Africa, and South America. Wood agreeing generally in the structure of its secondary tracheids with that of *Cordaites* is represented in Devonian rocks, and there can be no doubt as to the existence of Cordaitalean plants in pre-Carboniferous floras. It is represented in the Rhaetic flora of Tonkin and has recently been discovered in strata probably of Rhaetic age in Mexico.

LEAVES.

It is important to recognise the fact that leaves included under the generic name *Cordaites* were in many cases not borne on stems or branches with the anatomical characters of *Cordaites*. Scott in his account of the genus *Mesoxylon* says, 'I feel no doubt that most of the British specimens of Cordaitean leaves really belong to *Mesoxylon*, which is a much commoner type of stem in the Coal Measure petrifications than that of *Cordaites* itself¹.' Some of the Cordaitean leaves were probably attached to stems of the *Poroxyton* type² and it is not improbable that, as investigations are extended, additional genera of vegetative shoots will be discovered provided with leaves similar at least in external characters to those which it is customary to refer to *Cordaites*. In the present state of our knowledge we cannot make use of

¹ Scott (12) p. 1024.

² Grand'Eury (05).

anatomical characters as criteria by which to distribute the foliage of the *Cordaites* form among the genera *Cordaites*, *Mesoxylon*, and *Poroxylon*, using these names as designations of certain types of anatomical structure. The specimen reproduced in fig. 465 is in all probability a piece of a leaf of *Cordaites principalis*, but on anatomical grounds Miss Benson¹ has made it the type of a new species, *C. Felicis*, and more recently Scott² has brought forward evidence supporting the view that it is a leaf of *Mesoxylon*. As, therefore, neither impressions nor petrifications of Cordaitean leaves can in the great majority of cases be referred with confidence to their respective genera of stems, pending fuller information the only course would seem to be to use the name *Cordaites* in a comprehensive sense indicating in special cases where evidence is available the more precise systematic position of the specimen. The classification of Cordaitean leaves proposed by Grand'Eury³ is based partly on the form of the lamina and in part on the equality or inequality of the 'veins.' The actual veins, which are embedded in the fairly thick mesophyll, do not directly affect the superficial ribbing on the carbonised impression of the leaves and, as seen in fig. 465, the most prominent hypodermal strands of supporting tissue which would appear as the main veins or primary ribs on an impression do not correspond in position with the vascular bundles. Although in some cases the largest stereome-strands coincide with the veins, forming the upper and lower parts of I-shaped girders the centre of which is occupied by the veins, this is by no means always the case. Grand'Eury has drawn attention to the difference between the upper and lower surface of some carbonised leaves: in *C. crassifolius* (fig. 468, D)⁴ there are five to seven finer ribs between each pair of primary ribs on one face while the other shows ridges and grooves with a rib corresponding to each. Attention is called on a later page to the variable character of the ribbing even on different parts of the same lamina. The lower surface of the leaf, seen in section in fig. 465, would show a number of approximately equal ribs, or possibly primary ribs (midway between the veins) separated by two interstitial ribs, while on the upper face there would be

¹ Benson (12).

² Scott (12) p. 1022.

³ Grand'Eury (77) A. p. 208.

⁴ Grand'Eury (90) A. p. 321.

three rather smaller secondary ribs. In a section of a leaf called by Renault *C. crassus*¹, a specific name used also by Lesquereux² for an impression of a leaf originally described by Goeppert as *Noeggerathia crassa*, there are deep stereome-strands between the veins next the lower epidermis alternating with single smaller strands, while on the upper surface the hypodermal strands occur only immediately above the veins. In a section figured by Felix³ from North Germany as *C. robustus*, the hypodermal stereome forms continuous bands; on the upper face the bands are uniform in thickness but next the lower epidermis they form a series of ribs.

Grand'Eury's subgeneric terms *Cordaites*, *Dory-Cordaites*, and *Poa-Cordaites* have therefore very little value as regards differences in the ribbing of leaf-impressions: the large size of leaves included in *Dory-Cordaites* and the more acute apex of the lamina as compared with the obtuse apex of smaller leaves of *Cordaites* are features of limited application and of minor importance as diagnostic characters. The name *Poa-Cordaites* is, however, usefully employed for the narrower linear leaves with an obtuse apex.

The structure of a *Cordaites* leaf is clearly shown in fig. 465; the lamina is approximately 1 mm. thick and there are about 30 veins in a breadth of 2 cm. Strong I-shaped girders with the webbing composed of thick-walled cells divide the mesophyll into rectangular compartments: the intervening hypodermal strands differ in number and size on the two faces. The epidermis is not preserved: specimens of other leaves show that the stomata⁴ occur in rows on the lower surface. The mesophyll shows no differentiation into palisade and spongy parenchyma, and in this respect the leaf agrees with many other forms; but in some leaves the palisade-tissue is well developed, as in *C. lingulatus* Ren.⁵ The central region of the lamina consisted of lacunar tissue, portions of which are preserved, with a more compact sheath of parenchyma enclosing each vein. In some leaves there

¹ Renault (79) A. Pl. xvi. fig. 7.

⁵ Renault (79) A. Pl. xvi. fig. 5; Stopes (03) Pl. ix. fig. 1; Lignier (13²).

is a narrower sheath of thick-walled cells more sharply contrasted with the mesophyll. The vascular bundles agree in structure with those in the rachis of a Cycadean frond more closely than with the veins of an Araucarian or other Coniferous leaf. The xylem consists mainly of centripetal elements which form a deltoid strand with the protoxylem at the apex, and in close association with this is a larger or smaller amount of narrower centrifugal tracheids: in the section shown in fig. 465 the centrifugal xylem may extend all round the centripetal tracheids, but it usually forms an irregular arch with its base attached to the sides of the larger tracheal strand, *cp*, separated, except at the

FIG. 465. *Cordaites* leaf (*Cordaites Felicis* Bens.), probably borne on a *Mesoxylon* stem. *cp*, centripetal xylem; *ph*, phloem; *px*, protoxylem. (Kidston Coll. No. 2194.)

base of the arch, by a small amount of conjunctive parenchyma from the centripetal xylem. The phloem is not preserved and is represented only by a few patches, *ph*, below the centrifugal tracheids. Dr Benson¹ in her account of this type of leaf gives additional details and compares the anatomical features with those in other species. The dual nature of the xylem like that characteristic of recent Cycads has usually been regarded as a definite feature of *Cordaites* leaves; Dr Stopes, on the other hand,

¹ Benson (12).

interprets the narrower tracheids (occupying a position similar to those in fig. 465) in some sections of a leaf identified with *C. principalis* from Grand' Croix, as an inner sheath of transfusion elements ('primitive transfusion tissue') possibly derived from the centripetal xylem with which it is clearly connected at the sides precisely as in fig. 465; but in the Grand' Croix leaf the phloem is enclosed within the sheath of narrower tracheids and not external to it as it is in the section shown in fig. 465 and in a section of *C. lingulatus* figured by Dr Stopes. It is, however, difficult to recognise any fundamental difference between the 'inner transfusion tissue' and centripetal xylem. The cells of the outer sheath in Dr Stopes's specimens of *C. principalis* have bordered pits on their walls and this character is mentioned also by Renault in other specimens.

Prof. Lignier¹ has described the structure of fragments of adult leaves from the Stephanian of Grand' Croix (Loire) which he refers to *Cordaites lingulatus*, and the same author gives an interesting account of the anatomical features of a bud of the same species. The bud, which resembles in general appearance that of *Dolerophyllum* (fig. 430, p. 133) is 3 cm. long, oval in transverse section—as the result of compression—and consists of four convolute leaves and a piece of a fifth. The outer leaves have 75 to 80 veins: the inner laminae are sinistral in their curvature while the three outer leaves are dextral. In the second, the first in which the tissues are recognisable, the small desmogenstrands afford some evidence that the phloem preceded the xylem in the order of differentiation as is often the case in recent plants. The first tracheids occur almost in the centre of the desmogen-strand and to these are added the other tracheids of the centripetal xylem, the oldest elements being spiral, the next scalariform and the later tracheids reticulate. The centrifugal xylem is formed at a later stage, and at about the same time are differentiated the elements called by Dr Stopes the inner sheath and by Lignier the 'bois diaphragmatique.' Lignier also describes the development and structural features of the other tissues of the young leaves and compares the anatomical features of the

¹ Lignier (13²).

French leaves with those of *Cordaites Felicis* described by Prof. Benson.

The main features of *Cordaites* leaves are (i) the presence of two kinds of xylem in the veins, the larger centripetal tracheids, or chief water-conducting elements, and the narrower tracheids, in some cases attached to the sides of the centripetal xylem, in others forming free groups, usually between the protoxylem and the phloem, but sometimes enclosing the phloem; (ii) the frequent presence of a well-defined sheath of cells round each vein composed of comparatively thick-walled elements comparable with the transfusion-tracheids in Conifers; (iii) the presence of lacunar tissue in the centre of the mesophyll and in some cases of transversely extended tracheids similar to those in some Podocarp leaves; (iv) a well-developed system of stereome-strands and I-shaped girders. The structural features on the whole suggest a xerophilous type, and the frequent absence or feeble development of palisade tissue points to diffused rather than to brilliant sunlight.

The considerable range in size and form among Cordaitean leaves as well as the obvious dependence on conditions of preservation or growth of such a relatively unimportant feature as the presence or absence of the so-called false or interstitial veins—the variability of which has been demonstrated in several instances—renders specific determination exceedingly difficult. The following species are briefly described rather with a view to illustrate the nature of the characters employed by authors than as implying the existence of so many well-defined types.

Cordaites principalis (Germar).

This species was founded¹ on a large specimen from the Coal Measures of Wettin showing a fan-like cluster of longitudinally torn and partially overlapping leaves spread out in the position that would be assumed on the compression of a shoot with a close spiral phyllotaxis. This form of *Cordaites* is the most abundant in the British Coal Measures. The broadly linear lamina is characterised by an obtuse apex (fig. 466, A), a tendency to split into strips, close-set parallel ribs, the stouter ribs or veins

¹ Germar (48) B. p. 55, Pl. xxiii.

FIG. 466. A. *Cordaites principalis*, part of leaf. B. *Artisia transversa*, pith-cast. C. *Cordaites principalis*, branch with leaf-scars. (A, $\frac{2}{3}$ nat. size; B, C, nat. size; Kidston Coll.)

separated from one another by 2—3 or it may be as many as 5 finer ribs or interstitial 'veins.' A statement by Weiss that in Germar's type-specimen the longitudinal ribbing of the lamina is very imperfectly preserved confirms the scepticism that is justly felt as to the validity of this character as a satisfactory specific criterion.

The incomplete example shown in fig. 466, A, is 19·5 cm. long and has a maximum breadth of 3·5 cm., but the complete leaf was much larger and tapered gradually to the comparatively broad and slightly concave or amplexicaul base. The narrow elliptical proximal end of a specimen figured by Kidston¹ from the Middle Coal Measures of Yorkshire is 2·8 cm. broad indicating that the tangentially expanded leaf-scars on a branch recently deprived of its foliage must have been a conspicuous feature. In his synonymy of this species Kidston² includes *Knorria taxina*, a species founded by Lindley and Hutton³ on a piece of stem from the Coal Measures of Newcastle. The type-specimen, as Mr Howse⁴ states, is much larger than the published drawing and closely resembles in the decurrent leaf-bases with broad apices the piece of stem represented in fig. 466, C, which Kidston identifies as *C. principalis*. Geinitz⁵ refers to this species the seeds named *Cordaicarpus Cordai* (Gein.), but there is no evidence of connexion. Kidston⁶ points out that this seed is rare in Britain: he believes that *Cordaianthus Pitcairnae* (Lind. and Hutt.) is probably the inflorescence of *C. principalis*.

Cordaites principalis occurs in both Carboniferous and Permian strata. The leaves described by Lesquereux⁷ from Pennsylvania as *C. Mansfieldi* agree closely with *C. principalis*. Another similar or possibly identical form is represented by *C. Ottonis* Gein.⁸

⁸ Geinitz (62) p. 148, Pl. XXXV.

Cordaites borassifolius (Sternberg).

The leaves of this species, originally referred to *Flabellaria*¹, resemble those of *C. principalis* but differ in the ovate-lanceolate and less obtuse apex and in the presence of only one or rarely two finer striations between the stronger ribs. Corda's drawing² affords a good illustration of the crowded spiral disposition of the foliage comparable with that on an *Agathis* shoot. The lamina is usually 4—8 cm. broad but in exceptional cases may reach a breadth of 12 cm. The species occurs in the Coal Measures, especially in the Westphalian series and in Permian rocks. Feistmantel³ unites with this type *Cordaianthus Pitcairniae* (fig. 480, A), but as in other cases there may be a confusion between *C. borassifolius* and *C. principalis*. Leaves described by Lesquereux as *C. communis*⁴ are, as White says, not distinguished by any well-marked characters from this species. White⁵ figures some good examples of *C. borassifolius* from Missouri, reaching in one case a length of 40 cm., showing on the lamina the fructifications of a fungus, *Hysterites cordaitis*⁶ Grand'Eury. The leaves described from Canada and the United States as *C. Robbii*⁷ Daws. are closely allied to if not identical with Sternberg's type. Among other species differing in no definite character from *C. borassifolius* is *C. lancifolius* described by Schmalhausen⁸ from the Permian of Russia.

Cordaites lingulatus Grand'Eury.

The leaves of this species⁹ are characterised by the obovate lamina and bluntly rounded or almost truncate apex; it affords a good illustration of the uncertainty of the ribbing as a diagnostic character. The lamina of a well-preserved specimen from the Blanzky coalfield described by Zeiller¹⁰ reaches a length of 35 cm. and a breadth of 10—11 cm. decreasing to 4 cm. at the base (fig. 467). In the lower part of the lamina Zeiller describes the

¹ Sternberg (23) A. Pl. xviii.² Corda (45) A. Pl. xxiv. fig. 8.³ Feistmantel (72) p. 293.⁴ Lesquereux (78).⁵ White (99) B. p. 260, Pls. III. XVI. XLVI.⁶ Zeiller records the same fungus on leaves of *Cordaites* (*Noeggerathiopsis*) *Histopi* from Tonkin; Zeiller (03) B. p. 151.⁷ Stopes (14) p. 82.⁸ Schmalhausen (87) Pl. vi.⁹ Grand'Eury (77) A. p. 218, Pl. xx. figs. 1—4.¹⁰ Zeiller (06) B. p. 182, Pl. XLVI.; Grand'Eury (90) A. Pl. vii. figs. 1, 2.

FIG 467. *Cordaites lingulatus*. (After Zeiller; $\frac{2}{3}$ nat. size.)

ribs as unequal in prominence, the stronger ones being separated by 1—3 finer ribs, while in the middle and upper portions the ribs appear to be of equal size. Some of the finer ribs are due to folding of the lamina and are not represented, as are the ribs due to the presence of stereome-strands, by dark streaks in the detached cuticle.

Reference has already been made to the anatomical features of leaves of this species described by Lignier¹ and other authors.

Cordaites grandifolius Lesquereux.

The leaves so named by Lesquereux², from the Coal Measures of Pennsylvania, are distinguished by the elongate cuneate lamina, which reaches a length of 38 cm. with a narrow base and a slightly rounded truncate distal end, 16 cm. broad, characterised by a few broad and shallow crenulations. By contrast with some American specimens in Dr Kidston's collection Lesquereux's figures convey an imperfect idea of the size of the leaf. A large leaf from the Coal Measures of Belgium described by Cambier and Renier as a new species of *Psygmophyllum*, *P. Delvali*³, is perhaps identical with the American type; the lamina of sub-triangular form has approximately the same dimensions; the veins are numerous and repeatedly forked. The leaf is much longer than any known *Psygmophyllum* and the veins are much more numerous than in *P. majus* Arb.⁴, the largest representative of that genus. Palaeobotanists who have seen the type-specimen inform me that they have no doubt as to the Cordaitean nature of the Belgian specimens, which may be designated *Cordaites Delvali*. It is, however, not impossible that *Psygmophyllum* and *Cordaites* are allied genera: our knowledge of the former is limited to unimportant characters.

Cordaites (Dory-Cordaites) palmaeformis (Goepfert).

This Permian type, originally described by Goepfert⁵ as *Noeggerathia palmaeformis*, is characterised by numerous slender veins: according to Weiss⁶ there may be as many as 3—5 in 1 mm.

¹ Lignier (13²).

² Lesquereux (78) p. 318; (80) A. Pl. LXXVII.

³ Cambier and Renier (10); Renier (10²) Pl. 118.

⁴ See *postea*.

⁵ Goepfert (64) A. Pl. XXX. fig. 2.

⁶ Weiss, C. E. (72) p. 199.

The leaf is broadly lanceolate; it tapers gradually to an acute apex reaching a length of 80 cm. and a breadth of 10 cm. In habit the young foliage-shoots¹ resemble those of *C. principalis* and *C. borassifolius*. Grand'Eury records the frequent association of *Samaropsis* seeds with this species; it occurs in Upper Carboniferous and in Permian strata and is recorded from a few British localities.

Cordaites (*Poa-Cordaites*) *microstachys* Goldenberg.

Weiss² first figured this species from drawings supplied by Goldenberg at whose suggestion the name *C. microstachys* was adopted. The type-specimen consists of a slender axis bearing numerous narrow linear leaves and a few imperfect fertile axillary shoots. A specimen is figured by Kidston³ from the Upper Coal Measures of Radstock: it is a rare type in Britain. The species is readily distinguished from *C. principalis* and similar forms by the narrow lamina which varies considerably in length, rarely as long as 30 cm. and not exceeding 1 cm. in breadth. The apex is obtuse and the ribs are either equal in strength or 1—2 finer striae may alternate with the stronger ribs. The base of the lamina is 3—4 mm. wide and the leaf-scars have a slightly arched upper margin and an almost straight lower edge⁴. The foliage of this species, generally regarded as identical with *C. linearis* Grand'Eury, bears a close resemblance to that of the Mesozoic genus *Phoenicopsis* from which it is distinguished by the occurrence of the leaves in bunches.

C. gracilis Lesq.⁵ is a similar type. The shoot on which Lesquereux founded his genus *Desmiophyllum*⁶ may perhaps be an example of *Poa-Cordaites*. *Poa-Cordaites tenuifolius* Schmal.⁷ from the Permian of Russia may be identical with *C. microstachys*.

As examples of other forms of leaf referred to *Cordaites*, though as in other cases without any proof of connexion with branches having the anatomical features of the genus, reference

may be made to *Cordaites circularis* Grand'Eury¹ from Gard (fig. 468, B) and a smaller leaf from the same locality compared with *C. Lacoiei* (fig. 468, C) Lesq. *Cordaites circularis* is characterised by the almost orbicular lamina traversed by slightly spreading veins; it recalls some of the larger *Cyclopteris* pinnules of Pteridosperm fronds and is indistinguishable from some leaves assigned to the genus *Dolerophyllum*².

FIG. 468. A, *Cordaites* root-system (*Rhizo-Cordaites*); B, *Cordaites circularis* leaf; C, *Cordaites* sp., cf. *Cordaites Lacoiei*; D, *Cordaites crassifolius*, upper and lower surface of leaf. (After Grand'Eury.)

The species *C. Lacoiei* was founded by Lesquereux³ on some detached specimens 3—12 cm. long and 1.5—5 cm. broad; it is by no means certain that a specimen referred by Grand'Eury⁴ with some hesitation to this species is Cordaites.

The generic name *Scuto-Cordaites* was proposed by Renault⁵ for a specimen from Commeny consisting of a flattened branch bearing a few imperfectly preserved leaves. The surface of the branch shows semicircular leaf-scars on decurrent, spirally disposed leaf-cushions and bears a certain resemblance to a slender stem

¹ Grand'Eury (90) A. p. 325, Pl. VI. fig. 15.

of a Clathrarian *Sigillaria*. The leaves of the type-specimen of *Scuto-Cordaites Grand'Euryi* appear to be broadly linear, 13 cm. long, the breadth gradually increasing from the base: a short distance from the proximal end the lamina is broken up into narrow segments; the veins are .5 mm. apart with finer striations between them.

Some specimens from Pennsylvania made by Dawson¹ the type of a new sub-genus and named *Dictyo-Cordaites Lecoii* agree in shape and arrangement with some species of *Cordaites*, but differ in an occasional anastomosis of the veins as in *Psymphyllum flabellatum*. It is, however, impossible to determine the true nature of the fossils from the published figures.

CORDAITEAN LEAVES FROM INDIA, THE SOUTHERN HEMISPHERE, AND SIBERIA. *NOEGGERATHIOPSIS*, FEISTMANTEL; *RHIPTOZAMITES*, SCHMALHAUSEN; *EURYPHYLLUM*, FEISTMANTEL.

{ *Cordaites aequalis* Goepfert.

{ *Cordaites (Noeggerathiopsis) Hislopi* (Bunbury).

In 1845 Goepfert² instituted the species *Noeggerathia aequalis* (fig. 469) and *N. distans* for incomplete broadly linear and obovate leaves, from Siberian Permian strata, having a contracted base and equal parallel veins. The specimens so named are no doubt specifically identical. Goepfert's species *N. aequalis* has recently been carefully investigated by Zalesky³ who agrees with Kosmovsky⁴ in identifying it with *Noeggerathiopsis Hislopi* (Bunb.) and *Rhiptozamites Goeperti* Schmal. Schmalhausen⁵ had previously pointed out the probable identity of his species with *Noeggerathia palmaeformis* Goepf. (= *Cordaites*). The question of specific identity of these leaves from different localities and of other hardly distinguishable forms is of secondary importance; the main point is that they are all examples of Cordaitean leaves, *Cordaites* or some allied genus, and point to the existence of this group of Gymnosperms during Permo-Carboniferous times in Siberia, China, India, Australia, South Africa, and

S. America, also in the Rhaetic floras of Tonkin¹ and Mexico². The fragments from Devonian strata at Iguana Creek, Australia, named by McCoy³ *Cordaites australis* are probably pieces of the rachis of some large frond.

Wieland⁴ recently discovered Cordaitean leaves exhibiting a wide range in size and shape in the Mixteca flora of Mexico in the lower members of a series which extends from the 'upper borders of the Rhaetic' through the Liassic to the lower beds of the Inferior Oolite. These leaves are referred to *Noeggerathiopsis Hislopi*, and it is clear from an examination of photographs received from Dr Wieland, one of which is reproduced in fig. 470, that the Mexican *Cordaites* cannot be specifically distinguished from Bunbury's type as represented by specimens described from India, South Africa, Siberia, Tonkin, and elsewhere.

The occurrence of *Noeggerathiopsis* is also recorded by Newberry from the Rhaetic series of Honduras⁵.

Noeggerathiopsis. This genus was founded by Feistmantel⁶ for some leaves from Lower Gondwana rocks in India originally described by Bunbury⁷ as *Noeggerathia (Cyclopteris?) Hislopi* (figs. 470—472) and regarded by him as probably Cycadean. Several authors have added to our knowledge of this widely spread southern type and in many localities the leaves occur in association with platyspermic seeds of the *Samaropsis* or *Cordaicarpus* type, pieces of stems with Cordaitean leaf-scars, and petrified wood agreeing in the structure of the secondary xylem with that of European species of *Cordaites*. In some Permo-Carboniferous sandstones at Vereeniging, South Africa, stumps and spreading roots (fig. 478) resembling those described from France by Grand'Eury (cf. fig. 468, A) have also been discovered. A remarkable occurrence of roots and prostrate stems of some forest-tree was recorded some years ago in the bed of the Vaal river near Vereeniging where the surface of a seam of coal was exposed over an area of more than two acres⁸. Large

FIG. 470. *Cordaites (Noeggerathiopsis) Hislopi*. From Mexico. (After Wieland; $\frac{2}{3}$ nat. size.)

FIG. 471. *Cordaites (Noeggerathiopsis) Hislopi*. From Vereeniging. (A, ca, $\frac{1}{3}$ nat. size; B, ca, $\frac{1}{3}$ nat. size.)

branched roots (fig. 478) spreading over the coal for a distance of several feet and thick stems 40—50 ft in length with very few branches and but little decrease in diameter afford a striking picture of a forest-floor. The frequent occurrence of *Cordaites* (*Noeggerathiopsis*) *Hislopi* in the associated strata suggests a reference of the stems and roots to that species. Moreover the

FIG. 472. *Cordaites* (*Noeggerathiopsis*) *Hislopi*. From India.
(Calcutta Museum; $\frac{2}{3}$ nat. size.)

structure of the secondary xylem of some petrified pieces of stem sent to me by Mr Leslie from Vereeniging agrees closely with that of a European Cordaitean stem.

The leaves of *Cordaites* (*Noeggerathiopsis*) *Hislopi* vary considerably in size, in some cases reaching a length of 80 cm. (fig. 471);

the lamina tapers gradually from a short distance behind the obtuse apex to a relatively narrow base: in venation and form the leaves are very similar to those of *C. principalis* and other European and North American species. The specimen from India represented in fig. 472 shows several spatulate leaves attached in a close spiral to a branch. As White¹ and Zalesky have shown, the stronger ribs are separated by less prominent striations indicating the presence of two sizes of hypodermal strands. The obvious resemblance between *Noeggerathiopsis Hislopi* and species of *Cordaites* has long been recognised and many authors have included Feistmantel's genus in the *Cordaitales*². Prof. Zeiller³ preferred to retain the name *Noeggerathiopsis* as a precautionary measure, chiefly on the ground that the stomata appeared to be less definitely arranged in rows and more scattered than in the European leaves of *Cordaites*, and because of the absence of interstitial veins. We have as yet little information as to the arrangement of the stomata, but in view of the irregularity in stomatal grouping in recent leaves this feature is, perhaps, of minor importance. The presence of interstitial 'veins' has now been established in Indian⁴ and South American⁵ leaves. In a paper published in 1908⁶ the name *Cordaites* was substituted for *Noeggerathiopsis* and Zalesky's recent work supports this step. The description by Zalesky of the ribbing in Goeppert's species *Cordaites aequalis* from Siberia shows how uncertain and variable a character the venation is even in different parts of the same leaf.

Cordaites Clerci Zalesky.

This species (fig. 469, D) was instituted for some small lanceolate or spatulate leaves from the Petschora basin (Adzva River)⁷ reaching a length of 6 cm. and a breadth of 1 cm. It is separated from *Cordaites aequalis* on the ground that the veins are more numerous, as many as 44 in a breadth of 1 cm.

A recent investigation by Miss Holden⁸ of the carbonised

cuticles of some Indian specimens, sent to Cambridge by the Director of the Indian Geological Survey, and a comparison of them with preparations made from European *Cordaites* leaves, have revealed certain distinguishing features which support Zeiller's view that the Gondwana-Land leaves, though similar superficially to those of *Cordaites*, are probably distinct. It is, however, impossible in many cases to obtain any information with regard to epidermal characters, and though it would seem probable that had we a fuller knowledge of the Indian and southern hemisphere plants represented for the most part by leaf-impressions well-defined distinguishing features would be recognised, the comprehensive name *Cordaites* may conveniently be retained on the ground that in the absence of well-preserved cuticles no satisfactory distinguishing features are exhibited by the impressions of *Noeggerathiopsis*.

Phylladoderma. Zalesky.

Phylladoderma Arberi Zalesky.

Zalesky¹ founded this genus on some Permian leaves from the Petschora basin (Adzva River) which closely resemble those of *Cordaites* but are characterised by a coarser venation. The lanceolate lamina reaches a length of 18 cm. and a breadth of 4.2 cm.; the veins are 2 mm. apart and occasionally forked near the base of the leaf. The epidermal cells have straight walls and stomata are abundant on the lower surface. As Zalesky says, the systematic position of the leaves is uncertain though they are probably Cordaitean. The coarseness of the venation is a feature of minor importance and hardly worthy of generic recognition.

Rhoptozamites Schmalhausen.

This genus was instituted by Schmalhausen² for leaves from beds in the Kusnezsk basin regarded by him as Jurassic. These strata are now recognised as Permian³ and homotaxial with those from which Schmalhausen⁴ subsequently recorded the same species. The leaves, though smaller than many of the Indian and South African specimens of *Cordaites* (*Noeggerathiopsis*)

⁴ Schmalhausen (87) B. p. 37.

Hislopi, may belong to that species. Zeiller and others definitely assigned the Russian leaves to *Cordaites*.

Euryphyllum. The Indian leaves for which Feistmantel¹ proposed this name are, as several writers have pointed out, in all probability referable to *Cordaites*.

The general conclusion to be drawn from this imperfect summary of an extensive literature is that the employment of the generic names *Noeggerathiopsis*, *Rhoptozamites*, *Euryphyllum*, and others has tended to exaggerate the difference between the European and Southern botanical provinces during the Permo-Carboniferous period.

Scale-leaves, seeds, and stems.

The occurrence of small scale-like leaves of the type represented in fig. 468, C, in association with *Cordaites* (*Noeggerathiopsis*) *Hislopi*² in India, Brazil, Siberia, and elsewhere may mean that these organs are scales of large foliar buds. The occurrence of several forms of platyspermic seeds, in some cases apparently identical with European forms and sometimes distinct types, in close association with *Cordaites* (*Noeggerathiopsis*) *Hislopi* has already been mentioned. Examples of such seeds are described in Chapter xxxv. under the genus *Samaropsis*.

There are very few satisfactory examples of Cordaitean branches from the southern hemisphere. Schmalhausen³ figures good specimens from Siberian rocks from which his *Rhoptozamites* leaves were obtained. Branches with spirally disposed leaf-scars figured by Zeiller⁴ from the Rhaetic of Tonkin closely resemble *Cordaicladus*. Feistmantel's drawing of a fossil from the Karharbari series, compared by him with a Fern rhizome⁵, may be a Cordaitean branch, and the same author describes a stem⁶ from New South Wales as *Caulopteris Adamsi* which bears a close resemblance to a branch of *Cordaites*. Similarly a leafy shoot described from India by Zeiller as *Araucarites Oldhami*⁷ may be compared with branches of the *Poa-Cordaites* type.

STEMS. i. *Pith-casts.**Artisia.* Sternberg.

A character to which authors tend to attach excessive importance as a diagnostic feature is the almost invariable tendency of the parenchymatous pith of *Cordaites* to break up on contraction into transverse diaphragms, thus producing what is known as a discoid pith. In the stem shown in fig. 473 the pith is represented by a more or less cylindrical cast characterised by fairly regular transverse ribs and narrow grooves; in the upper part

FIG. 473. *Cordaites* (or *Mesoxylon*?) stem showing the discoid pith partially enclosed by wood. ($\frac{1}{2}$ nat. size.) M. S.

of the fossil the peripheral tissue of the pith is preserved in the form of narrow plates projecting from the inner face of the wood. As Renault¹ pointed out, this type of pith is the expression of certain conditions of growth and is not a satisfactory distinguishing feature of any particular genus or family. The same tendency to form a discoid pith is characteristic of *Mesoxylon*, and it occurs also in some other Palaeozoic genera. Corda long ago figured a stem attributed by him to *Lomatofloyos* with a typical discoid pith, and a similar pith is recorded in a stem of *Dicranophyllum*². Among recent plants *Juglans regia* affords perhaps the most familiar instance of an identical form of pith: the same type

¹ Renault (79) B. p. 287.

² Renault and Zeiller (88) A. Pl. LXXI.

occurs in the white Jasmine, in *Ceropegia peltata*, and some other flowering plants. An interesting case is that of the tree Groundsel, *Senecio praecox* D.C.¹, of Mexico: in this plant, which grows in arid districts, the pith serves as a water-store and as the water is drawn off the thick turgescient discs contract and form thin transverse diaphragms separated by wide spaces, as is also the case on drying in some succulent *Euphorbia* stems. It may be that in *Cordaites* the medullary region also served as a water-reservoir and the depth of the medullary discs would vary according to the state of their contents.

The earlier writers regarded the pith-casts as stems with scars of amplexicaul leaves: Artis² described specimens from the English Coal Measures as *Sternbergia*, one of which he stated to be 6 ft long; a few years later Sternberg³ proposed the name *Artisia* and this has been generally used on the ground that *Sternbergia* is the name of a recent flowering plant. A specimen of *Artisia transversa* (Art.) from the Coal Measures of Yorkshire is shown in fig. 466, B, and similar specimens varying considerably in diameter up to about 10 cm. are abundant in European and American Coal Measures. The prominence and depth of the transverse ridges, the presence or absence of anastomoses between adjacent discs are, as Zeiller⁴ says, of very doubtful value as specific characters. Dawson in 1846⁵ spoke of *Artisia* as probably the pith of a tree, a view suggested to him by Mr Dawes. In 1851 Williamson⁶ published a description of some specimens in which a pith-cast, *Artisia approximata* Lind. and Hutt., was enclosed by wood showing very clearly Cordaites characters. Further demonstration of the true nature of *Artisia* was supplied by Grand'Eury from St Étienne material. If the generic name *Artisia* is applied to all pith-casts showing the transverse ridges and grooves like those seen in fig. 466, B, it must be remembered that it is not safe to assume a connexion with *Cordaites* or *Mesoxylon*. A Liassic species described by Lignier⁷ from France as

⁷ Lignier (95) Pl. VII. fig. 13.

Artisia alternans is quoted by authors as evidence of the persistence of *Cordaites* into the Jurassic period; but in view of the fact that the discoid type of pith is not by any means confined to *Cordaites* or even to the Cordaitales the occurrence of *Artisia* is in itself of no great botanical significance.

It is also true that a discoid pith is not an invariable attribute of stems closely allied to the genus *Cordaites*; but if these reservations are made the use of the generic term *Artisia* serves a useful purpose.

ii. *Petrified stems.*

Dadoxylon. Endlicher.

Palaeobotanical literature contains numerous descriptions of Palaeozoic petrified wood occasionally enclosing an *Artisia* pith-cast described under such names as *Dadoxylon*, *Cordaioxylon*, *Araucarioxylon*, etc., and regarded as portions of Cordaitan stems. It is, however, certain that much of this material belonged to stems other than those of *Cordaites*. Recent research has demonstrated the insufficiency of the secondary xylem alone, however well preserved, as a safe guide to generic position: stems identical in the structure of the secondary xylem differ in that of the primary portion of the stele, and it is on the characters of the latter tissues that several genera have recently been founded. *Mesoxylon* affords a striking example of the importance of the primary xylem as a distinctive feature. As Gothan¹ points out, the species of *Calamopitys* recently made the type of a new genus *Eristophyton*² would, in the absence of the primary xylem, probably be regarded as Cordaitan. It is important to recognise the limitations imposed by the imperfection of the material; we cannot in most cases determine whether a specimen should be referred to *Cordaites* or *Mesoxylon*, and while it may be described as probably Cordaitan in affinity there remains the possibility that some of the Palaeozoic plants with secondary wood like that of *Cordaites*, if their reproductive organs were known, would not be included in the Cordaitales. Goepfert's species *Araucarites Tchihatcheffi*, which Renault³ quotes as *Cordaites*, has recently been assigned to a new genus *Mesopitys*⁴ because of certain

¹ Gothan (05) p. 28.

³ Renault (79) B. p. 288.

² See page 199.

⁴ See page 295.

distinctive features of the primary xylem. Additional examples might be quoted pointing to the tendency of recent and more thorough investigation to establish the fact that the occurrence of Permo-Carboniferous wood of the Araucarian type does not necessarily denote the existence of *Cordaite*s. The question of nomenclature is necessarily raised in this connexion.

In recent years it has been customary to assign Palaeozoic wood with Araucarian pitting to the genus *Dadoxylon*, while wood of the same general type from more recent strata is by many authors referred to *Araucarioxylon*¹. This arbitrary distinction based on a difference in age is open to serious objection. Fossil wood of the Araucarian type is widely scattered in strata ranging from Carboniferous to Jurassic periods; it also occurs in later formations. The fact that on the one hand Araucarian plants, as recognised by cones and foliage-shoots, are especially characteristic of Jurassic floras and occur more rarely in Rhaetic and Triassic floras, and on the other hand that *Cordaite*s and its allies reached their greatest development in Permo-Carboniferous times, renders it probable that in the majority of cases a distinctive name based on geological age would be in accordance with botanical differences. But we have no satisfactory data as to the upper limits of the Cordaiteae or the lower limits of the Araucarineae: in all probability the two families overlapped and co-existed for more than one geological period. It is, moreover, the plants from formations where overlapping occurred that are the most critical from a botanical standpoint. The age-distinction is therefore at best an artificial one and may be seriously misleading. Potonié² and Gothan³ have emphasised the desirability of adopting the name *Dadoxylon* for all wood of the Araucarian type irrespective of age. If a particular specimen can be correlated definitely with *Cordaite*s or some other genus it should be so designated, but the fragmentary nature of the records usually precludes this simple course. The most logical plan is to use the name *Dadoxylon* for all woods with Araucarian characters if there is no sufficient reason for employing a less provisional term. If

¹ Felix (86) A. p. 56; Knowlton (90); Zeiller (95) B. p. 627; Penhallow (00) p. 54.

² Potonié (02) p. 229.

³ Gothan (05) p. 13.

the evidence clearly points to the Araucarineae the generic name *Araucarioxylon* should be added in parentheses after *Dadoxylon*, but whether or not this is done, a statement as to the geological age of the fossil will in itself be some assistance in enabling the student to form an opinion on the balance of probability in favour of a Cordaitean or an Araucarian affinity. The course suggested by Gothan¹, namely to add *Cordaites* after *Dadoxylon* if an *Artisia* pith is present, is rendered inoperative now that we know that a discoid pith occurs in more than one genus. In this chapter we are concerned primarily with *Cordaites* and with such stems as may fairly be regarded as Cordaitean: examples of fossil wood from later formations are dealt with in another place. A distinction between *Araucarioxylon* and *Cordaioxylon* stems has been based by Felix on the nature of the pith-casts; those of the *Artisia* type he refers to *Cordaioxylon*, while Palaeozoic stems with *Tylodendron* pith-casts are assigned to *Araucarioxylon*². This distinction can, however, only be made in the comparatively few cases in which the pith-cast is preserved. Its validity is, moreover, open to question. A *Tylodendron* (= *Schizodendron*) cast shows on its surface the characters of the inner face of the secondary xylem, projecting spindle-shaped areas representing the inner ends of medullary rays and a reticulum of grooves formed by the more resistant and prominent inner edges of the rows of tracheids (fig. 746). A pith-cast of a stem in which the destruction by decay of the medullary parenchyma had not extended to the edge of the xylem-cylinder might show transverse diaphragms. The occurrence of *Tylodendron* casts means that decay had extended to the surface of the wood. But in view of the occurrence of *Tylodendron* casts in stems that are not those of *Cordaites* a short account of the genus is given on another page³.

The main features of the stem of *Cordaites* have already been enumerated. The stele agrees with that of *Araucaria* and *Agathis* and especially with *Agathis* in the double nature of the leaf-trace. Williamson⁴ in 1877 described pieces of wood from the English

¹ Gothan (05) p. 15.

² Sterzel (03).

³ See Chap. XLV.

⁴ Williamson (77) A. p. 226, Pls. VII.—IX.; (80) A. p. 516, Pl. XX. fig. 16; (83²) A. p. 470.

Coal Measures and the Lower Carboniferous of Scotland which he referred to *Dadoxylon* but without any specific name. These include the Coalbrookdale stem in which he had previously demonstrated the connexion between *Artisia* and *Dadoxylon*. The structure of the xylem is like that in *D. Brandlingii* and the specimens may belong to that species. The most interesting fact recorded by Williamson is the occurrence of double leaf-traces, a feature which led him to suspect a remote generic affinity to *Ginkgo*. This double trace may be an important diagnostic feature but unfortunately the majority of descriptions of species of *Dadoxylon* throw no light on the character of the foliar bundles.

Thomson and Allin¹ have recently pointed out that a double leaf-trace occurs in a stem from the Permian of Kansas described by Penhallow² as *Pityoxylon chasense* and referred to that genus because of the supposed occurrence of resin-canals in some of the medullary rays: the canals are apparently leaf-traces traversing broad rays in the secondary wood.

The primary xylem of *Cordaites* is in direct continuity with the secondary tracheids and does not form mesarch strands as in *Mesoxylon*. The pith is usually discoid. The pitting on the tracheids is a character of special importance: while it is true to say that as a rule the number of pits on the radial walls of a single tracheid is larger than in the Araucarineae, this is not always the case. In *Araucaria* there are occasionally as many as five rows of alternate polygonal pits (fig. 691, A) and in some Palaeozoic *Dadoxylons* there are only one³ or two rows. The very broad zone of transitional elements at the inner edge of the xylem-cylinder is a characteristic feature shared by the Araucarineae⁴; the spiral protoxylem-tracheids are succeeded by scalariform elements and these, by the gradual anastomosing of the transverse bars, pass into tracheids with multiseriate pitting. In this broad zone we probably have a primitive feature, an epitome in a single stem of the course of development of multiseriate from scalariform pitting. In some Palaeozoic species with wood of the pycnoxylic type and agreeing generally with typical *Cordaites*

¹ Thomson and Allin (12); Thomson (13) p. 14.

³ White (08) B. p. 583.

⁴ Seward and Ford (06) B. p. 341.

the bordered pits are sometimes separate and circular, and opposite pits occasionally replace the usual alternate arrangement. Another feature on which stress has been laid is that in *Cordaites* the pits occupy the whole breadth of the tracheal wall; but this, though frequently the case, is by no means a constant feature. In *Dadoxylon Newberryi*¹ the pits tend to form groups, leaving unpitted areas, as in the genus *Coenoxylon*². In the stem of *Dadoxylon materiaram* Daws. represented in fig. 475 the pits do not always cover the whole of the tracheid-walls: this stem is also instructive as an example of the different appearance presented by pitted tracheids according to the state of preservation. In some places an oblique pore is well shown while in others only the outer border of the pit is seen. Gothan³ has described a specimen in which some of the pits are circular and occupy only the central area of the xylem elements: separate circular pits occur also in *D. Pedroi* Zeill.⁴ (fig. 476). Similar departures from the normal are illustrated by recent species of Araucarineae. The absence of a torus is another feature shared by *Dadoxylon* and true Araucarian wood. Annual rings other than incomplete and spasmodically formed rows of narrower tracheids are not as a rule present, and in this respect also *Araucaria* affords a close analogy. Thomson⁵ has figured a transverse section of a root from English Coal Measures in which rings of growth are well defined; and other instances are recorded. In an Australian species named by Arber *D. australe*⁶, there are well-marked rings of growth, and this is equally the case in some Indian wood⁷ of Permo-Carboniferous age, more nearly allied to *Mesoxylon* than to *Cordaites*, and in a *Dadoxylon* of similar age from South Africa. On the other hand the statement that annual rings occur in Palaeozoic wood is often incorrect, partial rings having been confused with regular concentric cylinders of summer elements. Dawson and Matthew⁸ described rings in *D. ouangondianum*, and Goeppert and Stenzel⁹, who examined the Canadian material,

⁸ Matthew (10) p. 77, Pls. I., II.

⁹ Goeppert and Stenzel (88) p. 10.

refer to circles like annual rings; but Penhallow¹ states that there is no evidence of true growth-rings.

The medullary rays are uniseriate and consist of thin parenchymatous cells with unpitted walls; they vary considerably in depth, usually comparatively shallow but in some cases 40 or 50 cells deep. In recent Araucarineae the rays are generally shallower. The absence of special receptacles, other than occasional resiniferous tracheids, for products of secretion is a feature common to *Dadoxylon* and the Araucarineae. The phloem presents no features of special interest, but our knowledge of this tissue is comparatively meagre.

Among other examples of large *Dadoxylon* stems some of which no doubt bore Cordaitan foliage—though as a rule we have insufficient information as regards anatomical characters to enable a decision to be made between *Cordaites* and *Mesoxylon*—reference should be made to the imposing array of silicified trunks in the grounds of the Chemnitz Museum². These were obtained from Lower Permian strata at Hilbersdorf near Chemnitz from beds overlain by porphyry tuff and resting on quartz porphyry, the volcanic material which furnished the siliceous solutions. Several large pieces of wood were found in association with stems of *Medullosa* and *Psaronius*, leaves of *Cordaites*, *Artisia* pith-casts, and *Cardiocarpus* seeds with specimens of *Walchia*, *Gomphostrobus* and other plants. Sterzel describes a stem 16.5 met. long and 1.5 met. in diameter; on the main trunk the branch-scars are scattered but on some branches there is a tendency to a whorled arrangement. This and many other stems are referred to *Araucarioxylon* (or *Dadoxylon*) *saxonicum*, a species first described by Reichenbach as *Megadendron saxonicum*. In one specimen Sterzel states that the bordered pits are generally in 1—2 rows, though rarely in 3—4 rows, on the radial walls of the tracheids which they do not completely cover: the medullary rays reach a depth of between 20 and 30 cells. It is noteworthy that the stem 16.5 met. long has a pith-cast of the *Tylodendron* type.

¹ Penhallow (00) p. 67.

Dadoxylon (Cordaïtes) Brandlingii (Lindley and Hutton).

1831. *Pinites Brandlingii* Lindley and Hutton, Foss. Flor. Vol. I. Pl. I.
1850. *Araucarites Brandlingii* Goepfert, Foss. Conif. p. 232, Pls. xxxix.—xli.
1890. *Cordaioxylon Brandlingii* Schenk, in Schimper and Schenk, p. 853, fig. 408.

This species was founded on 'a fossil giant of the vegetable kingdom' discovered at Wideopen near Newcastle in Carboniferous strata on the estate of Mr Brandling. The stem, 72 ft long and far from complete, showed an irregular and not a whorled distribution of branch-scars. It is noteworthy that in *D. medullaris* (Goepf.)¹, a Permian species from Saxony, the branch-scars, while for the most part irregularly scattered, in one case showed an approach to a whorled disposition as in recent Araucarias. Witham² gave a fuller account of the structure of the stem than is included in the original description, and the species has been described by many later authors from both Permian and Carboniferous localities. The pith is discoid and the broad transitional region at the inner edge of the wood is a characteristic feature³. Thomson⁴ points out that there is a tendency to a retention of the scalariform type of pitting in the region of the medullary rays. There are 1—5 rows of pits on the radial walls of the tracheids. The rays may reach a depth of 40 cells; they are usually one cell broad. It has recently been shown that as many as six vascular strands⁵ may form one leaf-trace instead of the customary pair, a feature suggesting comparison with *Metacordaïtes Rigolloti* Ren. with its five foliar bundles. Other species agree very closely with *D. Brandlingii* and it is impossible to determine with accuracy the precise specific limits of stems agreeing generally with this type; but for the sake of emphasising the variation in anatomical structure it is worth while to draw attention to a few more or less divergent forms from different geographical areas.

⁵ *Ibid.* p. 16.

Dadoxylon protopityoides Felix.

An interesting feature in this Westphalian type from Germany is the occurrence of transversely elongated pits on the tracheids¹ associated with those of normal form closely simulating the pits in the xylem elements of *Protopitys*.

Dadoxylon nummularium White.

In this Brazilian wood² from Permo-Carboniferous beds the medullary rays are very numerous, mostly uniseriate and 1—30 cells in depth. The pits on the tracheids are in 1—2 rows and are often contiguous. In another type, *D. meridionale*, described by the same author³, the pits are strictly uniseriate and generally contiguous. As White says, the absence of the pith and cortex and of any evidence as to the structure of the primary xylem renders impossible any definite expression of opinion as to the affinity of these and many other species.

Dadoxylon Nicoli Seward.

Dr Arber⁴ in naming this species, from the Newcastle (Permo-Carboniferous) Series of New South Wales, *Dadoxylon australe*, does not mention Crié's earlier account of some wood from New Caledonia under the name *Araucarioxylon australe*⁵. The latter generic name according to the usage adopted in this volume should be superseded by *Dadoxylon*, and this necessitates a fresh specific name for Arber's specimens. The name *Nicoli* is suggested in place of *australe*, as the sections on which Arber founded his species form part of the Nicol collection in the British Museum.

The xylem shows distinct rings of growth, a feature also seen in Indian stems of approximately the same geological age and recorded by Shirley⁶ in wood from Queensland which needs more careful examination. The bordered pits, usually multiseriate and contiguous, are not infrequently in 1—2 rows and separate. The uniseriate medullary rays are very numerous as in White's Brazilian species *D. nummularium*, and as a rule 6—12 cells deep. Some well-preserved specimens from Permo-Carboniferous strata

in Natal and Zululand have been described by Warren¹ as *Dadoxylon australe* Arb., showing interesting anatomical features, but the material almost certainly includes more than one specific type and would repay more detailed investigation.

Dadoxylon materiarum Dawson.

This species was described by Dawson² from Carboniferous strata in Nova Scotia and afterwards referred by Penhallow³ to the genus *Cordaites*. In the transverse section reproduced in fig. 474, A, the tracheid-walls have been reduced in thickness by partial decay, but some of the bordered pits are clearly shown on the radial walls; the pits usually form 2—4 contiguous rows (fig. 475) in some cases with an oblique pore while others are represented either by the outer border of the pit or by the pore only. The narrow medullary rays are as a rule uniseriate and may be 60 cells deep (fig. 474, B). Dawson states that some specimens have large *Artisia* pith-casts, a fact that formerly would have been regarded as proof of the *Cordaites* nature of the wood, but in the absence of evidence with regard to the nature of the primary xylem it is impossible to say whether the stem is *Cordaites* or *Mesoxylon*.

Dadoxylon sp.

Some wood received from Mr Leslie, collected at Vereeniging, South Africa, in Permo-Carboniferous rocks, shows well-defined rings of growth. The pits form either a single row, a double, alternate and contiguous row, or rarely three series on the tracheid walls. The medullary rays are usually uniseriate and 1—30 cells deep.

Dadoxylon Kayi Arber.

This species is represented by some large trunks, in some cases with a diameter of 40 cm., discovered by Mr Kay in the Coal Measures of Worcestershire⁴. The pith is very small and shows no indication of a discoid structure, but owing to its poor preservation no sections could be obtained of this region. The secondary wood is characterised by the large number of uniseriate medullary

rays 1—27 cells in depth; the tracheids have usually two or sometimes three rows of alternate and contiguous bordered pits on the radial walls. Arber regards the absence of a discoid pith as a fatal objection to a reference of the stems to *Cordaites* and speaks of them as affording further evidence of the occurrence of Coniferae in the higher Coal Measures of the Midlands. It is, however, impossible to determine the position of the species in the absence of any data with regard to the structure of the perimedullary region, and without such information we are hardly justified in regarding *Dadoxylon Kayi* as a member of the Coniferales.

Dadoxylon Pedroi Zeiller.

This species from Upper Carboniferous or possibly Lower Permian strata in Brazil¹ has a pith 3·8 cm. in diameter composed of parenchyma with scattered secretory sacs and characterised by the occurrence of three equidistant bays projecting into the cylinder of wood (fig. 476, A) which extend through the length of the specimen (6 cm.): these, as Zeiller suggests, may be connected with the departure of leaf-traces or branches. The xylem is entirely composed of centrifugal elements and shows a broad transitional zone (fig. 476, B) including spiral, scalariform, and reticulate tracheids, but the bordered pits are less numerous and less crowded than in many species of *Dadoxylon*. The rays are 1—2 cells broad and reach a depth of 50 cells. The most striking features are the solid and not discoid pith with its three rounded bays and secretory canals, also the smaller number and frequently circular form of the pits on the tracheids. Zeiller considers that the stem is that of some Cordaitean plant though probably not a true *Cordaites*. White² questions the advisability of adopting the generic name *Dadoxylon* and suggests the possibility, though without any satisfactory evidence, that it is the stem of a *Gangamopteris*. Failing further information, there would seem to be no sufficient reason for the institution of a distinctive generic name.

¹ Zeiller (95) B. p. 619, Pl. ix. figs. 8—19.

² White (08) B. p. 577.

Dadoxylon permiense (Renault).

This Permian species from Autun¹ differs from typical examples of the genus in the differentiation of the pith into a central thin-walled region contracted into transverse diaphragms surrounded by a cylinder of stouter tissue and in the greater breadth of the

FIG. 476. *Dadoxylon Pedroi*. A, transverse section showing the pith and part of the secondary wood. B, longitudinal section of part of the secondary wood. (After Zeiller.)

medullary rays. The tracheids have 3—4 rows of pits of the usual type. Spirally disposed, decurrent, leaf-bases occur on the surface of the stem, and the cortex includes secretory canals and strands of hypodermal stereome. A small number of veins pass up the median part of the lamina which in this respect and in its

¹ Renault (96) A. p. 350; (93) A. Pl. LXXVII.

greater thickness differs from that of *Cordaites* leaves. Renault speaks of the rays as a cycadean feature, but they are only two cells in width and shorter than in recent Cycads.

Dadoxylon spetsbergense Gothan.

In this species¹ from Spitzbergen, of doubtful age though probably Palaeozoic, there is no xylem-parenchyma and the medullary rays are from 2 to 5 cells deep; the bordered pits occur in 1—2 or rarely 3 rows on the radial walls of the tracheids; they are alternate but not flattened and characterised by their small size (7μ high); they do not cover the whole face of the tracheids. It is pointed out that in many Palaeozoic and Mesozoic *Dadoxylons* the pits are larger than in recent species (16 — 17.5μ as compared with 9 — 12μ) while in *D. spetsbergense* they are still smaller. The large size of the medullary-ray cells is another noteworthy feature, also the absence of annual rings, a character possibly connected with conditions of growth in northern regions. It is, however, pointed out by Nathorst² that the fossil was not found *in situ* and, as he says, it may have been carried by currents from a more southern locality.

Metacordaites. Renault.

Metacordaites Rigolloti Renault.

Renault founded this species³ and genus on a stem from Autun which, like *D. Pedroi*, differs in certain respects from stems usually attributed to *Cordaites*. The pith is solid and contains secretory ducts and cells; the tracheids have often a single row of pits, and multiseriate pitting is much less common than in *Dadoxylon*. The medullary rays are generally 1—6 cells deep. A striking feature is the occurrence of groups of five vascular bundles penetrating the secondary wood in V-shaped groups, each group being regarded as a multiple leaf-trace, a type recently recognised by Thomson in *D. Brandlingii*. In one of Renault's figures a larger scar, presumably a branch-scar, is shown immediately above a group of foliar bundles. The genus *Metacordaites* is considered by its author to be intermediate between Conifers

¹ Gothan (10) p. 5, Pl. I. figs. 1—3.

² Nathorst (11³) p. 222.

³ Renault (96)

and the Cordaitales, but nearer to the former. This conclusion is, however, based on insufficient evidence, as nothing is known of the reproductive organs.

ROOTS.

In 1871 Williamson¹ gave an account of a petrified plant from the Lancashire Coal Measures which he named *Dictyoxydon radicans*, but he afterwards came to the conclusion that the specimens so named were portions of the subterranean axis of some other plant, possibly *Asterophyllites*, and proposed a new generic term *Amyelon*². In 1874 he brought forward fresh evidence in support of connecting *Amyelon radicans* with *Asterophyllites* or *Sphenophyllum*, genera which Williamson believed to be very closely related. It has since been recognised that *Amyelon* is the root of *Cordaites* or of some closely allied member of the Cordaitales. Our knowledge of Cordaitan roots is based chiefly on the work of Williamson and Renault³, and more recently Osborne⁴ has added new facts of considerable interest. In the larger roots the primary xylem may be diarch or there may be as many as four or five protoxylem groups (fig. 477). The primary tracheids are spiral or scalariform and the space, *s*, separating them from the surrounding secondary xylem seen in fig. 477, B, was no doubt originally occupied by conjunctive parenchyma. The secondary wood is composed of tracheids, with contiguous bordered pits identical with those in the xylem of the stem, and narrow medullary rays. The section, 4 mm. in diameter, represented in fig. 477, A, shows a tetrarch primary xylem strand enclosed by secondary wood composed of rather thin-walled elements succeeded by a zone of phloem including some secretory sacs, and beyond this is a cylinder of periderm, *p*. In a section of a root figured by Renault from Autun the periderm is separated from the stele by a broad band of parenchyma which appears to be cortical, but in the British specimens the deep-seated origin of the periderm is clearly shown: Osborne states that it arises in a layer immediately outside the endodermis. In one of the specimens figured

¹ Williamson (72²).

² Williamson (74) A. p. 67.

⁴ Osborne (09).

by Williamson¹ the secondary wood shows clearly marked irregular concentric lines simulating rings of growth, but there is no evidence of any regularly recurring variation in the diameter of the xylem-elements. From the descriptions of Williamson and Osborne it

FIG. 477. A, root of *Cordaites*. B, centre of the root enlarged; *p*, periderm; *s*, space. (Kidston Coll. 1906.)

is evident that the roots of *Cordaites* were profusely branched and, as the latter author has shown, the method of branching points to the formation of coralline roots like those of recent Cycads, some Conifers and Dicotyledons. Osborne found that the cortex

¹ Williamson (74) A. Pl. ix. fig. 56.

of small rootlets is composed of two zones, an outer parenchyma without cell-contents and an inner parenchymatous tissue characterised by the occurrence in some of the cells of tangled masses of fungal hyphae almost always unseptate. In some cases the hyphae bear terminal vesicles similar to those observed on fungal hyphae in the cortex of *Podocarpus* roots. Osborne makes out a good case for regarding the fungus as symbiotically related to the tissues of the lateral roots, a relationship identical with that in many existing trees, particularly *Myrica* and *Alnus*. It is suggested that the formation of the coralline root-tubercles is a feature consistent with the view that *Cordaites* lived in saline marshes, a physiologically dry habitat favourable to the occurrence of mycorrhiza.

FIG. 478. Root (*Cordaites*?) exposed in the bed of the Vaal river.
(After Mellor and Leslie.)

Reference has already been made to the habit of Cordaitean roots in the general account of the genus (figs. 468, A, 478). The specimen shown in fig. 478 may be a root of *Cordaites* (*Noeggerathiopsis*) *Hislopi*, but nothing is known as to its structure¹.

¹ Mellor and Leslie (06) B.

REPRODUCTIVE ORGANS.

Cordaianthus. Grand'Eury.

We have as yet no definite knowledge of the nature of the reproductive organs of *Mesoxylon* and *Poroxyton*, but having regard to their close resemblance in other respects to *Cordaites*, particularly in the case of *Mesoxylon*, the presumption is that some of the seeds and fertile shoots attributed to *Cordaites* may belong to other members of the Cordaitales. Despite the abundance of *Cordaites*, or at least of material assigned to that genus, and the comparative frequency of fertile shoots in actual connexion with foliage-shoots, the practical identity of *Mesoxylon* and *Cordaites* leaves precludes any confident use of the latter name in a strict sense.

In 1822 Brongniart¹ described a small bud-like fossil of Tertiary age as *Antholithes liliacea*, and this generic name in the form *Antholithus* became widely used for fertile shoots or flowers from different geological horizons. As knowledge became more precise other names replaced *Antholithus*, though Renault² retained it for some inflorescences from Commeny which could not definitely be included in *Cordaites*. Lindley and Hutton³ employed the genus for a specimen, now recognised as a Cordaitan fertile shoot, from the Coal Measures which they called *Antholithus Pitcairniae*, the specific name being chosen to indicate a possible affinity to the Bromeliaceous genus *Pitcairnia*. A few years later Morris⁴ described a similar inflorescence as *A. anomalus*. In 1872 Carruthers⁵ substituted Brongniart's term *Cardiocarpon* for *Antholithus* and called *A. Pitcairniae Cardiocarpon Lindleyi* and Morris's species *C. anomalum*. The specific name *Lindleyi* has been widely adopted, but there would seem to be no adequate reason for disregarding the priority-rule. It is, however, customary to use Grand'Eury's term *Cordaianthus* for all Cordaitan inflorescences. Goepfert⁶ suggested the name *Botryoconus* for an inflorescence similar to *C. Pitcairniae* and for this C. E. Weiss⁷ substituted *Noeggerathianthus* on the ground that he considered Goepfert's specimen to be the male inflorescence of *Noeggerathia*.

⁵ Carruthers (72³) B.

⁶ Goepfert (65) p. 152.

⁷ Weiss, C. E. (69) B. p. 201.

Grand'Eury resuscitated *Botryoconus*¹ for some spikes from the Gard coalfield connected by him with *Dory-Cordaites*. The nature of the seeds borne by the inflorescences has largely influenced authors in the choice of a generic name: Carruthers used *Cardiocarpon* while Zeiller² speaks of *Samaropsis Pitcairniae*. The genus *Cardiocarpon* was founded by Brongniart for compressed cordiform seeds, but it was not until later that their gymnospermous nature was recognised. Further reference to the nomenclature of seeds of the *Cardiocarpon* type will be found in Chapter xxxv. The correlation by Grand'Eury and other authors of different species of inflorescences and species of *Cordaites* is frequently based on association, and in the absence of more satisfactory evidence the safer course is to deal with Cordaitean fertile shoots in a general sense.

(a) *Ovulate shoots*. These are represented by a considerable number of forms in both European and American localities. In rare cases the compound shoot reaches a length of 30 cm. (fig. 479), but it is usually much shorter; the lateral compact buds may be more or less widely separated: the seeds have long pedicels (fig. 480, A) or appear to be sessile (fig. 480, B) and there may be one or several seeds on a single lateral shoot. The seeds are platyspermic and, as seen in fig. 480, A, in some inflorescences they show very clearly the *Samaropsis* features. It would, however, be unsafe to assume that all *Samaropsis* seeds were borne on Cordaitean plants. Among other types of seed referred by authors to *Cordaites* are *Cardiocarpus*, *Cordaicarpus*, *Sarcotaxus*, *Taxospermum*, *Diplotesta*, and *Leptocaryon*. But in most cases there is no evidence of actual connexion

FIG. 479. *Cordaianthus*.

² Zeiller (00²) B. p. 211.

between seeds and vegetative organs, and while it is possible to state with confidence that many of the seeds represented by impressions described as species of *Samaropsis* and *Cordaicarpus* are undoubtedly Cordaitan, it is certain that not all seeds referable to these genera were borne by Cordaitalean plants. Cordaitan seeds are characterised by certain morphological features recalling those found in recent Cycads and in the seeds of *Ginkgo* as illustrated by species of *Cardiocarpus* and some allied types. As most of the Palaeozoic seeds known in a petrified state cannot be assigned to their parent-plants they are dealt with in a separate chapter¹.

Cordaianthus Pitcairniae (Lindley and Hutton).

This type of inflorescence² is considered by Kidston to belong to the tree which bore leaves known as *Cordaites principalis*, but if this is the case it is probable that the stem possessed the anatomical characters of *Mesoxylon*.

FIG. 480. A, *Cordaianthus Pitcairniae* with *Samaropsis* seeds. B, *Cordaianthus Volkmanni*. B', portion of B enlarged. (A, B, nat. size; Kidston Coll. 2374, 1174.)

The portion of an inflorescence shown in fig. 480, A, from the Middle Coal Measures of Yorkshire, illustrates the occurrence of

¹ See Chap. xxxv.

² Lindley and Hutton (33) A. Pl. LXXXII.; Carruthers (72³) B. p. 7; Kidston (03) B. p. 782; (11) p. 235.

the bud-like fertile shoots and the stalked *Samaropsis* seeds. A species described by Renault¹ from Commeny as *Cordaianthus acicularis* may be identical with the British species.

Cordaianthus Volkmani Ettingshausen.

The example of this species² seen in fig. 480, B, shows the relatively small size of the lateral buds, presumably unexpanded, compared with the large subtending bracts.

Petrified specimens of *Cordaianthus*.

Our knowledge of the structure of *Cordaianthus* is based on the researches of Renault³, supplemented by those of Prof. Bertrand⁴ to whose kindness I owe the photographs reproduced in fig. 481. The inflorescences described by Renault are referred by him to different species, but in the following brief account these are treated from a generic standpoint. The tangential section of *Cordaianthus Williamsoni* Ren. shown in fig. 481, D, was originally figured by Renault and more recently by Bertrand; it shows the spirally disposed leaf-traces in the lower part of a stout axis, and at the sides some vascular bundles are seen passing up into the bracts. A very small proportion of the bracts subtend ovules; two are seen at *a* and *b*, and at *c* is the tangentially cut micropylar canal of a third borne near the apex and covered by the terminal cluster of bracts. The ovule *a*, separated by a narrow space from its short stalk, consists of a thick single integument—not two as stated by Renault—extended at the apex as a micropylar canal: the apical extension is more completely shown in the tangentially cut ovule *b*. The central body is much contracted and the two spaces, *s*, at the base are regarded by Bertrand as cavities in the integument separated from one another by a central strand of conducting tissue which gives off two bundles to the integument, one at each end of the long axis of the seed (fig. 481, A, *v*). The dark patch, *n* (fig. D), is the upper and broader end of the shrunken nucellus the apex of which extends upwards as a slender beak, and this originally no doubt fitted into the micropyle. Fig. 481, C, shows a female inflorescence

¹ Renault and Zeiller (90) A. p. 592, Pl. LXXXIII. fig. 31.

³ Renault (79) B. p. 304.

⁴ Bertrand, C. E. (11).

FIG. 481. A, B, *Cordiaianthus Grand'Euryi*, ovule showing apex of nucellus, B, with microspores, *p*; *pc*, pollen-chamber; *b*, beak of nucellus; *v*, vascular bundle. C, transverse section of flower-bud with ovules, *a*, *b*. D, *Cordiaianthus Williamsoni*, longitudinal section; *a-c* ovules; *s*, spaces; *n*, nucellus. E, *Cordiaianthus Zeilleri*, transverse section showing four large ovules and one aborted ovule (*a*); *v*, vascular bundle. F, transverse section of male flower; *m*, microsporangia. (From photographs supplied by Prof. Bertrand.)

in transverse section; the stele consists of a ring of bundles separated by broad medullary rays and enclosing a comparatively large pith: the leaf-traces are seen in the cortex and one is cut through as it bends out into a bract which is not yet free from the axis. Two ovules, seen in section at *a* and *b*, are represented by the bilaterally symmetrical and compressed integument enclosing small pieces of nucellar tissue. Fig. 481, E, is a transverse section of an inflorescence at a higher level and above the apex of the axis: there are four large ovules and one aborted ovule, *a*. Bertrand describes two vascular bundles in the integument of the ovule *a*, one at each end of the long axis.

Fig. 481, A, B, *Cordaianthus Grand'Euryi* Ren., shows a longitudinal section of the nucellus, 1.5×0.7 mm., and part of the integument of an ovule at the time of pollination, which was probably aided by the secretion of a drop of mucilage as in the ovules of recent Conifers. The integument, separated by a broad space from the nucellus, is cut in the plane of the two vascular strands, *v*. From the centre of its broad upper surface the nucellus projects upwards as a beak, *b*, and this originally engaged with the micropylar canal formed by the integument: the lighter patch below the beak is the pollen-chamber (fig. 481, B, *pc*) containing two microspores, and two more, *p*, are seen above the nucellar beak. In another species described by Renault, *C. Lacattii*, the nucellus fills the space bounded by the integument.

(*b*) *Staminate inflorescences*. The male inflorescence, though smaller, is similar in habit to the ovulate shoot: the secondary branch consists of a short axis bearing crowded, spirally disposed, bracts, and the actual flowers are represented by single stamens or groups of 2—3 highly specialised microsporophylls. Each microsporophyll consists of a long filament with a central vascular strand bearing at its apex 3—4 long microsporangia (fig. 481, F, *m*) which open longitudinally as seen in fig. 482, A. The microsporangia are 2.5—3 mm. long covered by dark palisade cells and thin-walled parenchyma, shown as indistinct patches in the photograph. Some of the elliptical and comparatively large microspores are seen in fig. 482, B; the exine is finely punctate and inside are the remains of a few thin cells in which presumably

spermatozoids were developed. The microspores shown in fig. 482, B, have a maximum length of 0.1 mm.: Renault describes some as 0.9 mm. long while others are much smaller. Fig. 481, F, is a transverse section of a staminate inflorescence showing near the centre five groups of microsporangia, each sporangium having the form of a curved incomplete dark band indicating that dehiscence has occurred.

FIG. 482. *Cordaianthus*. Microsporangia, A, and Microspores, B.
(University College Collection, London.)

Mesoxylon. Scott and Maslen.

This generic name was instituted for stems obtained by Messrs Lomax from the Lower Coal Measures of Lancashire¹ previously referred by Scott² to *Cordaites* and *Poroxylon*. Further investigation showed that while agreeing closely with those genera they possessed certain distinctive features demanding recognition. The name chosen suggests the intermediate nature of the stems. The more striking features may be summarised as follows: In the largest specimens so far described the stem,

¹ Scott and Maslen (10); Scott (12).

² Scott (09) B. pp. 511, 526.

including leaf-bases, reaches a diameter* of 5 or 6 cm.; the large pith consists in the central region of diaphragms of parenchyma separated by horizontal spaces produced by splitting and shrinkage consequent on the failure of the tissue to keep pace with the general growth of the stem. The secondary xylem is of the Araucarian type and has narrow medullary rays varying in depth from 1 to 25 cells. The leaf-traces are represented by twin-bundles which fuse in the downward direction, the level at which fusion occurs being regarded as a specific character. The presence of centripetal xylem is an essential feature of the traces: the occurrence of single or double traces consisting of centripetal elements and, externally, a large amount of centrifugal xylem is an important feature in which *Mesoxylon* differs from *Cordaites*. The double leaf-traces divide after emerging from the secondary wood and each strap-like leaf receives several collateral bundles (fig. 483, C). An axillary bud may occur at the base of each leaf (fig. 483, A, b). The phloem, including sieve-tubes and secretory sacs, is succeeded by a broad pericycle, and the comparatively narrow cortex is traversed by successive bands of periderm. In the outer region of the cortex the presence of radial bands of fibres is a characteristic feature. The reproductive organs are unknown. The anatomical features are well illustrated by *M. Sutcliffii* first described by Scott, who provisionally placed it in *Poroxylon*, and afterwards more fully investigated by Maslen¹.

Mesoxylon Sutcliffii Scott.

The average diameter of the stem is 3 cm.: the section reproduced in fig. 483, A, has a maximum breadth of 3.5 cm.; the leaf-bases cut at different levels give an irregular contour to the surface like that of a *Lepidodendron*. An axillary bud, either reproductive or vegetative, is seen at *b* consisting of a short axis bearing crowded bud-scales. The leaves are crowded and according to Maslen have a phyllotaxis of $\frac{8}{21}$: the lamina is linear like that of *Cordaites* with 16 collateral bundles in the petiole. The presence of a meristematic band at the base of the lamina affords evidence of a deciduous habit. The large size of the pith is a striking feature with its central tissues in the form of transverse diaphragms

¹ Maslen (11).

C. *lt*, leaf-traces in the cortex; *s*, stele of axillary branch; *ph*², secondary phloem. D. Leaf-trace bundles, *lt*, external to the phloem, *ph*². (A, C, D, sections in the Manchester Collection, 717 *b*; B, Cambridge Botany School, 530.)

and a narrower peripheral zone of solid parenchyma (fig. 483, A, *a*). The secondary wood of the stele is composed of tracheids with 2—3 contiguous alternate rows of bordered pits on the radial walls, but none on the tangential walls. In the stem shown in fig. 483, A, the secondary wood is preserved only in patches. Numerous blunt teeth varying in prominence project into the pith; these consist chiefly of serially disposed centrifugal tracheids distinguished by their spiral and scalariform structure and by the medullary rays which are broader than those in the more external xylem. Further reference is made to these perimedullary strands in the description of the leaf-traces. The medullary rays are uniseriate and usually 1—6 cells in depth: beyond the secondary wood is a cambium and a cylinder of secondary phloem (fig. 483, D, *ph*²) consisting of tubular elements, presumably sieve-tubes, and elongated secretory sacs. The pericycle is composed of several rows of rather large and short cells and has an ill-defined outer boundary. A succession of arcs of periderm-like tissue and phellogen, which may invade the pericycle and phloem, forms a prominent feature in the cortex; radially placed bands of fibres similar to those in *Lyginopteris* and other genera occur in the outer cortex. At the edge of the pith the more prominent projections of xylem are arranged in pairs (fig. 483, B) and as each pair travels downwards the component strands gradually fuse¹. Each bundle of a double trace consists internally of an arc of centripetal xylem, the elements of which are arranged in rows (fig. 483, B, *cp*), with a single protoxylem group in the middle of the inner face, *px*. It is not clear whether any primary centrifugal tracheids are present, but there are indications that such are occasionally represented. In most cases the primary xylem of the leaf-traces is exarch, but the existence of mesarch bundles is not improbable. The bulk of each foliar bundle is formed of a fan-shaped mass of secondary centrifugal xylem (fig. 483, B, *cf*) and an island of parenchyma occurs next the protoxylem. There is no clearly defined boundary between the outer or centrifugal xylem of the leaf-traces and the tracheids of the stem-wood; the latter may consist exclusively of tracheids

¹ Maslen (11) Pl. XXXIII. figs. 3—5.

with bordered pits or the inner rows of the xylem-cylinder may be of the scalariform or spiral type. Differences shown in transverse sections of the inner portion of the xylem are due to the circumstance that in certain parts of the inner face of the secondary wood leaf-traces are unrepresented, while in other places the dwindled remains of the outer, centrifugal, portions of a trace are still recognisable. As each double leaf-trace passes down the pith the bundles fuse and the single strand retains for a time some centripetal xylem; this gradually disappears and at a lower level the centripetal xylem also dies out. The space enclosing the obtuse apices of the bundles shown in fig. 483, B, was originally occupied by thin-walled tissue which accompanied the trace in its outward course. In *Mesoxylon Sutcliffii* the leaf-strands pass almost horizontally through the secondary wood, bend outwards in the phloem and follow a steeply ascending course to the leaves. In fig. 483, B, a double leaf-trace is seen at the inner edge of the secondary wood with the centrifugal xylem, *cf*, continuous with that of the stele: fig. 483, D, *lt*, shows a leaf-trace in the pericycle where one of the bundles has divided and the other is tangentially extended and partially divided. The branching is carried further in the cortex, as seen in fig. 483, C, where the trace is represented by a curved row of six bundles, *lt*, and at a higher level further subdivision may occur. The leaf-bundles are collateral and in the leaf retain both centripetal and centrifugal tracheids. In the section shown in fig. 483, C, the oval stele of an axillary shoot is seen at *s* subtended by the row of collateral bundles: the stele has a fairly large pith surrounded by a zone of secondary xylem with broad medullary rays.

Among other species of *Mesoxylon* mention may be made of *M. Lomaxi* and *M. poroxyloides*. *M. Lomaxi* Scott and Maslen¹ generally resembles *M. Sutcliffii* but shows the following distinctive features: the leaves are more scattered and less crowded; the twin-bundles of the leaf-traces fuse immediately on entering the pith, thus appearing for the most part as single and not double

¹ Scott (12) p. 1012, Pls. LXXXVII., LXXXIX.

strands in the perimedullary zone; the centripetal xylem is well developed, the medullary rays are deeper and the outer cortex has shorter bands of mechanical tissue.

In *Mesoxylon poroxyloides* Scott and Maslen¹, the twin-bundles of the traces unite soon after reaching the pith as in *M. Lomaxi*; the secondary tracheids have only two rows, or sometimes a single row, of bordered pits and the tracheids are rather smaller than in *M. Lomaxi* (20—40 μ as compared with 30—60 μ) and the medullary rays are shallower. There is a particularly broad zone of spiral and reticulate transitional tracheids at the inner edge of the wood as in *Cordaites* and in *Dadoxylon Pedroi* (fig. 476). The leaves of this species are believed to be represented by the type described by Dr Benson as *Cordaites Felicis* (fig. 465)², but, as already suggested, it is very probable that many or possibly nearly all the leaves from British Coal Measures described as *Cordaites* may belong to *Mesoxylon*.

The chief interest of the genus *Mesoxylon* is its close resemblance in certain characters to *Cordaites* and *Poroxyylon*: the presence of strands of centripetal xylem in the perimedullary region is an important feature in which *Mesoxylon* differs from stems assigned (under the generic name *Dadoxylon*) to *Cordaites*. *Mesoxylon* differs from *Poroxyylon* in having a discoid pith like that of *Cordaites*, but a more important difference is the absence in the leaf-trace xylem of *Mesoxylon* of bordered pits of the Araucarian type, whereas in *Poroxyylon* Araucarian pits occur in both the centripetal and centrifugal tracheids. In *Poroxyylon* the secondary xylem is manoxylic; in *Mesoxylon*, as in *Cordaites*, it is pycnoxylic.

The range of *Cordaites* and a consideration of other imperfectly known genera.

An increased precision in knowledge derived from anatomical investigation often tends to demonstrate the untrustworthiness of criteria based on external features previously employed with confidence. This inevitable though, from the point of view of the systematist, inconvenient result of intensive study is well illustrated by the recent discovery of the stems named by

¹ Scott (12) p. 1017, Pls. LXXXVIII., xc.

² Benson (12).

Scott and Maslen *Mesoxylon*¹. A separation of *Cordaites* from *Mesoxylon*, which no doubt extended far beyond the British area, is possible only if well-preserved petrified material is available. The leaves of *Mesoxylon*, so far as our imperfect knowledge of them enables us to express an opinion, are constructed on a plan almost identical with those of *Cordaites* and, as already stated, it is almost certain that many of the impressions referred to *Cordaites* were borne on *Mesoxylon* stems. An additional source of confusion is supplied by the *Cordaites*-like leaves of *Poroxylon*. It is evident, therefore, that even within the limits of the Carboniferous and Permian formations the recognition of true *Cordaites* leaves must often be attended with considerable risk of error. Apart from the possible confusion between the foliage of *Cordaites* and *Mesoxylon* there are other difficulties as regards detached leaves which depart more or less widely from the typical Cordaitean form. Leaves such as *C. circularis* (fig. 468, B) and *C. grandifolius* emphasise the lack of any thoroughly satisfactory dividing line separating single pinnules of *Cardiopteris* or *Cyclopteris* on the one hand and leaves of *Psymmophyllum* on the other from *Cordaites*. The petrified buds described as *Dolerophyllum*² have been quoted by several authors as examples of unexpanded shoots of *Cordaites* though anatomical evidence warrants a generic separation. In the case of species founded on leaves described in this chapter as *Cordaites* it should be remembered that further research may necessitate an alteration in nomenclature.

Among the species included in *Cordaites* is *Noeggerathiopsis Hislopi*³ (figs. 470—472), a type widely spread in India and in other parts of Gondwana-Land: if the change of generic name is accepted it involves the extension of the geographical range of *Cordaites* from Northern Europe and North America to the southern botanical province. We have as yet no proof of the existence of *Cordaites* in the Arctic regions. The range in time of *Cordaites* or of the Cordaitales has generally been stated to be from the Upper Devonian to the Permian. It is, however, by no means certain that the genus flourished before the Carboniferous period, though it is clear that closely allied types must have lived in

¹ See page 270.

² See page 132.

³ See page 238.

pre-Carboniferous floras. The strata in New Brunswick from which Dawson recorded his supposed Devonian *Cordaites* have been shown to be Upper Carboniferous in age¹. As regards the length of time during which the Cordaitales existed we have no decisive evidence. In recent years the tendency has been to extend their range into the Mesozoic era, and there are several pieces of evidence in favour of this. There is no doubt that considerations of age based on the arbitrary divisions of the geological scale sometimes insinuate themselves too thoroughly into questions connected with the duration of plant-types whether represented by families or genera. We have been accustomed to regard *Cordaites* as a genus confined to the Palaeozoic period, a type which with many others carried on the tradition of Upper Carboniferous forests to the Permian floras and then made way for the precursors of Mesozoic types. There is, however, no valid reason for supposing that *Cordaites* and other Palaeozoic genera did not survive as less prominent members in succeeding floras. It must be admitted that evidence in support of Mesozoic Cordaitales is not above suspicion, though the probability is that *Cordaites* or some allied genera still flourished in the earlier stages of the Mesozoic era. The data on which this opinion is based cannot be fully discussed in a general treatise, but a few of the facts may be briefly considered. Zeiller² and other authors have expressed the view that the Cordaitales were not exclusively Palaeozoic. In addition to *Cordaites* (*Noeggerathiopsis*) *Hislopi* recorded from Rhaetic floras, other possible representatives of the group are illustrated by specimens included in such genera as *Yuccites*, *Bambusium* and *Krammera*.

Pelourdea gen. nov.

The name *Yuccites*³ was given to some detached, broad, linear leaves from the Bunter sandstone of the Vosges which were compared with the foliage of *Yucca* and classed among Monocotyledons. The authors of the genus also described a cylindrical cast as a *Yuccites* stem, including both stem and leaves in *Yuccites vogesiacus*.

¹ Stopes (14); Kidston (02) B. p. 363.

² Zeiller (00²) B. p. 213.

³ Schimper and Mougeot (44) A. p. 42, Pl. XXI.

The supposed stem, as Fliche¹ has shown, is a pith-cast and is appropriately named by him *Endolepis vogesiacus*. The Vosges leaves are assigned by this author to the genus *Cordaites*, a change of name which may eventually be justified though as yet based on insufficient evidence. There are objections to the institution of a new name in place of *Yuccites*, but it is undesirable to retain a designation suggesting false ideas with regard to affinity. A new name *Pelourdea* (after M. Pelourde of Paris, whose recent death deprives Palaeobotany of an able and promising investigator) is therefore proposed for leaves of the *Yuccites* type which in form, venation, and spiral phyllotaxis agree with those of *Cordaites* but cannot confidently be assigned to that genus or even to the Cordaitales. For linear leaves, especially from Jurassic strata, resembling those of *Phoenicopsis* the name *Desmiophyllum*² is employed: these are very similar to those of *Pelourdea*; they are characterised by their fairly uniform breadth and afford no indication of their arrangement on the supporting axis.

Pelourdea vogesiaca (Schimper and Mougeot).

The linear-lanceolate leaves described by Schimper and Mougeot as *Yuccites vogesiacus* and transferred by Fliche to *Cordaites* are probably specifically identical with specimens described by Mr Wills³ from Lower Keuper rocks in Worcestershire. The English leaves were described by Arber⁴ as *Zamites grandis*,—the name *Zamites vogesiacus* having been previously used by Schimper and Mougeot,—on the ground that the supposed leaves were probably pinnae of a cycadean frond, a view in agreement with an opinion previously expressed with regard to similar leaves from Stonesfield⁵. A later discovery by Wills of specimens, on which the drawing reproduced in fig. 484 is based, of the same type of leaf showing the foliar nature of the fossils necessitated the abandonment of the pinna-hypothesis, and the original name *Yuccites vogesiacus* was resuscitated⁶. The leaves reach a length of 50 cm. and a maximum breadth of 6.5 cm.; the lamina is entire, lanceolate or linear-lanceolate, the apex

⁶ Arber (09²).

acuminate, and the lower part rather abruptly contracted and attached by a broad crescentic base; veins numerous, parallel, and occasionally forked. Fliche records the occurrence of a small *Artisia*-like pith-cast and pieces of stem with leaf-scars (4×3 mm.) in association with leaves of *Pelourdea vogesiaca* in

FIG. 484. *Pelourdea vogesiaca*. Reconstruction of a foliage-shoot.
(After Wills.)

Triassic strata in Lorraine. An imperfectly preserved specimen described by Fliche as *Cordaianthus Minieri*¹ resembles an inflorescence of *Cordaites*. It consists of an axis 15 cm. long, the lower part forming a peduncle, and on the upper portion are linear bracts subtending oblong bodies which may be lateral fertile shoots.

¹ Fliche (10) p. 264, Pl. xxvii. fig. 2.

Pelourdea hadroclada (Halle).

Dr Halle¹ recently published an account of some imperfect leaves and stem-fragments from the Rhaetic of Scania which he named *Phyllotenia* (?) *hadroclada*, the generic name provisionally adopted having been proposed by Salfeld² for some rather obscure remains from the Corallian of Germany. It appears to have escaped the notice of both authors that Saporta³ in 1894 had adopted the designation *Phyllotenia* for some examples of broad parallel-veined leaves from Lower Cretaceous rocks in Portugal very similar to Velenovsky's *Krammera mirabilis*⁴. Some other generic name must therefore be used. For the Rhaetic species the name *Pelourdea* would seem appropriate. The type-specimen consists of an axis 10—12 mm. in diameter with spirally disposed transversely elongated leaf-scars bearing sessile linear leaves similar to *Poa-Cordaites*; none of them are complete, the largest is 6 cm. long and 5—7 mm. broad with 8—12 parallel veins. An examination of the original specimens in the Stockholm Museum satisfied me that Dr Halle is justified in the opinion that they may be fragments of some Cordaitalean plant and that he was well advised to avoid the use of the name *Cordaites*. Salfeld's species, *Phyllotenia longifolia*, may be an imperfectly preserved example of *Phoenicopsis*⁵, but the material is too incomplete to be identified with any degree of confidence.

Pelourdea Imhofi (Heer).

The Triassic leaves from Switzerland described by Heer⁶, and more recently by Leuthardt⁷, as *Bambusium Imhofi*, were referred by Fliche⁸ to the genus *Cordaites*. The lamina is ensiform, 25 cm. long with a maximum breadth of 2.4 cm. Leuthardt's photograph of aerial stems and rhizomes of this supposed Monocotyledon are far from convincing.

Pelourdea keuperiana (Compter).

The leaves from the Lower Keuper of Thuringia assigned by Compter⁹ to *Cordaites* without adequate evidence resemble those

¹ Halle (10).³ Saporta (94) B. p. 216, Pl. xxxviii.⁴ Velenovsky (85) B. p. 1, Pls. I., IV.⁶ Heer (76) A. p. 86, Pl. xxx. fig. 10.⁸ Fliche (10) p. 175, Pls. xvi., xvii.² Salfeld (09) B. p. 26.⁵ See *postea*.⁷ Leuthardt (03), p. 6, Pl. I.⁹ Compter, G. (94), Pl. iv. fig. 9.

of *P. vogesiaca*, but there is no evidence as to their manner of attachment; they are 30—40 cm. long and from 1.5 to 2 cm. broad.

Pelourdea megaphylla (Phillips).

This species was first described by Phillips¹ from the Middle Jurassic Stonesfield Slate and afterwards referred to *Zamites*²: the leaves bear a striking resemblance to foliage of the type *Cordaites borassifolius*; the lamina is 30 cm. long and attains a breadth of 3 cm., the apex is acuminate and slightly contracted towards the broad concave base. My former comparison of these Stonesfield leaves with the long pinnae of *Ceratozamia mexicana* seemed to be supported by Phillips's type-specimen of *Palaeozamia longifolia*. It may be that the supposed pinnae in Phillips's type are spirally disposed leaves: if this is the case the specimen may be a fragment of a *Podozamites*; its specific identity with the larger detached specimens, though probable, cannot be demonstrated. Some leaves figured by Zigno³ from Jurassic rocks of Italy as *Yuccites Schimperianus* may be identical with *P. megaphylla*.

Pelourdea mirabilis (Velenovsky ex Corda ms.).

The generic name *Krammera*, suggested by Corda, was employed by Velenovsky⁴ for large *Cordaites*-like leaves from the Lower Cretaceous of Bohemia, for casts of cones regarded by him as stems, and for fruit-like bodies. The leaves, previously described as *Flabellaria chamaeropifolia* Goepp., *Dammara albens* Presl, etc., bear a close resemblance to the large broadly linear leaves of *Cordaites*; the lamina reaches a length of 40 cm. and between the veins occur 1—4 finer striations. The fossils identified by Velenovsky as stems bearing crowded imbricate scales, which he regarded as the persistent bases of *Krammera* leaves, are probably cones; they agree very closely in size and shape, also in the form of the scales, with cones of *Agathis* and some other recent Conifers. As the designation *Krammera* was instituted primarily for cones and not leaves the name *Pelourdea* is substituted for it.

³ Zigno (85), p. 7, Pl. xxvi.

⁴ Velenovsky (85) B. Pls. I.—III.

Niponophyllum. Stopes and Fujii.

Niponophyllum cordaitiforme Stopes and Fujii.

The generic name *Niponophyllum*¹ was proposed for some petrified specimens of leaves or possibly leaflets from Upper Cretaceous beds in Japan which, though not definitely assigned to a group or family, are considered by the authors of the genus 'to lie [anatomically] somewhere between *Cordaites* and *Cycadeoidea*' 'with a closer similarity to the former than to the latter if we compare the whole *Cordaites* leaf with our blade.' The data on which this conclusion is based are, however, insufficient to justify a reference of *Niponophyllum* to the Cordaitales or indeed to lend any substantial support to the opinion that the Japanese specimens are anatomically more akin to *Cordaites* than to other plants. The type-species is represented by two specimens of leaf-fragments about 0.4 mm. thick and from 6 to 9 mm. broad containing from 21 to 33 vascular bundles; the upper part of the mesophyll is composed of palisade tissue and the stomata appear to be confined to the lower epidermis. Each bundle is accompanied by an I-shaped girder, and small patches of sclerenchyma occur next the upper epidermis between the girders; there are no resin-canals: the vascular bundles are collateral, the xylem is said to be almost entirely centripetal and exarch, but in the absence of evidence afforded by longitudinal sections the details of structure cannot be definitely determined. A comparison is made with Cycadean leaves and with leaves of Araucarineae and Podocarpeae, also with *Cordaites*; another type with which *Niponophyllum* may be compared is *Desmiophyllum Solmsi*².

The genus is interesting as an example of a petrified gymnospermous type of leaf characterised by the absence of resin-ducts and transfusion-tracheids, the possession of collateral, apparently exarch, bundles enclosed in a double sheath; but the data supplied are insufficient to enable us to allocate the specimens to a position within the class.

¹ Stopes and Fujii (10) p. 16, Pl. III. figs. 14—16.

² See *postea*.

A specimen described by Schenk¹ as *Eolirion primigenium* from Lower Cretaceous beds in the Carpathian mountains closely resembles in habit a foliage-shoot of *Poa-Cordaites*; the leaves are narrow and linear with obtuse apices and attached, apparently, in a close spiral. Schenk assigns the plant to the Monocotyledons, but its systematic position must be left unsettled.

The list of Mesozoic specimens resembling *Cordaites* leaves might be extended. Apart from some Triassic and Rhaetic examples which may well be Cordaitalean, there are many others which, though similar in form and venation to *Cordaites*, are in all probability more closely related to *Agathis* and other genera; the species *Dammarites Bayeri* recently described by Zeiller² from the Upper Cretaceous of Bulgaria is a case in point. The Araucarian character of the wood of *Cordaites* precludes any satisfactory discrimination between Mesozoic Araucarian stems and those of Cordaitalean species, at least in the case of such material as is usually available.

Titanophyllum. Renault.

Titanophyllum Grand'Euryi Renault. The remarkable leaves on which this genus and species are founded³ were discovered in the Commentry coalfield; they occur as detached specimens and cannot be correlated with any known stem. Renault suggests that the Autun stems referred to *Colpoxyton* may have borne the *Titanophyllum* leaves, but this correlation rests only on the dimensions of the stems and the occurrence of transversely elongated scars on the surface. The lamina is thick and coriaceous, 70—75 cm. long and 20—25 cm. in breadth; the veins are parallel but not branched; numerous longitudinal striations on the upper surface indicate the presence of hypodermal stereome-strands; stomata are abundant on the lower surface and the more or less rectangular cells in the neighbourhood of the stomata appear to be papillose (fig. 485, A, B). The distal region of the lamina

¹ Schenk (71) p. 20, Pl. VII. fig. 4.

² Zeiller (05²) p. 17, Pl. VII. figs. 8—11.

³ Renault and Zeiller (90) A. p. 627, Pl. LXIX. figs. 1—4.

is often torn into strips (fig. 485, A); the approximately rectangular leaf has a broad elliptical base 9—10 × 3—4 cm.

FIG. 485. *Titanophyllum Grand'Euryi*. A, leaves $\frac{1}{30}$ nat. size; B, stomata on the lower surface of the lamina. (After Renault and Zeiller.)

Dr White¹ describes a specimen from the Lower Coal Measures of Missouri as ? *Titanophyllum Brittsii* which he speaks of as the thick base of a leaf similar to that described by Renault but, as White says, no formal diagnosis is possible without more satisfactory material. Such evidence as is available suggests that *Titanophyllum* is a type of Cordaitalean leaf probably closely allied to *Cordaites*.

CHAPTER XXXIV.

CORDAITALES.

C. PITYEAE.

Pitys. Witham.

THIS generic name in the form *Pitus* was first used by Witham¹ for some petrified pieces of large stems from Lower Carboniferous strata in the south of Scotland (Berwickshire). In an earlier paper Witham² gives an account of the beds on the banks of the Tweed from which the specimens of *Pitys* and other plants were obtained. The name was revived by Goeppert³ as a substitute for *Pissadendron*⁴ adopted by Endlicher and Unger: Scott⁵ employed the older name in the account of his investigations, which have added greatly to our knowledge of Witham's types. The distinguishing characters of *Pitys* are: the Araucarian pitting of the secondary xylem, the large pith, the occurrence of numerous small primary xylem strands of mesarch structure in the peripheral region of the pith, and the simple nature of the leaf-traces. Nothing is known of the extra-stelar tissues, and beyond the fact that the species were arborescent we have no information with regard to the foliar⁶ or reproductive organs.

Pitys antiqua Witham.

In 1899 Scott⁷ published a preliminary description of some sections in the possession of Dr Kidston from Lennel Braes (Berwickshire: Calciferous series) under the name *Araucarioxylon antiquum*, but in the more complete account the name *Pitys*⁸ is adopted. The following description is based on Scott's paper

¹ Witham (33) A. pp. 37, 71.

² Witham (30).

³ Goeppert (81) p. 403.

⁴ Endlicher (47) p. 297.

⁵ Scott (02) p. 346.

⁶ See footnote p. 288.

⁷ Scott (99²); Witham (33) A. Pls. III.—VIII. XVI.

⁸ Scott (02), p. 346, Pls. I., II., V., VI.

and on the examination of the sections. Fig. 486 represents a diagrammatic sketch of a section (2.7×2.7 cm.) of the central region of a stem which had lost most of its secondary wood. In some cases the pith reaches a diameter of 3 cm.; it consists of large parenchymatous cells broader than deep, several of which contain a black substance and are probably secretory elements: the intercellular spaces are fairly large. Horizontally extended gaps, due to shrinkage and collapse, occur in the pith and give to it an appearance not unlike that of *Cordaites*. Numerous small elliptical strands of primary xylem, 0.15—0.3 mm. in diameter, are scattered in the peripheral region (fig. 486) at varying distances from the inner edge of the secondary wood and occasionally,

FIG. 486. *Pitys antiqua*. Central region of stem, showing primary xylem strands as black dots. (Kidston Collection, 598 A.)

when about to bend outwards as a leaf-trace, a primary xylem-strand abuts directly on the secondary xylem. The protoxylem occupies a more or less central position in each mesarch strand (fig. 487, B, *px*): the centrifugal tracheids have the Araucarian pitting while the centripetal elements are spiral. A few parenchymatous cells are associated with the more central tracheids. A leaf-trace about to bend outwards into the zone of secondary wood is double, but at a slightly higher level in its course it assumes the form of a single strand. The foliar bundles are thus single and not true double traces. Scott recognised, at the extreme edge of the pith, an association with outgoing leaf-traces of a single reparatory strand deeper in the medullary tissue. In this species there is no evidence that an outgoing trace is accompanied by an arc of secondary xylem, but that such was the case is rendered highly probable by the discovery of an arc of wood added by the cambium to a leaf-trace in *Pitys Withami*¹. The radial disposition of the pith-cells, many of which appear to be secretory, around each primary xylem-strand (fig. 487, B) is a characteristic feature. A difficult problem, namely the relation of primary xylem and

¹ Scott (02) p. 355.

phloem, is raised by the fact that the primary strands are composed exclusively of xylem and are in most cases separated from the secondary wood by several parenchymatous cells. Scott favours the view that the primary phloem was originally at some distance from the primary xylem, the cambium being formed nearer to the phloem, an arrangement foreign to recent Gymnosperms. It is perhaps conceivable that the primary conducting strands included no true phloem.

FIG. 487. *Pitys antiqua*. A, radial section of secondary xylem; B, transverse section showing the inner edge of the secondary wood and two primary-xylem strands with protoxylem, *px*. (Kidston Coll.)

The secondary xylem consists of tracheids with 4—5 alternate rows of hexagonal pits on the radial walls (fig. 487, A) and not infrequently on the tangential faces. Near the ends of the tracheids the pits are occasionally more scattered and separate and may be reduced to a single row¹, but on the whole the pitting is essentially Araucarian. The medullary rays are generally 4 cells in breadth, but may be 7 cells broad. In depth the rays extend to 70 cells. As seen in fig. 487, B, the inner ends of the rays are especially broad owing to the tangential dilatation of the cells. The innermost secondary tracheids are characterised by pitting intermediate between spiral and reticulate. There are no regular rings of growth in the wood.

Pitys primaeva Witham. This species², also founded on material from the Calciferous sandstone of Berwickshire, differs

¹ Witham (33) A. Pl. VIII. fig. 2.

² *Ibid.* p. 39, Pls. VIII., XVI.; Scott (02) p. 355, Pls. II., VI.

from *P. antiqua* in the broader and shorter form and greater breadth of the medullary rays (fig. 488, A, B), also in the larger tracheids and in the less crowded arrangement of the bordered pits in which the circular form sometimes replaces the hexagonal

FIG. 488. *Pitys primaeva*. A, transverse section of the secondary xylem; B, tangential section of the secondary xylem. (From sections of the type-specimen in the Edinburgh University Botanical Department.)

type. The structure of the pith is not known, but Scott was able to recognise in the partially preserved pith of a branch indications of primary-xylem groups and other features pointing to a close resemblance to *P. antiqua*¹. A piece of stem originally

¹ Since this chapter was written Prof. W. T. Gordon has kindly supplied the following summary of his unpublished work on the genus *Pitys*.

'The re-examination of *Pitys primaeva* and *P. antiqua* in the light of the structure exhibited by numerous specimens of a new species recently discovered in Haddingtonshire has shown that all three types are similar as regards the structure of the primary wood. In each case the primary cylinder is comparable with that in *Archaeopitys Eastmanii* [see p. 290], *i.e.*, there are medullary as well as circum-medullary xylem-strands. In certain specimens of the new species, *Pitys Dayii*, the bark and leaves are preserved and thus the details of leaf-trace emission from the stem have been determined. The leaves are short and stout and taper gradually to a point, quite distinct from the long, thin, spatulate Cordaitan foliage. The internal structure of the leaf renders it easily distinguishable from the *Cordaites* type while it tends to accentuate the possible relationship of *Pitys* with the Lyginodendreae.'

described by Williamson¹ as *Lyginodendron* (?) *anomalum* from the Lower Carboniferous volcanic ash of the Isle of Arran would appear to be closely related to, if not specifically identical with, *P. primaeva* and, as Scott says, it should at least be included in the same genus.

Pitys Withami (Lindley and Hutton). The Craiglieth Tree.

1831. *Pinites Withami* Lindley and Hutton, Foss. Flora, Vol. I. Pl. II.

1831. *Pinites medullaris*, Ibid. Pl. III.

1902. *Pitys Withami* Scott, Trans. R. Soc. Edinb. Vol. XL. p. 354, Pl. II. fig. 10: Pl. VI. fig. 21.

This species was founded on some sections cut from an incomplete stem 36 feet long obtained in 1826 from the Calciferous sandstone of the Craigleith quarry near Edinburgh. The specimen named by Lindley and Hutton *Pinites medullaris* is no doubt specifically identical with the larger stem. In the same year (1831) Witham² published an account of a still larger stem from the same locality, 47 ft long and 5 ft in diameter in the lower part, and in his book the name *Pinites Withami* is adopted. A large specimen of this tree is erected in the grounds of the Natural History Museum, London, and other specimens are preserved in the Edinburgh Botanic Garden. Goeppert in 1850 referred the species to *Dadoxylon* and later to *Pitys*³, while Brongniart⁴ assigned it to his genus *Palaeoxylon*. Scott⁵ who examined Witham's sections placed it in *Pitys*. The pitting of the secondary tracheids is often multiseriate, but the medullary rays are narrower than in *Pitys antiqua* and *P. primaeva*, rarely exceeding 4 cells in breadth, though still of the manoxylic type. Primary-xylem strands occur in the peripheral region of the pith agreeing closely with those of *P. antiqua*. There are no regular and continuous annual rings though as Witham stated there are concentric markings on the wood which superficially resemble true rings. The leaf-traces are single and in their passage through the cylinder of wood an arc of secondary tracheids is added to the primary elements.

⁵ Scott (02) p. 354.

Archaeopitys. Scott and Jeffrey.

Archaeopitys Eastmani Scott and Jeffrey. The genus *Archaeopitys*¹ has recently been instituted for a specimen of a stem from the Lower Carboniferous rocks of Kentucky which differs from *Pitys antiqua*, the type with which it is most closely allied, in the position and behaviour of the primary vascular strands in the pith. The type-specimen is a piece of stem 2·7 cm. in diameter including a solid parenchymatous pith 5·5 mm. broad and a cylinder of secondary wood. The wood is similar to that of *Cordaites*; the tracheids have 2—3 rows of pits but for the most part the details of structure are not preserved; the medullary rays are both uniseriate and multiseriate and not very deep; the structure is more Cordaitean than Cycadean. A characteristic feature is the occurrence of about 30 vascular bundles in the medullary region: these mesarch strands, with the protoxylem near the centre, are scattered through the pith and several lie on the outer edge in contact with the secondary xylem or are partially embedded in the xylem-cylinder. The examination of a series of sections demonstrated the fusion of perimedullary with medullary strands and the occasional union of the strands of both regions with one another. It appears that the perimedullary strands are the leaf-traces while the strands deeper in the pith are merely branches from the peripheral leaf-trace strands.

In *Pitys antiqua* the medullary xylem strands are confined to the outer zone of the pith and constitute the leaf-traces: in *Archaeopitys*, on the other hand, the medullary strands are scattered through the pith and the leaf-traces are restricted to the circummedullary region in actual contact with the secondary xylem. In the Devonian genus *Callixylon* there are similar strands but they are confined to the edge of the pith and are usually in contact with the wood as are the circummedullary strands in *Archaeopitys*. The grouping of the secondary xylem of *Callixylon* into wedge-shaped masses at the inner edge of the cylinder is a characteristic feature; this feature is less definite in *Archaeopitys* and absent from *Pitys*.

¹ Scott and Jeffrey (14) p. 345, Pl. xxxi. figs. 31—36; text-figs. 4, 5.

Callixylon. Zalessky.

Callixylon Trifilievi Zalessky. This genus is represented by a single species¹, originally referred to *Dadoxylon*, founded on material from Upper Devonian rocks in the Donetz basin, Russia, and based solely on the anatomical characters of the secondary wood and central region of an arborescent stem. The wood is pycnoxylic and of the Araucarian type; the inner portion of the xylem-cylinder is divided into groups, similar to the regular wedges in a Calamite stem, consisting of tracheids converging towards an obtuse apex occupied by a primary xylem strand, fig. 489, A, *a*, *b*. On the radial walls of the tracheids the bordered pits not infrequently form a single row of flattened ovals, but more usually there are two or sometimes three rows of alternate contiguous pits (fig. 489, B): circular and separate pits also occur. As Zalessky states, the pits do not always occupy the whole radial face; unpitted patches sometimes interrupt the continuity of the pitted areas². Similar circular and more scattered pits are unusually abundant on the tangential walls. There are no complete rings of growth. The medullary rays are narrow and, except at their dilated inner ends, uniseriate; usually one or a few cells deep, they may reach a depth of 12 or more cells. The pits on the radial walls of the ray-cells are said to be 4—7 in the field. The pith consists of thin-walled flattened parenchyma frequently elongated in a radial direction. At the inner edge of the secondary xylem and generally in contact with it are several anastomosing strands of primary xylem, mesarch in structure but with the protoxylem nearer the inner edge. These bundles may be single (fig. 489, A, *a*) or double (fig. 489, A, *b*, and C) and closely resemble those of *Pitys antiqua* except in their closer relation to the secondary wood. The leaf-traces have not been described, but the occurrence of twin-bundles like those in fig. 489, C, suggests that they were double. The primary-xylem elements show particularly well transitional forms of pitting connecting the multiseriate and scalariform types.

Callixylon, though conveniently and justly regarded as a distinct genus, exhibits in its primary xylem a fairly close agreement

¹ Zalessky (09); (11) p. 29, Pl. iv.

² Zalessky (11) Pl. iv. fig. 3.

with *Pitys*¹. The above account is based in part on Zalessky's description and partly on specimens in Dr Kidston's possession.

Miss Elkins and W. Wieland² have recently described some Upper Devonian wood from Indiana characterised by a grouping

FIG. 489. *Callixylon Triflievi*. A, C, the inner margin of the secondary xylem showing strands of primary xylem, a, b, and C. B, tracheids of the secondary xylem. (A, C, from photographs supplied by Prof. Zalessky; B, Cambridge Botany School.)

of the circular or elliptical bordered pits in the radial walls of the tracheids similar to those in *Callixylon Triflievi* which they include

¹ Scott (12) p. 1024.

² Elkins and Wieland (14).

together with the Middle Devonian species *Cordaites Newberryi*¹ in Zalessky's genus. Though these two American species are comparable in the discontinuous arrangement of the tracheal pits with the Russian type the latter is characterised by the presence of primary xylem-strands, a feature that has not been recognised in the American stems: it would seem, then, undesirable to adopt the designation *Callixylon* in preference to *Dadoxylon* unless there is evidence as to similar characters in the primary region of the xylem.

Coenoxyton. Zalessky.

Coenoxyton Scotti Zalessky. Prof. Zalessky² gave the name *Coenoxyton* to a small and incomplete piece of stem of doubtful provenance but possibly from the Ural Permian beds. The pith, 2 cm. broad, consists of parenchyma associated in the central region with numerous large sclerous cells. In one section a sinuous band of meristematic tissue was observed near the periphery of the pith: the appearance of this tissue in a photograph given to me by Prof. Zalessky suggests comparison with occasional strips of similar dividing cells in the pith of *Lyginopteris*. The secondary wood is composed of tracheids with 1—2 rows of flattened or hexagonal pits on the radial walls and narrow uniseriate medullary rays reaching a depth of 15 cells and with 2—7 oval pits in the field. As in the wood of *Mesopitys Tchihatcheffi*³ there are distinct and apparently complete rings of growth.

It is on the ground of the arrangement and structure of the primary xylem that Zalessky instituted a new generic name. The primary xylem forms teeth of variable size which project into the pith from the edge of the secondary xylem: the prominent portions of the main mass of primary xylem give off branches, differing considerably in size and shape, some of which become separated by a comparatively broad band of parenchyma from the parent xylem-tissue. These bundles anastomose in their course through the pith and in doing so incorporate between them patches of parenchyma. The bundles of primary xylem are endarch. From the centrifugal strands at the periphery of the

¹ Penhallow (00) pp. 64, Pl. XII.

² Zalessky (11²) p. 13, figs. 1—4.

³ See page 295.

pith double leaf-traces are produced which pass almost horizontally through the secondary wood. As Zalessky points out, the leaf-traces in their dual nature and in the elongated and narrow form of the tracheal groups, as seen in tangential section of the secondary wood, bear a close resemblance to those of *Ginkgo biloba*.

This Russian genus agrees in its double leaf-trace with *Mesoxylon*, *Mesopitys*, and *Antarcticoxylon*: among recent plants *Ginkgo* would seem to be the most closely allied type.

Parapitys. Zalessky.

The designation *Parapitys*¹ has been proposed for a single Upper Carboniferous species characterised by the possession of secondary wood like that of *Cordaites*, double leaf-traces, and small mesarch primary xylem-strands. Nothing is known of the leaves or reproductive organs.

Parapitys Spenceri (Scott).

In 1880 Williamson² published a short account of a transverse section of a specimen found by Mr J. Spencer in Upper Carboniferous strata near Halifax in Yorkshire which afforded evidence of the occurrence of double leaf-traces. The following description is taken from Scott's account³ of the species, which he named *Dadoxylon Spenceri*. The parenchymatous pith, 5—6 mm. in diameter, is obtusely pentagonal, the prominent angles corresponding to the points of exit of paired leaf-traces like those of *Mesoxylon*, *Ginkgo*, and other genera. The secondary xylem consists of narrow tracheids with crowded multiseriate pits on the radial walls and narrow medullary rays one-cell broad and 1—8 cells deep. In contact with the inner margin of the secondary wood are a few small mesarch strands of primary xylem, the protoxylem and some parenchyma occupying a more or less central position. A leaf-trace about to enter the secondary xylem is represented by twin-bundles which retain their double nature as they traverse the stele, but at a lower level the two components fuse and appear as single bundles at the outer edge of the pith. The division of a leaf-trace into two before passing

¹ Zalessky (11) p. 28.

² Williamson (80) A. p. 516, Pl. xx. fig. 60.

³ Scott (02) p. 357, Pls. II., VI.

out, as in *Poroxyton*, constitutes a difference from *Lyginopteris* in which the division occurs later.

Zalessky's generic name *Parapitys* is an appropriate substitute for *Dadoxylon* in view of the presence of separate primary xylem strands, a feature foreign to typical *Dadoxylons* which agree with recent Conifers and Cycads in the absence of vascular strands distinct from the endarch centrifugal wood. As Scott¹ says, *Parapitys* 'is best regarded as a near ally of *Mesoxylon*.'

Mesopitys. Zalessky.

Mesopitys Tchihatcheffi (Goepfert). The genus *Mesopitys* was instituted by Zalessky for a Permian species founded by Goepfert² on a piece of decorticated stem from the Kousnetz basin in Siberia and afterwards more fully described by Goepfert and Stenzel³. The structure of the secondary wood led Goepfert to adopt the name *Araucarites* for which Kraus⁴ substituted *Araucarioxylon*. A recent investigation of additional material by Zalessky brought to light the existence of groups of primary xylem abutting on the secondary xylem and projecting into the pith, characterised by the occurrence of spiral protoxylem elements on the inner edge. The recognition of this important feature justified Zalessky in the adoption of a new generic term. In general anatomical characters *Mesopitys* agrees with *Eristophyton Beinertianum* (Goepf.) but is distinguished by the more feebly developed primary-xylem groups and by their endarch structure.

The examination of sections from some of Prof. Zalessky's material lent to me by Dr Kidston enables me to confirm Zalessky's description, though I am not convinced that the primary xylem-strands are exclusively endarch: in most of the primary groups the protoxylem is clearly on the inner edge, but in a few cases there may be a small amount of centripetal xylem present. The characters of *Mesopitys Tchihatcheffi* may be summarised as follows:

Annual rings well defined, varying considerably in breadth; the summer wood is represented by several rows of narrower

¹ Scott (12) p. 1028.

³ Goepfert and Stenzel (88) p. 33, Pls. v., vi.

⁴ Kraus in Schimper (72) A. p. 381.

tracheids (fig. 490, A). In the piece of stem shown in the figure the breadth of the wood from the flattened and crushed pith to the broken outer edge is 6 cm. The medullary rays are numerous, uniseriate, rarely 2 cells in breadth; the pits on the radial walls of the ray-cells, 7—10 in the field, are apparently simple, oval, and oblique: the rays are generally 3—4 cells in depth but may be deeper. There are 1—3 rows of hexagonal alternate rows of pits on the radial walls of the tracheids. The primary xylem consists of groups, varying in size and sometimes reduced to a very few elements, in contact with the secondary xylem, usually though probably not invariably endarch. In the two narrow radially elongated and partially destroyed primary strands shown in fig. 490, B, the protoxylem, *px*, is on the inner edge. The leaf-trace passes through the secondary wood as a single strand.

FIG. 490. *Mesopitys Tchihatcheffi*. A, transverse section showing rings of growth in the wood. B, primary xylem with protoxylem, *px*, and the edge of the secondary xylem, *x*². (Kidston collection, 2156.)

In the section reproduced in fig. 490, A, the crushed and flattened pith measures 9 by 2 mm.; it consists of thin-walled parenchyma with a few scattered thicker-walled cells.

Nothing is known as to the structure of the cortical tissue or leaves.

Antarcticoxylon. Seward.

Antarcticoxylon Priestleyi Seward. The specimen on which this genus was founded was discovered by Mr Raymond Priestley¹ in a boulder, probably derived from the Upper Beacon sandstone,

¹ Seward (14) p. 17, Pls. IV.—VIII.

on the Priestley Glacier south of 74° S. lat. in the course of the journey of the Northern Party of Capt. Scott's second Antarctic Expedition. The type-specimen is a piece of silicified stem 1 ft long and 3 ins. in diameter; there were no tissues preserved external to the secondary wood and it is impossible to say what proportion of the original thickness is represented. Annual rings are clearly marked at least macroscopically (fig. 491, C) though there is very little difference between the spring and summer tracheids: the centre of the compressed stem is occupied by a lighter coloured elliptical area 7 × 2 mm. which superficially resembles a pith, but in the peripheral region it consists of portions of a cylinder of spiral and scalariform tracheids, the actual pith being not more than 2—3 mm. in breadth. The pith consists of lacunar parenchyma separated by horizontal bands of dark cells containing some secreted substance (fig. 491, F): the preservation is, however, not sufficiently good to enable one to describe it in detail. The secondary xylem is of the pycnoxylic type; the tracheids have either a single row of contiguous and partially flattened pits on their radial walls or a double row of alternate polygonal pits; the medullary rays are nearly always uniseriate (fig. 491, E) and from 1 to 24 cells in depth. At the inner edge of the secondary wood there was a fairly broad zone of more delicate tracheids (fig. 491, A, *x*) characterised by spiral or scalariform bands and by their relatively small diameter. This innermost zone, which supplies the leaf-traces, is spoken of as the primary xylem; it appears to be endarch though this cannot be definitely determined. A characteristic feature of the primary xylem in the perimedullary region, as also in the leaf-traces on their way through the secondary wood, is the presence of short and broad tracheids (fig. 491, D, *t*) with reticulate thickening bands: these short elements may represent centripetal xylem and are similar to the short tracheids described by Scott¹ in the sheath of *Mesoxylon Lomaxi* and to the larger elements in the stem of *Megaloxylon*².

An interesting feature seen in transverse sections of the secondary wood is the occurrence of light bands concentric with the rings of growth which are broadest near the long axis of the stem (fig. 491, C). In their narrower parts these bands are clearly

¹ Scott (12).

FIG. 491. A—F, *Antarcticoxylon Priestleyi*. A, B, transverse sections of the xylem; *a*, small tracheids simulating protoxylem; *x*, xylem at the edge of the pith. C, transverse section showing leaf-traces, *l*, *a*, *b*. D, leaf-trace with short tracheids, *t*, in the pith; *s*, sclerous cells. E, tangential section. F, pith in longitudinal section. G, *Pityosporites antarcticus*; see Vol. IV. (All the sections are in the British Museum.)

due to the partial destruction of the secondary tracheids, but in other places crushed parenchymatous tissue occurs which may be a traumatic phenomenon or possibly comparable with Nördlinger's 'medullary spots'¹ formed by local hypertrophy of medullary tissue. Although the structure of the leaf-traces cannot be definitely determined, it would seem that each trace passed into the perimedullary region as a single bundle of relatively large size composed of spiral and scalariform tracheids narrower than the secondary elements. The traces during their outward course were accompanied by some parenchymatous tissue continuous with that in the pith, and the inner spiral tracheids of the trace were connected with isodiametric reticulate elements. The dimensions of the leaf-traces point to leaves of fairly large size.

In the structure of the secondary wood *Antarcticoxylon* agrees on the whole with an Araucarian stem: the broad zone of xylem composed of spiral and scalariform tracheids at the edge of the pith is a feature common to *Mesoxylon*, *Cordaites*, and *Araucaria*. There is no evidence of the occurrence of double leaf-traces such as characterise certain Cordaitalean genera and some existing members of the Araucarineae. In the single nature of the leaf-traces the Antarctic stem resembles *Mesopitys Tchihatcheffi* also in the presence of rings of growth², but in *Antarcticoxylon* the preservation of the primary xylem is too imperfect to admit of any satisfactory comparison as regards this important tissue with other types.

The precise age of the Beacon sandstone has not been determined, but the probability is that the upper beds from which the boulder containing *Antarcticoxylon* was derived are not older than the Rhaetic period. The chief interest of this imperfectly preserved stem with undoubted Araucarian affinities is its occurrence in the rocks of Antarctica in association with other remains of comparatively large stems.

CHAPTER XXXV.

PALAEOZOIC GYMNOSPERMOUS SEEDS.

SEEDS are abundantly represented as fossils from Carboniferous to Post-Tertiary deposits. The importance of fossil and sub-fossil species in the later geological series has been demonstrated by the investigations of Mr and Mrs Clement Reid and a few other workers in this neglected field. In cases where it is possible to assign seeds to their parent-plants the descriptions of casts, impressions, or petrifications are added to the account of vegetative organs; but it frequently happens that seeds are preserved only as detached specimens many of which have little or no value as botanical records, while others that afford striking examples of the possibilities of petrification as a means of preserving the most delicate structures, are of great importance. In Volume II. an account was given of such Palaeozoic seed-bearing organs as *Lepidocarpon* and *Miadesmia*, and the genera *Lagenostoma*, *Sphaerostoma*, and *Trigonocarpus* are dealt with in this volume under *Lyginopteris*, *Heterangium*, and *Medullosa*. Certain seeds afford some evidence as to the systematic position of the parent-plants though insufficient to warrant more than a surmise as to the nature of the vegetative organs: in several cases it is only from the resemblance of detached seeds to types that on the strength of more or less convincing evidence are referred to definite parent-plants that any conclusions can be drawn with regard to precise systematic position. In view of the occurrence of several different types of seeds that retain their morphological features, but cannot be assigned with any degree of certainty to genera founded on vegetative organs, a special chapter is devoted to a comparative study of selected examples with the object of

directing attention to data bearing on evolutionary problems. The chief interest of Palaeozoic seeds to the botanist lies in the facts they contribute towards the elucidation of questions connected with the promotion of the megasporangium and megaspore of the Pteridophyta to the higher stage represented by the integumented megasporangium (nucellus) and single megaspore that in the main fulfil the definition of a seed¹. 'With the evolution of the seed,' as Oliver says, 'the plant rose at a bound to a higher plane, and this structure in its perfected form has become the very centre of the plant's existence².' We can as yet form a very partial conception of the successive stages in the adoption of the seed-habit, but since 1855, the year in which Hooker and Binney³ published their paper on the structure of *Trigonocarpus*, ample proof has been furnished of the importance of Palaeozoic seeds from the standpoint of affinity between recent Gymnosperms and extinct seed-bearing plants, and of the *modus operandi* of evolutionary tendencies. A cursory examination of Palaeozoic seeds suffices to demonstrate their resemblance to those of recent Cycads and the seed of *Ginkgo biloba*; but while it is clearly with these Gymnosperms that the majority of the seeds described in the following pages are most closely allied, the extinct types possess many distinguishing features that throw light on some at least of the factors concerned in the production of the modern type. In many of the Palaeozoic seeds the nucellus stands free within the integument, to which it is attached only in the chalazal region, in contrast to the lateral union between integument and nucellus in the ovules of recent Cycads. It has been suggested by Oliver⁴ that the seed of the Conifer *Torreya* affords a clue to the interpretation of this difference and that the lower part of the seed in Cycads and *Torreya* represents a later intercalation in the basal portion of the ovule, the ancient type having a free nucellus in contrast to the nucellus of modern seeds which is free only at the apex. It has been objected⁵ that there are no adequate grounds for assuming the addition of an intercalated zone or of the elongation of the ovule that this implies, the more probable

¹ See Vol. II. p. 56.

³ Hooker and Binney (55).

⁴ Oliver (03).

⁵ Worsdell (05) p. 58; Salisbury (14) p. 67.

view being that the lateral union of nucellus and integument represents congenital fusion in the ancestral type, a fusion comparable with that of the coherent petals of a gamopetalous corolla. In the presence of a pollen-chamber most of the Palaeozoic seeds agree with those of recent Cycads, but in the extinct forms it is usually a more highly developed structure. The name pollen-chamber was given by Brongniart¹ to the pollen-containing cavity in the free region of the nucellus in the petrified seeds from St Étienne in ignorance of the use of the same term by Griffith² in a posthumous work published in 1852 for the nucellar chamber in *Cycas*³. The genus *Stephanospermum* (fig. 494, A) illustrates the means by which the pollen-chamber was liberally supplied with water and thus adapted to the requirements of fertilisation by motile gametes. The pollen-chamber and its vascular supply paved the way for siphonogamy, that is the development of a pollen-tube for the more direct transmission of the male sperms. The highly developed mantle of tracheal tissue at the periphery of the nucellus in *Stephanospermum*, represented on a reduced scale by the separate vascular strands of other seeds, may be compared with the tracheal investment to the nucellus in the recent Dicotyledonous genus *Cassytha*⁴. The presence of a nucellar vascular system in several Palaeozoic seeds is a feature in which they differ from those of recent Cycads with the exception of *Bowenia*. The retreat of the vascular supply from the immediate neighbourhood of the pollen-chamber in recent Cycads may, as Oliver points out, be correlated with the evolution of the pollen-tube—the substitution of siphonogamy for zoidiogy. The diagram reproduced in fig. 492 represents a synthetic type based on such seeds as *Stephanospermum* and *Cardiocarpus* which illustrate an arrangement of conducting tissue frequently found in Palaeozoic seeds: the main strand gives off a pair of bundles in the sarcotesta in the principal plane, as in *Cardiocarpus*⁵; from the tracheal mass in the chalazal region numerous bundles pass up the nucellus as far as the floor of the pollen-chamber. The

³ See Scott (09) B. p. 543.

⁴ Mirande (05).

⁵ For definition of *Cardiocarpus*, see page 338.

nature of the vascular supply in this generalised type and in individual genera should be compared with that in the seeds of recent Cycads¹ described in Chapter XXVIII.

Recent research has revealed the not unexpected fact that in such Upper Carboniferous petrified seeds as have been investigated—a small proportion of the large number produced in the Palaeozoic forests—there was a remarkable range in the mechanism connected with pollination and the maturation of the microspores. A comparison of the genera *Physostoma*, *Lagenostoma*, *Conostoma*, *Trigonocarpus*, *Stephanospermum* and others reveals the occurrence of very different though not unrelated structural features especially in the apical region of the seed. These seeds, including *Physostoma* probably the most archaic type, represent a stage in evolution already far removed from the starting-point: the diversity of plan recalls the variety in the form of the chloroplasts in the Green Algae, and in both cases we are in touch with an experimental phase representing a tentative advance towards greater efficiency.

In its differentiation into an outer fleshy region, the sarcotesta, a stony layer, the sclerotesta, and in many cases an inner flesh, the Palaeozoic seeds resemble recent Cycads: in both extinct and modern seeds the balance of evidence would seem to be in favour of attributing a single rather than a double origin to the integument.

Among the numerous types of Palaeozoic seeds are several which invite comparison with the fruits or carpels, apart from the seeds, of Angiosperms. Impressions of *Samaropsis* seeds (figs. 502, B—K; 503; 504) bear a close resemblance to the laterally expanded fruits of the common Crucifer *Thlaspi arvense*; the ribbed testa of *Hexagonocarpus* (fig. 506, H) and other genera

FIG. 492. 'A conjectural synthetic type of seed embodying the characters of such a seed as *Stephanospermum* with those of a *Cardiocarpus*'; *n*, nucellus; *pc*, pollen-chamber. (After Oliver.)

¹ See page 25.

recalls the fruit-wall of *Alstroemeria*; the recently described Lower Carboniferous seed *Thysanotesta sagittula* Nath. (fig. 506, F) simulates a carpel of *Erodium*. These and similar instances of a close parallelism in external features between organs that are not homologous, though in themselves of no morphological significance, are at least interesting as illustrating the plasticity displayed by reproductive structures, which in the Palaeozoic period marked a morphological achievement comparable in its importance with the still greater achievement represented by the highly specialised fruits of the modern Flowering plants. The range in form and surface-features of Angiospermous fruits was foreshadowed by Palaeozoic seeds. Structural types and in some cases, superadded to these, features which may reasonably be supposed to have facilitated dispersal had been acquired by the seeds of Palaeozoic plants in forms that in a much later period were adopted by fruits even to a greater degree than by seeds. Characters useful in seed-dispersal, that are now shared by fruits and seeds, are illustrated by the fleshy and possibly edible seeds of extinct Gymnosperms, the plumes and hairy beak of *Gnetopsis* (fig. 494, E) and *Thysanotesta* (fig. 506, F) suggestive of feathery stigmas and other appendages. The lacunar sarcotesta of *Aetheotesta*, the thick endotesta of *Pachytesta* (fig. 497), and the air-chamber of *Codonospermum* (fig. 498), are strictly comparable with aids to buoyancy in fruits of existing Flowering plants. The mucilage-hairs and superficial cells in *Physostoma* (fig. 494, I) and *Stephanospermum* may be compared with the thick mucilaginous investment of the megaspores of recent water-ferns and with similar tissues of some Angiospermous seeds.

The bionomics of Palaeozoic plants is a subject worthy of more serious attention than it has so far received. The search for morphological characters that may have facilitated the wanderings of widely distributed genera and species and a closer investigation of physiological-anatomical problems presented by the vegetative organs of petrified plants would not only extend our knowledge of the morphology of ancient types but would stimulate comparative study and, incidentally, relieve the dullness of pure description. It may be argued that we should first establish a more solid foundation by further observations on

living plants; but even at the risk of allowing speculation too free a hand the attempt is worth making, and it may be urged that, as in phylogenetic enquiries so in other branches of botany, facts obtained from plants of other ages may serve to supply deficiencies in knowledge based only on existing forms. One of the difficulties inseparable from the study of fossil plants, namely the identification of impressions and casts with specimens exhibiting anatomical characters, is particularly well illustrated by seeds. The description of a genus based on mere external form may sometimes be extended without great risk of error to include species founded on anatomical characters, but on the other hand, there are many instances in which—despite a general resemblance in form and size between petrifications and impressions—lack of evidence of generic identity requires the employment of distinctive names. The determination of impressions is, as Lesquereux recognised, 'subject to a great deal of uncertainty,' and many of the genera founded on external features are purely artificial and include species that have no essential features in common. Moreover in the case of petrified specimens the apparent absence of an external fleshy layer is often due to destruction before preservation: as Solms-Laubach¹ points out, it is obviously impossible to be certain as to the number of integumental layers in seeds that are not well preserved in all their parts. Goepfert founded a new genus, *Acanthocarpus*, on a Permian seed described as *A. xanthioides*², because of the occurrence of spinous processes attached to an obcordate kernel: these apparent spines are in all probability the remains of a very imperfectly preserved sarco-testa. The preservation of the central portion of a seed, that is the seed-cavity with the enclosing shell, conveniently called the nucule, has often led to an unnecessary multiplication of generic terms. Other examples of confusion resulting from different states of preservation are quoted in the accounts of some of the selected types.

Williamson in 1877 pointed out that we learn from the large number of different kinds of Palaeozoic seeds that 'there were in the Carboniferous forests many gymnospermous stems clothed

¹ Solms-Laubach (91) A. p. 118.

² Goepfert (65) p. 177, Pl. xxvi. figs. 27, 28.

with foliage of which we have not yet discovered any traces, probably because these Gymnosperms did not flourish upon the low swampy grounds which were the homes of the great mass of the coal-producing plants¹. Prof. Zeiller² has also drawn attention to the numerical excess of seeds over vegetative organs. This discrepancy has to a large extent been explained by the discovery that many of the supposed Ferns were seed-bearing plants, and a further explanation is suggested by the superiority of seeds over stems and leaves in their adaptation to dispersal by water.

In 1874 Brongniart³ described several petrified seeds from material discovered by Grand'Eury in the St Étienne coal-field, and seven years later his descriptions were republished⁴, with the addition of several beautifully executed drawings, as a posthumous volume edited by his distinguished pupil Renault. Williamson's researches supplied much additional information, and in recent years the more detailed study of French and English seeds by Bertrand and particularly by Oliver and his pupils has further emphasised the interest and importance of this field of work. Brongniart proposed a two-fold classification of French seeds: (i) bilaterally symmetrical seeds, more or less flattened in section, which he believed to be Cordaitan; (ii) radially symmetrical seeds, circular in transverse section: the latter group he considered to be less closely allied to recent types. The employment of the terms *Platyspermeae* and *Radiospermeae*, proposed by Oliver⁵ for Brongniart's divisions, serves a useful purpose if due regard is paid to the adequacy of the evidence as to symmetry and if it is recognised that this classification cannot be rigidly employed in all cases. It was pointed out by Brongniart that the occasional occurrence of tricarinate seeds of *Ginkgo* (fig. 631) and *Taxus* is an exception to the general rule of bilateral symmetry: seeds of *Cycas* are normally bilateral, but radially symmetrical forms also occur⁶. The genus *Conostoma* (fig. 494, B) represents an intermediate type which, though almost radially symmetrical, exhibits a slight tendency towards platyspermy. Evidence

⁶ Affourtit and La Rivière (15).

recently brought forward by Nathorst¹ renders probable a connexion of a presumably radiospermic seed *Lagenospermum Arberi*² with the Lower Carboniferous fronds *Adiantites bellidulus* Heer, and this furnishes an interesting illustration of the association of both platyspermic and radiospermic seeds with the same generic type of foliage. While retaining Radiosperm and Platysperm as convenient descriptive terms, I have not adopted them as group-designations on the ground that they do not in themselves serve as trustworthy criteria of relationship. Attention is called by Salisbury³ to the occurrence of bilaterally and radially symmetrical fruits among British Carices and to a similar mixture in the family Polygonaceae.

The acquisition of more detailed and accurate knowledge of Palaeozoic seeds led to an extension of the two-fold division of Brongniart and Oliver which is based on such characters as the position of the vascular tissue in relation to the integument and nucellus, the form of the pollen-chamber, and other features. The division Lagenostomales has been instituted for *Lagenostoma* and some other Radiosperms connected by certain important characters: these seeds may be referred to the Pteridospermeae though it is only in the case of *Lagenostoma*, and to a less extent *Sphaerostoma*, that a correlation between vegetative organs and seeds has been rendered sufficiently probable to justify an assumption of generic identity. The name Trigonocarpeae⁴ has recently been used for a section of Radiosperms represented by *Trigonocarpus*, *Stephanospermum*, and other genera. Although the genus *Stephanospermum*, as Oliver⁵ says, may be regarded as the type-genus of a group of seeds, it is more fitting, as the same author⁶ insists, to adopt a divisional term based on the generic name of the much more widely spread and more familiar *Trigonocarpus*. For the sake of uniformity in nomenclature it is proposed to adopt the name Trigonocarpaceae instead of Trigonocarpeae to rank with Lagenostomales.

The Platyspermeae comprise such seeds as *Cardiocarpus*, *Mitrospermum*, and *Rhabdospermum*, genera characterised by

¹ Nathorst (14) p. 32.

³ Salisbury (14) p. 71.

⁵ Oliver (04) B. p. 392.

² See page 173.

⁴ Salisbury (14).

⁶ Oliver (07).

well-marked anatomical features and probably Cordaitean; it has, however, been shown that typical Platysperms were also borne on leaves of Pteridosperms and, as Mrs Arber¹ says, the notion that every member of the Platyspermeae was necessarily a Cordaitean seed has been discredited by the discovery of the seeds of *Aneimites* (*Wardia*) and *Pecopteris Pluckenetii*². For general purposes it is hardly necessary to adopt the subdivisions of the Lagenostomales used by Oliver and Salisbury³, though as facts accumulate we shall no doubt be able to make further advances towards a natural system of classification. The following three divisions of Permo-Carboniferous seeds include genera founded on petrified specimens and thus afford valuable morphological data. The groups Lagenostomales and Trigonocarpales include types belonging to closely related plants, a relationship clearly expressed in the seed-characters.

I. LAGENOSTOMALES.

The seeds included in this group are for the most part Radiosperms, but in its slightly developed bilateral symmetry *Conostoma oblongum* is a type transitional between Radiosperms and Platysperms. The testa may be ribbed and the ribs vary in number. The nucellus (megaspore) is united to the integument not only at the base but laterally as far as the shoulder of the seed up to a level corresponding to the base of the pollen-chamber (lagenostome) as in all recent Cycads and in the majority of Conifers. The seeds proper apart from the cupule are supplied with a single set of vascular bundles; there is no vascular tissue in the nucellus, a feature no doubt correlated with the fusion of nucellus and integument⁴. The free portion of the integument is more or less deeply lobed or, in *Lagenostoma*, it forms a pyramidal canopy of fused lobes enclosing the lagenostome. The presence of a tapetal zone surrounding the megaspore is believed to be a feature characteristic of the group⁵. The testa, wholly or partially ribbed, is relatively thinner than in the Trigonocarpales and Cardiocarpales, and in its differentiation agrees less closely with the testa of recent Cycadean seeds. In *Lagenostoma* and possibly

¹ Arber, A. (10) p. 505.

² See Chapter XXXI.

⁴ Salisbury (14) p. 67.

⁵ Oliver (09), p. 99.

in other genera a loose sheath or cupule surrounded the ovule, while in *Gnetopsis* a similar envelope enclosed two to four seeds.

The microspores are multicellular and smaller than those of Trigonocarpaceae, the average dimensions (*Conostoma*, *Physostoma*, *Lagenostoma*) being $67\mu \times 52\mu$.

Genera. *Physostoma*; *Conostoma*; *Sphaerostoma*; *Lagenostoma*; *Gnetopsis*.

Lagenostoma may safely be referred to *Lyginopteris*, and *Sphaerostoma* with but little risk of error to *Heterangium*: the parent-plants of the other genera are unknown, but all may be regarded as the seeds of Pteridosperms and probably of genera more nearly allied to the Lyginopterideae than to the Medulloseae. The genus *Lagenospermum*, recently instituted by Nathorst¹, is dealt with in Chapter xxxi.

Physostoma. Williamson.

Physostoma elegans Williamson.

The generic name *Physostoma*² was applied by Williamson³ to a seed from the Lower Coal Measures of Lancashire which he named *P. elegans*; he afterwards described it as *Lagenostoma physoides*, but the original name has been revived by Oliver⁴ to whom our knowledge of this type is chiefly due. The specimens figured by Williamson⁵ as *Sporocarpon ornatum* also belong to *Physostoma elegans*. The seeds are circular in section, approximately 6 mm. long with a maximum diameter of 2 mm. The testa has about 10 longitudinal ribs passing in the apical region into a ring of free lobes or tentacles surrounding and considerably overtopping the nucellar apex: these tentacles take the place of a micropylar tube (fig. 494, I; fig. 493, D) and are a feature 'in which this seed differs from all other known seeds, fossil or recent⁶.' A single vascular strand passes through the chalazal region and divides into 10 bundles, one to each

⁶ Oliver (09) p. 75.

rib and tentacle. The single integument consists of a few layers of cells, those of the epidermis being prolonged into clavate mucilaginous hairs, fig. 494, I, *h*, that may reach a length of .5 mm. and in the living seed almost covered the whole surface of the testa, being especially long on the ribs and tentacles. There is no special development of sclerous tissue, the vascular bundles, *v*, being embedded in parenchyma in the inner portion of the integument. The nucellus is represented by a zone rich in secretory cells, and internal to this is a tapetum. Integument and nucellus are coalescent up to the apical region where the former splits into 10 tentacles. The nucellar apex has the form of a tall dome surrounded by a bell-shaped pollen-chamber (fig. 494, I, *pc*; fig. 493, C, D, *c*) into which it projects like the base of a wine-bottle. The circular opening of the pollen-chamber overtops the roof of the dome formed of the secretory tissue of the nucellus and the carbonised remains of the tapetum: this dark band surrounds the large megaspore-cavity (fig. 494, I). *Physostoma* is the only member of the Lagenostomales in which the megaspore projects into the free nucellar apex: in other genera intercalary growth has produced a more or less prominent plinth, the name given to the free portion of the nucellus between the megaspore and the pollen-chamber. Williamson¹ described the mammillated apex of the nucellus as pushed up into the base of the lagenostome which 'looks like a bladder half full of fluid resting upon and overhanging the end of a soda-water bottle': it was this appearance that suggested the name *Physostoma*. The section reproduced in fig. 493, D, shows in the centre the limiting tissue of the nucellus surrounded by the pollen-chamber, *c*, and external to this are the tentacles with their groups of long hairs: the vascular bundles are represented by spaces in the more internal small-celled tissue (see also fig. 494, I). A characteristic feature is the presence of a tapetum or megaspore-jacket² in the nucellus: immediately internal to the vascular bundles stretching from the chalaza to the apex of the megaspore-cavity is a layer of delicate cells with secretory sacs, and this is succeeded by a broad black layer of rather larger cells, a tissue which was probably in full activity in a younger stage of development.

¹ Williamson (76) p. 160.

² Oliver (09) p. 106.

FIG. 493. A, *Lagenostoma ovoides*, longitudinal section of the lagenostome. B, *Lagenostoma Lomari*, transverse section of the lagenostome and canopy; c, pollen-chamber; d, space between the nucellus and integument. (A, after Miss Prankerd; B, from a section in the Manchester Museum, R 1048.) C, *Physostoma elegans*, longitudinal section showing microspores in the pollen-chamber, c. (From a section in the University College Collection.) D, *Physostoma elegans*, transverse section of the apical region showing the tentacles, pollen-chamber, c, etc. E, *Telan-gium Scotti*, transverse section of sporangia (Manchester Coll. R 1047). F, G, *Stephanospermum akenioides*. F, section of sclerotesta. G, transverse section of sclerotesta from the nucellus. (University College Coll.)

A comparable tapetal layer is described by Lang¹ in the ovule of *Stangeria*: the majority of the sporogenous cells surrounding the megaspore become disintegrated and are absorbed, but the outermost zone forms a more definite tapetal layer: as already suggested, this tissue in *Physostoma* may be a group-character. No archegonia have been found, but in a few cases some of the delicate prothallus-tissue occurs in the interior of the seed. Microspores are often abundant in the pollen-chamber (fig. 493, C, c); in one seed 80 are recorded. The occurrence of so many microspores suggested to Oliver that insect-agency may have been responsible for the precision in pollination that is greater than one would expect in anemophilous plants. The spores are smaller than those of *Lagenostoma* ($55\mu \times 45\mu$) and in several of them the remains of a cellular tissue are preserved (fig. 494, N), also some sub-reniform bodies (fig. 494, M) similar to those described as spermatozoids by Dr Benson in *Lagenostoma* (fig. 408, D).

The most interesting features of *Physostoma* are: the absence of a continuous micropylar tube and its replacement by a circle of integumental lobes; the apical prolongation of the nucellar apex into the pollen-chamber, and the presence of long mucilaginous hairs on the integument. The large pollen-chamber is a character which distinguishes *Physostoma* from *Conostoma* and its form is very different from that in *Lagenostoma*.

The tentacles of the integument and the form of the nucellar apex are features consistent with Oliver's view that *Physostoma* is the most primitive of Palaeozoic seeds though, as Burlingame² says, the elaborate form of the encasing envelope marks a considerable advance beyond the earliest type of megasporangium integument.

A new type of *Physostoma* has been briefly described by Gordon³, without a specific designation, from the Lower Carboniferous beds of Pettycur (Fife): it was found in association with *Heterangium* and *Sphaerostoma ovale*.

We have no knowledge of the plant to which *Physostoma* belonged, but the general plan of organisation of the seed points to a near relationship to *Lagenostoma* and presumably, as regards the parent-plant, to a genus related to *Lyginopteris*.

¹ Lang (00) p. 288.

² Burlingame (15) p. 19.

³ Gordon, W. T. (10).

Conostoma. Williamson.

This name¹, suggested by the funnel-like pollen-chamber or lagenostome, was applied by Williamson² to some seeds from the Lower Coal Measures of Lancashire and Yorkshire and from the Lower Carboniferous beds of Burntisland. The Burntisland seeds, referred by Williamson to two species, have recently been united and described by Miss Benson as *Sphaerostoma ovale*³. The English species has been thoroughly investigated by Oliver and Salisbury⁴ who have also described a second species, *C. anglo-germanicum*, from the Coal Measures of Lancashire and Germany.

Conostoma oblongum Williamson.

This rare type is represented by approximately cylindrical seeds with an average length of 5 mm. and a maximum breadth of 2.3 mm. borne on a relatively stout stalk and tapering to a blunt apex characterised by a canopy of six short lobes (fig. 494, B, C) in marked contrast to the long tentacles of *Physostoma*. In the basal region the integument has six prominent ribs which soon die out when traced upwards: a transverse section through the body of the seed is hexagonal (fig. 494, D), the angles corresponding to the basal ribs, and there is a slight tendency to platyspermy. The testa has an epidermal mucilaginous layer which becomes exfoliated through the lifting-up of the cuticle by the underlying mucilage: below this, at the apex of the seed, is a cap of fleshy tissue (fig. 494, B, *sa*) which, it is suggested, may have had a secretory function in connexion with a drop-mechanism in pollination like that in recent Conifers. No microspores have been found in the pollen-chamber. The epidermis, called by Oliver and Salisbury the blow-off layer (fig. 494, B, *m*), together with the cap of soft tissue constitute a feebly developed sarcotesta. A sclerotesta consisting of a palisade-layer and a fibrous hypoderm extends over the main body of the seed below the epidermis; it forms the basal ribs and increases considerably in breadth at the apical region to form a sclerous cone penetrated by six strands of parenchyma enclosing vascular bundles (fig. 494, D) which pass up from the conducting tissue immediately external to the nucellus.

¹ κώνος, a cone.

⁴ Oliver and Salisbury (11).

FIG. 494. A, *Stephanospermum akenipides*; *s*, space between integument and nucellus; *n*, nucellus; *e*, inner part of testa; *sc*, sclerotesta; *t*, *t*, tracheidal mantle; *pc*, pollen-chamber; *a*, archegonia; *td*, tracheidal pad. B—D, *Conostoma oblongum*; *a*, level of the transverse section shown in fig. C; *b*, level of transverse section D; *m*, lobes of tissue surrounding the micropyle; *sa*, sarcotesta; *v*, vascular bundles; *p*, plinth. B', section of lagenostome and part of the integument; *f*, *f'*, flanges; *l'*, wall of micropyle-funnel. E, F, G, *Gnetopsis elliptica*; *t*, tent-pole. F, section of the plumes. G, section through the lagenostome. H, *Gnetopsis* from Barnsley, Yorkshire, slightly enlarged. I, *Physostoma elegans*; *h*, hairs. K, L, *Mitrospermum compressum*; *cf*, inner flesh; *n*, nucellus and megaspore. L, transverse section. M, microspores and (?) male gametes of *Physostoma elegans*. N, microspore of *Physostoma* showing part of exine and the internal cells. (A—I, N, M, after Oliver; H, Kidston Coll. No. 1255; K, L, after Mrs Arber.)

The nucellus is coalescent with the integument, as in *Physostoma*, as far as the level of the domical free apex of the nucellus where the tapetal tissue that lines the seed-cavity passes across the almost flat top of the central region originally occupied by the megaspore. In some sections prothallus-tissue was found with an apical 'tent-pole' protuberance. A striking feature of *Conostoma* is the mechanism for the reception of the microspores. The free part of the nucellus consists of the plinth, a broad tapering region originally filled with parenchyma but in most cases represented only by its epidermis: the plinth, *p*, is seen in fig. 494, B, to be two-storeyed, the upper and narrower storey being a space formerly filled by a pad of tissue suspended from the floor of the superposed lagenostome (pollen-chamber)¹. The greater development of the domical plinth is a feature in which *Conostoma* differs from *Physostoma*. At the apex of the plinth and resting on a slight depression is a small lagenostome, bowl-shaped in section, and like the pollen-chamber of *Lagenostoma*, formed as the result of enzyme-action on the apical papilla of the nucellus (fig. 494, B, B', *l'*). The mouth of the lagenostome engages with the micropylar tube by a projecting flange (fig. 494, B', *f*) of tissue lining the micropylar canal and by a second flange (*f'*) at the base of the lagenostome where the roof of the plinth (fig. 494, B', *p*) bends downwards and inwards. The walls of the lagenostome are formed by strong cells with thickening bands giving them the appearance of tracheids (*l'*), but the floor of the lagenostome is made of thinner cells which become disorganised, allowing the microspores to fall into the large plinth-cavity below (*p*, fig. 494, B), an arrangement comparable with the two-storeyed pollen-chamber of *Bowenia*² and, to a less extent, with the micropyle of the Conifer *Tsuga*. The microspores are multicellular and ellipsoidal measuring $75\mu \times 65\mu$.

The species *Conostoma anglo-germanicum* agrees closely with *C. oblongum* in general form and organisation, but it has eight ribs, four more prominent than the others, and differs also in other minor characters from the rather shorter seeds of the type-species. *Conostoma* differs from *Lagenostoma* in the absence of the tubular

¹ For a detailed account of the plinth see Oliver and Salisbury (11).

² Page 27.

prolongation of the lagenostome, the micropyle being like that in recent Gymnosperms. In *Conostoma* the tracheid-like elements of the lateral wall of the lagenostome are a characteristic feature, and no evidence has been found of the existence of a central core of tissue such as occupies the centre of the seed-apex in *Lagenostoma*. The long hairs of *Physostoma* are represented in *Conostoma* by the much smaller mucilaginous cells of the epidermis and in *Lagenostoma* by the less closely united mucilage-cells of the superficial layer of the testa.

Sphaerostoma. Benson.

As already pointed out in Chapter XXIX. where this genus is described as probably the seed of *Heterangium*, there is a fairly close general resemblance between *Sphaerostoma* and *Lagenostoma*. In the presence of free apical lobes the former genus resembles *Conostoma*, and while agreeing with *Lagenostoma* in its annular pollen-chamber it is peculiar in the retention of an epidermis over the roof of the pollen-chamber: as in *Lagenostoma* the seed is enclosed by an outer integument or cupule.

Lagenostoma. Williamson.

An account of this type of seed is included in the description of *Lyginopteris*¹. The more striking peculiarities are exhibited by the pollen-chamber and the free region of the integument: the annular pollen-chamber (fig. 493, D, c; fig. 409) surrounds a central nucellar cone and is prolonged upwards as a tube engaging with the micropyle in contrast to the form of the pollen-chamber and the absence of a tubular prolongation in *Conostoma*. The tentacles of *Physostoma* and the short apical lobes of *Conostoma* are replaced by an apical cone formed by the coalescence of the integument containing nine cavities originally filled with parenchyma (figs. 409; 493, B). The presence of a cupule is a characteristic feature of young seeds, but from negative evidence in the case of most other seeds it is unsafe to assume that the cupule of *Lagenostoma* is an exceptional feature. The nucellus and testa are united as far as the shoulders of the seed as in the seeds of recent Cycads and in contrast to their lateral independence in *Trigonocarpus*, *Stephanospermum*, and other genera.

¹ Page 55.

Gnetopsis. Renault.

This generic name was given by Renault¹ to some small petrified seeds from the Stephanian of Grand' Croix and to impressions from the Commentry coal-field which he believed to belong to some Gnetaceous plant. Saporta and Marion² and other authors have accepted these seeds as evidence of the existence of Palaeozoic Gnetales: it has, however, been shown³ that *Gnetopsis* has no claim to such relationship and is a type of seed closely allied to *Conostoma*. Renault described three species, afterwards adding three from another locality⁴; the genus is recorded also from Commentry⁵ and Gard⁶. More recently Depape and Carpentier⁷ have described examples from the Westphalian of Valenciennes which they place in the Pteridosperms in accordance with the conclusion of Oliver and Salisbury. *Gnetopsis* has also been discovered by Mr Hemingway in the Middle Coal Measures of England⁸ (fig. 494, H).

Gnetopsis elliptica Renault.

The seeds of this species, slightly oval in section, occur in groups of 2—4 in a cupular investment (fig. 506, E, p. 359) described by Renault as an ovary but correlated by Oliver and Salisbury with the cupule which surrounds the single ovule of *Lagenostoma*. The cupule is lined with hairs similar to those on the wall of the cupule of *Lagenostoma*. A characteristic feature of the French seeds is the presence of three or four long plumes of hairs at the apex (fig. 494, E, F). As seen in fig. 494, E, a small lagenostome (pollen-chamber) rests on the roof of a broad plinth precisely as in *Conostoma*, and four vascular bundles, corresponding to the six bundles in *Conostoma*, pass into the apical cap of sclerous tissue enclosed by a sarcotesta, *sa* (fig. 494, E, G). A 'tent-pole' prolongation (fig. 494, E, *t*) occurs at the apex of the prothallus. Renault described a portion of the integument as consisting of lacunar tissue which Oliver and Salisbury homologise with the superficial mucilaginous layer

¹ Renault (84) Pls. XIX.—XXII.² Saporta and Marion (85) p. 181.³ Oliver and Salisbury (11).⁴ Renault (96) A. p. 85, Pl. XLII.⁵ Renault and Zeiller (88) A. p. 640, Pls. 72, 82.⁶ Grand'Eury (90) A. Pl. VI. fig. 6.⁷ Depape and Carpentier (13) Pl. XII. figs. 1—3.⁸ Kidston (90) p. 64.

of *Conostoma*: this is seen above the sclerotesta in the apical region of fig. 494, E, *sa*.

Gnetopsis anglica Kidston ms.

This species (fig. 494, H) is represented by seeds from the Middle Coal Measures near Barnsley, Yorkshire, 4 mm. long with apical appendages at least 2.2 cm. in length and probably four in number. The appendages do not show the hairs which form a prominent feature in the French specimens, but this is probably the result of imperfect preservation: there are indications of hairs on other specimens in Dr Kidston's Collection. The type-specimen, in Dr Kidston's Collection, was generously lent to me for examination.

Gnetopsis, while agreeing with *Conostoma* in the more important features, is distinguished by the apical plumes, the very slight development of a tent-pole prolongation of the nucellar apex (fig. 494, E, *t*), the smaller number of vascular bundles, and by the presence of an enclosing cupule (fig. 506, E). In its slight departure from radial symmetry *Gnetopsis* forms a transition between the Radiospermeae and the Platyspermeae. It is undoubtedly the seed of a Pteridosperm, but nothing is known as to the nature of the vegetative organs of the parent-plant.

II. TRIGONOCARPALES.

In this group are included radially symmetrical seeds for the most part belonging to members of the Medulloseae. The peripheral zone of the nucellus is supplied with vascular tissue and the nucellus is free within the integument except at the base; it is superior and not semi-inferior¹ as in recent Cycads and in Lagenostomales. The ovule of *Myrica Gale*, in which the nucellus stands free within the single integument, affords an interesting parallel to seeds of this class in contrast to the usual Angiospermous type with a laterally coalescent nucellus. In *Myrica Gale*² the vascular supply is confined to the integument. There is a comparatively broad pollen-chamber and in some types the lateral tissue of the nucellus is prolonged as a tube within the micropyle. The usually ribbed testa is differentiated into an

¹ Oliver (02) p. 146.

² Kershaw (09).

outer flesh (sarcotesta), a sclerotesta, and probably in most cases an endotesta or inner flesh. The ribs of the sclerotesta are in the majority of genera in multiples of three and in position correspond to the outer ring of vascular bundles. The presence of lacunar tissue in the sarcotesta of several genera may be correlated with dispersal by water. The apical region of the integument is not lobed but extends as a longer or shorter micropylar tube above the summit of the nucellus. In the differentiation of the testa, the form of the pollen-chamber, and in some other features, the seeds of this group present a general agreement with those of recent Cycads.

The microspores are multicellular and larger than those of the Lagenostomales: in *Stephanospermum akenioides* they measure $160\mu \times 100\mu$ ¹ while in *Aetheotesta*² they reach $360\mu \times 290\mu$.

Genera. *Trigonocarpus*; *Tripterospermum*; *Ptychotesta*; *Hexapterospermum*; *Polypterospermum*; *Pachytesta*; *Stephanospermum*; *Polylophospermum*; *Codonospermum*; *Aetheotesta*; *Eriotesta*; *Gaudrya*.

Trigonocarpus. Brongniart.

A description of the morphological features of *Trigonocarpus Parkinsoni* and *T. shorensis* is given in the chapter on *Medullosa* (p. 117), as there is good evidence that they are the seeds of that genus. There is considerable difference in size and to some extent in the form of casts included in *Trigonocarpus* and, in the absence of anatomical data, it is hardly possible to determine the actual systematic position of many of the specimens so named. Dr Arber³ has recently proposed a new generic name *Schizospermum* for casts very like those of *T. Parkinsoni*, but distinguished by the splitting of the shell into three valves, a character which leads him to conclude that it is the external surface which is preserved and not a mere cast of the seed-cavity. It is, however, more probable that the specimens are casts of a split sclerotesta. In *Trigonocarpus pusillus*⁴ the shell is divided into three valves, the dividing lines being marked by greatly reduced ribs, and in *T. schizocarpoïdes* Grand'Eury⁵, a species that may not be a

¹ Oliver (04) B. p. 376.

² Renault (96) A. p. 272.

³ Arber, E. A. N. (14) p. 103, Pl. viii. figs. 48—50.

⁴ Brongniart (81) Pl. B. fig. 3.

⁵ Grand'Eury (77) A. Pl. xv. fig. 1.

true *Trigonocarpus*, there is also evidence of splitting. Arber points out that the species *Rhabdocarpus Boschianus* Berg. is founded on a *Trigonocarpus* from which the outer flesh has disappeared leaving the shell as the external covering. *Trigonocarpus* seeds are widely distributed in Carboniferous and Permian rocks in Europe and North America: from the latter continent Newberry¹ has described several different forms that afford good examples of the abundance and variety of the genus. Some of the specimens included by Newberry² in *Trigonocarpus* are probably distinct generic types: his species *T. multicarinatus* may be identical with the ribbed cast shown in fig. 506, A. The casts described by Lindley and Hutton and by other authors as *T. Dawesi*³ are nearly 5 cm. long, and if these are correctly included in the genus they point to the occurrence of seeds much larger than the type-species. The French species *Trigonocarpus pusillus*⁴ Brongn., one of the smallest Palaeozoic seeds, from 6.5 to 15 mm. long, differs from *Trigonocarpus Parkinsoni* and *T. shorensis* in the absence of prominent ribs and in the much feebler development of the sarcotesta. Specimens of the German type *T. sporites* Weiss, believed by some authors to be megaspores, were described by Zeiller⁵ from Valenciennes as seeds: these are from 2.5 to 3.5 mm. long and have three small ribs. Zeiller quotes the presence of cell-outlines on the surface as evidence of their seed-nature, but it may be that this feature represents a sculpturing of the exine of a spore. Typical *Trigonocarpus* seeds agree in several morphological characters with those of recent Cycads. They differ in the lack of a lateral union between nucellus and integument; the presence of nucellar tracheids, though a feature shared with *Bowenia*, distinguishes them from the majority of recent Cycadean seeds. In the comparatively long and fleshy micropylar tube a seed of *Encephalartos Lehmanni* presents a fairly close resemblance to a *Trigonocarpus*. Salisbury has pointed out that the three species *T. Parkinsoni*, *T. shorensis*, *T. pusillus* form a consecutive series illustrating the gradual disappearance of the secondary ribs that form a prominent feature

¹ Newberry (73).

⁵ Zeiller (88) A. p. 652, Pl. 94, fig. 17.

in *T. Parkinsoni*; but for a comparison of these with other types of fossil and recent seeds the reader is referred to Salisbury's summary¹.

Tripterospermum. Brongniart.

The seed on which this genus was founded by Brongniart² is clearly very closely related to *Trigonocarpus* and, as Oliver³ says, the distinguishing character described by the author of the genus is unimportant. Brongniart describes the type species, *T. rostratum*, as characterised by the presence of three prominent wings composed of a testa differentiated into an inner hard tissue and an outer lacunar tissue. It is, however, hardly possible to say whether the outer soft tissue was originally flattened in the form of 'wings' or pressed down on to the harder shell. Renault⁴ notes the association of seeds that he refers to this genus with the leaves of *Dorycordaites*, but apart from the improbability of any connexion between *Tripterospermum* and *Cordaites*, Renault's seeds are too imperfect to demonstrate their identity with Brongniart's genus. Kidston⁵ has described an impression of a three-winged seed from the coal-field of Staffordshire as *Tripterospermum ellipticum*, a form described on page 357 as *Polypterocarpus anglicus* (fig. 496, B).

Ptychotesta. Brongniart.

The type-species of this genus⁶, *Ptychotesta tenuis*⁷, about 3 cm. long, is characterised by six very prominent flanges or wings formed by the fissured or folded sclerotesta (fig. 495, B). There is no information as to the vascular supply or other anatomical details. It is not at all improbable that there is no real distinction between this genus and Brongniart's genus *Hexapterospermum*.

Hexapterospermum. Brongniart.

In this genus Brongniart⁸ included two species, *Hexapterospermum stenopterum* and *H. pachypterum*: the shell is hexagonal

in transverse section, each angle being prolonged as a narrow flange. In one of the sections figured by Brongniart (fig. 495, E) the ribs are not fissured: this is said to be a feature distinguishing *Hexapterospermum* from *Ptychotesta*, but the occurrence of a fissured rib in another section suggests that in the structure of

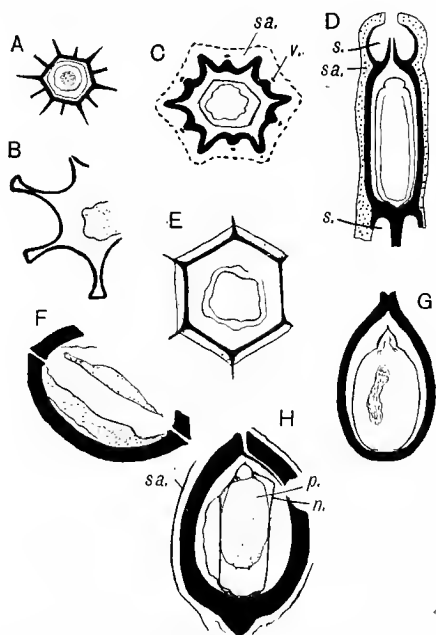

FIG. 495. A, *Polypterosperrum Renaultii*. B, *Ptychotesta tenuis*. C, D, *Polylophospermum stephanense*; sa, sarcotesta; s, spaces; v, vascular bundles. E, *Hexapterospermum stenopterum*. the ribs there is no essential difference between the two genera. In *Ptychotesta pachypterum* the testa is prolonged at the chalazal end as in *Polylophospermum*, and it is possible that there is no generic difference. Williamson described a cast from the Coal Measures of Lancashire as *Hexapterospermum* [= *Hexagonocarpus*] *Noegerrathi*¹ (fig. 506, H), but in the absence of anatomical characters it is preferable to avoid the use of Brongniart's term and to assign them to Renault's genus *Hexagonocarpus*². Similarly

¹ Williamson (77) B. p. 253.

² See page 356.

the seeds referred by Dr P. Bertrand¹ to *Hexapterospermum* may appropriately be included in the genus *Hexagonocarpus*.

Polyptospermum. Brongniart.

This generic name was proposed for an ovoid seed from St Étienne described as *Polyptospermum Renaulti*²; hexagonal in section with six deep and sharp flanges at the angles alternating with six secondary ridges distinguished by their blunter edges and slightly smaller depth (fig. 495, A). Without further anatomical details it is hardly possible to say whether or not the species represents a well-defined generic type, but it is not improbable that a fuller knowledge would confirm Brongniart's institution of a new generic designation. The seeds described by Arber³ and Kidston⁴ respectively as *Radiospermum ornatum* and *Polyptospermum ornatum* are transferred to *Polygonocarpus* on the ground that they afford no evidence of anatomical characters of the *Polyptospermum* type.

Pachytesta. Brongniart.

Brongniart⁵ established this genus for some unusually large seeds (fig. 496, A) from the Coal Measures of France reaching a length of 11—12 cm. and resembling in form and size a hen's egg. Petrified examples have been described by Brongniart and Renault⁶, and Oliver⁷ has given a lucid statement of the more interesting features of this Permo-Carboniferous genus.

Pachytesta gigantea (Grand'Eury).

In the separation of nucellus and integument *Pachytesta* agrees with *Stephanospermum* and *Trigonocarpus*. There is a double series of vascular bundles in the outer part of the testa or exotesta (fig. 497, *ex*) consisting of a spongy tissue bounded externally and internally by sclerotic layers: the exotesta is succeeded by a broader endotesta of spongy consistency which Renault suggested may have

⁷ Oliver (02).

served as a floating mechanism, and this is intimately associated with the nucellus by means of grooves engaging with short ridges (fig. 497, *nr*) on the surface of the nucellar tissue. The exotesta is divided into three valves by radial extensions of the sclerotic tissue (*b*, *c*, fig. 497; at *a* the exotesta is shown in an unsplit condition). In connexion with each radial plate are two curved plates of fibrous tissue which extend towards the grooves in the

FIG. 496. A, *Pachytista incrassata*. B, *Polypterocarpus anglicus*. (A, after Renault; B, after Kidston.)

endotesta (fig. 497, *t*): as Oliver suggests, these plates may have served a mechanical purpose for the support of the bulky nucellus. The peripheral region of the nucellus is supplied by several vascular bundles (fig. 497, *n*) from the tracheal chalazal disc. The exotesta is regarded by Oliver as corresponding to the sarcotesta and sclerotesta of other seeds, and the grooves in the endotesta interlocking with the nucellar ridges are compared with the

intérllocking of nucellus and canopy in *Lagenostoma*, as also with the ruminated endosperm of *Torreya*.

We have no definite information as to the plants which bore *Pachytesta*, but it is probable that they were members of the Medulloseae. Grand'Eury¹ believes *Pachytesta* to be the seed of *Alethopteris Grandini*, though this view requires confirmation. This author figures several *Pachytesta* seeds attached in two oblique rows to a comparatively slender axis which may be the rachis of

FIG. 497. *Pachytesta*. Transverse section of a seed showing the exotesta, *ex.*, with sclerous layers and vascular strands (black), the endotesta (dotted), the nucellus with its ring of vascular bundles, *n.*, and the prothallus, *p.* The three radial plates in the exotesta are seen at *a*, *b*, *c*, with the trabeclulae, *t.*, and internal to these are the grooves in the endotesta engaging with ribs on the nucellus, *nr.* (After Oliver.)

a large compound frond². Renault and Zeiller³ have figured specimens of *P. gigantea* and *P. incrassata* from Commeny which afford a good idea of the form of these large seeds; the genus is recorded also from Gard, Blanzay⁴, and other localities. Kidston⁵ described a large oval seed, blunt at each end, from the Middle Coal Measures of Lancashire as *Carpolithus Wildii* which he thinks may be allied to *Pachytesta*, but adds, 'I do not think we are justified in placing mere impressions of plants in genera,

¹ Grand'Eury (04).

⁴ Zeiller (06) B. p. 229.

⁵ Kidston (92) p. 8.

whose distinctive characters are derived from their internal organisation, unless there is conclusive evidence to show their identity.' On this specimen Arber¹ has founded a new genus *Megalospermum*, but as the type-specimen shows no distinctive features other than large dimensions it would seem preferable to retain the more general designation *Carpolithus*².

Another example of a seed that may be generically identical with *Pachytesta* is that described by Lesquereux from North American Coal Measures as *Rhabdocarpus Mansfieldi* and more recently recorded by White from Missouri as *Rhabdocarpus (Pachytesta) Mansfieldi*³. There is little doubt that this and other species of seeds preserved as impressions are examples of *Pachytesta* but, as Kidston says, it is preferable to reserve the name for specimens showing anatomical features.

Stephanospermum. Brongniart.

The genus *Stephanospermum*, founded by Brongniart⁴ on petrified specimens from French Stephanian beds, affords a good example of a radiospermic seed without ribs differing in certain well-marked characters from such seeds as *Lagenostoma*, *Physostoma*, and *Conostoma*, notably in the complete separation of the nucellus from the integument and in the possession of a nucellar vascular system. The descriptions by Brongniart and Renault⁵ have been extended by the thorough investigations of Oliver⁶.

Stephanospermum akenioides Brongniart.

This species is represented by ellipsoidal seeds, 10 mm. long with a maximum breadth of 4—4·5 mm., circular in transverse section. The integument consists of a thick sclerotesta lined internally by a thinner soft layer, the endotesta (fig. 494, A, *sc*, *e*), and in all probability covered by an outer flesh or sarcotesta as in *Trigonocarpus*, though this tissue is not preserved and is omitted from the section shown in fig. 494, A. The sclerotesta is composed of a broad outer band of thick-walled palisade cells—the contracted contents of which are a striking feature in the silicified seeds (fig. 493, F); these

⁵ Renault (80²).

⁶ Oliver (04) B.

are succeeded by an inner zone of longitudinal fibres. In the structure of the palisade-layer *Stephanospermum* bears a close resemblance to the sporocarp wall of *Pitularia*¹. In the apical region the shell forms a circular ridge surrounding a peri-micropylar trough, a character expressed by the term 'crown-seed'² employed by Grand'Eury: the trough sometimes contains partially destroyed tissue that may be a remnant of a sarcotesta. A *Stephanospermum* seed, with its apical core and surrounding depression with remnants of some partially destroyed tissue, may be compared with a fruit of *Attolia speciosa* (Palmae) in which a tuft of fibrous tissue picked out by decay from the mesocarp surmounts the conically pointed apex of the harder interior of the fruit-wall. The base of the sclerotesta is perforated by a vascular strand which expands into a tracheal disc, *td*, fig. 494, A, at the base of the megaspore from which a continuous mantle 2—3 cells broad, of short spiral and scalariform tracheids (fig. 493, G), spreads over the whole of the nucellus immediately below the nucellar epidermis as far as the lower part of the sides of the pollen-chamber: this mantle forms the floor of the large domical pollen-chamber excavated out of the nucellar cone (fig. 494, A, *pc*). The fact that in sections of older seeds the tracheal floor shows signs of splitting and disorganisation led Oliver to conclude that in the living seed the tracheids underwent a gradual disintegration prior to fertilisation, thus allowing the passage of the antherozoids to the egg-cells (fig. 494, A, *a*). The presence of a continuous tracheal sheath instead of separate vascular bundles is a special feature in which *Stephanospermum* differs from *Trigonocarpus* and other Palaeozoic seeds as well as from those of recent Cycads; as Oliver suggests, 'the apparent perfection of the vascular mantle in *Stephanospermum* may have proved an obstacle to further development'³ and was not retained by the more successful types. In its tracheal sheath *Stephanospermum* resembles the seeds of *Ginkgo*. The nucellar cone is prolonged as a beak into the micropyle formed by the tubular integument. The megaspore occupies the central portion of the seed and in the course of its development it compressed the megasporangium (nucellus) to such an extent that little more

¹ Russow (72) Pls. III., IV.

² στέφανος, a crown.

³ Oliver (04) B. p. 395.

than the epidermis remains: there is a definite megaspore-membrane surrounding the prothallus-tissue in which there were probably two archegonia (fig. 494, A, *a*)¹. The nucellus stands free within the integument from which it is separated by a space (*s*, fig. 494, A). Microspores are frequently met with in the pollen-chamber in which they matured after their introduction through the micropyle, probably with the aid of a drop of mucilage: they are large oval bodies with an average size of $160\mu \times 100\mu$, some reaching over 200μ in length and, as Renault was the first to point out, within a finely granulate exospore there are several thin-walled cells: this statement was not accepted by some authors but Prof. Oliver's researches have amply confirmed it, and an examination of the original preparations convinced me that Renault had correctly described the structural features. Oliver shows that there are about 20 cells within each microspore regularly arranged as rows of five wedge-shaped elements with their pointed ends directed towards the centre, and he thinks that these cells may have undergone further division to produce sperm-mother-cells, though there is not such good evidence of this as in the differently constituted microspores of *Stephanospermum caryoides*. No trace of pollen-tubes was found and it is probable that the antherozoids were liberated by the rupture of the delicate prothallus-tissue. The tracheal sheath afforded an adequate means of water-supply to the pollen-chamber and this enabled the motile antherozoids to reach the archegonia.

Stephanospermum caryoides Oliver².

This species, founded on a specimen from Grand' Croix, is a larger seed (15.5×12.5 mm.) and more globular than *S. akenioides*; there is a shorter micropylar beak and a less developed peri-micropylar trough. As in *S. akenioides* the nucellus is free from the base and the two species conform to the same general type of construction. The microspores are distinguished by the presence of only two internal cells which do not occupy the whole of the spore-cavity but are surrounded by a large peripheral cell comparable with the tubecell in recent microspores, though there is no proof that a tube

¹ Brongniart (81) Pl. XVI. figs. 4, 6.

² *Ibid.* p. 373, Pl. XLII. figs. 17—20; XLIV. figs. 36—43.

was formed: in the case of *S. akenioides* Oliver considers that fertilisation was not assisted by the production of a pollen-tube. The two cells by further division gave rise to a secondary cell-complex consisting of at least eight antherozoid-mother-cells. No antherozoids have been found in the microspores but it is possible that two small bodies, $17\mu \times 15\mu$, met with in a pollen-chamber may represent the nuclei of sperms. Their small size differentiates them from the much larger male gametes of Cycads and from the supposed sperms of *Physostoma* and *Lagenostoma*.

We have no proof as to the nature of the plant which bore seeds of the *Stephanospermum* type, but it is significant that the specimens occur in close association with fragments of *Alethopteris* and *Myeloxylon*, a circumstance that favours the view, based on the resemblance of these seeds to *Trigonocarpus*, that *Stephanospermum* is the seed of a member of the Medulloseae.

Polylophospermum¹. Brongniart.

The type-species *Polylophospermum stephanense* Brongn.², founded on partially preserved material from Grand'Croix, is a narrow hexagonal seed 15 mm. long. Additional facts as to the structural features have been contributed by Oliver³. The testa is differentiated into an inner shell (sclerotesta) and an outer flesh (*sa*, fig. 495, C, D): the sclerotesta has six prominent, fissured, ribs, one at each angle, and between these are six solid and less prominent secondary ribs. Oliver states that there is an outer series of vascular bundles in the sarcotesta, one bundle immediately external to each secondary rib (fig. 495, C, *v*). In the presence of two kinds of ribs and in the relation of ribs to tracheal strands *Polylophospermum* agrees with *Trigonocarpus Parkinsoni*. Strands of short tracheids supply the peripheral region of the nucellus and, as in *Stephanospermum*, reticulate elements extend as far as the floor of the large pollen-chamber. There was probably no lateral union between nucellus and integument. A striking feature is the prolongation of the testa at each end of the seed to form an open chamber surrounding the micropylar beak and the seed-base (fig. 495, D, *s, s*): the apical chamber,

¹ λόφος, a ridge.

² Brongniart (74) p. 256, Pl. xxiii. figs. 6—8; (81) Pl. C, figs. 6—8.

³ Oliver (04²) B. Pl. II. figs. 5—10; (07) fig. 1.

though relatively more prominent, is comparable with that in *Stephanospermum*, while the basal chamber recalls that in the seed named by Scott and Maslen *Trigonocarpus Oliveri*¹ but subsequently removed by Salisbury² from that genus. There is no evidence as to the parent-plant of *Polylophospermum*, but it may be assumed to have been a Pteridosperm, probably one of the Medulloseae.

*Codonospermum*³. Brongniart.

Our knowledge of this peculiar genus is derived from Brongniart's description of the type-species *Codonospermum anomalum*⁴ (fig. 506, B, C) from St Étienne and from Renault's account of *C. olivaeforme*⁵. The seeds are globular or ellipsoidal and reach a length of 2 cm.: the testa is differentiated into an outer flesh

FIG. 498. A, B, *Codonospermum*. A, *C. olivaeforme*, longitudinal section showing the seed-proper and the air-chamber, *s.*; *pc.*, pollen-chamber. B, Diagrammatic sketch of a *Codonospermum* showing the vascular supply, *v.*, and the fibrous arcs, *f.*, in the wall of the lower part of the seed. C, *Aetheotesta elliptica*, *s.*, sarcotesta with lacunae; *v.*, vascular supply. (After Renault.)

and a sclerotesta and has usually eight ribs. The most striking feature is the division of the seed into two regions, an upper portion containing the nucellus and megaspore and a lower portion in the form of an empty chamber that probably served as a float

¹ Scott and Maslen (07) Pl. XIII. fig. 19.

⁵ Renault (93) A. Pl. LXXXVII.; (96) A. p. 393.

(fig. 498, A, s). Externally the upper half or seed-proper forms a depressed cupola with eight slightly developed ribs, separated by a circular transverse constriction from the basal chamber (fig. 498, B). There is a fairly large pollen-chamber, *pc*, in which Renault found multicellular microspores in *C. olivaeforme*. In *C. anomalum* 16 vascular bundles (fig. 498, B, v) surround the central region of the seed probably in the peripheral tissue of the nucellus; these bundles unite in the chalazal region to form a strand that passes up the centre of the empty chamber. In *C. anomalum* the testa of the lower half has eight ribs and corresponding with each rib is a strand of fibrous tissue (fig. 498, B, f). In *C. olivaeforme* the testa is thicker than in *C. anomalum* and the lower region of the seed is smooth and circular in section.

Impressions of *Codonospermum* are described¹ from Comentry, from the Loire—the Gard district², and by Zeiller³ from Blanzly. There is no decisive evidence as to the parent-plant, but some French authors⁴ regard the frequent association of *Codonospermum* with leaves of *Dolerophyllum* as significant.

Aetheotesta. Brongniart.

Aetheotesta elliptica Renault.

Brongniart instituted the genus *Aetheotesta*⁵ for an incomplete seed (*A. subglobosa*) from Grand' Croix, and Renault⁶ subsequently founded the species *A. elliptica* on much better material. The testa of the elliptical seed, 3 cm. long, consists of an outer region very thin on the flanks but highly developed at the apex and base which forms a sarcotesta characterised in the apical region by large radially disposed spaces, fig. 498, C, s; the sclerotesta, composed of harder tissue, is prolonged as an apical beak. There is a large pollen-chamber, *pc*, in which Renault found multicellular microspores (320 μ —400 μ). In the chalazal region the main vascular supply forms a cup-like investment, *v*, in the basal portion of the

⁶ Renault 96 A. p. 272.

nucellus, and at a higher level this breaks up into several nucellar strands. Renault thinks that *Aetheotesta* is the seed of *Dolerophyllum*, but there is no proof of any connexion. The presence of large spaces in the sarcotesta may be interpreted, as Renault suggests, as evidence of adaptation to dispersal by water.

Eriotesta. Brongniart.

Brongniart¹ instituted this genus² on an incomplete transverse section of a seed from Grand' Croix, 8 mm. in diameter, which he called *Eriotesta velutina*, characterised by a ribbed and probably octagonal testa bearing numerous elongated hairs over the whole surface. The material is, however, too meagre to throw any light on the important features of the seed.

Gaudrya. Grand'Eury.

Gaudrya trivalvis Grand'Eury.

The generic name *Gaudrya*³ was proposed for two petrified seeds from the Gard coal-field briefly described as *G. trivalvis*, the type-species, and *G. lagenaria*. The testa of the former species shows signs of splitting along three equidistant lines; it consists of a sarcotesta enclosing an endotesta with six longitudinal ribs: Grand'Eury speaks of lacunae between the endotesta and nucellus which he regards as spaces in a tissue which made the seed buoyant and facilitated dispersal by water. It is not clear whether the nucellus and integument were originally connected or laterally free: the lacunae may be the remains of an inner flesh and not spaces in a spongy tissue. The genus is radiospermic and characterised by a long micropyle and a broad pollen-chamber. On the available evidence it is difficult to assign the specimens to their systematic position, but the genus is probably a member of the Trigonocarpales.

III. CARDIOPALLES.

Platyspermic seeds for the most part belonging to Cordaitalean plants and agreeing in their plan of organisation, even more

¹ Brongniart (74) p. 256, Pl. xxiii. figs. 4, 5; (81) p. 27, Pl. C, figs. 4, 5.

² ἔριον, wool.

³ Grand'Eury (90) A. p. 308, Pls. iv. fig. 12, vi. fig. 5.

closely than the seeds of the Trigonocarpales, with those of recent Cycads. The nucellus is free laterally from the integument and there is a series of vascular bundles in the nucellus. The testa consists of an outer flesh, the sarcotesta, which may reach a considerable thickness, a shell or sclerotesta, and in some genera an endotesta. In seeds preserved as impressions the sarcotesta often gives them a winged appearance (*Samaropsis*). The pollen-chamber is relatively small, resembling in this respect the chamber in recent Cycads. A central prolongation of the prothallustissue in the form of a blunt column or 'tent-pole' is a characteristic feature; the same feature occurs in seeds of the Lagenostomales, but in the Cordaitales it resembles more nearly the 'tent-pole,' as it was called by Hirase, in recent Cycadean seeds and in *Ginkgo*. The presence of two vascular strands in the sarcotesta in the principal plane of the seeds is a character shared with the seeds of *Cycas*: the position and course of these bundles are useful characters for distinguishing different types within the group. The microspores are multicellular.

Genera. *Cardiocarpus*; *Cyclospermum*; *Cycadinocarpus*; *Rhabdospermum*; *Mitrospermum*; *Diplotesta*; *Leptocaryon*; *Taxospermum*; *Compsotesta*. These generic names are all used in the following pages for seeds known to possess certain anatomical features; there are also included in the Cardiocarpales the genera *Samaropsis*, *Cordaicarpus*, and *Rhabdocarpus*, but it is proposed to limit their use to specimens which furnish no anatomical data and cannot therefore be assigned with equal confidence to a section of seeds based on definite morphological characters. It is certain that some at least of the seeds described under these names would, if preserved as petrified specimens, be included in one or other of the genera named above.

There is ample proof that some of these seeds were borne on Cordaitan plants and that the group as a whole represents the seeds of the Cordaitales¹. It is, however, certain that some Platyspermic seeds were produced by Pteridosperms. No little confusion has been caused by the employment of the same generic names for petrified seeds and for casts and impressions affording no evidence as to similarity in anatomical characters. With

¹ See page 264.

a view to avoid the risks necessarily entailed by following this practice it is suggested that a clearer distinction should be drawn between genera based primarily on structural features and form-genera. The following notes on the genera *Cardiocarpus*, *Cordaicarpus*, *Cyclocarpon*, *Cycadinocarpus*, *Jordania*, and *Samaropsis*, may serve to illustrate some of the difficulties connected with the terminology of Palaeozoic seeds.

Cardiocarpus. Brongniart¹ proposed the name *Cardiocarpon* in 1828 for Upper Carboniferous seeds described as compressed lenticular, cordiform or reniform 'fruits' with an acute apex: in his later work² he recognised their true morphological nature and gave an account of some exceptionally well-preserved examples from Grand' Croix. Brongniart in common with other authors believed *Cardiocarpus* seeds to belong to Cordaitan plants, a view that in several cases is based on conclusive evidence. The specimen represented in fig. 501, D, illustrates the characteristic form of a cast of a *Cardiocarpus* seed, and the sections shown in fig. 501, A and B, are from an identical or a very closely allied species. The generic characters are: (i) the presence of a narrow flattened border or wing surrounding a platyspermic nucule, (ii) the cordiform base and more or less pointed apex, (iii) the differentiation of the testa into a sarcotesta and sclerotesta free from the nucellus except at the base, (iv) the 'tent-pole' prolongation of the prothallus (fig. 510, A, b) and the presence of a fairly large pollen-chamber, *pc*, (v) the occurrence of two sets of vascular bundles, an inner nucellar series and two double vascular strands (fig. 500, A, v, B) which are given off from the main supply before it reaches the sclerotesta. The term *Cardiocarpus* as used by Brongniart signifies a type of seed possessing both certain anatomical and external characters. The proposal is to restrict the generic appellation to seeds exhibiting definite structural features agreeing in essentials with *Cardiocarpus sclerotesta* and *C. drupaceus*.

Cordaicarpus. This name was first employed by Geinitz³ in the form *Cordaicarpon*, the type-species being *C. Cordai* (fig. 502, C) from the Coal Measures of Germany, a seed referred by the

¹ Brongniart (28) A. p. 87.

* Brongniart (74) p. 245 (81).

³ Geinitz (62) p. 150; Kidston (11) p. 240; Geinitz (55) A. Pl. xxi. figs. 7—16.

author of the genus to *Cordaites principalis* but, as Kidston has pointed out, there is evidence that this correlation may be incorrect: there is, however, no doubt as to its Cordaitean parentage. Specimens included in this genus agree closely with species of *Cardiocarpus*, but they are usually described as being distinguished by the absence of a flat border and by a more rounded and less cordate base. In the example of *Cordaicarpus Cordai* shown in fig. 502, C, and in other species assigned by authors to this genus there is a narrow border and the form of the base is an inconstant character. As Kidston¹ and other authors point out, there are no definite and constant characters by which to distinguish *Cardiocarpus* from *Cordaicarpus* as regards the form of the seeds preserved as casts or impressions. A further account of *Cordaicarpus* is given on a later page.

Cordaispermum. This designation was formerly adopted by Renault² for seeds having the form and anatomical features of *Cardiocarpus* which there is good reason for attributing to *Cordaites* or to some allied genus. In view of the fact that the majority of the seeds under consideration are undoubtedly Cordaitean there is no need to employ this additional generic name.

Cyclocarpon. Fiedler³ instituted this term for seeds previously described by Berger as *Cardiocarpon emarginatum* (fig. 502, B, now included in *Samaropsis*) and added a new species *Cyclocarpon nummularium*. Brongniart⁴ subsequently described the structure of two species, *C. tenue* and *C. nummularis*, which he referred to Fiedler's genus, and Bertrand⁵ has shown that these differ from the genus *Cardiocarpus* in the recurrent course of the bundles given off from the chalazal strand as in the genus *Rhabdospermum* (cf. fig. 501, E). There are no good grounds for retaining the designation *Cyclocarpon* for casts and impressions, as the specimens so named are indistinguishable from impressions referred to *Cordaicarpus*. The generic name *Cyclocarpus*, retained by Bertrand only for *C. tenuis* and *C. nummularis* simply for anatomical reasons, is now altered to *CyclospERMUM* on the ground that the

³ Fiedler (57) p. 291.

⁴ Brongniart (81) Pls. iv., v.

⁵ Bertrand, C. E. (08²).

designation *Cyclocarpon* has been used for impressions affording no information with regard to anatomical features.

Cycadinocarpus. Renault¹ transferred to this genus Brongniart's species *Cardiocarpus augustodunensis* on the ground that the vascular system exhibits in a greater degree than the other types included by Brongniart in *Cardiocarpus* a resemblance to that in recent cycadean seeds. Bertrand² confirms Renault's account and retains *Cycadinocarpus augustodunensis* as a species worthy of generic distinction. A short account of this seed is given on a later page.

Jordania. This name was given by Fiedler³ to compressed ovate-cordate seeds characterised by a broad membranous border bearing a superficial resemblance to the seeds of *Bignonia*. The type-species, *J. bignonioides* (fig. 502, I), from the Coal Measures of Saarbrücken has the form usually associated with the designation *Samaropsis*, and as the latter term is generally adopted there are no adequate reasons for the retention of *Jordania*. The name *Jordania* has also been applied, by Schenk⁴, to fossil Dicotyledonous wood and was previously used by Boissier⁵.

Samaropsis. Goepfert⁶ defined *Samaropsis* as 'Fructus samaroides membranaceus, compressus, margine alatus, monospermus.' The type-species, *S. ulmiformis*, from the Permian of Brenau, is a small seed with a broad wing or border, but a better example of *Samaropsis* is figured by Goepfert as the wing of an insect⁷. Examples of the genus are shown in figs. 502, A—H; 503; 504). Seeds included in *Samaropsis* differ from those referred to *Cordaicarpus* in the presence of a broader and more clearly defined border which in some cases, as in the genus *Mitrospermum* (fig. 494, K, L), undoubtedly represents a lateral wing-like extension of the sarcotesta. In some instances the wing may be a tangentially expanded integument comparable with the perianth of *Welwitschia*, and in some Jurassic seeds referred by Heer⁸ to *Samaropsis* the lateral appendages are probably true

⁸ Heer (77) ii. Pl. xix. See also Nathorst (86) Pl. xxv. figs. 10—14.

wings. It is advisable to restrict the designation *Samaropsis* to Palaeozoic seeds. Nucules deprived of the broad border would be referred to *Cordaicarpus* as usually employed for impressions. The generic name *Samaropsis* serves a useful purpose as a distinctive term for platyspermic seeds preserved as casts or impressions characterised by the possession of a wide border or wing broader than in typical examples of *Cordaicarpus*. The specimen represented in fig. 499 affords a good illustration of the difference between *Samaropsis* and *Cordaicarpus*. In this specimen the border clearly consists of two portions, an inner narrower border (black in the drawing) and an outer more delicate portion; the former is the impression of the sclerotesta and the outer represents the fleshy sarcotesta which in the living seed may have formed a wing. If, as often happens, the seed were preserved with the narrow border only it would be assigned to *Cordaicarpus*, many species of which are undoubtedly incomplete *Samaropsis* seeds.

FIG. 499. *Samaropsis emarginata*, from the Westphalian series, Yorkshire. (Kidston Coll., 4227; $\times 2$.)

The seeds described by Lindley and Hutton as *Cardiocarpon acutum* (fig. 444, p. 171) have been made by Arber¹ the type of a new genus *Cornucarpus*, the distinguishing feature being the triangular form and the apical horns of the wing. The seeds figured by Arber² from the Kent coalfield as *Cornucarpus acutus* are, however, not identical with the type of Lindley and Hutton, which has the characters of *Samaropsis*. *Samaropsis* is widely distributed in Permo-Carboniferous rocks in Europe and North America and is recorded also from India³ (fig. 504), China⁴, South Africa⁵ (fig. 503), South America⁶ (fig. 502, F, G) and Australia⁷. Some seeds of this form were certainly borne on Cordaitean plants (cf fig. 480, A), but seeds of similar type have been found in organic connexion with the foliage of Pteridosperms (figs. 442, 445, pp. 167, 172). The Permian 'cone-scales' bearing

⁷ Feistmantel (90) A. p. 164.

seeds described by Geinitz as *Cardiocarpon triangulare*¹, represented by well preserved impressions in the Dresden Museum, appear to be of the *Samaropsis* type: the same author referred some *Samaropsis* seeds to the Conifer *Walchia*, but Weiss² dissents from this correlation as the seeds often occur in beds in which *Walchia* is not represented. Renault states that the seeds of the fertile shoot described by him as *Cycadospadix Milleryensis*³ from Autun [= *Strobilites Milleryensis* (Ren.)] closely resemble *Samaropsis fluitans* Daws. as figured by Weiss. The suggestion by White⁴ that *Samaropsis* seeds were borne on fertile leaves of *Gangamopteris* adds a further difficulty to the use of the generic characters of *Samaropsis* as criteria of systematic position. The Permian seeds figured by Goeppert⁵ as *Oreodoxites Martianus* are possibly specimens of *Samaropsis*.

The designation *Samaropsis*, though usually restricted to Palaeozoic species, is applied by some authors to 'winged' seeds from Mesozoic strata; but as some of the Jurassic seeds⁶ so named appear to have true wings like those of some recent Conifers it is advisable to adhere to the more limited use of the name.

It is safe to assert that many *Samaropsis* seeds agreed generally in structure with Cordaitan seeds such as the petrified examples described by Brongniart as *Cardiocarpus*. The species *Mitrospermum compressum*⁷ is an example of a petrified seed having the external features of *Samaropsis*.

Cardiocarpus.

This generic title I propose to restrict to petrified seeds exhibiting the characters described by Brongniart⁸ and more recently by Bertrand⁹ in *C. sclerotesta* and *C. drupaceus*. In general organisation seeds of this generic type agree with those of recent Cycads and with the seed of *Ginkgo biloba*, but there are certain distinguishing features. An important character is

⁹ Bertrand, C. E. (08²); (08³).

afforded by the course and place of origin of the lower vascular strands from the main supply at the base of the seed. The outer vascular system consists of two bundles given off from the main strand, before it reaches the sclerotesta, which pass up the sarcotesta (fig. 500, B). In *Rhabdospermum*, on the other hand, the corresponding bundles arise at a higher level and form recurrent strands which penetrate the sclerotesta before passing up the fleshy part of the integument (cf. fig. 501, E).

Cardiocarpus sclerotesta Brongniart. The testa is differentiated into an inner shell and an outer sarcotesta (fig. 501, A; the sclerotesta is shown in black); there is a well developed pollen-chamber (*pc*) and below this the prothallus-tissue is prolonged as a blunt and short tent-pole, *b*, as in *Ginkgo* and in several fossil seeds. On each side of the apical tent-pole the slightly shrunken prothallus shows two small archegonia, *a*, which in the relatively small size and spherical form of the egg-cells resemble those of *Ginkgo*. In transverse section (fig. 501, B) the seed is

bi-convex and at each end of the major axis the sclerotesta forms a small keel. There are two sets of vascular bundles concerned in the supply of material to the ovule; a lower pair of bundles given off from the central strand in the sarcotesta (fig. 500, B) which pass to the apical region in the inner tissues of the sarcotesta in the principal plane (fig. 500, A, *v*), and an inner set of bundles that pass up the peripheral tissue of the nucellus.

The species described by Brongniart as *Cardiocarpus* (*Cyclocarpus*) *tenuis* and *C. nummularis* have been removed by

FIG. 500. *Cardiocarpus drupaceus* var. *expansus*. A, transverse section of the testa approximately in the middle of the seed; *v*, vascular bundles. B, diagrammatic sketch, adapted from Brongniart's drawing of the base of the seed showing the sarcotesta, *sa*, the sclerotesta, *sc*, and the pad of vascular tissue, *d*, at the base of the nucellus. (After Brongniart.)

Bertrand¹ from *Cardiocarpus* on the ground that the integumental bundles pursue a course like that in *Rhabdospermum*; it is now referred to the new genus *Cyclospermum*².

(A, B, C, after Brongniart; D, after Renault and Zeiller; E, adapted from Brongniart.)

Cyclospermum. Gen. nov. (= *Cyclocarpus* Bertrand).

As stated on a previous page Bertrand³ re-establishes the generic name *Cyclocarpus*, founded on impressions without reference to anatomical characters, for two petrified seeds from St Étienne

¹ Bertrand, C. E. (08).

² This name has been used for a section of a genus of recent Umbelliferae but not as a generic name (De Candolle's 'Prodromus,' Pars iv. p. 105, 1830).

³ Bertrand (08³) p. 454; (08²) p. 392.

described by Brongniart as *Cardiocarpus tenuis* and *Cyclocarpus nummularis*¹. These types differ from *Rhabdospermum* in the absence of an apical snout but agree with that genus in the steeply descending course of the vascular strands in the basal region of the seed. As stated on a previous page, the name *Cyclosporum* is proposed as a substitute for *Cyclocarpus* because of the employment of the latter term for impressions.

Cycadinocarpus. Schimper².

Cycadinocarpus augustudunensis (Brongniart³). In the possession of two sets of vascular bundles this type agrees with *Cardiocarpus*, but the more internal strands pass up on the inner face of the sclerotesta without penetrating into the nucellus, a feature in which *Cycadinocarpus* agrees with the majority of recent cycadean seeds: the outer bundles are given off from the main supply after it has entered the sclerotesta and not before as in *Cardiocarpus*; they follow an oblique course in the sclerotesta and emerge into the sarcotesta at the shoulders of the basal curve of the seed. As in *Cardiocarpus* and *Rhabdospermum* the two outer bundles lie in the principal plane of the seed. There is a pollen-chamber at the apex of the nucellus and the latter tissue is prolonged as a tent-pole which engages with the micropyle. In the absence of data as to the course of the vascular bundles in the chalazal region it would not be possible to distinguish between this genus and *Cardiocarpus*.

Rhabdocarpus Berger and **Rhabdospermum** gen. nov.

It is proposed to restrict the name *Rhabdocarpus*⁴ to impressions and casts of seeds of the type represented by *R. tunicatus* as figured by Berger⁵ and reproduced in fig. 506, K, the term *Rhabdospermum* being applied to seeds of similar form in which are shown certain distinguishing anatomical features. *Rhabdocarpus tunicatus* Berger is a species founded on a specimen from the Coal Measures of Silesia characterised by an outer carbonised testa prolonged apically as a blunt snout and, as seen in fig. 506, K, covering an apparently ribbed nucule, but the 'ribs' are due to

¹ Brongniart (81) Pls. iv. v.

² Schimper (72) A. p. 208.

³ Brongniart (81) Pl. III.; Bertrand, C. E. (08).

⁴ ῥάβδος, a rod.

⁵ Berger (48) p. 20, Pl. I. fig. 8.

the presence of fibrous strands and are not ribs in the ordinary sense. The outer tissue shows numerous longitudinal striations due presumably to the presence of fibrous elements in the sarcotesta like those shown in the petrified seed represented in fig. 501, C. The genus is defined by Berger as follows: 'Semina ovata vel elliptico-oblonga secundum longitudinem parallela nervosa vel tenuissime striata, putamine (interdum deficiente) instructa.' As used by Berger and many other authors *Rhabdocarpus* includes a miscellaneous collection of seeds often differing widely from the type-species. Many of the examples correctly referred to Berger's genus are platyspermic though a bilateral symmetry is by no means always clear. Renault and Zeiller¹ in their definition of *Rhabdocarpus* include bilateral symmetry as a characteristic feature and speak of the seeds as oblong or oval with a pointed or truncate apex and a rounded base. Impressions of *Rhabdocarpus* differ from those of *Cardiocarpus* or *Cordaicarpus* in their more elongate form, always longer than broad, and in the absence of a basal sinus. The seeds found attached to *Neuropteris* pinnae and, in external features, agreeing with many specimens included in Berger's genus, have been transferred by P. Bertrand² and Arber³ to a new genus *Neurospermum*⁴. Arber⁵ in his recent revision of British seeds proposes to restrict the name *Rhabdocarpus* to platyspermic seeds having a 'large unsymmetrical nucule enclosed in a large unsymmetrical wing or sarcotesta,' that is to forms symmetrical in one plane. In this category he includes *Rhabdocarpus tunicatus* Berg. (fig. 506, K) and *R. subtunicatus*⁶ Grand'Eury, but it is not clear on what grounds Berger's species is spoken of as symmetrical in only one plane: in the species *R. Lilleanus* Arb.⁷ the symmetry is hardly sufficiently well defined to rank as a generic character. In the case of the *Neuropteris* seeds the apical snout is slightly curved, thus giving them an unsymmetrical appearance (cf. fig. 422, p. 114). The Carboniferous and Permian seeds usually referred to *Rhabdo-*

⁷ Arber (14) Pl. vii. fig. 21.

carpus are transferred by Arber to his genus *Platyspermum*¹, a designation for which it is proposed to substitute Nathorst's genus *Holcospermum*². In seeds preserved as more or less flattened impressions it is practically impossible in many cases accurately to determine the symmetry: as fig. 506, A, shows, casts indistinguishable from some examples of *Platyspermum* are radially symmetrical. Brongniart³ extended the original definition of *Rhabdocarpus* to include certain anatomical characters, and these have been more fully defined by Bertrand⁴. It is for seeds showing these anatomical features that the name *Rhabdospermum* is now proposed. This course is followed on the ground that it is advisable to avoid confusion between petrified specimens and impressions which in spite of superficial resemblance may not be closely related. In some cases it is practically certain that an impression of the *Rhabdocarpus* type is generically identical with a seed of similar form showing the anatomical structure of *Rhabdospermum*, but unless identity is established a distinct terminology is preferable. The use of the generic name *Rhabdospermum* carries with it an implication of platyspermy, but under *Rhabdocarpus* may be included seeds which are radiospermic and platyspermic. Some seeds agreeing with *Rhabdospermum* are referred by Grand'Eury⁵ to *Poroxydon*, and it is probable that *Rhabdospermum* like *Cardiocarpus* is a Cordaitean seed. On the other hand *Rhabdocarpus* may well include species, apart from those

¹ In selecting a generic name for a fossil plant or part of a plant it has not been the universal practice to avoid the use of a designation previously employed for a recent plant. It is clearly in accordance with the Rules adopted by the International Botanical Congress and with general convenience to avoid the employment of the same name for two different generic types even if one is known only in a fossil state. My attention has been called by Mr W. N. Edwards of the British Museum to the fact that the names *Platyspermum*, *Microspermum*, and *Pterospermum* recently proposed by Dr Arber for Palaeozoic seeds have previously been given to recent flowering plants. Though I have often neglected to consult the *Index Kewensis* and the *Genera Siphonogamarum* before proposing a 'new' generic term, I fully recognise the importance of avoiding the employment of names in current use or names which have 'lapsed into synonymy*.'

⁵ Grand'Eury (05).

* Règles internationales de la nomenclature botanique adoptées par le Congrès Internat. Bot. de Vienne, 1905, etc. T. Briquet, Jena, 1912, p. 37.

transferred to *Neurospermum*, that belong to Pteridosperms. A species, *Rhabdocarpus Oliveri*, recently described by Kidston¹ from the Staffordshire coalfield is an example of a radiospermic seed which may be assigned to a Pteridosperm. The type-specimen is an ovate seed 4 cm. long and 2 cm. broad agreeing in form and surface-features with *Rhabdocarpus* as already defined, but the evidence it affords of internal structure is insufficient to determine its position with regard to genera founded on anatomical characters. Other examples of *Rhabdocarpus* are described by Lesquereux² and White³ from American Coal Measures, by Grand'Eury⁴ from the Loire, by Renault⁵ from Autun, and by many other authors.

Rhabdospermum. Gen. nov.

The platyspermic seeds included in this genus agree in size and form with impressions assigned to *Rhabdocarpus* and as regards the main features conform anatomically to *Cardiocarpus*; they were probably borne on Cordaitean plants. Fig. 501, C, represents a longitudinal section of the species *Rhabdospermum cyclocaryon* described by Brongniart as *Rhabdocarpus cyclocaryon*: the sarcotesta is particularly well developed in the apical region; at the apex a portion of the micropyle is seen at *m* and near the nucellus are pieces of the sclerotesta shown in black. The presence of anastomosing fibres near the surface is a characteristic feature: these, as Bertrand points out, do not form a hypodermal tissue in the strict sense as they may be separated by some of the thin-walled parenchyma of the sarcotesta from the epidermis. The sclerotesta is only partially preserved but the inner portion forms a dark line enclosing the nucellus, the superficial tissue of which is separated from the shrunken prothallus represented by the almost spherical dotted region: the remains of an archegonium are seen at *a* (fig. 501, C) and the characteristic tent-pole apex of the prothallus is shown at *b*. While in shape and in the general plan of organisation *Rhabdospermum* agrees with *Cardiocarpus*, the vascular system in the chalazal region constitutes a distinguishing feature. In *Rhabdospermum* the main vascular strand

¹ Kidston (14) Pl. xvi. figs. 6—8.

⁵ Renault (93) A. Pl. LXXXVI.

passes through the sclerotesta, *e*, *e'*, fig. 501, E, before giving off two bundles which bend back ('faisceaux récurrents'), traverse the shell, and then pass up the sarcotesta in correspondence with the feebly developed lateral keels as far as the micropyle, while in *Cardiocarpus* (fig. 500, B) the bundles are given off before the main strand reaches the sclerotesta. Similar recurrent bundles occur also in *Mitrospermum* (fig. 494, K)¹.

Mitrospermum. A. Arber.

Mitrospermum compressum (Williamson). Mrs Arber² proposed the name *Mitrospermum*³, suggested by the peculiar form of the seed-base, as a substitute for *Cardiocarpus* for Williamson's species *C. compressum*⁴ from the Lower Coal Measures of Lancashire. The seed is platyspermic and there is some evidence that it split into two valves along the principal plane (the longer axis of the section, fig. 494, L). The diagrammatic and partially restored longitudinal section reproduced in fig. 494, K, shows the main features: a sarcotesta, *sa*, covers the surface of the testa as a thin layer except at the edges of the flattened sides where it forms a wing-like border; preserved as an impression the seed would be assigned to *Samaropsis*. The sclerotesta, *sc*, has a pointed apex which surrounds the lower third of the micropyle and a broad base perforated by the chalazal vascular strand. There was probably a narrow inner flesh as in *Trigonocarpus* and recent Cycadean seeds (fig. 494, K, *cf.*). The nucellus was free from the integument except at the base, as in *Trigonocarpus* and *Stephanospermum* (fig. 494, K, *n*): internal to the shrivelled remains of the inner flesh there was a nucellar tapetum surrounding the megaspore. Details as to the pollen-chamber are lacking though there are indications that it resembled that of some species of Cordaitan seeds. The main vascular supply passes through the sclerotesta and then forms a low cushion of short reticulate elements below the base of the nucellus from which two bundles are given off (fig. 494, K, *v*) in the principal plane. The course of the bundles which pierce the sclerotesta led Mrs Arber to remove this seed from *Cardiocarpus*, as recently defined by Bertrand⁵, since in that genus the integumental bundles have

¹ See page 314.

² Arber, A. (10).

³ *μίτρα*, a Persian cap.

⁴ Williamson (77) B. p. 257, Pls. xv. xvi.

⁵ Bertrand, C. E. (08²).

their origin below the sclerotesta. In the course of the vascular bundles *Mitrospermum* is intermediate between *Rhabdospermum* and *Taxospermum*.

This genus is founded on a detached seed, but its resemblance to undoubted Cordaitean species favours its attribution to that group though, as Mrs Arber points out, some markedly platyspermic seeds are known to have been borne on fern-like fronds and *Mitrospermum* may belong to some genus of Pteridosperms.

Diplotesta. Brongniart.

Diplotesta Grand'Euryana Brongniart. The generic name *Diplotesta*, suggested by Grand'Eury, was given by Brongniart¹ to a Grand' Croix seed which he compared with that of the Conifer *Cephalotaxus*. The type-specimen is elliptical and platyspermic (fig. 495, H, p. 322), and differs from *Taxospermum* in the cordate form of the seed-cavity, also in the more restricted union of nucellus and testa. The testa is differentiated into a sarcotesta (*sa*) and sclerotesta, and the latter forms two feebly developed keels in the principal plane: a characteristic feature shared with *Mitrospermum* is the splitting of the shell into two equal valves (fig. 495, F). Fig. 495, H, shows the contracted cylindrical nucellus and the pollen-chamber: the sarcotesta (*sa*) is only partially preserved. *Diplotesta* differs from *Cardiocarpus* in the course of the integumental vascular bundles which are of the type illustrated by *Rhabdospermum*, *Taxospermum*, and *Cyclocarpus*, but from these genera it is distinguished by the dehiscence of the shell, also by its form and certain anatomical features as described by Brongniart and Bertrand².

In this genus Bertrand includes Brongniart's species *Sarcotaxus avellana* (fig. 495, F), a correlation suggested by the latter author.

Leptocaryon. Brongniart.

Brongniart³ founded this genus for a single species, *Leptocaryon avellana*, represented by a Grand' Croix specimen 12 × 10 mm., which he believed to be related to *Taxus*. *Leptocaryon* differs

¹ Brongniart (74) p. 247, Pl. XXI. figs. 12—14; (81) p. 21, Pl. A. fig. 12; Pl. XIV; Renault (80²) p. 106, Pl. xv. figs. 12, 13; Grand'Eury (77) A. p. 239, Pl. xxvi. fig. 27.

² Bertrand, C. E. (07²).

³ Brongniart (74) p. 248, Pl. XXI. fig. 17; (81) p. 22, Pl. A. fig. 17; Pl. VI.

from *Taxospermum* in the structure of the testa, but resembles it in external features. Bertrand¹ in his revision and extension of Brongniart's account says that the sections throw no light on the nature of the vascular supply, and it is therefore impossible to form a satisfactory opinion as to the relationships of the genus. Renault² referred this genus to the Cordaitales, but we have no evidence as to the parent-plant.

Taxospermum. Brongniart.

Brongniart³ gave this name to a small elliptical seed, 15×9 mm., recalling in external features the seed of *Taxus*, a genus to which he believed the Grand' Croix species to be related. The type-species *Taxospermum Grüneri* (fig. 495, G) has a comparatively thin testa characterised by the absence of a sub-chalazal pad formed by the swelling of the sclerotesta. The nucellus is attached by a broad base to the testa and the two regions appear to be connected for a short distance on the flanks⁴; in this feature the seed is comparable with that of the Conifer *Torreya* and differs from the other platysperms, *Diplostesta*, *Rhabdospermum*, etc. Bertrand⁵ states that the main vascular strand extends from the hilum to the chalaza before giving off the two opposite bundles which 'follow the floor of the shell-cavity, and on reaching the flanks traverse the shell obliquely from below upwards⁶.' In the course and position of the integumental bundles *Taxospermum* differs from *Cardiocarpus*, *Cycadinocarpus*, and *Rhabdospermum*. In this genus Bertrand includes *Sarcotaxus angulosus* Brongn. and *S. olivaeformis* Brongn.⁷

Compsotesta. Bertrand ex Brongniart ms.

Compsotesta Brongniarti Bertrand. The generic name *Compsotesta*⁸, though adopted by Brongniart for some incomplete specimens from Grand' Croix, was not published either by him or Renault: it has recently been revived by Bertrand⁹ in his

account of the anatomical details of Brongniart's sections. This seed appears to be closely allied to the polypterous forms *Ptychotesta* and *Hexapterospermum*: the testa consists of a sarcotesta differentiated into two zones the outer of which contains vascular bundles in correspondence with the ribs, and an inner shell. There is a nucellar vascular supply and the nucellus is free on the flanks as in *Stephanospermum* and *Trigonocarpus*.

Samaropsis. Goepfert.

The characters of this Permian and Carboniferous genus have already been described: the name has reference only to superficial features especially the samara-like 'wing,' and connotes no special anatomical features.

Samaropsis fluitans (Dawson). The species described by Dawson¹ as *Cardiocarpum fluitans* from Carboniferous strata in Nova Scotia, is represented by oval seeds with a fairly broad border usually showing an apical notch. Fig. 502, A, is a copy of Dawson's figure: the apparent absence of an apical sinus in the 'wing' is probably due either to an error in interpretation or to some imperfection in the specimen. As fig. 502, A, shows, the type-specimens are far from satisfactory, and it may be that they are not specifically identical with the more complete specimens from European strata referred to Dawson's species. Zeiller² points out that seeds of this species vary considerably in size, but there is always in well-preserved examples a bifid beak at the apex. Seeds of similar form though not specifically identical are described from the Coal Measures of Missouri as *Cardiocarpon* (*Samaropsis*) *Branneri* Fairch. and White³. Good examples of *S. fluitans* are figured by Weiss⁴ from the Coal Measures of Saarbrücken and the species is widely distributed in Upper Carboniferous beds generally.

Samaropsis bicaudata Kidston. This species (fig. 502, E) originally described⁵ from Lower Carboniferous rocks in Scotland as *Cardiocarpus bicaudata* and subsequently assigned to *Samaropsis*,

¹ Dawson (66) A. p. 165, Pl. XII. fig. 74; Zeiller (06) B. p. 226; Kidston (11) p. 236.

⁴ Weiss, C. E. (72) Pl. XVIII.

⁵ Kidston (94) B. Pl. VI. fig. 3; (02) B. Pl. LVIII. figs. 5, 6.

is characterised by a greater development of the flat wing-like border which is divided into two long tapering basal lobes. Seeds of similar form are figured by Lesquereux¹ from Pennsylvania as *Cardiocarpus* (*Ptilocarpus*) *bicornutus*.

Samaropsis (*Samarospermum*) *moravica* (Helmhacher). This type² (fig. 502, H) is characterised by the great length of the wing-like border and on that account it was transferred by Arber to a new genus. It was originally described by Helmhache from the Permian of Moravia as *Jordania moravica* and the type-specimen has been re-figured by Zeiller³ who records the species from Upper Carboniferous and Permian rocks in France: it is recorded also from several localities in Germany⁴. Seeds figured by Potonié⁵ from the Permian of Thuringia as *Samaropsis Crampii* (Hartt) are undoubtedly examples of *S. moravica*: the true *S. Crampii* has recently been well illustrated by Dr Stopes⁶ from the Westphalian of New Brunswick. The species is recorded by Arber⁷ from the Kent coalfield.

Samaropsis emarginata (Goeppert and Barger).

The seed represented in fig. 502, B, from the Lower Coal Measures of Kilmarnock, Scotland⁸, affords a good example of the genus: the species was originally described by Berger as *Cardiocarpon emarginatum* and it was on this type that Fiedler founded the genus *Cyclocarpon*⁹. It has been referred by many authors to *Cardiocarpon* and might be regarded as a type intermediate between *Cordaicarpus*, as used in this chapter, and *Samaropsis*, though the breadth of the border is more in keeping with the latter designation. The figured specimen is 1.6 cm. long and 1.4 cm. broad; the nucule has a slightly cordate base and shows several faint converging ribs which are too inconspicuous to be represented in a natural-size drawing. A narrow median groove in the apical region shows the position of a vascular strand.

² Andrews (75) p. 425, Pl. XLVI, fig. 2.

sent to Dr Kidston by Mr Claypole. The whole seed is 5 cm. wide and 3.5 cm. in depth; it is characterised by a short and relatively broad nucule surrounded by a very broad and flat border showing faintly marked radially disposed lines and in places some irregularly distributed pits. The apex is emarginate and there is a broad and deep sinus in the sarcotesta in the chalazal region. The seed resembles *Samaropsis alata* Kidst.¹ and *S. Baileyi* (Daws.)² but it differs from these in the greater breadth of the 'wing' and in the form of the nucule.

The seed described by Fiedler³ as *Jordania bignonioides* (fig. 502, I) agrees closely with *S. alata* Kidst. but is probably specifically distinct.

Samaropsis barcellosa (White).

White⁴ described this species (fig. 502, G) from Permo-Carboniferous rocks in Brazil (Rio Grande do Sul) as *Cardiocarpon barcellosum*. The nucule is said to be cordate but, as seen in the figure, there is no clear indication of a basal sinus: the presence of a relatively broad 'wing,' as White says, entitles the seed 'to a place in the *Samaropsis* section of the genus.' The author of the species compares it with seeds described from Westphalian rocks in Ohio⁵ and Pennsylvania⁶. It is interesting to find a type which is common in both Europe and North America in the western portion of Gondwana Land. Seeds of similar form are recorded also from India, South Africa, and Australia⁷.

Samaropsis Seixasi (White).

This Brazilian species from the same beds is described by White as *Gangamopteris (Samaropsis) Seixasi*⁸: it is characterised by a small ovate nucule 8—10 mm. long and 5 mm. broad, in some specimens surrounded by a complete 'wing' extending above the apex and below the base, giving the seed an appearance similar to

that of *Samaropsis* (*Samarospermum*) *moravica* while sometimes, as in the example shown in fig. 502, F, the broad border is preserved only at the sides. These seeds are abundant in the Santa Catharina beds, where they were discovered by Dr Esdras do Prado Seixas, in association with leaves of *Gangamopteris*, and White thinks that they were borne on the fertile leaves of that genus which he has named *Arberia*¹. Although there is as yet no proof of a connexion between *Gangamopteris* and seeds of this or any other type it is almost certain that it was a seed-producing plant.

Samaropsis Leslii sp. nov.

The seed on which this species is founded was discovered by Mr T. N. Leslie in the Ecca beds (Permo-Carboniferous) of Vereeniging, South Africa, a locality from which the same geologist has obtained leaves of *Cordaites*, *Psymophyllum*, *Glossopteris* and other genera². In the slightly cordate base and tapered apex (fig. 503) the nucule agrees closely with those of European examples, but the Vereeniging type is distinguished by its larger dimensions and by the wider border indicating a thick sarcotesta continued basally into a stout stalk. The apex is emarginate and a median rib marks the position of a vascular strand. There is no evidence as to the nature of the parent-plant.

FIG. 503. *Samaropsis Leslii*.
From Vereeniging, S. Africa.
(Mr Leslie's Collection; nat.
size.)

Samaropsis indica (Zeiller).

Prof. Zeiller³ described this species as *Cardiocarpus indicus* from the Karharbari (Lower Gondwana) beds of India. An examination of the type-specimens enables me to confirm the

¹ Vol. II. p. 517.

² Seward and Leslie (08) B.

³ Zeiller (02) B. p. 37, Pl. VII. figs. 7, 8; Arber (05) B. p. 205, fig. 44.

accuracy of the original account. The platyspermic seed is 5.5 cm. long and 4.5 cm. broad; a cordate nucule is enclosed by a flat border similar to that of *Samaropsis Leslii* but narrower especially on the sides of the nucule. At the apex there is a deep sinus extending to the nucule, and at the base a fairly broad band of carbonaceous matter shows the position of the chalazal vascular strand. The seed is characterised by its large size and by its almost orbicular form: it occurs as a detached specimen in beds containing *Cordaites (Noeggerathiopsis)* and *Glossopteris*.

A species from Arkansas described by Lesquereux¹ as *Cardiocarpus ingens* [= *Cordaicarpus ingens* (Lesq.)] affords another example of a large seed similar to *C. indicus* and, except in its more orbicular form, to *Samaropsis Leslii*.

Samaropsis Milleri (Feistmantel).

An examination of the type-specimen from the Calcutta Museum enables me to amplify the original description in an important particular. The species was found in Lower Gondwana (Kathârbari) beds in India and referred by Feistmantel² to the genus *Carpolithes*. Arber³, who tentatively employed the generic name *Cardiocarpus* in place of *Carpolithes*, suggests that the seeds may be radiospermic, as Feistmantel's drawings show only a very narrow border to the nucule. The specimen reproduced in fig. 504 was figured by Feistmantel without any indication of a definite sarcotesta or wing, but as seen in the drawing the ovate cordate sclerotesta is surrounded on one side and at the base by an outer envelope: this is clearly seen at the apex where it shows a rounded termination sloping downwards towards the micropyle precisely as in *Samaropsis indica* (Zeill.). The border is narrow at the sides and broader at the base as in *S. Leslii*. The seed

FIG. 504. *Samaropsis Milleri*. (Indian Geological Survey, Calcutta; nat. size.)

³ Arber (05) B. p. 205.

is 4.5 cm. long and 2.3 cm. broad, differing from *S. indica* in its rather smaller size and in the slightly narrower nucule. Though there is no decisive evidence as to the parent-plant the occurrence of a specimen of this species partially covered by a scale-leaf of a type¹ very similar to that which is generally recognised as belonging to *Glossopteris* suggests the possibility that the seeds may belong to that genus. Scale-leaves of *Glossopteris* are described in Volume II., but it may be added here that leaves similar in form to those from India, Australia, and elsewhere are figured by Geinitz² from the Altai Mountains as *Trigonocarpus? actaeonelloides*: the specimens are represented with the basal scar at the apex.

Cordaicarpus. Geinitz.

In view of the fact that the generic names *Cardiocarpus*, *Cordaicarpus*, and other designations have been applied to casts and impressions which cannot be distinguished by any constant or important feature it is proposed to adopt the name *Cordaicarpus* for platyspermic seeds, preserved as casts or impressions, having a comparatively narrow border enclosing an ovate or cordate-ovate nucule; the base is either rounded or cordate. The choice between *Cordaicarpus* and *Samaropsis* depends on the breadth of the border. *Cordaicarpus*, though more suggestive of a Cordaitean alliance, may in some cases be a Pteridosperm seed.

Cordaicarpus Cordai (Geinitz). Lenticular seeds more or less orbicular or broadly ovate (fig. 502, C, D), often slightly cordate at the base of the nucule and with a broadly acute apex: the border is narrow or sometimes hardly represented as in the seeds described by Berger as *Rhabdocarpus ovoides*, a species similar to but more oval than *Cordaicarpus Cordai*. The latter species³ occurs in several coalfields in Britain, France, Germany, and elsewhere. Fig. 502, C, shows a good example from the Middle Coal Measures of Yorkshire, 9 mm. long by 8 mm. broad; on the very slightly cordate nucule are several faint ribs converging towards the base and apex and between them fine striations,

¹ Vol. II. p. 500.

characters too indistinct to be reproduced in the natural-size drawing. The flat border represents the sclerotesta. The seed shown in fig. 502, D, from the Westphalian series of Warwickshire belongs to the same species or is a closely allied type: the faint suggestion of reticulation on its surface might be regarded as a reason for referring it to *C. areolatus* Boul.¹, a form characterised by a reticulation on the testa, described by Zeiller² and other authors. This reticulation is, however, in some cases at least, formed by crumpling and splitting of the superficial carbonised film into more or less regular meshes: the figured specimen occurs with several other seeds of the same type, most of which have a smooth surface. Dr Kidston tells me that a recent critical examination of seeds in his collection leads him to regard some specimens (*e.g.* fig. 502, D) previously referred by him to *C. Cordai* as identical with *Carpolithes membranaceus* Goepf.³

FIG. 505. *Cordaicarpus Cordai*. Cuticle of the testa. (Kidston Collection.)

The photograph reproduced in fig. 505 shows the result of chemically treating the carbonised cuticle of a seed of *Cordaicarpus Cordai*, a method little used as yet in the case of Palaeozoic plants

but which may be useful in distinguishing seeds which cannot be satisfactorily separated by microscopic features. The superficial cells have very thick walls and present an appearance similar to that of the sclerous cells in the testas of some petrified specimens.

The larger seed shown in fig. 501, D, from Commentry, described by Renault and Zeiller¹ as *Cardiocarpus sclerotesta*, is another example of *Cordaicarpus* as now defined.

IV. MISCELLANEOUS SEEDS.

In this section are included genera based on characters of comparatively little morphological importance; their claim to treatment under a common heading is that we know little or nothing of their anatomical features or of the parent-plants.

i. *Ribbed seeds.*

The seeds represented by the following genera possess ribs or flanges usually in multiples of three; the transverse section may be triangular, hexagonal, or polygonal. The symmetry is generally radial, but it is difficult to determine whether a slight departure from the radiospermic form is an original feature or the result of pressure. Some of the ribbed seeds with which we are now concerned are no doubt closely allied to *Trigonocarpus* and should be included in the Trigonocarpaceae, but others may well be distinct forms.

Genera: *Hexagonocarpus*, *Decagonocarpus*, *Polypterocarpus*, *Rhynchogonium*, *Boroviczia*, *Diplopterotesta*, *Musocarpus*, *Holcospermum*.

Hexagonocarpus. Renault.

This generic name is adopted by Renault² for casts from Commentry which, while probably identical with Brongniart's *Hexapterospermum*, afford no confirmatory anatomical evidence. The species *Hexagonocarpus crassus*³ is represented by casts or nucules characterised by six well-defined ribs and grooves with a length of nearly 3 cm. In this genus may be included the cast from the Coal Measures of Lancashire described by Williamson⁴

¹ Renault and Zeiller (88) A. Pl. LXXII. fig. 3.

² *Ibid.* p. 649.

³ *Ibid.* Pl. LXXII. figs. 53—55.

⁴ Williamson (77) B. p. 253, Pl. XVI. figs. 115 a, 115 b.

as *Hexapterospermum Noeggerathi* (fig. 506, H), and another British example is afforded by *Hexagonocarpus Hookeri* Kidst.¹, a rare fossil in the South Staffordshire coalfield. It is impossible confidently to assign these ribbed casts to genera founded on petrified specimens as they almost certainly belong to different types, but the employment of the name *Hexagonocarpus* may conveniently be used for casts or impressions of seeds with six longitudinal ribs differing in their relatively broader and less prominent form from the wing-like flanges of *Polypterocarpus* (cf. fig. 496, B). The seeds described by Dr P. Bertrand² as *Hexapterospermum modestae*, and believed by him to belong to a plant with *Neuropteris* fronds, should be included in *Hexagonocarpus* as we have no definite knowledge of their anatomical features.

Decagonocarpus. Renault.

This name, proposed by Renault³, is applied to seeds without petrified tissues characterised by ten ribs; an example is afforded by *Decagonocarpus olivaeformis* from the Commentry coalfield, an elliptical seed which bears a close resemblance to *Holcospermum sulcatum* (fig. 506, A) except in the smaller number of ribs.

Polypterocarpus. Grand'Eury.

Grand'Eury⁴ adopted this generic name for seeds from St Étienne characterised by the presence of three, six, or more deep wings or flanges. The term *Pterospermum* has recently been proposed by Arber⁵ for a seed from the Coal Measures of Staffordshire, which he names *P. anglicum*: the type-species of the genus has three deep wings, one from each angle. For the same seed Kidston⁶ proposed the name *Tripterosperrum ellipticum*, but as Arber's account was published first his specific name has priority. *Pterospermum* had, however, been previously used for a genus of Sterculiaceae, and partly on this account but mainly because Grand'Eury's genus *Polypterocarpus* is available the latter designation is adopted. In *Polypterocarpus anglicus* (fig. 496, B) the

⁶ Kidston (14) p. 157, Pl. XIV. figs. 1, 2.

flanges project slightly beyond the apex of the seed and there is a small notch at the base; the nucule is 5 cm. long and 1 cm. broad. While it is not improbable that this seed is generically identical with Brongniart's *Tripterosperrum*¹, it is safer, in the absence of structural details, to employ the less committal term. There is no information with regard to the nature of the parent-plants of species of *Polypterocarpus*. The English seed from the Middle Coal Measures of Derbyshire and the Staffordshire coal-field described by Arber² as *Radiosperrum ornatum* and by Kidston³ as *Polypterosperrum ornatum* affords another example of *Polypterocarpus* as the generic name is here employed.

Rhynchogonium. Heer.

Heer⁴ proposed this generic name for some globose, ovate, or oblong 'fruits' from Lower Carboniferous strata in Spitzbergen, including also fragments of 'leaves' which without satisfactory evidence he believed to belong to the same plant. The supposed fruits are clearly seeds, and Nathorst regards the 'leaves' as portions of a Fern rachis. Heer described four species, but these have since been reduced to two, and indeed it is probable that only one type, *Rhynchogonium costatum*, is represented. Nathorst⁵ compares Heer's seeds with a Lower Carboniferous species described by Young⁶ as *Trigonocarpum gloagianum*, the resemblance of which to the Spitzbergen seeds was pointed out by Kidston. A seed of *Rhynchogonium costatum* is about the size of a hazel-nut and may reach a length of 21 mm.; it is ovate, with a broad rounded base, and in the upper third is tapered and conical, the sides of the characteristic snout being distinguished from the smooth surface of the rest of the seed by the presence of eight ribs converging towards the apex (506, G). Zalessky⁷ recorded closely allied seeds from Lower Carboniferous beds in Northern Russia, assigning them to a new genus *Boroviczia*, the type-species being *B. Karpinskii*; he adduced arguments in favour of Heer's interpretation of the fossils as fruits but, according to Nathorst, this view has been abandoned. In his recent memoir on the Culm

flora of Spitzbergen Nathorst¹ discusses the morphological nature of *Rhynchogonium* seeds and describes additional specimens. Without the aid of petrified examples it is hardly possible to determine the true nature of the fossils.

FIG. 506. A, *Holcospermum sulcatum*. B, C, *Codonospermum anomalum*. D, *Diplopterostea spitzbergensis* ($\times 3$). E, *Gnetopsis elliptica* (cupule). F, *Thysanotesta sagittula*. G, *Rhynchogonium costatum*. H, *Hexagonocarpus Noeggerathi*. I, *Boroviczia Karpinskii*. K, *Rhabdospermum tunicatum*. (A, Kidston Collection; B, after Grand'Eury; C, after Renault and Zeiller; D, F, G, after Nathorst; E, after Renault; H, after Williamson; I, after Zalesky; K, after Berger.)

Some specimens of *Rhynchogonium sulcatum* in Dr Kidston's collection show the original surface-features: the carbonised integument is divided in the upper region into linear lobes separated from one another at their origin by fairly wide sinuses, a type of integument suggesting comparison with *Physostoma*. This species was originally described by Lindley and Hutton as *Carpolithes sulcata*² from Lower Carboniferous rocks at Newhaven in Scotland and has recently been figured by Zalesky³ from specimens in

¹ Nathorst (14) p. 23, Pl. xv. figs. 44—51.

² Lindley and Hutton (37) A. Pl. 220.

³ Zalesky (05).

the Kidston collection from the Lower Calciferous sandstone of Midlothian. Nothing definite can be said as to the parent-plant, but it is significant that in Midlothian *Rhynchogonium sulcatum* occurs in a bed full of isolated pinnules of a *Cardiopteris* almost to the exclusion of any other fossils¹.

The seed figured by Nathorst² from the Culm of Spitzbergen as *Lagenospermum? glandiforme* agrees closely with *Rhynchogonium* and *Boroviczia*, and it is impossible to decide whether the lobed appearance is due to the presence of a cupule or to the divisions of an integument.

Boroviczia. Zalessky.

The specimens from Lower Carboniferous beds in Russia³ on which this genus was founded are perhaps unnecessarily separated from *Rhynchogonium*; they are ovate and beaked, 10 mm. long with a maximum breadth of 6 mm. The type-species, *Boroviczia Karpinskii* (fig. 506, I), is represented both by specimens in which the cast is complete and by others in which the apical snout of the integument is split into separate lobes identical in form and apparently in number with those of *Rhynchogonium*. Nathorst⁴, who retains the generic name and describes two additional species from Spitzbergen, points out that in *Boroviczia* the tapered apex is more sharply differentiated from the broader basal portion, a difference hardly worthy of generic recognition. If *Boroviczia* is retained as a genus distinct from *Rhynchogonium* it should include the seeds described by Young as *Trigonocarpum gloagianum*.

Diplopterotesta. Nathorst.

Diplopterotesta spitzbergensis (Heer). Heer⁵ included in *Samaropsis* some seeds, described as *Samaropsis spitzbergensis*, from Lower Carboniferous strata in Spitzbergen which differ considerably from typical examples of the genus. These have recently been made the type of a new genus *Diplopterotesta*⁶: they are platyspermic seeds nearly twice as long as broad, 6—9×3·5—5 mm.,

¹ For this information I am indebted to Dr Kidston.

² Nathorst (14) p. 32, Pl. xv. fig. 58.

³ Zalessky (05).

⁴ Nathorst (14) p. 27, Pl. v. figs. 19—22; Pl. xv. fig.

⁵ Heer (77) i. p. 24, Pl. v. figs. 18—22.

⁶ Nathorst (14) p. 35, Pl. xv. figs. 77—82.

characterised by a thin sclerotesta expanded throughout the length of the seed into two prominent transversely striated wing-like ribs or flanges (fig. 506, D). At the apex, which is broad in contrast to the pointed basal end of the seed, the sclerotesta forms a crown of eight lobes about the flat summit of the seed-body. As Nathorst points out, this species closely resembles the Carboniferous seeds figured by Grand'Eury¹ as *Polyptero-carpus*, but in the latter type there are more than two wings. Nathorst's figures, one of which is reproduced in fig. 506, D, suggest a difficulty in determining the number of the flanges, which would seem to be more than two, but this appearance is regarded by Nathorst as misleading and he believes that except at the apex there are only two wings.

Musocarpus. Brongniart.

Brongniart² proposed this name for two species, *M. prismaticus* and *M. difformis*, from French Coal Measures, but gave no description of the specimens. The type-species, described from the Loire by Grand'Eury as *Musocarpus prismaticus*³, is an ovate seed nearly 3 cm. long with six longitudinal ribs, three being more prominent than the others, and characterised by a ribbed prolongation of the base of uniform diameter spoken of as a carpophore, which was apparently articulated to the lower part of the seed-proper from which it was easily detached by a natural absciss-layer. Nothing is known of the structure or of the affinity of the genus. Some specimens in Dr Kidston's collection from Westphalian beds in Lanarkshire are closely allied to or perhaps identical with *M. prismaticus*. In the presence of a distinct basal region *Musocarpus* resembles *Codonospermum*⁴, though without any knowledge of the anatomy of the former type it is impossible to say whether or not this resemblance has any morphological importance.

Holcospermum. Nathorst.

Holcospermum sulcatum (Sternberg). The cast reproduced in fig. 506, A, affords a good example of a form of seed recorded

¹ Grand'Eury (77) A. Pl. xvi. figs. 2—4.

² Brongniart (28) A. p. 137.

³ Grand'Eury (77) A. p. 184, Pl. xv. fig. 3.

⁴ See page 330.

under several generic names and not uncommon in Upper Palaeozoic rocks in Europe and North America, which in most cases cannot be assigned to a genus implying the possession of certain anatomical characters. This type was figured by Sternberg¹ from the Coal Measures of Radnitz as *Carpolites sulcatus*. Some 'fruits' collected on the beach near Newhaven, Midlothian, from the Calciferous Sandstone series, are figured by Lindley and Hutton² as *Carpolithes sulcata*, but as already stated these have been transferred³ to the genus *Rhynchogonium*. Several authors have referred specimens of the type now included in *Holcospermum* to *Rhabdocarpus*, but that genus, as stated on a previous page, is restricted to seeds agreeing in form with *R. tunicatus*. Renault⁴ instituted the genus *Colpospermum* for a partially petrified seed from Commeny agreeing externally with *Carpolites sulcatus* Sternb. and regarded by him as specifically identical, characterised by longitudinal ribs which represent folds of the testa, the intervening grooves being occupied by an irregular reticulum formed by occasionally anastomosing smaller ribs. The generic name *Colpospermum* should therefore be reserved for ribbed seeds showing the anatomical features described by Renault and Zeiller: its application to Sternberg's species is inadvisable on the ground that we have no information with regard to the morphological nature of the ribbing. More recently Arber⁵ has proposed the name *Platyspermum*, a name previously applied to a Cruciferous plant, for Stephanian and Permian seeds formerly assigned to Berger's genus *Rhabdocarpus*, which are symmetrical in two planes. In this genus he includes *Platyspermum sulcatum* and among other species *P. Kidstoni* founded on a seed originally identified by Kidston⁶ as *Rhabdocarpus multistriatus* Sternb. which, though probably a distinct species, is of the same general type as *C. sulcatus* Sternb.

The cast represented in fig. 506, A, from the Middle Coal Measures of Yorkshire is 3.5 cm. long and has 18 regular longi-

⁵ Arber (14) p. 95, Pl. VI. fig. 11.

⁶ Kidston (88) B. Pl. XXIII. fig. 4.

tudinal ribs: it is radially symmetrical and does not conform in this respect to Arber's definition of *Platyspermum*. In many cases, e.g. the flattened seed figured by Kidston as *Rhabdocarpus multistriatus*, it is impossible to determine the symmetry of the seed. The old generic name *Carpolites*, *Carpolithes* or *Carpolithus* has been used in a very wide sense and does not connote any well-defined features; it should be reserved, in the form *Carpolithus* as used by Linnaeus, for seeds that cannot be assigned to a systematic position or which do not exhibit any distinctive characters worthy of emphasis by the institution of a special name. The generic term *Holcospermum*, recently proposed by Nathorst¹, is a suitable name for this type of seed; as defined by the author, it includes seeds that may be radiospermic or platyspermic. Specimens of the type-species, *H. dubium*², from the Lower Carboniferous beds of Spitzbergen, agree closely in size and shape with some examples of *Rhynchogonium* and *Boroviczia*, but they are distinguished by prominent ribs extending the whole length of the cast. In some seeds similar to *H. sulcatum* the ribs form sharp ridges, but the difference between rounded and sharp ridges is often determined by the method of preservation: a specimen deprived of its outer flesh would form a cast more sharply ribbed than a seed in which the sarcotesta had been moulded on to the ribbed sclerotesta. On the other hand some ribs are formed by blunt sclerotestal folds as in *Colpospermum*: both types of ribbing are included in the genus *Holcospermum*.

ii. Other Genera.

Malacotesta. Williamson.

This generic name was instituted by Williamson³ for a petrified seed from the Coal Measures of Lancashire which he named *Malacotesta oblonga*: the type-specimen is a small seed 6—7 mm. long characterised by a thick fleshy integument. The structure is however insufficiently known to admit of a satisfactory comparison of the imperfectly preserved specimen figured by Williamson with other types.

¹ Nathorst (14) p. 28.

² *Ibid.* Pl. xv. figs. 53, 54.

³ Williamson (77) B. p. 246, Pl. XIII. figs. 88—93.

Thysanotesta. Nathorst.

Nathorst¹ founded this genus on a single seed from the Lower Carboniferous plant-beds of Spitzbergen which exhibits features sufficiently distinctive to justify its recognition as the type of a separate genus.

Thysanotesta sagittula Nathorst. The type-specimen is a long and narrow seed, 20 mm. long, ovate below and prolonged apically into a slender beak, 8 mm. in length, which probably represents a micropylar tube; the beak bears numerous stiff hairs (fig. 506, F). The seed closely resembles a carpel of *Erodium* without the horizontal part of the awn. There is no evidence as to the nature of the parent-plant but the species affords an interesting example of a Palaeozoic seed apparently adapted for wind-dispersal, or possibly the bristles may have served the same purpose as in the fruits of *Erodium*. Attention is called elsewhere² to the frequent resemblance of Palaeozoic seeds such as *Thysanotesta* to fruits of recent flowering plants.

Carpolithus. Linnaeus.

Nathorst³ has pointed out that this generic name was employed by Linnaeus for fossil fruits: in the form *Carpolites* (Sternberg) or *Carpolithes*⁴ it has been widely used and differently defined by authors, usually in a comprehensive sense including fossil seeds from both Palaeozoic and Mesozoic strata which cannot be assigned to a definite position in the plant-kingdom. It is desirable to adopt some designation for seeds from strata of different ages which do not exhibit any features sufficiently distinctive to justify the creation of a special genus. By employing such a name as *Carpolithus*, without attempting to define its characters within prescribed limits, for casts or impressions of seeds which are not distinguished by any striking characters and cannot be allocated to any particular section of seed-bearing plants the unnecessary multiplication of generic titles is avoided: when any additional data are obtained differentiating particular types from other forms of *Carpolithus* the provisional term should be superseded by some distinctive generic name. Among seeds from the Coal Measures

¹ Nathorst (14) p. 33. Pl. xv. figs. 69, 70.

² See page 304.

³ Nathorst (14) p. 33.

⁴ Seward (95) A. p. 101.

there are several examples of both large and small types without any regular ribs or lacking such features as serve to distinguish the genera already described, which are appropriately included in *Carpolithus*. The two species *Carpolithus Wildii* Kidst.¹ and *C. bivalvis* Goepp.² are two examples of seeds from Upper Carboniferous rocks which it is desirable to refer to this comprehensive genus pending further discoveries as to their morphological features. The Jurassic species *C. conicus* Lind. and Hutt.³ is another type which it has been customary to include in *Carpolithus*. (*Microspermum*. Arber.)

The generic name *Microspermum* has recently been proposed by Arber⁴ for some Westphalian seeds described by Carpentier⁵ from the North of France as *Carpolithes? samaroides* and for similar fossils from the Middle Coal Measures of Nottingham. The supposed seeds are small, ovate or pyriform bodies, 5—12 mm. long and 2·5—6 mm. broad, with one extremity broadly rounded and the other acute: one side is keeled, the other grooved, and a large foramen occurs near the broader end and on the grooved surface. Arber emphasises the fact that the specimens are symmetrical in one plane only. As the author of the genus points out the morphological nature of the fossils is not thoroughly established, nor is the parent-plant known. In view of the ill-defined characters of the specimens so far discovered it is hardly desirable to institute a new generic name implying their seed-nature; moreover *Microspermum* has previously been employed for a genus of Compositae. An examination of specimens leads me to doubt their seed-nature and it would seem more likely that they are foliar organs, possibly bracts which originally bore seeds or sporangia.

An examination of some of the specimens of supposed Permian seeds for which Geinitz⁶ proposed the generic name *Gurlelmites* convinced me that they are inorganic structures, probably nodules in shale smoothed and rounded by slickensiding.

CHAPTER XXXVI.

CYCADOPHYTA.

THE term *Cycadophyta*, suggested by Nathorst¹, is used in a comprehensive sense to include both recent Cycads and the much larger number of extinct types which it is customary to speak of as Cycadean plants or fossil Cycads. The designation 'Cycads' in the case of the majority of the fossil forms is, however, open to criticism on the ground that they differ too widely from existing genera to be associated with them in one class. It would be pedantic and inconvenient to give up the almost universal practice of extending the term Cycad beyond the limits defined by the characters of recent species. The important point is to adopt some classification which gives expression to our views as to the degree of affinity between recent and extinct types. In a considerable number of cases, especially impressions of presumably Cycadean fronds and stems that occur without any fertile shoots, it is impossible to determine the degree of relationship to modern types. It was with a view to a rational group-designation for such fossils that Nathorst proposed the term *Cycadophyta*, including in it the two classes *Cycadales* and *Bennettitales*. The *Cycadales* comprise the recent genera and such extinct types as may legitimately be included in the same class, but as we shall see later there are hardly any fossil species that can be assigned to this section on thoroughly satisfactory grounds. The term *Bennettitales* is used by Engler, Nathorst, and several other authors as a class-designation for a large number of Mesozoic Cycads agreeing in their more important morphological characters with the Lower Cretaceous stems on which Carruthers² founded

¹ Nathorst (02) p. 3.

² Carruthers (70) p. 694.

the genus *Bennettites*, placing it in a new tribe, the Bennettiteae. Some authors have followed Carruthers in the use of the family-name Bennettiteae for a subdivision of the Cycadales equal in rank to the Cycadaceae, while others, wishing to give greater emphasis to the difference between the extinct and recent plants, prefer to adopt the class-name Bennettitales. Carruthers regarded *Bennettites* as occupying the same position in relation to other Cycads as *Taxus* holds with regard to the cone-bearing members of the Coniferae. The adoption of Bennettitales is intended to convey the impression that the class is more distantly related to the recent Cycads than is implied by the analogy of *Taxus*. Nathorst¹, as the result of his discovery of certain reproductive organs associated with some Rhaetic fronds described as *Dioonites spectabilis*, proposed a third subdivision, the Dioonitales, but he subsequently² restored the fronds to their original designation *Nilssonia pterophylloides*, and on further examination found that the supposed microspore-bearing organs were seeds. *Nilssonia pterophylloides* would therefore find a more natural place in the class Nilssoniales instituted by Thomas³.

BENNETTITALES.

Cycadeoidea. Buckland.

In 1827 Buckland⁴ proposed the generic name *Cycadeoidea* for some petrified stems from the Purbeck beds in the Isle of Portland and published a description of two species, *Cycadeoidea megalophylla* and *C. microphylla*. Brongniart⁵ considered Buckland's term *Cycadeoidea* inappropriate and proposed in its place *Mantellia*, the type-species being *Mantellia nidiformis* Brongn., the Portland stem which Buckland a month or two later called independently *Cycadeoidea megalophylla*. Subsequently Brongniart⁶ withdrew *Mantellia* as it had been previously used by Parkinson for a sponge and substituted *Cycadites*. Some years later Carruthers⁷ revived *Mantellia* for a type of Cycadean stem from Portland

¹ Nathorst (02) p. 23.

⁷ Carruthers (70) p. 678.

though one species, apparently indistinguishable from those referred to *Mantellia*, he named *Bennettites portlandicus*. There is no adequate reason for the retention of the generic name *Mantellia*. The close resemblance of the short and thick stems (12—30 cm. in height) described by Buckland to those of some recent Cycads was recognised by Robert Brown and Loddiges and the former suggested to Buckland the inclusion of the fossils in a new family Cycadeoideae. It was this suggestion that led Buckland to adopt *Cycadeoidea* as a generic name. In a later account of the Portland stems Buckland¹, in deference to Brongniart's opinion, substituted Brongniart's name *Cycadites* for *Cycadeoidea*. It is noteworthy that no reference is made in the original description to the occurrence of lateral shoots among the persistent petiole-bases that encase the Portland stems, but in a later account such shoots are represented in one of the figured stems and are compared with the buds occasionally produced on stems of *Cycas*². The subsequent researches of Carruthers³ demonstrated the reproductive nature of precisely similar lateral shoots in the stem on which he founded the genus *Bennettites*. The generic name *Echinostipes* given by Pomel⁴, who had a passion for instituting new nomenclature, to Buckland's Portland stems has not been adopted: his genus *Crossozamia* proposed for certain stems and fronds was revived by Carruthers⁵ but has not been generally used. A further complication in the nomenclature of Cycadean stems was introduced by Saporta's institution⁶ of *Bulbopodium* and *Cylindropodium*: in the former genus he included the small ovoid stem figured by Lindley and Hutton as *Cycadeoidea pygmaea*⁷ and two French Jurassic species which might reasonably be assigned to *Cycadeoidea*. To *Cylindropodium* were referred some large French stems from Jurassic strata: an examination of the type-specimens in Paris convinced me that they are typical forms of *Cycadeoidea*. As Ward⁸ has pointed out, both Saporta's genera may be merged in *Cycadeoidea*. Fliche and

⁷ Lindley and Hutton (35) A. Pl. 143.

⁸ Ward (94).

Zeiller¹ also include the small globular stems named by Saporta *Bulbopodium* in the older genus *Cycadeoidea*: one such type from the Portlandian of Boulogne is described by these authors as *Cycadeoidea pumila*. Saporta also proposed the name *Platylepis*², the type-species being *Cycadeoidea micromyela* Mor., from the Lias of Calvados, which has recently been investigated by Lignier³ who wisely adopts Morière's designation. Another unnecessary generic name is *Schizopodium* given by Morière to a stem, *S. Renaulti*⁴, regarded by Lignier as indistinguishable specifically from *C. micromyela*.

The two names *Cycadeoidea* and *Bennettites* have been used by authors for stems which are unquestionably generically identical and as is often the case much confusion has been caused through the failure of palaeobotanists to arrive at an agreement. Lester Ward, a staunch advocate of the rule of priority, repeatedly pointed out that Buckland's name *Cycadeoidea* should take precedence of *Bennettites* on the ground that stems for which these genera were instituted are clearly of the same type, and he added that the older genus, though abandoned by its author, cannot be given up without violating the inexorable rules of priority. On the other hand it has been urged that the genus *Bennettites* as defined by Carruthers is characterised by the possession of (i) fertile shoots bearing strobili and (ii) vegetative organs exhibiting certain anatomical characters. Buckland's species of *Cycadeoidea*, though bearing lateral shoots, are not well enough preserved to afford definite information as to the morphological features of the strobili, nor have we satisfactory data with regard to the degree of resemblance between the vegetative features of *Bennettites* and the Portland stems. Carruthers laid stress on the elliptical section of the stele in *Bennettites* in contrast to the cylindrical cylinder of Buckland's *Cycadeoidea* trunks. Subsequent research has shown that this difference is not in itself a valid criterion either of generic or specific rank but, as Wieland says, it is an open question to what extent the stem structure of *Cycadeoidea* and *Bennettites* agrees. The probability is that were our knowledge of the Portland stems less incomplete, they would

¹ Fliche and Zeiller (04).

² Saporta (75) A. p. 276, Pl. 120.

³ Lignier (01).

⁴ *Ibid.* (13) p. 93.

be found to possess no anatomical features inconsistent with this generic union. Granting the correctness of this view, the adoption of the later generic term would be a reasonable course to follow on the ground that it stands for stems showing well preserved structure, while *Cycadeoidea* was in the first instance applied to stems showing only partially preserved stumps of strobili, and the name was not retained by its author. Graf Solms-Laubach¹ and some other authors have used *Bennettites* for Cycadean stems possessing strobili of known structure such as those of *Bennettites Gibsonianus*, reserving *Cycadeoidea* for similar stems but without strobili sufficiently well preserved to afford evidence of morphological characters. This practice I followed in 1895², but my usage of the two generic names has not been consistent, the name *Cycadeoidea* being afterwards employed³ in a more comprehensive sense. The investigation of the reproductive shoots of American Lower Cretaceous and Upper Jurassic Cycadean stems⁴ has demonstrated the practical identity of their ovulate strobili with those of the English *Bennettites*. It is clear that the American stems as well as numerous specimens from Italy and other European localities are generically inseparable from *Bennettites*. The adoption of *Cycadeoidea* by Wieland, following Ward, has naturally strengthened the claim of Buckland's genus at least so far as wide usage is concerned, and with some reluctance I propose to fall in with this terminology and for the sake of convenience to give up the use of *Bennettites*. Among Mesozoic Cycadean stems agreeing with those of recent genera in habit and in the presence of an armour of persistent leaf-bases are several which afford no evidence either of the occurrence of fertile shoots or of lateral shoots with terminal flowers. To such stems the name *Cycadeoidea* has been applied, the designation *Bennettites* being restricted to stems with lateral fertile shoots: this practice of treating the absence of reproductive shoots as a characteristic feature of *Cycadeoidea* is regarded by Wieland as illogical and artificial; and if, as seems probable, he is correct in believing that the majority of the Mesozoic Cycadean plants culminated their vegetative period by prolific development of flowers, the absence of flowering

¹ Solms-Laubach (91).

³ *Ibid.* (04) B. p. 44.

² Seward (95) A. p. 139.

⁴ Wieland (06).

branches would be contingent on a certain stage of development and not a generic character. Dr Stopes¹ has recently published facts with regard to the anatomical features of Cycadean stems which have a bearing on the vexed question of nomenclature, but are more important from a morphological point of view as they indicate a closer agreement between certain types of Lower Cretaceous stems and those of *Cycas* and other recent genera, in which successive rings of vascular tissue are developed, than has previously been recognised. In her diagnosis of *Cycadeoidea* she includes the following statement: 'In its internal anatomy the trunk shows two or more (up to eight are recorded) zones of secondary wood, the zones composed of distinct series of tracheids each more or less regularly arranged in radial sequence.' It is claimed that the addition of this character constitutes for the first time a clear distinction between *Cycadeoidea* and *Bennettites*. Dr Stopes states that the two stems on which Buckland founded the genus *Cycadeoidea* are lost and adds that Buckland's type has certain anatomical features which are not found in *Bennettites*. Buckland in his description of *C. microphylla* states that there are 'two laminated circles' in the stem instead of the usual single cylinder, a character suggestive of *Cycas*. In the original figure of this species there are no indications of any lateral fertile shoots though, as Dr Stopes says, many of the Portland stems undoubtedly possessed such flowers. This author makes no reference to Buckland's later description of *C. microphylla*: in this it is stated that the stem bears numerous buds rising from the axillae of petioles, and these are shown in the illustration². Without access to the actual specimen it is impossible to say whether or not the two 'laminated circles' described and figured by Buckland³ are two distinct cylinders or parts of one cylinder separated by the infiltration of some inorganic substance. In his description of *Cycadeoidea Yatesii* Carruthers spoke of the occurrence of two cylinders of wood, and this was confirmed in a subsequent account of the type-specimen⁴. Dr Stopes gives a fuller account of Carruthers' type and re-confirms the existence of two vascular

¹ Stopes (15) p. 309.

² Buckland (37) A. Vol. II. p. 98, Pl. LXI. fig. 1.

³ *Ibid.* (28) Pl. XLIX.

⁴ Seward (95) A. p. 166.

cylinders; she also describes a new species, *C. buzzardensis*¹ (fig. 578), in which there are 3—8 or more cylinders. Neither of these stems affords any evidence of the possession of fertile shoots; they agree closely with stems of the *Bucklandia* type in their comparatively slender habit and differ in this respect from Buckland's Portland species. The occurrence of more than one vascular cylinder in the stems *Cycadeoidea* (= *Bucklandia*) *Yatesii* and *C.* (= *Bucklandia*) *buzzardensis* suggests the possibility that this feature was characteristic of other species included in *Bucklandia*.

It is clear that some at least of the stems referred to the genus *Bucklandia* bore flowers of the *Williamsonia* type², and it is not improbable that the stems described by Dr Stopes as *Cycadeoidea Yatesii* and *C. buzzardensis* (fig. 578) possessed fertile shoots comparable with those of the Middle Jurassic species *W. gigas*. Dr Stopes's contribution, while establishing a close agreement in anatomical features between some Lower Cretaceous stems and those of *Cycas*, does not warrant the further conclusion that these stems were in other morphological characters closely allied to modern Cycads. The main features of *Cycadeoidea* may be summarised as follows: The principal trunk is generally unbranched (fig. 507) and identical in habit with some species of *Macrozamia*, *Dioon*, and *Encephalartos* (cf. figs. 379, 382); in some species, e.g. *Cycadeoidea Marshiana*, *C. superba*³, *C. nana*⁴, the plant is represented by several approximately equal, thick, tuberous stems, in some cases easily separated from one another: a similar clustered habit is exhibited by certain forms of *Encephalartos*. The size of a *Cycadeoidea* trunk varies from a few centimetres in length with a diameter of similar dimensions, as in *C. pumila*, to over a metre long as in *C. gigantea* (fig. 535), or as much as 3—4 metres in *C. Jenneyana* with a diameter of about half a metre. The surface is covered with persistent leaf-bases, exactly as in many recent Cycads, embedded in a thick mass of ramental scales which often stand out as a prominent reticulum, the petioles having partially decayed before the penetration of the mineralising solution through their harder tissues

¹ Stopes (15) p. 309.

³ Wieland (06) Pls. VI.—XIII.

⁴ *Ibid.* (12) p. 88, fig. 10.

FIG. 507. *Cycadeoidea marylandica*. The first American stem to be described. On the side of the stem shown in the photograph there are about 30 young strobili scattered among the leaf-bases. (After Wieland; $\frac{1}{4}$ nat. size.)

(fig. 507). On the conical terminal bud preserved in some stems (fig. 536) the foliage-leaves are replaced by linear scales. The leaf-bases often show the vascular bundles which form a simpler system than in the majority of recent species, their arrangement being, as Wieland says, more Fern-like; they form a series of collateral strands following the outline of the petiole-base¹ with a U-shaped invagination in the middle of the upper face (fig. 517, A). Beyond the structure of the bundles at the base of the fronds and in the cortex of the stem our knowledge of the anatomy of the vascular supply of the rachises is very meagre. At the petiole-base each bundle consists either entirely of radial rows of centrifugal scalariform tracheids and medullary rays usually one-cell broad (fig. 519, B) or of centrifugal and centripetal xylem in varying proportions. The ground-tissue is well supplied with large secretory canals and in the larger leaf-bases there is a considerable development of periderm at the surface (fig. 517, B) as in recent Cycads. The ramenta formed from the epidermal cells consist in most species of fairly broad scales one-cell thick at the edges and broader in the middle; in *Cycadeoidea nigra*² they are generally one-cell thick throughout and similar ramenta are common in *C. Gibsoniana* (fig. 517, B). In *C. micromyela* unicellular hairs replace the scaly ramenta, but transitional forms occur between hairs and scales. In *Williamsonia scotica* (fig. 562) and in an Indian species of that genus the ramenta are exclusively long hairs as in recent Cycads, the scale-form of the ramenta in *Cycadeoidea* being a Fern-character. The degree of development of the ramental tissue varies in different species; in *C. Stihwelli* and *C. excelsa* it is feebly developed while in *Cycadeoidea micromyela* the ramenta almost cover the exposed leaf-base armour. The exceptional abundance of the ramental scales is a striking characteristic of some American stems referred to a separate genus, *Cycadella*³. In the abundance of the ramental tissue, in the compact structure of the well protected cones, and in the thickly cuticularised epidermis of the bracts and leaves *Cycadeoidea* exhibits xerophilous characters in a very high degree.

¹ Wieland (06) p. 63, fig. 33.

² See Wieland (06) for additional facts and illustrations.

³ See page 417.

With very few exceptions the stems of *Cycadeoidea* so far described afford no satisfactory evidence of the presence of more than one vascular cylinder in the main stem: in this respect *Cycadeoidea* agrees with such recent Cycads as *Dioon*, *Ceratozamia*, and *Stangeria*. In the stem of *C. Jenneyana* the secondary

FIG. 508. *Cycadeoidea Wielandi*. Transverse sections of the secondary xylem of the stem. A, the middle region; B, the inner edge of the xylem. (After Wieland; $\times 100$.)

vascular tissue reaches a considerable thickness and shows signs of 'rings' in the xylem, but these are probably the result of some periodic interference with the uniform growth and not an indication of more than one xylem-cylinder. The secondary xylem (figs. 508, 509) consists only of centrifugal tracheids with some spiral elements on the inner edge; though manoxylic, *Cycadeoidea*

has more compact wood than that of recent Cycads; the medullary rays are 1—2 cells broad except near the perimedullary region where they are broader and the individual cells are tangentially stretched (fig. 508, B). The tracheids are scalariform, but in *C. micromyela*, an exceptional type, some of the xylem-elements have 1—2 rows of separate bordered pits (fig. 538). The phloem

FIG. 509. *Cycadeoidea Wielandi*. Tangential section of secondary xylem of the stem. (After Wieland; $\times 100$.)

(fig. 518, B) is characterised by an alternation of thick-walled elements and thinner cells¹. From the main stele branches are given off to supply the flowering shoots in the form of a cylindrical stele like that of the primary axis, and each leaf-trace arises as a single bundle which, in the form of a U-shaped strand (fig. 519, A),

¹ Wieland (06) p. 76; Capellini and Solms-Laubach (92) Pl. v. fig. 6.

pursues a straight course to the leaf-base (fig. 510) where it breaks up into several branches (fig. 538, B). Both leaf-trace

FIG. 510. *Cycadeoidea* sp. A piece of stem showing (A) the persistent leaf-bases in side-view and at *b* the scars where the bases have broken off, and (B) the inner face of the same piece with the exposed leaf-traces passing into the leaves; one of the traces is seen at *t* in fig. A. (From a specimen in the British Museum; $\frac{1}{2}$ nat. size.)

FIG. 511. *Cycadeoidea Gibsoniana*. Stele in the cortex. (British Museum, 8406.)

and peduncle stele are given off from the lower edge of a medullary ray. In the parenchymatous cortex large secretory canals (fig. 518, B) are a conspicuous feature, and accessory cortical

steles similar to those in *Cycas* occasionally occur (fig. 511). The large pith consists of parenchyma and secretory canals, and internal periderm¹ may be present; no medullary bundles have been discovered.

FIG. 512. *Cycadeoidea ingens*. Transverse section of a young frond, above the tip of the rachis, embedded in ramenta. The rachis is situated on the upper side of the two ranks of pinnae. The arrow points towards the axis of the stem. (After Wieland; $\times 4$.)

The correlation of the numerous fronds² preserved in Mesozoic strata with their parent-stems is seldom possible. It is known that leaves of the *Zamites* type were borne on stems (*Bucklandia*) agreeing with *Cycadeoidea* in certain features but

¹ Capellini and Solms-Laubach (92) Pl. v. fig. 2.

² See Chapter XXXIX.

differing in the habit of the fertile shoots (fig. 542), and there is evidence that similar stems bore *Ptilophyllum* and *Dictyozamites* fronds¹; but only unexpanded leaves have been found in actual connexion with *Cycadeoidea* stems. Wieland² discovered young pinnate fronds, agreeing in the form of the pinnae with *Zamites* and with some forms of *Encephalartos*, embedded in a thick mass of ramental scales in the terminal bud of a stem: the rachises were erect and the two-ranked pinnae imbricate and folded inwards (fig. 512), the vernation being like that of *Dioon* and not circinate as in *Cycas* and Ferns. The mesophyll of the leathery pinnae is differentiated into palisade and lacunar parenchyma, and the bundles are said to be 'mesarch' though on this point more information is desirable. Each bundle is surrounded by a sheath of thick-walled cells and the same tissue forms I-shaped girders as in similar recent leaves. In one species, *Cycadella ramentosa*³, the rachis of a young frond found among the leaf-bases had a broad U-shaped vascular strand.

In most *Cycadeoidea* stems a characteristic feature is the occurrence of reduced leaves, or bracts, arranged spirally about a cone which sometimes projects slightly beyond the general level of the persistent leaf-bases, or the cones may be fully developed yet still more or less hidden within the armour of petiole-bases (fig. 517, C). These cones, or flowers, are borne at the apex of lateral axillary shoots, and it is characteristic of the genus that they never project more than a very short distance beyond the truncate stumps of the old leaf-bases. The axis of a flowering branch bears numerous linear, hairy, bracts (figs. 513; 514, b) which with their thick felt of ramenta constitute an efficient protective investment. The summit of a fertile shoot forms a rounded hemispherical cushion (fig. 514), or the receptacle may be more elongate and conical (fig. 513) and in some species pyriform⁴. The flowers are generally bisporangiate, but the fact that in flowers with mature microsporophylls the ovules are small and apparently immature (fig. 513) makes it difficult to determine whether the megasporophylls are merely immature or functionless as in the male flower of *Welwitschia* (cf. fig. 818). It would

¹ See page 489.

² Wieland (99); (06) p. 87.

³ Wieland in Ward (05) B. p. 200, Pl. LXIII.

⁴ Wieland (14).

seem, however, that in most cases the flowers were bisexual¹ (fig. 513). A remarkable feature is the enormous number of flowers on a single stem; in *Cycadeoidea Dartoni*², 54 cm. long and 35 cm. broad, 500—600 flowers were counted on one

FIG. 513. *Cycadeoidea*. Restoration of an unexpanded bisporangiate strobilus with some of the hairy bracts removed. Compare *Cycadeoidea dacotensis*, figs. 529, 530. (After Wieland; *ca nat. size.*)

side. On the other hand the large stem of *C. gigantea* (fig. 536) shows no flowers. All the flowers on a single trunk are approximately in the same stage of development: it would seem, as

¹ The flowers are frequently described as protandrous but, as Dr Scott pointed out to me, we have no definite evidence on this point.

² Wieland (11²) p. 134; Coulter and Chamberlain (10) p. 67, fig. 55.

Wieland points out, that after a vegetative period of some considerable duration the plant produced a large crop of flowers, and it is conceivable that as in *Corypha* and some other recent Flowering

FIG. 514. Ovulate strobilus of *Cycadeoidea*. Longitudinal section showing the pith, *m*, stele, *x*, *p*, and cortex, *c*, of the stem, the ovulate strobilus with bracts, *b*, seeds, *s*, etc., enclosed by foliage-leaves, *l*; *a*, insertion of leaves on the stem; *d*, insertion of disc of microsporophylls. (After Wieland.)

plants this supreme effort set a limit to the plant's existence. In the development of flowers from the old stem *Cycadeoidea* affords a striking example of cauliflory.

The structure of the flowers is one of the most obvious differences between *Cycadeoidea* and recent Cycads (cf. figs. 393, 394). The bisexual flowers of the fossil stems are comparatively small, not exceeding a few centimetres in length, like a hen's egg or a medium-sized pear and in marked contrast to the male and female cones of modern Cycads (cf. figs. 393, 394). A verticil of pinnate microsporophylls is attached by a circular collar formed of the concrescent bases of the sporophylls to the lower portion of the receptacle; each pinnule bears several shortly-stalked synangia divided into loculi containing microspores usually with smooth walls and similar, except in their larger size, to those of modern Cycads (fig. 532). Sections of some microspores figured by Wieland¹ show what appear to be cells in the spore-cavity, but they are larger than ordinary prothallial cells and their true nature is doubtful. We lack information both as regards the nature of the male gametes and the tissue formed on the germination of the spores. The free portions of the microsporophyll-whorl may consist of as many as 20 pinnate sporophylls, but the number is generally smaller; these are much longer than the ovulate part of the flower and in an immature state the ends of the sporophylls are bent inwards and downwards (fig. 513) between the bracts and the receptacle. After expanding and shedding the spores the whole male disc is thrown off leaving a narrow rim below the hemispherical or conical receptacle (fig. 514, *d*). The sterile distal end of a microsporophyll is generally slightly expanded and spatulate; in *C. colossalis*² it bears a pair of wing-like appendages (fig. 533).

The upper part of the receptacle is covered with two kinds of organs which together form a layer of uniform depth; these are believed to be homologous, foliar structures; the majority are sterile and have the form of slender long and narrow appendages (fig. 514) each normally with a single axial vascular strand. These so-called interseminal scales increase in breadth in the apical region and form polygonal summits less than a millimetre in breadth or exceeding 2 mm. The low pyramidal apices of the interseminal scales give a mosaic-like appearance to the surface of the ovulate receptacle (fig. 515). In the lower part of the receptacle these sterile

¹ Wieland (06) p. 160, fig. 84.

² *Ibid.* (14).

sporophylls are the only appendages, but over the greater part of the receptacle they are intermixed with a smaller number of similar appendages which bear a single terminal orthotropic ovule (fig. 514, s). Each ovule-bearing organ or megasporophyll (seed-stalk) is surrounded by 5—6 interseminal scales, and the narrow cylindrical micropylar tubes are readily distinguished

FIG. 515. *Cycadeoidea* sp. Surface-view of a young ovulate strobilus showing the swollen ends of interseminal scales grouped about the circular micropyles. (After Wieland; $\times 10$.)

from the sterile sporophylls in surface-view (figs. 516, 564). The seeds appear to be exalbuminous and the embryo is dicotyledonous (figs. 516, 521, 523)¹. The seeds are very small in comparison with those of living Cycads. The structure of the megasporophylls, both sterile and fertile, is described in more detail in the account of *Cycadeoidea Morierei* and other forms. Fig. 516 represents a longitudinal section of one of the smallest seeds of *Cycadeoidea*, between 3 and 4 mm. long; an embryo occupies the

¹ See also Wieland (11²) p. 152, fig. 9.

greater part of the seed-cavity: the micropylar tube is formed of three layers, a strong inner palisade-layer, a thin middle layer, and an outer palisade-tissue, the interior of the tube being filled with parenchyma; at the shoulder of the seed above the root-end of the embryo the surface of the testa is characterised by 5—6 wings formed by the radial extension of palisade-cells. After the shedding of the spores and the abscission of the microsporophylls the flowering shoot probably increased slightly in length, thus pushing the ripening seeds beyond the ends of the surrounding leaf-bases. The ripe flowers were eventually cut off by an absciss-layer immediately below the receptacle (figs. 521, C, a; 522, a), large cuplike depressions being left on the surface of the stem (fig. 534). The ovulate cone on which the species *Cycadeoidea Morierei* is founded probably represents the condition of a naturally detached flower of a *Cycadeoidea*. It is possible that the detached flowers freed from their encircling bracts may have been edible, the small seeds being dispersed by animal agency.

FIG. 516. *Cycadeoidea Dartoni*. Longitudinal section of seed with embryo. (After Wieland; $\times 19$.)

The splendid petrified stem, *Cycadeoidea etrusca* Cap.¹, one of the treasures of the Bologna Museum, was found on a tomb 20 miles west of that city where it was doubtless placed by the Etruscans who obtained it from the Upper Jurassic scaly clays in the Apennine Hills. It was in an imperfectly preserved flower of this fossil that Graf Solms-Laubach discovered some microspores, but it was not until Wieland's examination of the more complete American stems that information was obtained as to the spore-bearing organs. Another Italian stem, *Cycadeoidea montiana* Cap., was described in 1753 as a 'congeries of barnacles².' The specimen named by Goeppert *Raumeria Reichen-*

² Ward (96) Pl. crv.

*bachiana*¹ was described in the middle of the eighteenth century as a mass of *Hippurites* or coral cups: this was found in a swamp in Galicia and is now one of the most striking objects in the Dresden Museum; a brief account of it is given on page 409. In 1859 Tyson discovered two large trunks in the Potomac beds of Maryland for which Fontaine subsequently proposed the name *Tysonia marylandica*², but as Ward pointed out the species is clearly a *Cycadeoidea* (fig. 507). In 1894 Lester Ward³ recorded several additional stems from Tyson's locality. It is, however, from the Black Hills of Dakota, an isolated spur of the Rocky Mountains, formed of older rocks encircled by Lower Cretaceous strata⁴, that the greatest number of Cycadean trunks have been obtained: the magnificent collection now in the Yale Museum is largely due to the energy and munificence of the late Prof. Marsh. From the Upper Jurassic beds in Carbon Co., Wyoming⁵, several stems have been collected, and a preliminary study of their external features led Ward to institute 20 species of a new genus *Cycadella*. Stems have also been discovered in the Freezout Hills of Wyoming and additional specimens have been found in the Potomac formation of Maryland. The discovery of over 1000 specimens of Cycadean stems in the Lower Cretaceous and Upper Jurassic beds of a few localities in the United States bears striking testimony to the abundance of these extinct Gymnosperms during the latter part of the Mesozoic era. It is perhaps true that, as Lester Ward wrote, 'Cycads are to the vegetable kingdom what Dinosaurs are to the animal, each representing the culmination in Mesozoic times of the ruling Dynasties in the life of their age⁶.' Although the number of stems obtained from European countries is relatively small, the abundance of specimens in the Upper Jurassic strata of the Isle of Portland and Northern Italy and their occurrence in Belgium⁷, France, Germany, Austria, Poland, India and elsewhere, together with an abundance of Cycadean fronds in practically all Jurassic and Lower Cretaceous plant-bearing beds, demonstrate the dominant position of the Ben-

nettitaless. The occurrence of the genus *Williamsonia* in many European localities as well as in India, Afghanistan, and other countries, and the not infrequent occurrence of stems assigned to *Bucklandia*, *Yatesia*, *Cylindropodium*, and other genera furnish evidence of the rich development of the Bennettitales in later Jurassic and Lower Cretaceous floras. Wieland's recent discovery¹ of numerous Cycadean fronds, *Williamsonia* flowers, and stems in Liassic rocks in Mexico shows that the group had already assumed an important position in the early part of the Jurassic period.

The memoir by Carruthers² on British Cycadean stems contains the first account of the morphological features of Bennettitalean flowers based on petrified material. In 1891 Solms-Laubach contributed an important paper on the Bennettitean flower and several years later Lignier³ contributed additional data derived from a careful study of a well preserved strobilus⁴ from the Gault of Normandy. Wieland's researches⁵ added very greatly to our knowledge, particularly with regard to the morphology of the microsporophylls. Among the earlier descriptions of the reproductive organs of the Bennettitales is Buckland's account⁶ of a specimen from the Inferior Oolite of Charmouth, Dorset (fig. 560), which he referred to the genus *Podocarya* (= *Williamsonia Bucklandi*⁷): a thorough examination of the type-specimen, which unfortunately cannot be found, would probably furnish many important facts.

{*Cycadeoidea* (*Bennettites*) *Gibsoniana* (*Carruthers*).

{*Cycadeoidea* (*Bennettites*) *Saxbyana* (*Brown*).

These two species serve to illustrate the type of stem for which Carruthers instituted the tribe Bennettiteae and the genus *Bennettites*. *Bennettites Gibsonianus* is the most important of the five species described by Carruthers⁸, as it was from its fertile shoots that information was first obtained as to the nature of the ovulate strobili of the Bennettitales. *B. Saxbyanus*⁹, originally described

as *Cycadites Saxbyanus* from a specimen found by Mr Saxby at Bonchurch in the Isle of Wight and represented by Wealden examples from Brook Point, is chiefly interesting for the clear preservation of the anatomical features of the stem. Three other species were also described by Carruthers; they are: *Bennettites maximus* Carr., a large stem similar to *B. Saxbyanus*, in the Museum of the Geological Survey; *B. portlandicus* from the Lower Purbeck of the Isle of Portland, in the collection of the Geological Society; and *B. Peachianus*, a piece of a compressed stem, in the British Museum, from the Upper Jurassic of Helmsdale in N.E. Scotland.

Cycadeoidea (Bennettites) Gibsoniana.

This species was founded on a petrified portion of a large stem of Lower Greensand age discovered by Mr Gibson in Luccomb

FIG. 517. *Cycadeoidea Gibsoniana*. A, transverse section of petiole showing vascular bundles and ramenta; B, portion of A enlarged showing periderm and ramenta. C, tangential section of stem with leaf-bases, ramenta (black) and two flowers, 1, 2. (A, slightly enlarged, Manchester Collection, R, 1069; C, after Carruthers.)

China in the Isle of Wight: the type-specimen is represented by pieces of the original block in the British Museum and in one of the Museums at the Royal Gardens, Kew. The following

description is based partly on the published accounts and in part on an examination of sections in the British Museum, the Manchester University Museum, and in Dr Scott's collection.

The elliptical form of the stem and vascular cylinder as seen in transverse section, regarded by Carruthers¹ as a feature characteristic of the genus, has no morphological significance and is in part at least due to compression. In the large pith, the armour of persistent petiole-bases separated by dense ramental scales (fig. 517, A, B), and in habit, *Cycadeoidea Gibsoniana* agrees generally with the stems of many recent Cycads, but the resemblance of the vegetative organs is in marked contrast to the differences exhibited by the reproductive shoots. The pith consists of parenchyma with scattered secretory ducts but no medullary vascular bundles. In the pith of *Cycadeoidea Peachiana* there are patches of tissue superficially resembling vascular strands, but these are probably bands of internal phloem like those described by Solms-Laubach² in some Italian stems. In none of the English stems are there any clear indications of the occurrence of more than one cambium in the stele. The secondary xylem is entirely centrifugal with some smaller crushed elements, presumably protoxylem, at the inner edge where the medullary rays are especially broad. The xylem is of the manoxylic type (fig. 518, A) as in recent Cycads; though the medullary rays, 1—2 cells broad, are rather smaller than in recent species. The tracheids are scalariform as in *Stangeria* (fig. 397). As in recent Cycads there is a broad cylinder of secondary phloem (fig. 518, B)³ composed of alternate layers of thick-walled and thinner elements—sieve-tubes and parenchyma: traces of lateral sieve-plates occur on some of the elongated elements. Each leaf-trace arises as a single strand from the lower edge of a mesh formed by the large inner end of a medullary ray: on emerging into the inner cortex the trace has the form of a U-shaped strand (fig. 519, A, *lt*) which passes direct to the petiole, following a steeply ascending course in *Cycadeoidea Saxbyana* and almost horizontal in *C. Gibsoniana*. Before entering the base of a leaf the trace breaks up

into several collateral strands and these form a simple pattern as seen in a tangential section of the leaf-bases (fig. 517, A, C), the central bundles on the upper side forming a U-shaped involution. There is no indication of any girdling of the foliar bundles. The arrangement of the petiolar bundles is simpler and more Fern-like than in the majority of existing Cycads. Each vascular bundle consists in the petiole-base mainly of centrifugal secondary xylem and medullary-ray tissue (fig. 519, B); a group of centripetal tracheids is usually recognisable internal to the protoxylem: the

FIG. 519. *Cycadeoidea Gibsoniana*. A, transverse section of the vascular cylinder of stem, with leaf-trace, *lt*; *c*, cambium, *px*, protoxylem. B, vascular bundle of petiole. (British Museum.)

structure is of the mesarch type with a variable amount of centripetal xylem, and agrees generally with that in recent Cycads.

The comparatively narrow cortex is composed of parenchyma with scattered secretory sacs (fig. 518, B, *s*), and occasionally an elliptical vascular strand (fig. 511) is present which is probably cauline as are the similar strands in *Cycas*. The persistent petiole-bases are covered with ramental scales which form a dense interfoliar packing: these frequently consist of a single layer of fairly thick-walled cells or, as seen in transverse section, of spindle-like scales one-cell thick at the edges and 2—3 cells broad in the middle (fig. 517, B).

The presence of fertile shoots, presumably axillary, is one of the most striking features of Bennettitean stems. The branching is monopodial and not sympodial as in most recent Cycads. The nearest approach to the method of branching in *Cycadeoidea* is afforded by some stems of *Macrozamia* recently described by Chamberlain¹. It is not improbable that some of the flowering branches of *Cycadeoidea* were branched. Solms-Laubach² states that he observed certain characters in the secondary axes of *Cycadeoidea Gibsoniana* which led him to suspect that there may have been fascicled systems of fertile shoots emerging in a body or in close proximity to one another between the leaf-bases of the stem. An example of a branched flowering shoot is described in *Williamsonia scotica*³. A fertile shoot agrees in structure with the main axis and Scott⁴ states that the phloem is particularly well developed, a feature by no means unusual in fertile branches. These lateral shoots (fig. 514) bear numerous linear bracts each with three collateral vascular bundles, and ground-tissue composed of thick-walled cells characterised by scalariform pitting (fig. 520): secretory sacs are abundant. The hypodermal stereome is especially developed on the inner face of the bracts. The apex of a lateral shoot has the form of a rounded cushion (figs. 514; 521, A, C) similar to the receptacle of many Composites, and on this are borne the sporophylls. It is characteristic of *Cycadeoidea* that the flowers project very slightly beyond the surface of the stem and the peduncles are not exposed except in tangential sections through the leaf-base armour (fig. 517, C, 1, 2). On the fall of the flower or ripe 'fruit,' which is effected by an absciss-layer (figs. 521, C, a; 522, a), a cup-like scar is left on the stem (cf. fig. 534). This method of flower-production suggests comparison, *mutatis mutandis*, with the phenomenon of cauliflory in

⁴ Scott (09) B, p. 571.

certain recent Flowering plants; it is one of the distinguishing features between *Cycadeoidea* and stems bearing longer fertile shoots with flowers of the *Williamsonia* type.

FIG. 521. *Cycadeoidea* (*Bennettites*) *Gibsoniana*. A, C, longitudinal sections; *a*, absciss-layer; *b*, bracts; *pr*, 'pericarp'; *s*, scales, sterile and fertile. B, transverse section of female flower; *i*, interseminal scales; *m*, megasporophylls. D, transverse section of seed showing the testa, *t*, separated by a space, *sp*, from the embryo. E, embryo; *r*, radicle. (A, B, D, E, after Solms-Laubach; C, section in the British Museum.)

Fig. 517, C, shows a tangentially cut surface of a portion of the stem of *Cycadeoidea Gibsoniana* with two axillary fertile shoots; one, 1, is cut across below the receptacle and shows the axis surrounded by bracts while the other, 2, is seen at a higher level, above the receptacle, where the section has exposed the numerous

sporophylls. The rounded surface of the receptacle is covered with a dense cluster of long slender appendages, seed-stalks and interseminal scales, the latter being much more numerous than the former (fig. 521, A, B). These organs are believed to be homologous foliar structures, the seed-stalks being megasporophylls and the interseminal scales abortive or potential sporophylls (see also figs. 562, 563). Fig. 514 shows the form of a single flower from an American stem closely allied to *Cycadeoidea Gibsoniana*.

FIG. 522. *Cycadeoidea Gibsoniana*. Longitudinal section of flower showing half the receptacle with part of the absciss-layer, *u*. (British Museum.)

The megasporophylls are more or less polygonal in transverse section: there is a central concentric vascular strand surrounded by a thick cortex (fig. 527): at its upper end the sporophyll bears a single orthotropous seed containing a dicotyledonous embryo (figs. 521, D, E; 523). The vascular strand pierces the base of the testa and expands to form a shallow cup of tracheal tissue in the chalaza; there are no bundles in the single integument. The testa (fig. 521, D, *t*) consists of three regions, a median layer of rather large rectangular or palisade-cells with an inner and outer tissue composed of much smaller cells. The testa is prolonged

distally as a slender cylindrical column or micropylar tube at the base of which it becomes broader owing to the increase in breadth of the middle or palisade layer. A nucellar beak projects as a cone into the base of the micropylar tube. No pollen-chamber has been found. It is noteworthy that the micropyle is closed in the ripe seeds. Internal to the testa there is a crushed membrane separated from the embryo by a space (fig. 521, D, *sp*): this is the remains of the nucellus and, as Solms-Laubach points out, there is no proof that any endosperm was present in the ripe seeds¹. The embryo consists of a short axis, the conical radicle and the very short apex of the epicotyl, also two equal cotyledons each with a few vascular bundles (fig. 521, D). The long interseminal scales, as seen in transverse section in the lower part of a flower between the sporophylls, appear as compressed polygonal organs (fig. 521, B, *i*) with an axial vascular strand surrounded by parenchyma and limited by a strong epidermis; they pass up between the seed-stalks, *m*, and in the distal end become considerably enlarged (figs. 514, 515), gradually expanding to form a truncate or slightly pyramidal apex (figs. 553, 563). The swollen peltate apices of adjacent scales form a continuous covering to the flower interrupted, except in the lower sterile part of the flower, by symmetrically disposed cylindrical micropylar tubes (fig. 515). The peripheral interseminal scales form a homogeneous parenchymatous tissue which springs from below the edge of the receptacle (fig. 521, A, B, *pr*) and the individuality of the scales composing this 'pericarp' is indicated by occasional invaginations

FIG. 523. *Cycadeoidea Gibsoniana*.
Seed with embryo. (British
Museum, 41388.)

¹ It is possible that, as Scott suggests, a small patch of endosperm is represented in a seed of this species figured by him. Scott (09) B. p. 569, fig. 203, D, *e*.

of the epidermal layer which marks the boundary of the polygonal areas. The structure of the megasporophylls and scales is more fully described in the case of *Cycadeoidea (Bennettites) Morierei*¹.

The flowers of *Cycadeoidea Gibsoniana* appear to be unisexual and ovulate: in view of the discovery by Wieland of numerous bisexual fertile shoots on American species of *Cycadeoidea* it would be reasonable to regard the apparently unisexual flowers of the English species as originally bisexual but preserved at a stage subsequent to the loss, by abscission, of the disc of microsporophylls. Fig. 514 shows a flower of an American *Cycadeoidea* practically identical with those of *C. Gibsoniana*, but the remains of the staminate disc are clearly seen at *d* below the swollen apex of the flowering axis. In the photograph of half of the same region in *C. Gibsoniana* reproduced in fig. 522 there is no indication of any similar trace of a whorl of microsporophylls. Admitting the fact that a shrivelled remnant of the persistent base of a whorl of microsporophylls might easily escape observation, it is difficult to believe that any fertile leaves ever existed in the flower represented in figs. 521, 522. It is equally difficult to regard the specimen represented in fig. 561 as other than a true unisexual (ovulate) flower.

Cycadeoidea (Bennettites) Morierei (Saporta and Marion).

The name *Bennettites* was adopted by Lignier for this species which was founded on a detached flower from the Gault² of Vaches-Noires, Normandy. It was first described by Morière³, then by Saporta and Marion⁴, who named it *Williamsonia Morierei*, and it has since been thoroughly investigated by Lignier⁵. There is no evidence as to the nature of the parent-stem though Morière suggested a possible connexion with *Zamia Brongniarti* Mor. (figured by Saporta⁶ as *Fittonia Brongniarti*) from the same locality. There can be no reasonable doubt that *Bennettites Morierei* was borne on a lateral branch of a stem of the *Cycadeoidea* type:

¹ See page 396.

² The age was at first believed to be Oxfordian, but Lignier subsequently (09) referred the rocks to a Lower Cretaceous horizon.

³ Morière (69).

⁴ Saporta and Marion (81) A.; (85) p. 244; Saporta (91) p. 168, Pls. 148, 149.

⁵ Lignier (94²); (04); (09); (11).

⁶ Saporta (75) A. p. 328, Pl. 123.

it is constructed on essentially the same plan as the flowers of *Cycadeoidea (Bennettites) Gibsoniana*, and in both cases there is no indication of the presence of microsporophylls. The type-specimen is 5.5 cm. long and 3.5 cm. broad, ovoid, and characterised by a depressed cushion-like receptacle as in *Cycadeoidea Gibsoniana*. The enveloping bracts with their ramental scales agree generally in structure with those of the English species and, except as regards the ramenta, with *Williamsonia scotica*: numerous stomata occur on the lower surface; the ground-tissue consists of thick-walled parenchyma and the narrow pit-canals simulate the scalariform bands in *Cycadeoidea Gibsoniana* (cf. fig. 520). The pitted sclerous cells in the bracts of *W. scotica* are of the same type. There is an anastomosing system of secretory canals, also several vascular bundles like those in *C. Gibsoniana* but more numerous; the latter are composed of a group of phloem-elements abutting externally on fibres, a well-defined cambium, and radially disposed scalariform tracheids: internal to the protoxylem is a group of elements considered by Lignier to be centripetal xylem. From the branching and slightly divergent course of the bundles in the upper part of the bracts Lignier concluded that these organs represent the basal portions of leaves originally provided with a terminal limb. It may be that the small lateral appendages to some of the bracts of *Williamsonia scotica* (fig. 561, *l*) afford support to this view.

Megasporophylls (seed-stalks and seeds). These organs, 3—4.5 cm. long and approximately 1.5 mm. in diameter, are in most cases imperfectly preserved. In transverse section and at a level of 1 cm. above the receptacle a stalk bearing an atrophied seed shows the following features: an epidermis with very thick internal walls encloses a parenchymatous ground-tissue with an axial conducting strand. At a higher level the epidermal cells have walls of uniform thickness, and a hypodermal layer of cells with coloured contents is differentiated from the ground-tissue (fig. 524, *D, ac*). As the seed-base is approached the epidermal cells tend to separate from one another and divide longitudinally, the compact epidermal layer being replaced by an envelope of tubular, dissociated, cells (fig. 524, *D, Et*). Similar tubular elements occur in the seed-stalks of *Cycadeoidea Gibsoniana*.

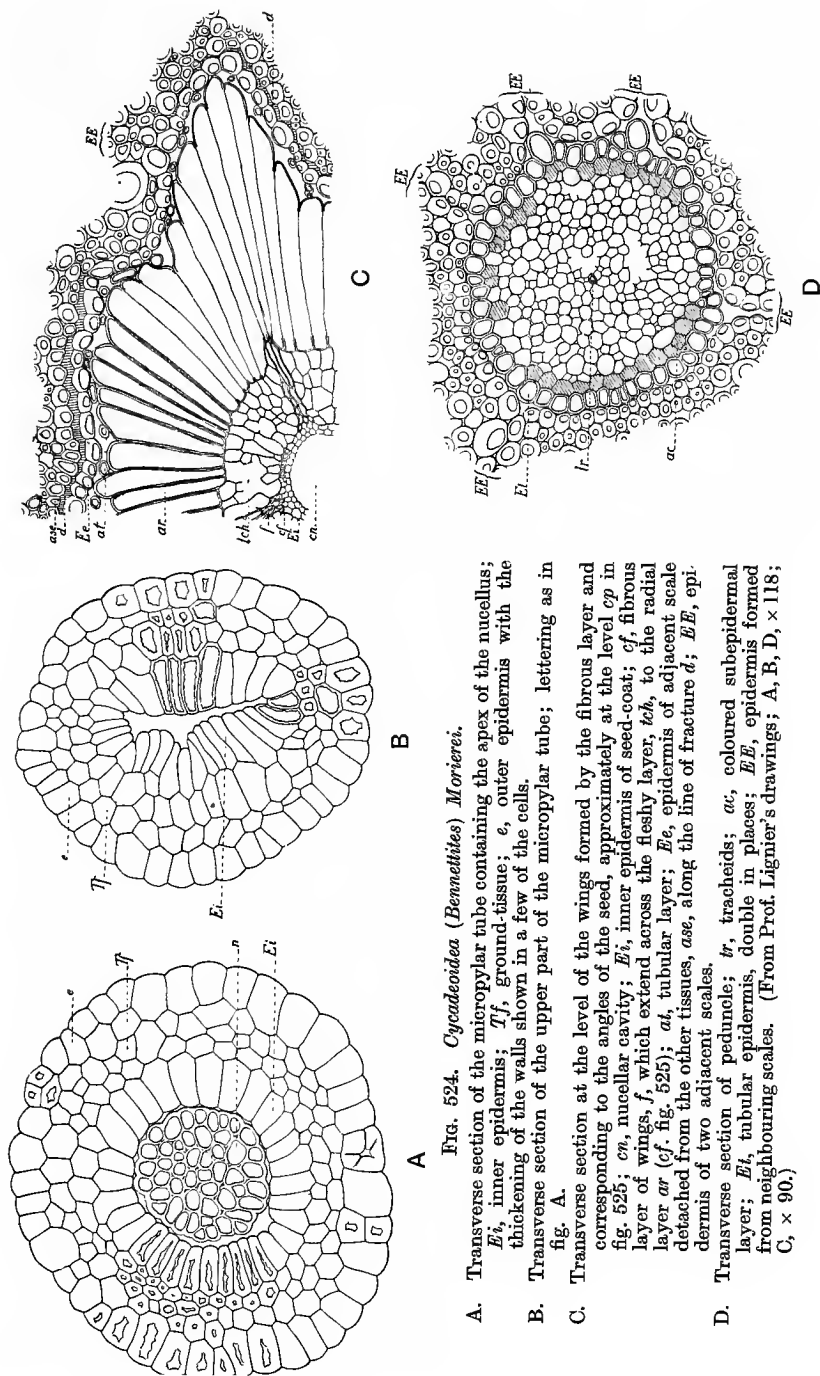

FIG. 524. *Cycadeoidea (Bennettites) Morieri*.

- A. Transverse section of the micropylar tube containing the apex of the nucellus; *Ei*, inner epidermis; *Tf*, ground-tissue; *e*, outer epidermis with the thickening of the walls shown in a few of the cells.
- B. Transverse section of the upper part of the micropylar tube; lettering as in fig. A.
- C. Transverse section at the level of the wings formed by the fibrous layer and corresponding to the angles of the seed, approximately at the level *cp* in fig. 525; *cn*, nucellar cavity; *Ei*, inner epidermis of seed-coat; *cf*, fibrous layer of wings, *f*, which extend across the fleshy layer, *lch*, to the radial layer *ar* (cf. fig. 525); *at*, tubular layer; *Ee*, epidermis of adjacent scale detached from the other tissues, *ase*, along the line of fracture *d*; *EE*, epidermis of two adjacent scales.
- D. Transverse section of peduncle; *tr*, tracheids; *ac*, coloured subepidermal layer; *Ei*, tubular epidermis, double in places; *EE*, epidermis formed from neighbouring scales. (From Prof. Lignier's drawings; A, B, D, $\times 118$; C, $\times 90$.)

A fully developed seed-stalk bearing a complete seed cut across in the middle region shows the following features: a concentric vascular strand surrounded by thin-walled parenchyma and the coloured hypodermal layer (fig. 524, D, *ac*), the whole being enclosed in the tubular envelope of epidermal origin (*Et*) which is more strongly developed than in the stalks of imperfect seeds: there may be as many as 10—12 tubular cells on one radius. When traced downwards towards the receptacle the tubular envelope decreases in breadth, though the cells become more numerous and smaller, until in the immediate neighbourhood of the receptacle the tubular tissue is transformed into a compact parenchyma of large cells each of which corresponds to a group of tubes formed by the septation of the cells. Traced upwards this thin-walled parenchyma gradually passes into thick-walled tubes, and near the seed-base the tubular envelope is reduced to two layers, an inner consisting of relatively small cells with sinuous radial walls (the folded layer of Lignier) and an outer tubular layer. Lignier describes an interesting abnormality, a bifid seed-stalk enclosed in a common epidermis which he compares with the occasional branching of the seed-stalks of *Ginkgo biloba*.

Seeds. The seeds (figs. 525, 526), $6-7 \times 2.5-3$ mm., are tetragonal or pentagonal in the upper half (fig. 527, 1, 2), the angles being formed by thick but not very prominent wings of tissue (fig. 524, C, *cf*); they are orthotropous and have a single integument (figs. 525, 526). The tubular layer forming the outer portion of a seed-stalk near the seed-base is prolonged over the surface of the testa as a discontinuous covering in the form of isolated or small groups of tubes, giving a striated appearance to the seeds. This layer though apparently a part of the seed is derived from the neighbouring interseminal scales of which it is the epidermal layer; it consists of elongated cells and scattered stomata¹. The folded layer persists only in the lower part of the seed, being replaced by a layer of radially extended cells (radial layer; *ar*, figs. 524, C; 525, *ar*; 527, *c*) in the upper region of the seed. In the micropylar region both the tubular and folded layers undergo further change; the external, tubular, layer forms a kind of epidermis (*at*, figs. 524, 525), the subepidermal layer,

¹ Lignier (94) p. 57; (12).

consisting of the radially elongated cells (figs. 524, 525, *ar*; 527, *c*). The superficial layer assumes a different aspect in the micropylar region, its cells being thicker walled, as are also those of the sub-epidermal layer (fig. 524, A and B). The micropylar canal

FIG. 525. *Cycadeoidea* (*Bennettites*) *Morierei*. Section of a seed and adjacent interseminal scales. *tm*, micropylar tube; *n*, nucellar beak in the micropylar canal, *cm*; *cp*, pollen-chamber; *co*, archegonia (?); *em*, position of the embryo; *ch*, chalaza; *dn*, remains of the nucellus; *af*, fibrous layer passing below into the shell, *cq*, and the peduncle, *Tf*; *tch*, fleshy layer; *ar*, radial and tubular layers represented in the peduncle by the tubular envelope *at*; *Ec*, swollen ends of the interseminal scales. (From a drawing kindly supplied by Prof. Lignier; $\times 10$.)

(figs. 524, 525, *cm*) is cylindrical in the lower part but at the apex is reduced to a long and narrow slit bounded by an internal epidermis of radially stretched cells which in the lower portion of the tube are thinner walled and isodiametric. The rest of the testa is differentiated into two regions; an outer

fleshy region immediately internal to the folded (or radial) layer and an inner fibrous region next the nucellus, which is one-layer broad between the wings but opposite the wings it extends radially outwards across the fleshy tissue to the radial layer

FIG. 526. *Cycadeoidea (Bennettites) Morierei*. Longitudinal section of a seed and interseminal scales. (From a photograph supplied by Prof. Lignier.)

(figs. 524, C; 525; 527): in the winged portion of the seed this tissue forms the inner fibrous portion of the wings but in the lower part of the seed below the wings it forms a single layer of uniform breadth finally spreading out as a basal cup in the chalazal region where it is pierced by the vascular strand. The fleshy portion of the testa forms one layer in the proximal part of the

seed and becomes several layers wide between the fibrous wings in the upper part. This fleshy tissue appears to be derived from the coloured, subepidermal, layer of the seed-stalk, while the internal parenchyma is regarded by Lignier as the equivalent of the fibrous layer of the testa. In the micropylar tube the fibrous layers are replaced by 2—3 layers of sclerous cells (fig. 524, A, B). The testa has no vascular supply: the concentric strand of the seed-stalk passes through the fibrous tissue at the base of the seed and reaches the base of the nucellus (fig. 525). The nucellar apex extends into the lower part of the micropyle (fig. 525, *n*), and in some cases Lignier noticed an axial canal formed by the breaking-down of the cells which abutted below on a cavity above the embryo, probably the remains of a pollen-chamber (figs. 525, 527). No microspores have been found. Two dark spots shown at *co*, fig. 525, may represent archegonia but this is doubtful, especially as the seed contains a well-developed embryo. The nucellus is free from the testa only in the apical region and a dicotyledonous embryo occupies the interior without any trace of endosperm. Lignier points out that in some seeds containing embryos the nucellar beak is not completely perforated: in this fact and in the absence of microspores in the micropylar canals he is inclined to see evidence of parthenogenesis¹.

In several respects the seeds of *Cycadeoidea* agree with those of *Gnetum*: reference should be made to the account of the seed of *Gnetum africanum* in Chapter LII. and to the papers referred to in the footnote².

Interseminal scales. The young seed-stalks agree very closely with the interseminal scales: each seed-stalk is surrounded by 5—6 scales (fig. 527) as in other Bennettitean flowers (fig. 564). For the greater part of their length the interseminal scales are compressed, but above the seeds, where they are free from pressure (fig. 526), they become much thicker and form a covering ('pericarp') as in *Cycadeoidea Gibsoniana*. In its upper region an interseminal scale consists of an epidermis with strongly thickened inner walls, hypodermal thick-walled cells and parenchymatous ground-tissue with a single axial bundle. In the lower part the scale is more flattened and the thick-walled hypoderm is replaced

¹ Lignier (11).

² Berridge (11); Thoday, M. G. (11).

by thin-walled parenchyma. Some of the scales at the periphery of the receptacle where there are no seed-stalks are broader and may have six vascular bundles; this, Lignier suggested, might be regarded as evidence of the reduction of the intersemental scales from leaves possessing a terminal limb; but a further examination of scales at the periphery of the flower led him to the conclusion that the distal swelling of the scales is solely due to the hypertrophy of conjunctive tissue and is not the result of the modification of a reduced limb¹. The morphological value of the intersemental scales and seed-stalks has not been definitely settled, though the probability is that they are homologous organs

FIG. 527. *Cycadeoidea Morierei*. Transverse section of intersemental scales and seeds near the apex of the latter; seeds 1 and 2 show the pollen-chamber, *a*; the fibrous layer, *b*, forming wings and extending across the fleshy tissue; *c*, the radial layer; seeds 3 and 4 are aborted. (After Lignier.)

The letters *a*, *b*, *c*, in this figure correspond to *cp*, *cf*, and *ar* in figs. 525, 526.

and foliar. Solms-Laubach² suggested that both may be axial, the seed-stalks representing axes ending in a flower reduced to a single ovule; or, he adds, the seed-stalks may just as well be carpels, though in that case we should have the unusual phenomenon of terminal seeds. The intersemental scales may be aborted seed-stalks crushed between the latter; or if the seed-stalks are axes, the scales may be foliar. He is inclined to see in the scales the bracts and prophylls of seed-stalks to which must be added such bracteoles, preceding the seed or flower, as may happen to spring from the seed-stalks. Pearson³, on the assumption that

¹ Lignier (04).

² Solms-Laubach (91).

³ Pearson (09).

the seed-stalks are axial structures, institutes a comparison between *Welwitschia* and *Bennettites* and regards each flower of *Welwitschia* as a much reduced Bennettitean strobilus. Lignier believes the interseminal scales to be leaves borne on the swollen apex (receptacle) of an axis of the second order, while the seed-stalks are fertile leaves of a unifoliar bud of the third order possibly axillary though not necessarily so to the interseminal scales. My own view, influenced by the examination of the immature flower of *Williamsonia scotica*, is that the seed-stalks (megasporophylls) and scales are homologous, the former being sporophylls and the latter sterile foliage leaves, the whole flower, as Wettstein¹ says, consisting of a conical axis bearing numerous fertile and sterile carpels enclosed by a perianth of bracts. Worsdell², who shares Čelakovsky's opinion that sporophylls were originally radially symmetrical organs bearing a terminal sporangium, regards the flowers of *Cycadeoidea Gibsoniana* and other species as more primitive than those of recent Cycads: he does not see any justification for the view that the Bennettitalean flowers are in advance of those of existing Cycadean plants as regards a supposed tendency towards the Angiospermous type. He maintains that *Bennettites* 'shows absolutely no indication of such an advanced structure in its essential organs, the sporophylls, which remain primitively radial in structure, bearing the ovules in a terminal position.'

Cycadeoidea dacotensis (McBride).

McBride³ first described this Lower Cretaceous species from the Black Hills of South Dakota as *Bennettites dacotensis*, the generic name *Cycadeoidea* being adopted by Ward⁴ who distinguished some of McBride's specimens as *Cycadeoidea McBridei*. The stem is elliptical in section, 32 cm. long and 45 cm. in girth: owing to the partial decay of the petiole-bases the ramental reticulum forms a prominent feature. Numerous flowers, all of which are approximately at the same stage of development, project like conical buttons above the general level of the stem-surface⁵. The bisporangiate flowers consist of a conical receptacle bearing interseminal scales and megasporophylls, the whole being

⁵ Wieland (06) p. 185. See Wieland's description for further details.

FIG. 528. *Cycadeoidea dacotensis*. Longitudinal section through a bisporangiate strobilus; *s*, folded microsporophylls with synangia; *o*, receptacle bearing short megasporophylls and interseminal scales; *a*, eroded surface of bracts; *r*, rameta between the bracts and leaf-bases; *l*, leaf-base; *c*, cortex of stem; *t*, vascular cylinder of peduncle. (After Wieland; nat. size.)

FIG. 529. *Cycadeoidea dacotensis*. Transverse sections of a young ovulate strobilus. A, near the summit of the strobilus 2 cm. below the surface of the armour of leaf-bases, showing numerous bracts surrounding the receptacle and embedded in a mass of ramenta, also sections of some leaf-bases with vascular bundles. B, in this section, 2.5 cm. below A, the peduncle of the strobilus is seen with a cylinder of vascular bundles; *b*, a bract belonging to an adjacent strobilus. (After Wieland; nat. size.)

surrounded by spirally disposed bracts (fig. 529). A whorl of 18 or 19 nearly mature microsporophylls is attached to the base of the receptacle (figs. 528, 530); each microsporophyll has a strong rachis extending beyond the apex of the flower-axis

FIG. 530. *Cycadeoidea dacotensis*. Transverse sections through a bisporangiate strobilus. A, showing the receptacle with its interseminal scales and ovules, the continuous disc of microsporophylls, *m*, with vascular bundles, and the separate (*m'*) infolded portions of the microsporophylls with some synangia; bracts and ramenta. B, this section, cut above the apex of the receptacle, shows the microsporophylls and synangia. (After Wieland.)

and bent inwards and downwards with the distal end tucked between the ascending rachis and the receptacle. The slender pinnules, in two alternate series, are bent downwards and bear

synangia in rows. A transverse section just below the ovulate portion of the cone shows a continuous ring of tissue encircling the receptacle with vascular bundles parallel to the surface (fig. 530, *A, m*); at a higher level the bundles fall into groups preparatory to the breaking up of the disc into separate microsporophylls. Immediately above the apex of the central cone the coherent basal portion of the verticil of sporophylls is replaced by the separate rachises which in section have the form of isosceles triangles (fig. 530, *B*). Each microsporophyll is approximately 10 cm. long; the longest pinnule being 1.5 cm. in length and bearing two lateral series of synangia, 10 in each row. At maturity the

FIG. 531. *Cycadeoidea dactensis*. Synangia exposed by weathering and showing the radially disposed loculi. (After Wieland; $\times 6$.)

microsporophylls probably spread out and the whole whorl was thrown off leaving an annular rim (fig. 514, *d*) such as is often seen at the base of older ovulate strobili. The immaturity of the ovules in this (fig. 528) and other specimens led to the suggestion that the strobili of *Cycadeoidea* were protandrous. The synangia (fig. 531) are several times broader than long and similar in size to those of the Fern *Marattia*. In each synangium are two rows of elongated loculi (fig. 532) containing oval microspores usually with a smooth exine and rather larger than those of recent Cycads. The synangium-wall is composed of a palisade-layer of thick-walled cells and a layer of smaller and thinner cells: the palisade-layer is narrowest at the apex where dehiscence occurs and broadest at the base where the hypodermal tissue is more abundant and forms a short thick pedicel. The two rows

of loculi are bounded by flattened cells and there are 10—20 loculi in each of the two rows: dehiscence of the individual loculi occurs in the middle of the inner wall.

Cycadeoidea Marshiana Ward.

This Lower Cretaceous Black Hills species¹ affords an admirable example of a method of branching exhibited by some stems: as shown in Wieland's photographs² there may be five or six large and massive trunks all in the same stage of fructification, differing but little in size and forming a cluster resembling independent plants growing in close proximity to one another. There is apparently no central or major axis and the habit is therefore very different from that of a branching *Bucklandia*. *Cycadeoidea Marshiana* bore large ovulate pyriform strobili projecting slightly beyond the leaf-bases; they are 5 cm. long with a maximum diameter of 3.5 cm. and have an elongated receptacle bearing short scales and sporophylls. The apical bud of one of the trunks shows particularly well in transverse section the dense ramental packing between the bud-scales³. Similar clusters of short and thick trunks occur in *Cycadeoidea superba* and other American species.

In the small bisporangiate flowers of this species⁴ the microsporophylls, 11 or 12 in the verticil, are characterised by the presence of a ventral furrow which, as Wieland suggests, may be comparable on a much simpler scale with the winged sporophylls of *Cycadeoidea colossalis* (fig. 533). The disc splits up at a distance

FIG. 532. *Cycadeoidea dacotensis*. Synangium in longitudinal section showing the thick pedicel, the line of dehiscence, and two loculi with a few microspores. (After Wieland; $\times 40$.)

of 1 cm. above the apex of the receptacle into the microsporophylls, each of which is 5.5 cm. long and bears two rows of pinnules which in the middle region have a length of 1 cm.; a microsporophyll is elongate, elliptical, and acuminate. In this species as in some others there is a brush of sterile scales at the apex of the receptacle.

Cycadeoidea colossalis Ward.

Wieland¹ has recently described some interesting features in the microsporophylls of a bisporangiate flower assigned to this Lower Cretaceous species from the Black Hills illustrating a departure from the usual type. The hairy bracts extend considerably above the apex of the flower-proper; in fig. 533, A, a transverse section above the receptacle, they are shown grouped about a circle of V-shaped structures, converging towards a central point, which are the sterile prolongations of the ten rachises of the free portions of the staminate disc. Each rachis is divided by a deep ventral furrow into a pair of wings (fig. 533, B, C), and it is these pairs of wings that form the V-shaped structures in fig. 533, A. The wings form a dome-like group above the flower-apex (fig. 533, D, E). The synangia are borne in two rows on the concrescent disc and on the free sporophylls, which in this type are much simpler than in other species and agree in the absence of pinnules with some forms of *Williamsonia* (cf. fig. 556). The receptacle is pyriform and bears very short scales and seed-stalks; from its apex several interseminal scales are prolonged as a terminal brush, a feature of interest in connexion with flowers of *Williamsonia*. Wieland compares the wings of the microsporophylls to the two horns on the distal surface of the corresponding organs of *Ceratozamia* and draws a comparison between them and the canopy of some Palaeozoic seeds, but it is doubtful whether homologies can be established between these elaborate sporophylls and the integuments of Pteridosperm seeds².

Cycadeoidea Reichenbachiana (Goepfert).

Goepfert referred this species to his genus *Raumeria*³, a generic name retained by Carruthers though, as Solms-Laubach⁴ points

¹ Wieland (14).

² This subject is more fully dealt with by Wieland in the Volume published since the above was written [Wieland (16)].

³ Goepfert (53).

FIG. 533. *Cycadeoidea colossalis*. Diagrammatic restorations of the bisporangiate flower. A, transverse section above the receptacle showing the bracts (black), a petiole with vascular bundles, ramenta, and (1-10) the wings of the microsporophylls. B, C, longitudinal section of flower showing the receptacle with the small megasporophylls, the staminate disc with winged microsporophylls and synangia, and the terminal brush of interseminal scales (indicated by the arrow in B). The megasporophylls and synangia are represented larger than the actual size. D, this shows on one side the dome-like arrangement of the microsporophylls and, on the right, a microsporophyll in side-view. E, longitudinal section as far as the plane *T* surmounted by the apex of the collection of microsporophylls; *c*, *s*, microsporophyll with synangia; *A*, recurved apex of microsporophyll; *B*, bracts; *D*, insertion of disc; *L*, outer bracts next the petiole bases. (After Wieland; *ca.* nat. size.)

out, the abundance of lateral fertile shoots among the leaf-bases shows it to be essentially similar to *Cycadeoidea Gibsoniana*. The type-specimen in the Dresden Museum is a splendid example of a fossil cycadean stem; it is probably of Lower Cretaceous age, but was found in Galicia as an isolated specimen. It consists of a portion of a cylindrical trunk similar in habit to *C. gigantea*, .5 met. high and about the same in diameter. The pith, according

FIG. 534. *Cycadeoidea Reichenbachiana*. Cup-like cavity on the stem showing the axis and surrounding bracts of a lateral fertile shoot. (After Schuster, from a block kindly supplied by Prof. Rothpletz.)

to Schuster¹, is 13 cm. in diameter and the xylem 8 cm. broad. There are many flowering shoots some of which are represented by cup-like depressions, the base of the cup consisting of the cylindrical axis and the sides bearing the impress of the encircling bracts (fig. 534). Goeppert compared these lateral shoots with the buds frequently produced on the stems of *Cycas*. It is interesting to find that some of the cups correspond very closely

¹ Schuster (11). An excellent photograph of the stem is reproduced in this paper.

in size with *Williamsonia* flowers, another indication of the very close agreement between the *Williamsonia* and *Bennettites* types of strobili. Some flowers still in place show 16 bipinnate microsporophylls that were petrified before the synangium-bearing fronds unfolded¹. The ramental scales and other tissues figured by Schuster are of the usual type. A second specimen found as a boulder in Silesia and named by Goeppert *Raumeria Schulziana* may, as he suggests, be a younger example of *C. Reichenbachiana*. Another Galician stem, probably also Lower Cretaceous in age, is described by Raciborski² as *Cycadeoidea Niedzwiedzki*.

Cycadeoidea gigantea Seward.

This species is founded on a large stem from the Upper Purbeck series of the Isle of Portland³ where it was discovered in a shaly clay 17 ft above the great Dirt bed which yielded the trunks described by Buckland and other authors (fig. 535). The stem (fig. 554) is 1 met. 18 cm. high and has a maximum diameter of 1 met. 7 cm. It is the tallest fossil Cycadean stem so far found in a single piece though *Cycadeoidea Jenneyana* probably reached a greater height. The stem is elliptical in section (fig. 537), a form due in part at least to compression. The only tissues preserved are in the superficial region of the persistent leaf-bases. As the result of decay before mineralisation many of the petiole-bases are represented by cavities or meshes in a prominent reticulum of silicified ramental scales. Towards the apex the leaf-bases are smaller and a conical bud surrounded by linear scale-leaves occupies the summit: an irregular cap of ramental scales forms the apex of the terminal bud. In section the bud would no doubt present an appearance like that shown in Wieland's photograph of the terminal cone of *C. Marshiana*⁴. There is a striking resemblance both in the ramental cap and in the form of the protective scales between the fossil stem and such a Cycad as *Encephalartos Altensteinii*⁵. A remarkable feature of *C. gigantea* is the absence of any fertile shoots among the leaf-bases. In one tangential section a small bud was found, but it affords

FIG. 535. Section of the quarry in the Isle of Portland in which *Cycadeoidea gigantea* was found.

FIG. 536. *Cycadeoidea gigantea*. (The original is in the British Museum; $\frac{1}{3}$ nat. size.)

no evidence of the presence of any reproductive organs. A similar bud is described by Lignier¹ in the stem of *C. micromyela*. The absence of lateral flowers is, however, hardly a sufficient reason for separating this stem generically from other species of *Cycadeoidea*: negative evidence in this case is of doubtful value. While it is possible that the strobili were terminal as in most recent Cycads, it is more probable that they were lateral. The surface-features, though not perfect, are for the most part sufficiently well preserved to enable one to recognise the bract-encircled axes of strobili were any present. If as Wieland believes, and he is probably correct, the production of flowers was the culminating event in the life of these Cycadean plants, the absence of fertile shoots is merely an expression of immaturity. It is,

FIG. 537. *Cycadeoidea gigantea*. Transverse section of the stem.

however, difficult to understand how lateral branches could find their way to the surface among the crowded and cork-covered leaf-bases of the stem. The absence of flowers may be due to some unfavourable external conditions. The petioles consist of parenchymatous ground-tissue with many secretory sacs and in some cases twelve partially preserved vascular bundles: the xylem consists of radial rows of centrifugal tracheids and medullary rays, but it is not possible to say whether any centripetal xylem was present. A fairly thick band of phelloderm and periderm, apparently subepidermal in origin, forms the peripheral tissue, and in places epidermal cells with attached ramenta are clearly preserved. The ramenta are of the type characteristic of the majority of fossil Cycadean stems. Stomata were found showing a pair of guard-cells and apparently two subsidiary cells: the epidermal cells have straight walls.

¹ Lignier (01).

Cycadeoidea micromyela Morière.

This Liassic species from Normandy has been fully investigated by Lignier¹; originally referred to the Conifers, it was afterwards described by Morière² as *Cycadeoidea micromyela*. As regards external features the stem is of the usual *Cycadeoidea* type: Saporta³ assigned it to the genus *Platylepis*. The secondary xylem consists of tracheids with bordered pits on the radial walls arranged as single contiguous rows, resembling scalariform pitting, or as 1—2 rows of separate circular pits (fig. 538, A), a type

FIG. 538. *Cycadeoidea micromyela*. A, tracheids from the stele. B, course of the vascular bundles at the base of a leaf. C, section of a leaf-trace entering the stele; *m*, *l*, median and lateral lobes of the trace. (After Lignier.)

different from that of the great majority of Mesozoic species. The uniseriate medullary rays are 7—20 cells deep, a character recalling the compact wood of Indian *Williamsonia* stems. Ramental scales are for the most part replaced by long unicellular hairs like those of *Williamsonia scotica* and some Indian stems. Lignier states that true ramenta occur on the young leaves and in older fronds become transformed by separation of the cells into long tubes. Each leaf-trace arises as a single bundle dividing into three as it leaves the stele and eventually splits up into several collateral bundles (fig. 538, B, C). The stele is elliptical. No

¹ Lignier (01).

² Morière (69).

³ Saporta (75) A. Pl. L.

fertile shoots are preserved: a single axillary bud is described which agrees very closely with that in *Cycadeoidea gigantea*.

Cycadeoidea Jenneyana Ward.

The stems of this species, from the Black Hills of Dakota¹, resemble those of *Cycadeoidea gigantea* and *C. Reichenbachiana*

FIG. 539. *Cycadeoidea Jenneyana* (?). Longitudinal section of an ovulate strobilus, showing the pyriform receptacle with vascular supply, the long interseminal scales and megasporophylls, and a few of the surrounding bracts. (After Wieland; $\times 1\frac{1}{2}$ nat. size.)

in their thick columnar form but differ from the former in the presence of bisporangiate flowers associated with the leaf-bases. This species probably reached a length of 3—4 met. A striking feature² is the unusual thickness of the xylem-cylinder, which

¹ Ward (94) p. 87; (98) p. 216.

² Wieland (06) p. 79, Pl. XIV.

shows clear indications of concentric rings, probably the expression of seasonal changes during the production of secondary conducting tissue by a single cambium. Similar concentric rings have been described in the stems of the recent Cycad *Dioon spinulosum*¹. Fig. 539 represents an ovulate strobilus referred to this species by Wieland.

Cycadeoidea pumila Fliche and Zeiller.

This French Portlandian species² affords a good example of a very small bulbiform trunk, 3.5—4 by 2.5—3 cm., superficially resembling a Pine-cone: the leaf-bases are, however, less uniform in size and shape than Abietineous cone-scales; there are also indications of interpetiolar rammenta and a small lateral, presumably fertile, branch. A stem of similar form is described by Saporta³ from Corallian beds in France as *Bulbopodium micromerum*, and *Cycadeoidea nana* Ward⁴ from Dakota is another example of a small *Zamia*-like Mesozoic stem. A small tuberous stem, 8 × 7.5 cm., was described by Lindley and Hutton from Lyme Regis as *Cycadeoidea pygmaea*⁵; no flowers are shown in the drawing, but occasional irregularities in the arrangement of the leaf-bases may be due to the presence of lateral fertile shoots.

Cycadella. Ward.

This generic name was instituted by Lester Ward⁶ for some petrified stems from Jurassic beds in Wyoming of relatively small size, bulbous or more or less spherical, and characterised by the presence of a thick layer (5—15 mm.) of dense rammental tissue. The unusually vigorous development of the rammental scales is an interesting feature, though it is perhaps questionable whether it is worthy of generic recognition. The flowers of *Cycadella*, though less than those of most *Cycadeoidea* stems, are of the same type. In a later account of the genus Ward⁷ describes a few additional species and in *Cycadella ramentosa* he notes the preservation of young fronds. The fronds are small and bear a few pinnae :

⁷ *Ibid.* (05) B. p. 198, Pls. XLVI.—LXIII.

the xylem is said by Wieland¹ to be mesarch, but in the absence of more details the foliar bundles cannot be fully described. In some *Cycadellas* young flowers, less than 1 cm. in diameter, are preserved, those of *Cycadella wyomingensis* (7 mm. in diameter) being the smallest bisporangiate strobili so far recorded. The French species, *Cycadeoidea micromyela* Mor., resembles *Cycadella* in the profuse development of ramental tissue which may cover the surface of the stem.

Amphibennettites. Fliche.

This generic name was instituted² for two species founded on very imperfectly preserved 'fruits' of Lower Cretaceous (Albian) age from the Argonne which, though in close agreement with *Bennettites* as represented by *B. Gibsonianus* and *B. Morierei*, are referred to a separate genus on the ground that the preservation is not such as to establish their generic identity with those species and because of certain distinctive features.

Amphibennettites Bleicheri Fliche. The ovulate strobili are sub-elliptical, 3.5 × 3 cm., with several elliptical pits close to the surface originally occupied by seeds borne on short stalks and larger than the seeds of other species of *Cycadeoidea* (*Bennettites*). Interseminal scales occur between the seeds. The second species, *Amphibennettites Renaulti*, is rather larger and more conical: the seeds reach a length of 11 mm. greater than that of any of the American seeds described by Wieland. In neither species is there any indication of an involucre of bracts. The preservation of the specimens leaves much to be desired, but it would seem that the Argonne fossils agree in their main characters with Bennettitean strobili and it is doubtful whether a distinctive generic name is necessary. The occurrence of seeds over the whole surface, a feature that suggested the name *Amphibennettites*, may be only apparent and the result of cutting the cone transversely. It is worthy of note that one of Fliche's sections³ bears a close resemblance to an Araucarian cone, and in the absence of structure the two types of cone might easily be confused.

³ *Ibid.* Pl. v. fig. 3.

Vectia. Stopes. Genus *incertae sedis*.

Vectia luccombensis Stopes.

The generic name *Vectia* has been given by Dr Stopes¹ to some petrified secondary phloem discovered by her at Lucomb Chine in the Isle of Wight: the fossil is from Aptian beds. The mass of phloem is 26 mm. in breadth and consists of regularly alternating bands of thin-walled sieve-tubes and very thick fibres associated with a little parenchyma (fig. 540). To the naked eye the specimen presents an appearance suggestive of rings of growth but this is due to the presence of bands of 2—3 narrow cells which are probably

FIG. 540. *Vectia luccombensis*. Transverse section showing the alternation of fibres, s^1 , s^2 , and radial pairs of pitted elements, v^1 and v^2 ; m , medullary-ray cells; a , parenchyma cell between four thin-walled elements; sp , pits between adjacent fibres; l , much reduced lumen of fibre. (After Stopes.)

cork. The whole is penetrated by uniseriate medullary rays. A striking feature is the regular alternation of single rows of fibres with two bands of sieve-tubes; in places the two bands of sieve-tubes are separated by 2—4 rows of very flat, presumably, cork-cells, and similar bands may be adjacent to or pass obliquely across the fibres. The elongated elements described as sieve-tubes, though thin in comparison with the fibres, have thickened walls and on their radial faces are single rows of circular pits, often in pairs; these are almost certainly sieve-areas which have

¹ Stopes (15) p. 247, Pls. xxiii.—xxv., text-figs. 72—75.

lost the finer pitting of the sieve-plates. The fibres are more or less square in transverse section and have excessively thick walls, the lumen being reduced to a small hole. Parenchymatous cells (fig. 540, *a*) occupy the angles between the sieve-tubes and occasionally stretch tangentially between a pair of tubes: these are compared by Dr Stopes to companion-cells, but their manner of occurrence hardly justifies the interesting suggestion that they may be precursors of the Angiosperm companion-cells. The medullary rays may be as wide as the elements which they traverse; they are characterised by their wavy walls, as seen in radial longitudinal sections; no pitting was noticed. A remarkable feature of the specimen is its considerable breadth: it is pointed out that in a giant stem of *Sequoia* with a girth of over 40 ft the secondary phloem does not exceed 3—4 mm. in breadth. The great thickness of the phloem in the fossil suggests comparison with the corresponding tissue in recent and fossil Cycadean stems, and the alternation of hard and soft phloem is a feature exhibited also by *Cycadeoidea Gibsoniana* (fig. 518, B). Dr Stopes concludes that the phloem is in the main similar to that in some Cupressineae, Taxineae, and Taxodineae. It is noteworthy that similar phloem with sieve-tubes and fibres associated with cork is described by Graf Solms-Laubach¹ from Upper Jurassic beds in Franz Josef Land. The systematic position of *Vectia* cannot be definitely determined, but I believe that it is more closely allied to Cycadean than to Coniferous phloem.

NOTE. It is unfortunate that Mr Wieland's second volume dealing with American Cycads [Wieland (16)] did not come into my hands until nearly the whole of this volume was in type. Students will find in it many additions to our knowledge of *Cycadeoidea* and *Williamsonia*, much theoretical discussion that is suggestive and interesting, useful summaries of our knowledge of fossil Cycads, and many beautiful photographic plates illustrating the morphology of American species of *Cycadeoidea*.

¹ Solms-Laubach (04) p. 12, Pl. II. figs. 5, 6.

CHAPTER XXXVII.

BENNETTITALES (*continued*).

WILLIAMSONIA. Carruthers.

THIS genus was first figured by Young and Bird¹ from specimens obtained from Lower Estuarine beds near Whitby: these authors compared the fossils to the head of an Artichoke (*Cynara integrifolia*), 'the covering or calyx consisting of numerous lanceolate and striated leaves' (fig. 544). In 1840 Williamson² noticed the association with fronds of *Zamia gigas* Lind. and Hutt. of 'a remarkable fossil, apparently connected with the fructification of a *Cycas*,' and some years later Yates³ expressed the opinion that the fructifications figured by Young and Bird probably belonged to the plants which bore the fronds known as *Zamites gigas*. Leckenby⁴ figured some leaves of *Palaeozamia pecten* (= *Ptilophyllum pecten*) in close association with a small flower of *Williamsonia* which was subsequently recognised as a whorl of microsporophylls. In 1870 two papers of exceptional interest were published, one by Williamson⁵ who was the first to attempt an exhaustive account of the genus, and the other by Carruthers⁶ who proposed the name *Williamsonia*, thus associating 'with a group of the most characteristic Yorkshire fossils two men (father and son) who have largely contributed to the exposition of Yorkshire geology.' Carruthers instituted a new tribe Williamsonieae for the genus *Williamsonia*, the type-species being *Williamsonia gigas*: the specific name had been previously given by Lindley and Hutton to the fronds (*Zamia gigas*) of the plant

¹ Young and Bird (22) A. For a fuller account of the history of our knowledge of *Williamsonia*, see Seward (95) A. p. 146

⁵ Williamson (70).

³ Yates (55).

⁶ Carruthers (70).

which was believed to have borne the flowers for which the new designation was proposed. Two other species, *Williamsonia hastula* and *W. pecten*, were assigned to the new genus. The conclusion arrived at by Williamson as to a connexion between *Zamites gigas* and *Williamsonia* flowers was, however, not accepted by Saporta¹, who figured and described several exceptionally good specimens from the Yorkshire coast which formed part of the Yates collection in the Paris Natural History Museum. In 1897 a short account was published² of the Yates specimens, an examination of which convinced me of the correctness of Williamson's views as to an organic connexion between stems, peduncles, flowers, and fronds. During a visit to Paris several photographs were taken, but these were not published: similar photographs have since been reproduced by Wieland³ and reduced copies from two negatives in my possession are shown in figs. 541, 542. The restoration by Williamson in his well-known memoir is probably correct so far as the general habit of the plant is concerned, though the flowers which he speaks of as male are now known to be ovulate. The position of the male organs, whether borne separately or on the same axis as the megasporophylls, has not been definitely settled.

In 1891 the Marquis of Saporta thus introduced his discussion on *Williamsonia*,—‘avec les *Williamsonia* nous abordons un des problèmes les plus difficiles, un des sujets des plus controversés, mais aussi les plus curieux, peut-être même le plus remarquable de tous ceux que nous offre l'ensemble des plantes jurassiques.’ Wieland's investigations have placed us in possession of many important facts with regard to the closely allied flowers of *Cycadeoidea* and have enabled us considerably to extend our knowledge beyond the stage represented by the work of Carruthers, Williamson, and other authors; and more recently Nathorst's important discoveries have demonstrated the close agreement between *Williamsonia* and *Bennettites* (*Cycadeoidea*). Several problems still remain unsolved. Having regard to the deficiency of the data concerning the morphology of the *Williamsonia* type of flower and the wider question as to a phylogenetic relationship that some botanists believe to exist between the Bennettitales

¹ Saporta (91).

² Seward (97⁴).

³ Wieland (11).

and the Angiosperms, Saporta's words are still pertinent. Wieland's discoveries in Mexico¹ have furnished additional evidence of the wide geographical distribution of the *Williamsonia* type of flower in the Jurassic period, and it may be confidently asserted that the Bennettitales, including both *Williamsonia* and *Cycadeoidea*, occupied a dominant position in the floras of the world during the stage of plant-development immediately preceding the evolution and rapid spread of the Angiosperms, the present dominant class.

There has been considerable uncertainty among authors with regard to the application of the name *Williamsonia*. In former accounts of the genus the name was employed by me both for leaves and flowers on the ground that Williamson was correct in his opinion as to the connexion between *Williamsonia gigas* and *Zamites gigas*. The type of frond to which the latter term is applied is by no means uncommon in Jurassic strata though it is not always associated with flowers, and the use of the generic term *Williamsonia* is therefore not invariably justifiable. Nathorst² has recently reiterated his opinion that it is inadvisable to employ the name *Williamsonia* except for the flowers or the complete plant and strongly urges palaeobotanists to retain the provisional genus *Zamites* when the fronds only are in question. While agreeing with the contention that the greatest care should be exercised to avoid the use of generic names implying a correlation of vegetative and reproductive organs that rests on any evidence short of demonstration, it may be suggested that the better plan is to add the name *Williamsonia* in parentheses after *Zamites* or *Ptilophyllum* in cases where there is no reason to doubt that the fronds belong to a *Williamsonia* plant.

Williamsonia gigas (Williamson).

The species selected for a rather detailed description is still imperfectly known, but it is particularly interesting as the type on which the first scientific account of the genus was based. The name *Williamsonia gigas* is now generally employed for the flowers which bore megasporophylls as the essential organs: they may have been bisporangiate,—a view that seems to me

¹ Wieland (13).

² Nathorst (13).

the more probable,—but this has not been demonstrated. There are very few cases in which fronds of *Zamites gigas* occur in

FIG. 541. *Williamsonia gigas*. Fronds (*Zamites gigas*) and flowering shoot, *a*, attached to a stem (*Bucklandia*). (Yates Collection, Paris; nat. size.)

organic connexion with stems, and we cannot with safety employ other than a provisional generic term for fossil stems which it

is believed bore flowers of the *Williamsonia* type. For the imperfectly preserved piece of stem shown in fig. 541 the name *Williamsonia* (*Bucklandia*) *gigas* is employed, as there is no reasonable doubt that in addition to the fronds of *Zamites gigas* it bore peduncles (fig. 541, *a*), with *Williamsonia* flowers. This

FIG. 542. *Williamsonia gigas*. Flowering shoot and flower-bud.
(Yates Collection, Paris.)

and other stems found in close association with *Williamsonia* flowers in England, India, and Mexico are of the type known as *Bucklandia*¹; but it would in most instances be unwise to add *Williamsonia* even as a subordinate title. Casts of stems in close association with fronds and flowers are not uncommon in

¹ See page 480.

collections of plants from the Yorkshire coast; the surface-features are of the type shown in fig. 576, rhomboidal or lozenge-shaped bases of petioles as described under the genus *Bucklandia*¹. The stem reproduced in fig. 541, about 5 cm. broad, is imperfectly preserved and the leaf-bases are not clearly seen. Saporta's figure² conveys but a poor idea of the actual specimen. To one side of the stem, 5 cm. from the lower, broken, end, are attached the petioles of two clearly preserved fronds of *Zamites gigas*, and above these is part of a third frond apparently in its original position. The main axis is prolonged obliquely upwards to the left as a branch, *a*, 3 cm. broad and 14 cm. long, covered with hairy bracts and bearing distally several narrow, linear-lanceolate, scale-leaves. This branch is undoubtedly a fertile shoot or peduncle. A specimen figured (from a drawing) by Saporta³ as a peduncle of a *Williamsonia* flower and reproduced in fig. 542 is, in surface-features, identical with the branch *a* shown in fig. 541, but at the apex it bears a bud covered with linear bracts identical with those of *Williamsonia gigas*. This bud is almost certainly a young flower. Similar peduncles are described by Williamson, and he speaks of one which is bifurcated: this specimen is probably that reproduced in fig. 543 and now in the Leeds Museum: at the base the axis is 3.5 cm. in diameter; the two divergent arms bear numerous bracts identical with those of *Williamsonia gigas* and in addition are a few shorter ovate scales recalling those figured by Nathorst as probably belonging to *Williamsonia pecten*. The Leeds specimen is from the Lower sandstone and shale near Scarborough. Similar branched peduncles are represented in the Whitby Museum and in the National Collection. Wieland⁴ has also figured a peduncle bearing a 'typical fruit bud' of *Williamsonia gigas* similar to that reproduced in fig. 542. These specimens fully justify Williamson's restoration published in his paper of 1870.

In a former account of this species⁵ the opinion was expressed that the flowers described by Williamson as male were ovulate and constructed on the plan of those of *Bennettites Gibsonianus*

Carr. This conclusion has since been confirmed by Nathorst¹ who succeeded in obtaining excellent preparations of the cuticular membranes of intersemental scales and micropylar tubes (fig. 545), demonstrating their very close agreement with those of the flowers of *Cycadeoidea*.

One of Williamson's 'carpellary discs' has been shown by Nathorst to be a verticil of microsporophylls bearing synangia, but both this author and Lignier² think that the two specimens figured by Williamson as carpellary discs are distinct organs, one being a staminate whorl and the other a sterile infundibuliform organ. My own view is that both are of the same nature and consist of microsporophylls.

FIG. 544. *Williamsonia gigas*. Portion of a flower showing the protective bracts, the annular zone formed by numerous sterile sporophylls and intersemental scales, and the large central cavity originally occupied by the receptacle. (From a specimen in the Williamson collection, Cambridge Botany School; nat. size.)

Fig. 544 represents the usual form in which the flowers of *W. gigas* are found; it consists of linear bracts covered with hairs identical with those on the peduncles shown in figs. 541—543; they surround a pyriform axis and form what Williamson called

¹ Nathorst (09) (11).

² Lignier (07).

an involucre. The base of the fossil is characterised by an annular zone formed of crowded, radially disposed, narrow ridges now known to be casts of interseminal scales. At the outer edge of this annular area impressions of the peltate ends of interseminal scales are not infrequently preserved. Fig. 545 is a photograph of one of Nathorst's preparations showing the very great similarity between a micropylar tube of *W. gigas* and the corresponding structures in *Cycadeoidea*. The small micropylar tubes are surrounded by 5—6 polygonal expanded apices of interseminal scales as in *Cycadeoidea* (fig. 515; cf. also fig. 563), and the apex of each peltate distal end projects slightly as a central papilla composed of more strongly cuticularised cells. In most specimens the megasporophylls and interseminal scales (sterile megasporophylls) are preserved only as an annular zone at the base of the receptacle (fig. 548, *as*), but it is clear from some specimens of *W. gigas* and other species figured by Saporta¹, Nathorst², and Krasser³ that originally the whole surface of the pyriform axis was beset with these organs which fell off, presumably, when the seeds had reached maturity. No satisfactory examples of seeds have been found in English specimens. Krasser has described some specimens of *Williamsonia* from Jurassic rocks in Sardinia to which he assigns some associated seeds, but, as he admits, there is no proof of any connexion. In some cases a funnel-like depression is seen at the upper end of a strobilus of *W. gigas* (fig. 546, B, C, *a*) identical in the occurrence of radially disposed ridges with the annular zone at the base and due to the preservation of interseminal scales and aborted megasporophylls in the upper part of the receptacle: in this region also the impressions of polygonal apices of the scales are sometimes found. The probability is that while the greater part of the armour of scales and seeds was thrown off, at the upper and lower end of the

FIG. 545. *Williamsonia gigas*. Micropylar tube. (After Nathorst.)

¹ Saporta (91) Pl. 248.

² Nathorst (09) Pl. III.

³ Krasser (12).

receptacle some sterile megasporophylls and scales remained (fig. 548, *as*, *dl*).

Williamson regarded the funnel-shaped depression as the impression of the lower surface of a laterally expanded portion of

FIG. 546. *Williamsonia gigas*. A, apical portion of flower. B, cast of A; *a*, persistent interseminal scales. C, flower in longitudinal section. C', interseminal scales from the base. (Williamson Collection, Botany School, Cambridge.)

the axis of the flower, and to this expansion he gave the name lenticular disc (figs. 546, 547, *a*). It is, however, much more likely that the apparent extension of the axis is due to the

preservation of the sterile zone of armour which formed a cluster of appendages, the impressions of which are seen on the sides of the funnel-like depression, the receptacle being prolonged as a slender axis (fig. 547, C). The next point to consider is the form of the axis beyond the level of the collar of sterile armour.

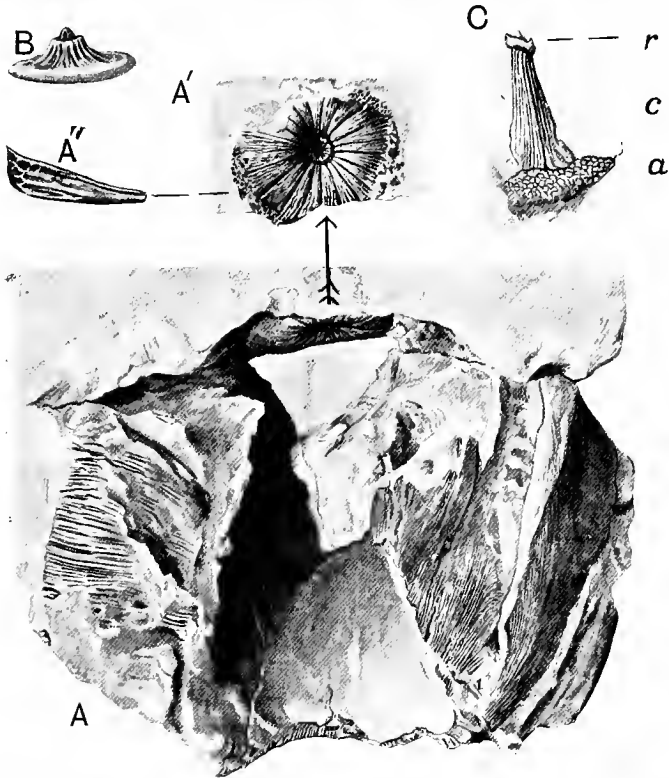

FIG. 547. *Williamsonia gigas*. A, flower in longitudinal section, showing, especially on the left side, interseminal scales and megasporophylls and a pyriform cavity representing the central axis (nat. size). A', the under surface of the apical region. A'', interseminal scales from A'. B, cast of A'. C, apical region of another specimen; a, interseminal scales; c, column; r, ridge. (Williamson Collection, Botany School, Cambridge.)

Williamson described the axis as spreading out to form the lenticular disc and then prolonged as a narrow conical pyramidal axis which is slightly extended horizontally immediately below a terminal mammilla: the apical mammilla he designated the

corona (fig. 547, C, *r*). As already stated, the lenticular disc is probably not an expanded part of the axis but the result of the preservation of a spreading mop-like cluster of interseminal

FIG. 548. *Williamsonia gigas*. Restoration showing an ovulate strobilus bearing a terminal infundibuliform appendage. Lignier, to whom the restoration is due, points out that the apical portion of the axis at *dl* should be represented as straight and not, as in the figure, horizontally expanded. *bi*, bracts; *as*, persistent interseminal scales forming the annular zone; *r*, receptacle; *cs*, caducous megasporophylls and interseminal scales; *dl*, persistent interseminal scales, an extension of which formed the large funnel-like appendage, *at*; *ap*, apex of the receptacle. (After Lignier.)

scales. This is the view expressed by Lignier¹ who kindly furnished the block from which fig. 548 is reproduced. The lower

¹ Lignier (03).

face of Williamson's lenticular disc is characterised by a series of spoke-like radiating ridges (fig. 547, A') between which are less distinct radially disposed lines, and at the periphery there are impressions (fig. 547, A''), continuous with some of the radiating ridges, of the terminal shields of interseminal scales. In fig. 547, drawn from one of the original specimens described by Williamson, these features are shown at A' and B: fig. A' represents the circular area, which is at right-angles to the axis of the flower, in surface-view. In the centre of this circular area is a depression ending in a short papilla surrounded by a narrow basal rim: this feature is shown on a cast of the specimen represented in fig. 547, B. In this case Williamson's corona is seated on a very short axis whereas in fig. 547, C, also from one of Williamson's specimens, the corona forms the apex of a longer pyramidal axis. Wieland¹ regarded the circular area seen in fig. 547, A, as the impression of the apical portion of a bisporangiate strobilus, the ridges marking the edges of the incurved distal portions of microsporophylls bent over the apex of the ovulate cone (*cf.* fig. 513), and he interpreted the polygonal depressions at the periphery (fig. 547, A'') as those of sori, an interpretation entirely different from that of Lignier. The latter author² in part reasserted his opinion but modified it as regards the meaning of the ridges on the circular area, agreeing so far with Wieland as to consider them as having been formed by the folded-over rachises of microsporophylls attached as a concretescent collar to the base of the ovulate cone. This interpretation does not, however, explain the relation between the radial striations on the circular area and the polygonal impressions at its periphery. Wieland still dissents from Lignier's opinion and suggests that the circular area has not been demonstrated to belong to the apical end of a flower. Fig. 547 shows that its position is apical. Fig. 548 represents Lignier's view as to the nature of the rim surrounding the apical mammilla: he suggested that several interseminal scales borne at the apical region of the receptacle were concretescent and formed linear bracts the edges of which are represented by the main ridges in fig. 547, A'. These concretescent scales bent upwards and were closely applied to or perhaps

¹ Wieland (06) p. 152.

² Lignier (07); Wieland (11) p. 462.

con crescent with the pyramidal axis and were then prolonged as a wide infundibuliform apparatus (Williamson's carpellary disc). This organ was, however, easily detached, and the rim seen at *r* in fig. 547, C, represents its narrow broken base. With this view I am in general agreement; but while Lignier regards the funnel-like appendage as sterile and considers that similar organs, but with a large central cavity at the base of the funnel, may have been microsporophyll-discs which were borne below the ovulate strobilus in the position occupied by the microsporophylls in *Cycadeoidea* (fig. 528)—my inclination is to see in the terminal appendage a whorl of concrescent microsporophylls. This view lacks the support of demonstration. It is obvious from Williamson's specimens and from others described by Saporta, Nathorst, and Lignier that the receptacle of *Williamsonia gigas* was not so simple in its termination as that of the flowers of *Cycadeoidea*. In *Cycadeoidea dacotensis* Wieland showed that the apex of the receptacle bore a tuft of long interseminal scales, and it is readily conceivable that these apical appendages were still further developed in some *Williamsonia* flowers to form a whorl of concrescent leaves borne on the prolonged apex of the axis. There is little doubt as to the homology of interseminal scales and microsporophylls, and there is no difficulty in supposing that while in some flowers the foliar organs assumed the form of interseminal scales of unusual length, in other species they became microsporophylls.

It is noteworthy that the radiating ridges on the circular area shown in fig. 547, A', agree in position and approximately at least in number with those on the sides of the cupular disc of the microsporophyll-verticil of *Williamsonia whitbiensis*¹. Nathorst describes a specimen seen in a private collection in which an infundibuliform appendage appeared to be preserved *in situ* at the apex of a flower of *Williamsonia gigas* (cf. fig. 548, at). Thomas², in his description of *Williamsoniella*, compares the radial ridges on the apical sterile portion of a flower of *Williamsonia gigas* to the ridges on his *Williamsoniella* which are formed by the tips of infolded microsporophylls.

¹ Nathorst (11) Pl. II.

² Thomas (15²).

Williamsonia gigas (Microsporophylls).

In the course of an examination of the *Williamsonia* specimens (from Yorkshire) in Paris in July of last year (1914) Mr Thomas¹ found a specimen previously overlooked, which is undoubtedly either a male flower or, as I am inclined to think, the staminate disc of a bisporangiate flower of *Williamsonia gigas*. The nature of the matrix shows that it came from the neighbourhood of

FIG. 549. *Williamsonia gigas*. A, diagrammatic drawing showing the position of the synangia, at S, and part of the staminate disc. B, a single synangium; $\times 6$. (After Thomas.)

Whitby. It consists of an urn-shaped organ formed of the concrescent bases of 18—20 microsporophylls each 7—8 mm. wide; the cup is 5—6 cm. broad, the base being torn but tapered (fig. 549) as though originally prolonged downwards into a stalk as in *W. spectabilis*. Along the middle line of each sporophyll is a series of depressions, probably the same in nature as those on *W. whitbiensis* described by Nathorst, though it is not clear whether, in this case at least, they represent aborted synangia.

¹ Thomas (15).

Some reniform synangia (fig. 549, B) occur in the rock just above the cup. The sporophylls spread outwards from the base and then curve inwards, bending outwards again as they become free. A portion of a microsporophyll is shown in fig. 550 bearing segments projecting inwards as in *W. spectabilis* (fig. 551). This specimen, which occurs in association with female flowers, is regarded by Mr Thomas as part of a unisexual flower. He discusses the possibility of its connexion with an ovulate receptacle and expresses the opinion that if it were borne at the upper end of a bisporangiate flower the whole would be top-heavy and the arrangement uneconomical. On the other hand if, as suggested on page 434, the flowers were bisexual the staminate disc, which reached maturity before the ovules, may have been thrown off, as in *Cycadeoidea*, before the seeds were ripe. The form of the disc resembles that of the Indian specimen described on another page as *Williamsonia* sp., cf. *W. setosa* Nath.; it does not, I venture to think, afford an argument against the view that the microsporophyll-cup of some *Williamsonia* flowers was attached near the apex of the receptacle and was formed of modified foliar organs homologous with those which, in the ovulate portion of the flower, constitute the interseminal scales and megasporophylls.

FIG. 550. *Williamsonia gigas*. Side-view of an incomplete staminate disc showing the basal cup torn at the lower end and part of one of the free microsporophylls. (Diagrammatic drawing, after Thomas; nat. size.)

A further consideration of the microsporophylls of *Williamsonia* will be found in a later section of this chapter.

Williamsonia spectabilis Nathorst.

This species¹, the first example of undoubted microspore-bearing organs referred to *Williamsonia*, was founded on material

¹ Nathorst (09) p. 6, Pls. I., II; (11) p. 5, Pls. I., III; (12).

discovered by Prof. Nathorst in the Lower Estuarine series of Whitby; it has also been obtained from beds of the same age at Marske in the Cleveland district of Yorkshire¹. *Williamsonia spectabilis*, though indubitably a male organ, has not been found attached to a stem, and there is no decisive evidence as to its connexion with a particular species of frond. Nathorst believes that it belongs to the plant which bore the leaves known as

FIG. 551. *Williamsonia spectabilis* and leaves of *Ptilophyllum pecten*. (After Nathorst; $\frac{5}{8}$ nat. size.)

Ptilophyllum pecten, an opinion based chiefly on association. The more complete specimens consist of a broad funnel-shaped organ prolonged below into a slender stalk and divided at the margin into several linear-lanceolate segments (microsporophylls) the apices of which were rolled inwards like young fern-fronds (figs. 551, 552). The synangia agree closely in form and in such structural features as can be made out from cuticular preparations with those described by Wieland in American species of *Cycadeoidea*; they are slightly reniform, 5—6 mm. long and 2 mm. broad and divided into several loculi by transverse partitions

¹ Thomas (13²) p. 230, Pl. xxiv. figs. 1—3.

(fig. 552). The microspores, 58—65 μ in length, are rather narrow, ovate and very similar to those described by Solms-Laubach¹ in *Cycadeoidea etrusca*. The synangia are attached in two rows to slender lateral segments which appear to be given off from the upper face near the median line of the broad linear sporophylls (fig. 565, A). Nathorst points out that the position of the fertile pinnae brings the sporophylls into close relation with the vegetative fronds of *Ptilophyllum pecten* and other Cycadean fronds in which the pinnae are attached to the upper face of the rachis.

FIG. 552. *Williamsonia spectabilis*. Restoration of an almost mature male flower. (After Thomas; approximately nat. size.)

While the longer pinnae in the middle portion of a sporophyll bear several synangia, those near the base and apex are shorter and, in the proximal region nearer the broad cup formed by the coherent bases of the sporophylls, occur singly, thus approaching the condition characteristic of *W. whitbiensis* (fig. 565, B) in which they are sessile on the simple microsporophylls. It is noteworthy that in some specimens figured by Nathorst there is a tendency

¹ Capellini and Solms-Laubach (92) Pl. v. fig. 7.

of the lower part of the cup to break away from the coherent bases of the sporophylls (fig. 551)¹, and it is not unlikely that some of the impressions described as infundibuliform appendages are incomplete examples of *Williamsonia spectabilis*.

Williamsonia Leckenbyi Nathorst.

This species, founded on specimens from the Middle Estuarine beds exposed on the Yorkshire coast at Cloughton Wyke², is characterised by the almost spherical form of the strobilus, 4.5—5 cm. in diameter. The relatively small receptacle is covered by a thick mass of megasporophylls and interseminal scales except in the lower part which bears only sterile scales. Nathorst believes that the seeds were very small, but no undoubted examples have been found. A specimen in the British Museum, figured in 1900³, shows the surface-view of an impression of the base of

FIG. 553. *Williamsonia Leckenbyi*. Surface-view and in section.
(Restoration after Nathorst.)

the flower; a small circular raised boss occupies the centre—the scar of the receptacle—and surrounding this is a reticulum formed by the impression of the distal ends of the interseminal scales. The uniform nature of the reticulum, the meshes of which are all of the same type, shows that in the basal region of the flower the organs borne on the receptacle were all sterile as in *Cycadeoidea (Bennettites) Morierei*. Except in the smaller diameter of the receptacle this specimen is practically identical with that of *Williamsonia Carruthersi* Sew. reproduced in fig. 559. The form of the strobilus is shown in Nathorst's restoration⁴ represented in fig. 553. The interseminal scales have broad peltate

¹ Nathorst (09) Pl. I. figs. 1—3.

² *Ibid.* (80) p. 39. See also Saporta (91) p. 161, Pl. 248.

³ Seward (00) B. p. 201, fig. 35.

⁴ Nathorst (09) p. 14, Pls. II., III.

distal ends characterised by a patch of lighter and thinner-walled cells at the apex (fig. 554); the micropylar tubes are slightly expanded at the summit and their epidermal cells are papillose as in *Williamsonia scotica* (cf. fig. 563, B). Nathorst in 1909 adopted the name *Williamsonia pecten* Carr.¹ for the specimens originally referred to *W. Leckenbyi* as well as for microsporophylls that he believed to belong to the same plant as the ovulate strobili: but in a later paper² he restricts the name *Williamsonia pecten* to the male strobili, reserving *W. Leckenbyi* for the ovulate forms, as there is no proof that both were borne on the same plant. From the evidence at present available it is reasonable to regard *W. Leckenbyi* as a unisexual flower. In all probability the fronds

FIG. 554. *Williamsonia Leckenbyi*. Micropyle and interseminal scale.
(After Nathorst.)

known as *Ptilophyllum pecten* are the foliage of the parent-plant of *W. Leckenbyi*, though in the absence of proof it is advisable to retain both names.

Williamsonia whitbiensis Nathorst.

Under this name Nathorst³ described some interesting specimens of microsporophylls formerly attributed by him to *Williamsonia pecten*, but the discovery of additional material led him to distinguish the Whitby (Lower Estuarine) fossils as *W. whitbiensis*, retaining the name *W. pecten* for the type originally figured by Leckenby⁴ from the Middle Estuarine series at Cloughton Wyke on the Yorkshire coast. In the type-specimen, 8—10 cm. in

¹ Carruthers (70) p. 694.

² Nathorst (11) p. 19.

³ Nathorst (11) p. 9, Pls. II., III. See also Nathorst (09) p. 8, Pls. I., II.

⁴ Leckenby (64) A.

diameter, there are 15 linear segments coalescent basally into a thick cup differing from that of *W. spectabilis* in the absence of a stalk (figs. 555, 556). A more important distinctive feature is the production of synangia on the simple sporophylls (figs. 556, B; 565, B) and not on special fertile segments as in *W. spectabilis*

FIG. 555. *Williamsonia whitbiensis*. (After Nathorst; $\frac{1}{2}$ nat. size.)

FIG. 556. *Williamsonia whitbiensis*. A, male flower. B, sporophyll with synangia. (After Nathorst.)

(fig. 552). The inner face of each sporophyll, as seen in impressions, shows two regular rows of small depressions, one on each side of the median line; these become gradually smaller towards the base of the cup-like disc (figs. 555, 556). On the actual carbonised surface of the inner face of the cup small and transversely elongated projections take the place of

the depressions and these show the same decrease in size when traced from the free segments to the cupular organ. Nathorst obtained microspores only from the larger projections and none from the smaller, a circumstance which may indicate that only the upper and larger synangia were fully developed¹.

This species is especially interesting as throwing light on the nature of one of the specimens (from the Whitby Museum) figured by Williamson as a 'carpellary disc'²: the 'seeds' of Williamson are no doubt, as Nathorst believes, synangia, while the smaller pairs of markings figured by Williamson represent rudimentary synangia and not 'abortive ovules.' Though the specific identity of Williamson's specimen and *Williamsonia whitbiensis* is not certain, the latter is undoubtedly a closely allied form of a microsporophyll-verticil. A specimen figured in 1900 as a flower of *Williamsonia pecten*³, designated by Nathorst *Williamsonia* sp., is a very similar if not an identical type; it consists of a fairly deep basal cup the surface of which is characterised by the presence of several regular ridges between which are pairs of small depressions containing carbonaceous matter. In the light of Nathorst's researches it is clear that this is an incomplete example of a whorl of microsporophylls. The base of the disc is incomplete, but it is certain from the small size of the basal hole with torn edges that the cup could not have been attached to the base of a receptacle as are the microsporophylls in Wieland's bisporangiate flowers of *Cycadeoidea*. The specimens referred by Nathorst to *Williamsonia pecten*⁴ (Leck. *ex parte*) are similar to those described as *W. whitbiensis*, but differ in the texture of the cup and in the degree of cuticularisation of the synangial walls. The synangia of *W. pecten* are of the usual reniform type and multicellular as in *W. spectabilis*.

¹ Nathorst (12) p. 7.

² Williamson (70) Pl. LII. fig. 1; Pl. LIII. fig. 2.

³ Seward (00) B. p. 201, Pl. II. fig. 7.

⁴ Nathorst (11) p. 19, Pl. v. figs. 1—8; Pl. vi. figs. 1—3. The name *Palaeozamia pecten* was applied by Leckenby [Leckenby (64) A. p. 77, Pl. IX. fig. 47] both to the fronds and an associated flower which is now recognised as a whorl of microsporophylls. I formerly employed the name *Williamsonia pecten* for fronds and flowers, but in view of Nathorst's work it is advisable to follow his example and to use separate names for male and female flowers when there is no proof that they belong to one type; similarly the fronds may conveniently be spoken of as *Ptilophyllum pecten*.

Williamsonia setosa Nathorst.

The distinguishing features of this species¹, founded on material collected by Dr Halle from Lower Estuarine beds at Whitby, are (i) the greater number of linear sporophylls which bear numerous bristles or stout hairs, (ii) the loose coherence of the contracted proximal portion of the linear segments, and (iii) a narrower basal disc in place of the deeper cup of other species. One of the specimens referred to this species, formerly regarded by Nathorst as an infundibuliform organ of an ovulate strobilus of *W. gigas*², bears a striking resemblance to an Indian fossil described by Feistmantel from India³.

INDIAN SPECIES OF WILLIAMSONIA (FLOWERS).

Several specimens of *Williamsonia* have been described from the Rajmahal and other Jurassic series in India, some of which exhibit a close agreement with *Williamsonia gigas*. It is, however, noteworthy that no fronds of the *Zamites gigas* type have been discovered in Indian beds; on the other hand the association of fronds of the same type as *Ptilophyllum pecten* with Williamsonian strobili is significant, as also the occurrence of stems apparently identical in surface-features with English and Mexican species.

Williamsonia sp.

Oldham and Morris⁴ figured a specimen from the Rajmahal Hills consisting of a circular disc enclosed by a zone of 'closely packed tubes,' the basal portion of an ovulate *Williamsonia* strobilus, which they regarded as a pressed mass of young leaves 'probably related to *Palaeozamia*' [*Ptilophyllum*]. The figured specimen shows that the radially disposed 'tubes' surrounding the circular area are interseminal scales some of which are seen at the periphery in surface-view as small polygonal areas as in English specimens. Feistmantel⁵ refigured this specimen and referred it to *Williamsonia gigas* though on insufficient grounds. To the same species Feistmantel⁶ assigns two other specimens from the Rajmahal series, one of which consists of several narrow

linear bracts partially enclosing a strobilus with a portion of the annular zone at the base in which the seminiferous scales are shown in longitudinal-view and a few in apical-view.

Williamsonia sp. cf. *Williamsonia setosa* Nathorst.

A third example from the same locality (fig. 557) is described by Feistmantel¹ as part of one of Williamson's 'carpellary discs',²

FIG. 557. *Williamsonia* sp. A, whorl of microsporophylls; s, synangia (?). C, side-view of the basal portion of A. B, part of a microsporophyll enlarged. (Indian Geological Survey; A, nat. size.)

a comparison that is fully justified. The accompanying drawing has been carefully made from the actual specimen: portions of 10 very hairy bracts radiate in a horizontal plane from a con-

¹ Feistmantel (77²) Pl. XLIV. figs. 3, 4.

² Williamson (70) Pl. LII. fig. 1.

tinuous lamina with a wrinkled and ridged surface bent sharply back at right-angles to the bracts and forming a double curve as seen in the sectional view (fig. 557, C). The form assumed by the vertical part of the disc is, I believe, the result of compression. Wieland¹ regards this fossil as a whorl of microsporophylls originally attached to the lower portion of the receptacle of a bisexual flower. Close to the edge of one of the bracts is an imperfectly preserved structure (fig. 557, B, s) which may represent two alternately arranged rows of synangia belonging to one of the hairy bracts; but we have no evidence as to the position of the microsporophylls on the flower-axis. The central space enclosed by the crushed concrescent portion of the disc is large enough to have embraced a receptacle but, on the other hand, the portion preserved may have broken off from a proximal cup like that of *W. spectabilis*², which, as Nathorst's specimens show, is sometimes broken across near the upper edge of the basal funnel. This specimen is spoken of by Feistmantel as *Williamsonia gigas*. It is impossible to say whether these Rajmahal specimens belong to one species, and they are therefore provisionally designated *Williamsonia* sp. and *Williamsonia* sp. cf. *W. setosa*.

Williamsonia microps Feistmantel.

This species is based on a compressed ovate strobilus surrounded by linear bracts and a portion of the cylindrical axis³. It is possible that this smaller, bud-like, specimen may be a younger example of the species referred by Feistmantel to *Williamsonia gigas*.

Williamsonia Blandfordi Feistmantel.

Founded on a small strobilus enclosed by linear bracts, from the Jurassic rocks of Cutch⁴, very similar to *Williamsonia pecten*; as seen in fig. 558, drawn from the original specimen, the flower is associated with a *Ptilophyllum* frond indistinguishable from some examples of *Ptilophyllum pecten*.

¹ Wieland (11) p. 460, fig. 16 B.

³ Feistmantel (77²) Pl. xli. fig. 4; (77) Pl. I. fig. 6; Pl. II. fig. 4.

⁴ *Ibid.* (76²) p. 52, Pl. XII. figs. 5—7; (77⁵) Pl. I. figs. 4, 5; Pl. II. fig. 6.

Williamsonia indica, sp. nov.

This name is proposed for some imperfect specimens described by Feistmantel from the Godavari district and named by him *Williamsonia* sp. cf. *Williamsonia gigas*¹. They differ from *Williamsonia gigas* in the larger size of the bracts which reach a length of 13 cm. and may be compared with those of a large specimen recorded from Mexico as *Williamsonia Cuauhtemoc*².

FIG. 558. *Williamsonia Blandfordi* and *Ptilophyllum* frond.
(Geological Survey of India; nat. size.)

It is almost certain that some at least of the Indian flowers were borne on stems with the foliage known as *Ptilophyllum acutifolium*, an inference based not only on the almost constant association of flowers and fronds but also on the juxtaposition of both kinds of organs with stems precisely similar to those described from England and Mexico. Though none of the specimens are sufficiently well preserved to afford much information as to structural features, Miss Bancroft³ has shown that the bracts of

¹ Feistmantel (77³) p. 181, Pl. VII. figs. 1—4; (77¹) Pl. II. figs. 1—3.

² My thanks are due to Mr Wieland for a photograph of this species that is mentioned but not figured in his paper on the Mexican Flora, Wieland (13).

³ Bancroft (13) p. 76, Pl. VII. figs. 1—5.

one of the examples assigned by Feistmantel to *W. gigas* are similar anatomically to those of *Williamsonia scotica* and are clothed with simple hairs. The important point is the very close correspondence between the Indian and English types of *Williamsonia*, as regards flowers, fronds, and stems.

BRITISH SPECIMENS.

Williamsonia Carruthersi Seward.

This species was founded on several specimens from Wealden beds on the Sussex coast none of which afford information as to

FIG. 559. *Williamsonia Carruthersi*. A, unexpanded flower. A', the reticulate lamellae projecting from the face of a bract. B, the basal portion of a larger and expanded flower showing the impressions of the interseminal scales and the base of the receptacle. (British Museum, A, V. 3177; B, V. 3201.)

anatomical structure¹. It is not improbable that more than one species is represented. The ovulate cone, 6 cm. long, is surrounded by several linear bracts (fig. 559, A) and in shape resembles *Bennettites Morierei* Lign.; the bracts are broken across near the base, as is frequently the case in *Williamsonia gigas*, exposing an annular zone formed by persistent interseminal scales. From the inner

¹ Seward (95) A. p. 157, Pls. x., xi.

face of some of the bracts project slender radiating plates (fig. 559, A') which no doubt mark the boundary of the superficial and relatively large interseminal scales, like those forming the so-called pericarp in *Bennettites Gibsonianus*. The receptacle appears to have been conical, a feature recalling *Bennettites* rather than *Williamsonia*. The saucer-like impression shown in fig. 559, B, is practically identical with the corresponding portion of *Williamsonia Leckenbyi*: the centre is occupied by a raised area, the basal part of the receptacle, on which a series of peripheral prominences represents the vascular strands; the sides of the saucer show very clearly the reticulum formed by the distal ends of interseminal scales. One reason for assigning this species to *Williamsonia* rather than to *Bennettites* (or *Cycadeoidea*) is the occurrence in the same bed of a peduncle 12 cm. long and 3 cm. broad which probably belonged to the parent-plant of the cone. The surface of the peduncle shows spirally disposed scars of bracts crowded at the distal end and more widely separated in the lower portion.

Williamsonia Bucklandi (Unger).

In 1837 Buckland¹ gave an account of a 'unique and beautiful fossil fruit' from Inferior Oolite beds at Charmouth in Dorsetshire and stated that the type-specimen was in the Oxford Museum. Professor Sollas kindly searched for the specimen some years ago but without success. Buckland considered that the fruit was related to the Pandanaceae and described it as follows: 'The size of this fruit is that of a large orange, its surface is occupied by a stellated covering or epicarpium, composed of hexagonal tubercles, forming the summits of cells, which occupy the entire circumference of the fruit. Within each cell is contained a single seed, resembling a small grain of rice more or less compressed, and usually hexagonal. When the epicarpium is removed, the points of the seeds are seen, thickly studded over the surface of the fruit. The bases of the cells are separated from the receptacle by a congeries of foot-stalks formed of a dense mass of fibres, resembling the fibres beneath the base of the seeds of the modern *Pandanus*.' At the suggestion of Robert Brown he called the

¹ Buckland (37) Vol. I. p. 505, Vol. II. p. 101, Pl. LXIII. figs. 2—10.

'fruit' *Podocarya*, the specific name *Bucklandi* being afterwards given by Unger¹. Brongniart² called attention to the resemblance of Buckland's specimen to *Williamsonia*, and that name has been adopted by Saporta³, Nathorst, and other authors⁴. Sowerby's drawings illustrating the original description, one of which is reproduced in fig. 560, show that this unusually fine specimen is an ovulate Bennettitean strobilus very similar in its thick conical

FIG. 560. *Williamsonia Bucklandi*. (After Buckland; $\frac{1}{2}$ nat. size.)

receptacle to some of Wieland's species of *Cycadeoidea*, e.g. *C. dacotensis* (fig. 528): the armour of scales and megasporophylls agrees exactly with that of some species of *Williamsonia* from Yorkshire and with the flowers of *Cycadeoidea*. Though included in the genus *Williamsonia* it would not be out of place in *Cycadeoidea*.

Williamsonia scotica Seward.

The type-specimen was found by Hugh Miller near Cromarty (N.E. Scotland) and figured as a cone of peculiar form⁵; it was obtained from a limestone nodule probably derived from Upper Jurassic rocks. The fossil is 11 cm. long and has a maximum

¹ Unger (50) A. p. 327.

⁵ Miller (57) B. p. 480. For a detailed description and illustrations, see Seward (12²).

breadth of 6 cm. (fig. 561): numerous linear bracts cover the surface and in the lower portion many of them are broken. A noteworthy feature is the absence of any clean-cut base, a fact pointing to fracture rather than a natural abscission of the fertile axis. The following description may serve to give a general idea of the salient characters. Flowering shoot ovoid, covered with linear bracts some of which are prolonged above the conical apex as slender tapered organs and two of them bear a few short lateral

FIG. 561. *Williamsonia scotica*. Strobilus in surface-view; *l*, bract with short lateral appendages. (Royal Scottish Museum, Edinburgh; $\frac{2}{3}$ nat. size.)

appendages (fig. 561, *l*), probably reduced leaflets, near their distal ends. The cylindrical axis, completely hidden by bracts, 1.5 cm. in its widest part, bears in the lower or sterile region bracts and long hairs and in the upper part interseminal scales and immature megasporophylls which together form a narrow band (fig. 562, *S*) 2 mm. broad extending over the incompletely preserved and conical apex, as in some of the American examples

of *Cycadeoidea*. The strobilus was probably borne at the apex of a lateral branch given off from a stem covered with persistent petiole-bases: there is no evidence that this was the case, but the appearance of the ovoid cone suggests comparison with those of *Williamsonia gigas* which were terminal on fairly long branches and not partially hidden among the bases of fronds as in *Cycadeoidea*. It is, however, possible that the cone of *Williamsonia scotica* is a lateral structure: this suggestion is based on the occurrence of a small branch or bud, which may be the apex of the whole fertile shoot, given off from the cone-axis but only revealed

FIG. 562. *Williamsonia scotica*. Transverse section; S, scales and megasporophylls; a, bract showing detached superficial tissue on the inner side. (ca. \times 2.)

in transverse sections. The interseminal scales, 2 mm. long and 0.23 mm. broad at the truncate distal end (fig. 563), are polygonal in section and arranged as rosettes of 5—6 around each megasporophyll (fig. 564, a section tangential to the peripheral layer of scales and sporophylls). The megasporophylls, equal in length to the scales, consist of a cylindrical axis bearing a terminal megasporangium, an undifferentiated nucellus, enclosed in a single integument prolonged as a micropylar tube above the conical end of the nucellus (fig. 563, B, C, a). Fig. 562 represents a transverse section through the cone showing the cylindrical axis with its compact covering layer (fig. 563, A, s) of sterile and fertile appendages, and beyond this sections of the enveloping bracts embedded in a dense felt of long hairs. The tissue of the axis, though very imperfectly preserved, shows occasional groups

FIG. 563. *Williamsonia scotica*. Megasporophylls and interseminal scales in longitudinal section. A, part of the axis showing the attachment, *s*, of a scale and megasporophyll. B, apex of micropylar tube showing funnel-shaped cavity and papillose epidermal cells on the integument and on the adjacent scale; *a*, apex of nucellus. C, upper part of a scale and megasporophyll; *a*, apex of nucellus. (A, ca. $\times 20$; B, C, $\times 100$.)

of secretory sacs and a few patches of scalariform tracheids: there is evidence of the occurrence of peripheral conducting tissue in the lower portion of the axis such as occurs in the peduncles of American species of *Cycadeoidea* described by Wieland. The bracts nearer the axis are more shrivelled than those farther away, the result of the feebler development of hypodermal stereome in the more internal bracts. Sunken stomata occur on the lower surface of some of the bracts: several collateral bundles are present in each and large secretory ducts are abundant. The

FIG. 564. *Williamsonia scotica*. Transverse section near the distal end of a micropylar tube and the surrounding polygonal interseminal scales. (ca. $\times 100$.)

numerous hairs on the bracts and the sterile region of the cone are outgrowths of epidermal cells; most of them consist of a short basal cell and a very long thick-walled tubular hair reaching a length of several centimetres. In some cases the basal cell bears a group of short cells each of which is the starting-point of a long hair: this is worthy of notice from the point of view of comparison with the rammenta of other Bennettitalean flowers. The short proximal cell of a hair is surrounded by a cuticular ring like a rounded base-moulding where it rests on the epidermis: this has been aptly compared to the dark rings that form

a striking feature of the cuticular membrane of *Ptilophyllum* leaflets¹.

In the examination of the type-specimen the first section cut was transverse to the axis (fig. 562), and this happened to traverse the lowest part of the fertile region of the receptacle, as was shown by the fact that in the next lower section the axis bore only bracts and hairs. It is clear that the sterile portion of the receptacle passed abruptly upwards into the fertile region, and it is extremely unlikely that any microsporophylls were borne at the base of that portion of the cone-axis which produced the scales and megasporophylls. The cone was, in all probability, unisexual. On the analogy of the cones shown in figs. 513, 514, one would expect to find between the sterile and fertile regions either a verticil of microsporophylls or the remains of an annular disc from which the effete sporophylls had been detached. There is no trace of any such disc, and the fact of the immaturity of the megasporophylls renders it unlikely that were the cone bisexual the microsporophylls would have been detached. As previous records show, there is nothing improbable in the occurrence of a unisexual Bennettitean flower. These remarks are made in view of an opinion expressed by Dr Wieland that the bracts with lateral appendages (fig. 561, *l*), to which allusion has been made, are microsporophylls and that if the cone had been sliced longitudinally the presence of a microsporophyll-disc would have been discovered. The latter possibility has already been considered, and as regards the former there is nothing in the structure of the small lateral appendages of the longest bracts to indicate that they were connected with spore-production. It is not unlikely that the bracts with small outgrowths (fig. 561, *l*) correspond to the more leaf-like bracts of *Wielandiella* and *Williamsoniella*. The two sets of organs spoken of as interseminal scales and megasporophylls are probably homologous, foliar, structures; in the one case leaves transformed into cylindrical organs bearing terminal integumented and undifferentiated megasporangia and, in the other, sterile or sterilised sporophylls. The polygonal truncate distal end of an interseminal scale is flat or slightly concave and covered by

¹ Thomas and Bancroft (13) p. 184.

a thick epidermis, and on the sides of the scale many of the surface-cells are strongly papillose (figs. 563, 564). The rest of the interseminal scale consists mainly of elongated cells, which in the lower portion of the axis of the scale assume a tubular form, presumably immature conducting elements: in one scale only was any tracheal tissue found and that was represented by 2—3 scalariform tracheids. The scales appear to arise from the axis like the bracts as superficial outgrowths, and probably in a later stage of development the centre of each scale would be occupied by a vascular strand. The megasporophylls bear a close resemblance to the scales, but in transverse section they appear as smaller and circular organs each the centre of a group of polygonal interseminal scales precisely as in other Bennettitean flowers (fig. 564; cf. fig. 515). The proximal part of a megasporophyll consists of a column of parenchyma (fig. 563, A, s) extending through half of the length; from this column is detached a narrow cylinder of small crushed cells which most likely represents the remains of tissue that originally occupied the space surrounding the axial column. At a higher level the axial column becomes broader and its short cells more elongated and slightly divergent towards the sloping sides of the conical nucellus. The loose cylinder of tissue is attached to the nucellar cone and prolonged beyond its apex as a broad integument enclosing a very small micropyle (fig. 563, C). The apex of the integument has the form of a shallow funnel: its epidermal cells are papillose (fig. 563, B, C) and the presence of short transversely elongated cells is a characteristic feature of the tissue lining the micropylar canal. The bracts agree generally with those of *Cycadeoidea Gibsoniana*, *Cycadeoidea Morierei*, and the American species. The ground tissue is composed of sclerenchyma comparable with the scalariform elements in the bracts of *Cycadeoidea Gibsoniana* (cf. fig. 520). It is in the possession of long hairs like those on the leaves of *Dioon* and other recent Cycads that *Williamsonia scotica* differs from previously described flowers in all of which the fern-like ramental scales are a conspicuous feature. It is interesting to find that similar hairs are substituted for scales in some Indian stems described by Miss Bancroft¹. Lignier² mentions the occurrence of long unicellular hairs on

¹ Bancroft (13).

² Lignier (01).

Cycadeoidea micromyela (p. 415), a Jurassic French species, but the ramenta are in part multicellular lamellae and the presence of transitional forms suggests a possible derivation of hairs from scales both in fossil species and in recent Cycads. The megasporophylls and interseminal scales are much shorter than in *Cycadeoidea Gibsoniana* and other species in which the axis of the cone forms a depressed receptacle (cf. fig. 521, A, C), but they correspond closely with those of several American species. In *Cycadeoidea Gibsoniana* and *C. Morierei* the distal ends of the interseminal scales are much broader and their diameter greatly exceeds that of the micropylar tubes, 2.8 mm. as compared with 0.25 mm., whereas in *Williamsonia scotica* the scales are 0.23 mm. broad and the micropylar tubes 0.15 mm. The mummified micropylar tubes of *W. pecten* bear a striking resemblance in form and in the papillose epidermal cells to those of the Scotch species.

There are two additional points suggested by the structure of the fertile region, namely the possibility that the megasporophylls are arrested rather than immature organs and, secondly, the method of pollination. In regard to the first there would seem to be no adequate reason for doubting the correctness of the view that the sporophylls are potentially perfect ovules which were petrified at a comparatively early stage in development. The dense woolly covering investing the surface of the scales and megasporophylls recalls an inflorescence of *Aesculus hippocastanum* in its winter-fur and hardly suggests a collection of ovules accessible to microspores. In all probability at a later stage the protecting bracts with their felt of hairs would bend outwards leaving exposed the receptive micropyles.

MICROSPOROPHYLLS.

In view of the association of microsporophylls and ovulate strobili in the flowers of *Cycadeoidea* described by Wieland, most of which are bisexual, it is reasonable to expect a similar association in the flowers of *Williamsonia* which agree closely in the essential features of both micro- and mega-sporophylls with those of *Cycadeoidea*. It is, therefore, surprising that in no single case have the microsporophylls attributed to *Williamsonia* been found

in actual connexion with a receptacle bearing interseminal scales and megasporophylls. The same statement holds good with regard to the *Williamsonias* discovered in Mexico. Nathorst believes that the microsporophylls on which he has founded several species are unisexual flowers with the possible exception of *W. pyramidalis*¹. This species, found by Dr Halle at Cloughton Wyke, is represented by a small ovulate strobilus characterised by a conical receptacle with a blunt mucronate apex: with it is associated a microsporophyll bearing synangia. The orientation of the two specimens is such as to suggest an original connexion. As Nathorst says, there is, however, no proof that the two belong to one flower. Wieland², though believing that the existence of bisporangiate *Williamsonia* flowers is 'reasonably certain,' agrees with Nathorst's conclusion as to the unisexual character of *W. spectabilis* and *W. pecten*. On the other hand, he regards the microsporophyll-verticil which was first described by Williamson as a carpellary disc, then named by Nathorst³ *W. bituberculata* and afterwards identified as a microsporophyll-disc closely allied to *W. whitbiensis*, as the staminate part of *W. gigas*. This view is, in my opinion, impossible to reconcile with the nature of the specimen. If, as Wieland suggests, it is the staminal collar split off from the base of a large ovulate cone like that of *Williamsonia gigas*, one would expect to find a central space in the middle of the cupular base large enough to embrace the receptacle. Neither in this specimen nor in several other forms of microsporophyll-verticils is there such a central space. It is clear that the discs described as *W. spectabilis*, *W. whitbiensis*, and other species were not borne as concrescent collars on a stout axis as are the corresponding organs in *Cycadeoidea*. The Indian specimen reproduced in fig. 557 and the very closely allied type *W. setosa* are incomplete at the centre and may possibly have been borne at the base of an ovulate bisporangiate strobilus, but there is no definite evidence that this was the case. Moreover, in *W. spectabilis* the lower part of the cup (fig. 551) easily splits away from the rest of the staminate disc, and this may explain the central space in the specimen shown in fig. 549, A. If *W. spectabilis*,

¹ Nathorst (11) p. 24, Pl. v. figs. 9—11.

² Wieland (11) p. 462.

³ Nathorst (09) p. 10; (11) p. 14.

to take one example, is a complete flower there are certain difficulties which are not easily explained: as Nathorst has shown, in this type there is a short stalk, but in *W. whitbiensis* the base of the funnel has no stalk and there is no interruption of the stout lamina at the centre or any indication of a scar. Nathorst compares the funnel-like region of *W. whitbiensis* to a kind of cupule which became detached after flowering¹. But a cupule is supported on an axis and, though no scar is apparent on some of the more complete specimens, it is obvious that the verticil must have been supplied with vascular tissue from some axial organ. This brings us to the consideration of a morphological point which cannot be definitely answered. Nathorst has previously raised the question—is it possible that the microsporophylls were attached to the upper part of an ovulate strobilus; were the flowers bisexual and epigynous? He believes the answer to be in the negative. Reference has already been made to the probable occurrence at the apex of the receptacle of *Williamsonia gigas* of a funnel-like organ of the type described by Williamson as ‘carpellary disc²,’ a term under which Nathorst³ believes that Williamson included two different things,—staminate discs borne on separate, unisexual, flowers, and sterile organs called by Lignier⁴ the infundibuliform apparatus. The latter, it is believed, were attached to the apex of an ovulate strobilus as shown in fig. 548, comparable in position with the leaves at the summit of an inflorescence of *Ananas*. A comparison of the fossils regarded as infundibuliform appendages with some of the microsporophyll-verticils shows that they are identical in form, the only difference being that on the former there are no synangia. This fact can hardly be regarded as negative evidence fatal to the morphological identity of these sterile and fertile organs. The available evidence, though far from complete, is favourable to the view that in some *Williamsonia* flowers, e.g. *W. gigas*, the microsporophylls were produced at the apex of the axis in the position shown in fig. 548. To cite a rough analogy,—in *Cycadeoidea* the flower was hypogynous as in *Erica*; in *Williamsonia*

¹ Nathorst (09) p. 10.

² Williamson (70) Pl. LII.: see also Seward (00) B, Pl. VIII. fig. 1.

³ Nathorst (09) p. 12, fig. 2.

⁴ Lignier (03²) p. 34.

epigynous as in *Vaccinium*. This view does not exclude the possibility of the existence of unisexual flowers in some species, but the evidence in favour of a separation of the sexes is by no means decisive. Another difficulty is the absence of protective bracts in the case of the microsporophylls, a striking contrast to the bract-enclosed ovulate strobili of *Williamsonia* or to the bract-covered flowers of *Cycadeoidea*. Were the microsporophylls borne on a separate axis general considerations would lead us to expect the association of bracts with the essential organs. The

FIG. 565. A, *Williamsonia spectabilis*, microsporophyll; B, *W. whitbiensis*, section of sporophyll; C, *W. mexicana*. (A, B, after Nathorst; C, after Wieland.)

fact that no such association has been recorded is a fact favourable to the view that the flowers were bisporangiate.

The student is warned that the opinion expressed with regard to the position of the microsporophylls is contrary to that which is held by several palaeobotanists¹:

Williamsonia mexicana Wieland.

This species is one of the numerous types discovered by Wieland in Mexico². It is distinguished by the deep campanulate

¹ In addition to the papers already quoted, reference should also be made to Thomas (15²).

² Wieland (09) p. 430 (the species is here referred to as the 'El consuelo *Williamsonia*'); (11) p. 461, fig. 17 C.

conrescent portion of the whorl of microsporophylls and by the ten short free lobes which bear two rows of lateral synangia (fig. 565, C). Among the British forms *Williamsonia whitbiensis* would appear to be the most closely allied type. *W. mexicana* occurs in association with *Otozamites* fronds, as is the case with an Italian specimen figured by Zigno¹, but in the Mexican species there is no conclusive evidence of organic connexion.

OTHER SPECIES OF WILLIAMSONIA.

Williamsonia Haydeni Seward.

A Jurassic species from Afghanistan² founded on a single specimen of a flattened broadly-oval flower similar to *W. gigas* but smaller and enclosed by narrow linear bracts. An interesting feature is the occurrence of a funnel-shaped depression at the apex showing radiating lines on its surface as in the *Williamsonia* represented in fig. 546, A. In all probability these lines denote the persistence of a collar of interseminal scales on the upper part of the elongated conical receptacle. An examination of the carbonaceous material revealed the presence of some short rods agreeing in size and shape with the interseminal scales of other species.

Williamsonia Otozamitis (Zigno).

Zigno³ instituted the generic name *Blastolepis* for some specimens from the Jurassic rocks of north Italy which he referred to three species, *B. falcata*, *B. acuminata*, and *B. Otozamitis*. These are true *Williamsonias* closely allied to *W. gigas*. An examination of the type-specimen of *B. Otozamitis* in the Padua collection led me to the conclusion that Zigno was correct in representing the ovulate strobilus, which shows an annular area like that in specimens of *W. gigas*, as being in organic connexion with an *Otozamites* frond. Wieland has recently discovered species of *Williamsonia* in Mexico that he correlates with *Otozamites* leaves.

Williamsonia sp. Seward.

Though by no means satisfactory as a trustworthy record of the genus, the specimens so designated from the Kimmeridgian of Scotland⁴ are probably imperfect examples of the genus.

¹ Zigno (85) Pl. XLII.

² Seward (12) p. 26, Pl. III. fig. 44; Pl. VII. fig. 86.

³ Zigno (85) p. 173, Pl. XLII. figs. 9—11.

⁴ Seward (11²) p. 691, Pl. v. fig. 99.

Williamsonia oregonensis Fontaine.

The type-specimen from Jurassic rocks in Oregon¹ consists of a stout axis bearing several contiguous linear bracts forming a more or less spherical cluster 5 cm. broad. The form suggests a *Williamsonia*, but the evidence is hardly decisive.

Williamsonia Forchammeri Nathorst.

A Bornholm species² from Lower Jurassic strata represented by an annular zone surrounding a central area, probably a portion of an ovulate strobilus.

Williamsonia minima Saporta.

This Upper Jurassic species from Portugal³ consists of a number of small bracts or leaves attached to a central axis and is of no value as evidence of the occurrence of *Williamsonia*.

Williamsonia problematica (Newberry).

This species was first described from the Amboy clays as *Palaeanthus* (*Williamsonia*) *problematica*⁴ and compared to a Composite inflorescence with long ray-florets. More recently Hollick⁵ has referred to this species specimens from the Cretaceous of Long Island and Martha's Vineyard, but none of them afford conclusive evidence of Williamsonian affinity. Some of the examples, as suggested by Hollick, agree fairly closely with *Williamsonia cretacea* Heer.

Williamsonia Smockii Newberry.

The curious urn-like bodies from the Amboy clays⁶ on which this species is based are not unlike the capsules of a *Papaver* but bear no real resemblance to a *Williamsonia*.

Williamsonia Riesii Hollick.

A species from the Cretaceous rocks of Martha's Vineyard⁷ referred to *Williamsonia* on rather slender grounds and represented by imperfect material.

Williamsonia (?) *phoenicopsoides* Ward.

This fossil from the Cretaceous of the Black Hills, Dakota¹, is much too imperfect to be accepted as a record of *Williamsonia*.

Williamsonia elongata Lesquereux.

This species, founded on part of a conical receptacle with some appendages superficially resembling those of *Williamsonia*², is too incomplete to be determined with any confidence. The type-specimen is from Cenomanian beds in Kansas.

Williamsonia virginiensis Fontaine.

This is undoubtedly a true member of the genus; it is characterised by narrow ovate bracts bearing conspicuous hairs surrounding the base of a receptacle which shows a portion of an annular zone of interseminal scales³.

Williamsonia (?) *gallinacea* Ward.

This species from the Potomac beds⁴ is of no value as a record of *Williamsonia*.

Williamsonia (?) *Bibbinsi* Ward.

The imperfectly preserved specimen from the Potomac series so named by Ward⁵ is probably part of an Abietineous cone as stated by Berry⁶ who includes Ward's type with other specimens referred to *Abietites macrocarpus* Font.

Williamsonia cretacea Heer.

Two specimens, figured by Heer⁷ from the Lower Cretaceous of Greenland, on which this species is founded, consist of an axis covered with small scale-leaves and at the broad apex bearing numerous narrow linear bracts forming a more or less spherical cluster 3.8 cm. in breadth. The species resembles *W. problematica* (Newb.).

Williamsonia recentior Dawson.

The specimens from the Middle Cretaceous of Canada figured by Dawson¹ under this name are very imperfect and of no botanical value.

WIELANDIELLA. Nathorst.

The specimens on which this genus is founded were originally described by Nathorst from Hör in Scania as *Williamsonia angustifolia*²: in a second paper³ a restoration of the plant was published

FIG. 566. *Wielandiella angustifolia*. (After Nathorst.)

(fig. 566). The examination of additional specimens from the Rhaetic of Bjuf and of cuticular preparations led to the establishment of a new genus *Wielandia*⁴ for which *Wielandiella*⁵ was afterwards substituted, *Wielandia* having been previously employed for an existing plant. *Wielandiella* agrees in the general morphology of its bisporangiate flowers with *Cycadeoidea*, but differs widely from nearly all other members of the Bennettitales in the repeatedly forked slender stem which is in marked contrast to the vegetative axis of any recent Cycad. Among recent Cycads with

¹ Dawson (85) p. 12, Pl. iv. fig. 1.

⁵ *Ibid.* p. 33.

terminal strobili an indication of a primitive dichasium is afforded by the occurrence of an aborted bud in a stem of *Dioon edule* described by South and Compton¹; but in the habit of the stem *Wielandiella* is far removed from any recent Cycadean type. The microsporophylls are smaller and simpler than in *Williamsonia* or *Cycadeoidea* and the foliage-leaves are of the *Anomozamites* type (cf. fig. 615).

Wielandiella angustifolia Nathorst.

In an account of this species in 1902 Nathorst described two types of strobilus, male and female, but a re-investigation of the material led to a modification of the earlier conclusions. The

FIG. 567. *Wielandiella angustifolia*. Branched stem and receptacle.
(After Nathorst.)

stem is slender, rarely exceeding 1.5 cm. in breadth, repeatedly branched as a dichasial system with a fertile shoot in the forks formed by the equal and widely divergent branches. Nathorst's restoration, as he points out, may exaggerate the regularity of the branching, but an examination of the original specimens in the Stockholm Museum convinced me that the habit represented in fig. 566 is substantially correct. The method of branching is similar to that in the inflorescences of Gnetalean plants and recalls some *Gleichenia* fronds. The surface of the thicker pieces of stem shows fine longitudinal striae, while transverse striations like those on the axis of a *Heterangium* frond characterise the

¹ South and Compton (08) p. 225, fig. 36.

more slender specimens. Closely set polygonal leaf-scars cover the stem for a short distance below each bifurcation and the surface of the short and relatively stout peduncles of the strobili (fig. 567). Though for the most part confined to the region of false dichotomy, leaf-scars occasionally occur on other parts of the stem. Small fronds, 7—8 cm. long, agreeing closely with *Anomozamites minor* Brongn., occur in the same beds at Bjuf, and the striking resemblance between their long linear and winged petioles and the transversely striated bracts enclosing the strobili of *Wielandiella* amply justifies Nathorst's conclusion that *Wielandiella* bore fronds of the *Anomozamites* form¹. Small scars marking the position of bracts occur immediately below each strobilus and occasionally form narrow zones between the larger foliage leaf-scars. The strobili are met with in two forms representing two states of preservation and, probably, different ages. In one form the strobilus consists of a small pyriform axis separated from the peduncle by an annular swelling characterised by parallel striations (fig. 567), the so-called palisade-ring. From this ring Nathorst obtained many microspores scattered and in groups on the surface of short sporophylls, 2.5—3 mm. in length. It is these sporophylls which form the parallel striations; they occur as a circle of rather broad linear organs with irregularly toothed distal ends and an epidermis of papillose cells. The oval microspores, 32—42 μ long, vary in size and, as Nathorst says, this may indicate immaturity. The precise mode of occurrence of the spores has not been ascertained, but they were probably produced in sporangia on the surface of the small microsporophylls. These strobili have in all probability lost the female organs which were borne on the pyriform axis, and the inference is that the strobili were protogynous. Thomas² compares the ring at the base of the flower-axis from which spores were obtained by Nathorst to the whorl of microsporophylls of *Williamsoniella*, but in *Wielandiella* the sporophylls are greatly reduced and possibly functionless. *Wielandiella* may be intermediate between the bisexual *Williamsoniella* and the unisexual *Williamsonia scotica*. In the second form of strobilus the pyriform axis is hidden and

¹ For figures of the stem and flowers, see Nathorst (02); (09).

² Thomas (15²).

the specimens consist of a central ovate body, approximately 3 cm. long, surrounded by several linear bracts (fig. 568, A). The carbonised surface of the central region revealed on chemical treatment a fairly regular pattern formed by the contiguous polygonal ends of interseminal scales arranged round smaller cylindrical micropylar tubes which project beyond the level of the scales (fig. 568, B). This arrangement agrees closely with that of the corresponding organs in *Williamsonia* and *Cycadeoidea*

FIG. 568. *Wielandiella angustifolia*. A, conical receptacle with bracts. B, surface-view of scales and micropylar tubes. (After Nathorst; A, $\frac{3}{4}$ nat. size.)

(*cf.* figs. 515, 564). In *Wielandiella* the micropylar tubes are of uniform diameter and the cells of the epidermis have smooth walls in contrast to the micropylar tubes of *Williamsonia* (fig. 563). The strobilus in this state, before the scales and ovules have become detached from the axis, may be described as a small *Williamsonia*, but the habit of the stem is in itself a sufficient reason for the use of a distinctive generic name¹.

A second species, *Wielandiella punctata*, described by Nathorst² from Scania is founded on pieces of forked stems associated with fragments of a palisade-ring formed of contiguous segments (microsporophylls) with microspores 58μ in length. Fronds of *Anozamites minor* occur in the same beds.

¹ Nathorst retains the name *Anozamites minor* for the leaves, restricting *Wielandiella* to the plant as a whole including strobili and stems which usually occur in organic union [Nathorst (13)].

² Nathorst (09) p. 25, Pl. VII. figs. 14—22.

Mr Hamshaw Thomas¹ described some specimens from the Middle Jurassic beds of Marske in Yorkshire which he suggested might be pieces of a *Wielandiella* stem. Additional material was subsequently found and this enabled Thomas to produce evidence in favour of connecting the branched vegetative axis with bisporangiate strobili and the fronds of *Taeniopteris vittata*. For the stems and flowers the new designation *Williamsoniella* has been proposed. Further research will no doubt show that the *Wielandiella* type of stem was not exceptional in Rhaetic and Jurassic floras.

Nathorst² suggests the possibility that some specimens from the Solenhofen Slates described by Thiselton-Dyer³ as *Condylites squamatus* may be allied to *Wielandiella*. The generic name *Condylites* was suggested by the elbow-like branching of stems which bore imperfectly preserved and apparently terminal cones; the surface of the branches is covered with the scars of leaves. The resemblance to *Wielandiella* is, however, slight and it would seem more probable that the Solenhofen fossils are Coniferous, though, as Nathorst says, the supposed scale-like 'leaves' may be scars of Cycadean fronds.

Wieland⁴ records the occurrence in Mexico of stems similar to those of *Wielandiella* associated with some *Otozamites* fronds.

WILLIAMSONIELLA. Thomas.

This genus was instituted for specimens discovered by Mr Hamshaw Thomas⁵ in the Middle Estuarine series of the Middle Jurassic plant-bed at Gristhorpe on the Yorkshire coast, and the genus is recorded also from the Cleveland district in the same county. *Williamsoniella* occurs in those parts of the Gristhorpe bed where fronds of *Taeniopteris vittata* are abundant.

Williamsoniella coronata Thomas.

The type-species is represented by fertile shoots consisting of a central axis bearing both megasporophylls and microsporophylls (figs. 569, 571, A). Below its crown-like sterile apex the pyriform peduncle is covered with small interseminal scales and ovules

¹ Thomas (13²), p. 239.

² Thiselton-Dyer (72).

³ Thomas (15²).

⁴ Nathorst (02) p. 16.

⁵ Wieland (11) p. 458.

similar to those of *Williamsonia*: this portion is 6 mm. in diameter and 1 cm. long. A whorl of separate cuneate microsporophylls forms a hypogynous ring below the basal interseminal scales: each sporophyll is attached by a narrow base (fig. 570) and bears 5—6 reniform synangia containing microspores. The flower is thus bisexual: it affords no conclusive evidence of the occurrence of any covering bracts like those of most Bennettitalean flowers. In young specimens the microsporophylls are closely packed

FIG. 569. *Williamsoniella coronata*.

Vertical section of the flower showing the pyriform axis with small megasporophylls and interseminal scales and the microsporophylls with synangia. (After Thomas; $\times 2$.)

FIG. 570. *Williamsoniella coronata*. Diagrammatic sketch of a microsporophyll in section and in side-view. (After Thomas; $\times 3$.)

round the axis (fig. 571, B). The flower-stalks reach a length of 3.5 cm. and are 3 mm. in diameter. Fig. 571, C, shows a receptacle from which the sporophylls have fallen: the microsporophylls having been no doubt attached to the collar-like swelling at the base. Towards the apex the axis becomes broader and at *s* a few interseminal scales are left: above these is the apical disc (corona) characterised by longitudinal ribs. An apical disc is

reproduced in fig. 572; it has the form of a royal crown 1—2 mm. high with 12—16 vertical ridges separating flat surfaces formed by the pressure of microsporophyll apices in the unexpanded

FIG. 571. *Williamsoniella coronata*. A, flower showing two microsporophylls and the central axis with megasporophylls. B, apical view of an unexpanded flower. C, flower-axis showing the shallow grooves made by the infolded microsporophylls, which have fallen, and a few megasporophylls, s. (After Thomas; A, $\times 1\frac{1}{3}$; B, C, $\times 3$.)

flower. The corona is surmounted by a small conical elevation which represents the apex of the fertile axis. An apical view of an unexpanded flower is shown in fig. 571, B; the tips of 12 sporophylls are closely pressed against the corona which probably consists in part at least of fused interseminal scales. The microsporophylls were shed after the dehiscence of the synangia. Each sporophyll is flattened on the sides and thicker on the curved outer edge; the synangia, usually in two rows of three, are borne on the sloping sides (figs. 569, 570). The surface of a microsporophyll is covered with small rounded projections which produce a characteristic appearance. The form of a microsporophyll in section is shown in fig. 570: the synangia are similar in shape to those of *Cycadeoidea*

FIG. 572. *Williamsoniella coronata*. Apical disc with megasporophylls and interseminal scales at the base. (After Thomas; $\times 3$.)

and *Williamsonia* (cf. figs. 531, 549, etc.) but there are no external indications of septa like those seen in some other types. On macerating some specimens it was found that the spores occur in about 20 groups. The circular or elliptical spores are 0.02 mm. in diameter. The walls of the epidermal cells of the microsporophylls are straight: the stomata, which show the features characteristic of the Bennettitales, agree closely with those of *Taeniopteris vittata*.

The interseminal scales associated with the ovules and covering the pyriform axis above the microsporophylls are more or less flattened and hexagonal and the micropylar tubes often project far beyond the scales. Each micropyle-tube is surrounded by 5—6 interseminal scales (cf. fig. 564). The ovules differ from those of *Cycadeoidea Gibsoniana* in the absence of a distinct pedicel and agree with the corresponding organs of *Williamsonia scotica*¹. In the absence of epidermal papillae the micropylar tubes resemble those of *Wielandiella angustifolia*. As already stated, the flowers appear to be without protective bracts, but in the shale from which the specimens were obtained a few bract-like organs were discovered consisting of a lanceolate lamina 1.5 cm.

¹ See page 449.

FIG. 573. *Williamsoniella coronata*. Restoration of part of a plant: the upper leaves are represented only by the petiole-bases. (After Thomas; ca. $\frac{2}{3}$ nat. size.)

long, and 2—3 mm. broad near the base, and some showed a small oval lamina at the apex with a midrib and dichotomously branched lateral veins. These bracts with the terminal lamina are regarded by Thomas as almost certainly reduced leaves of the *Taeniopteris vittata* type: they are represented in the restoration (fig. 573) as occurring at the base of the flower-peduncle. Stomata were found on the bracts exactly like those on the microsporophylls, and this affords a strong argument in support of the view that *Williamsoniella* belongs to the plant which bore *Taeniopteris* fronds. There is a close parallelism between the bracts accompanying *Williamsoniella* flowers and those described by Nathorst in connexion with *Wielandiella*¹. It seems reasonable to regard the bracts as serving the purpose of bud-scales.

An important point is the constant association with the flowers of *Taeniopteris vittata* fronds, a species described in Vol. II. and by most palaeobotanists regarded as a Fern frond. *Taeniopteris* leaves occasionally show a clean-cut base² and in specimens described by Thomas there are two small humps on the surface of the proximal end of the petiole which represent vascular bundles. Humps of similar size occur on the leaf-scars of stems which are believed to have borne both *Taeniopteris* leaves and *Williamsoniella* flowers. Fragments of the stems were found in association with flowers: they are 7 mm.—2 cm. in diameter and frequently forked and there is evidence that the flowers were borne at the forks, the shoot forming a dichasial system. The habit of the plant is represented in fig. 573 reproduced from Mr Thomas's paper.

Williamsoniella Lignieri (Nathorst).

This species described by Nathorst as *Williamsonia? Lignieri* from Whitby is regarded by Thomas as a *Williamsoniella*. The stomata on the microsporophylls agree with those of *Taeniopteris* and the spores obtained from Nathorst's flower-buds are like those of *Williamsoniella coronata*. Evidence is adduced by Thomas in favour of regarding *W. Lignieri* as bisexual and not unisexual as Nathorst supposed.

¹ See page 463.

² Seward (00) B. XVI. fig. 1; Thomas, H. H. (15²) Pl. XIV. fig. 26.

In habit *Williamsoniella* resembles *Wielandiella*: in the latter genus the foliage-leaves were confined to portions of the stem near the forks, while in *Williamsoniella* they were more uniformly scattered: *Wielandiella* bore leaves of the *Anomozamites* form while *Williamsoniella* flowers are always associated with *Taeniopteris* fronds. The much greater spore-output of *Williamsonia* may, it is suggested by Thomas, be correlated with the unisexual nature of the flowers of that species. The microsporophylls of *Williamsoniella* differ in their more reduced form from the pinnate microsporophylls of *Williamsonia*, e.g. *W. spectabilis*, and agree more closely with those of *Wielandiella*. The microsporophylls of *Williamsoniella* are free and not connate at the base as in *Cycadeoidea* and *Williamsonia*. In its pyriform axis *Williamsoniella* resembles *Williamsonia gigas* and differs from *Williamsonia Leckenbyi* in the possession of a sterile apical corona: *Williamsoniella* has megasporophylls and microsporophylls both of which appear to be functional, while in *Cycadeoidea* fully developed microsporophylls occur in association with megasporophylls which are immature and must have matured much later than the microsporophylls. The new genus agrees with *Williamsonia* in its general features, but the flowers are smaller and are characterised by the considerable reduction and simplification of the male organs.

CYCADOCEPHALUS. Nathorst.

This genus was founded¹ on a specimen from the Lower Rhaetic of Scania, at first regarded as a megastrobilus and on further examination² found to be a collection of microsporophylls resembling those of *Williamsonia* and *Cycadeoidea*. The type-species is *Cycadocephalus Sewardi*, and a second species, *C. minor*, was subsequently discovered by Dr Halle at a slightly higher horizon in the Rhaetic series. Prof. Nathorst's most recent account of the genus affords a striking illustration of the possibilities of the method, which he has employed with conspicuous success, of investigating carbonised fossils by means of cuticular preparations.

¹ Nathorst (02) p. 7, Pl. 1.

² *Ibid.* (09) p. 27, Pl. VIII.; (12²) Pls. I., II; (12).

Cycadocephalus Sewardi Nathorst.

The type-specimen consists of an oval cluster of 16—18 linear microsporophylls, 9 cm. long, springing from a small circular disc formed of their concrescent and narrow bases. The whole flower (fig. 574) exclusive of the peduncle is 10 cm. long and 7 cm. broad. The portion of the comparatively slender peduncle that is preserved shows no trace of leaf-scars. In the

FIG. 574. *Cycadocephalus Sewardi*. A, surface-view; *a*, appendages. B, the same specimen, after the removal of some of the microsporophylls, showing the appendages. C, section of a microsporophyll showing the attachment of appendages. D, section of an appendage. (After Nathorst. A, B, $\frac{1}{2}$ nat. size.)

middle of each linear microsporophyll is a keel-like midrib and on either side of this is a series of linear appendages (fig. 574) 2—3 cm. long lying in a radial direction towards the centre of the flower. These appendages were originally thought to be seeds (fig. 574, *a*), but it was suggested by Wieland that they might be synangia, the circle of leaves being the male portion of a bisexual flower of the *Cycadeoidea* type. Nathorst's more

complete investigation of the specimen confirmed the first of these suggestions, but there is no evidence that there was an ovulate receptacle in the centre of the flower. The appendages are attached by a rather broad and slightly cordate, base and are represented by a thin carbonised cuticle of rectangular cells showing in one case a row of imperfectly preserved stomata: on this are numerous groups of tetrahedral microspores, about 55μ in diameter, which show a more or less well marked arrangement in rows transverse to the long axis of the thin laminae. It is clear from Nathorst's researches that the groups were enclosed in loculi bounded by thin-walled cells¹, the loculi being in transverse rows on each side of a midrib. Nathorst speaks of the appendages as synangia characterised by the large number of the sporogenous compartments, and he compares them especially to the fertile leaflets of *Danaea elliptica* as described by Bower², each appendage being comparable with a revolute *Danaea* pinnule in which the edges of the lamina are united. This is illustrated by the section of an appendage (fig. 574, D) reproduced from Nathorst's restoration of a *Cycadocephalus* microsporophyll. From a morphological point of view it would seem more appropriate to speak of the appendages as highly modified pinnules rather than synangia. The second species, *C. minor*, agrees closely except in its smaller size with the type-species. Nathorst regards *Cycadocephalus* as a unisexual flower differing from those of *Williamsonia* and from the microsporophyll-verticils of *Cycadeoidea* in the structure of the synangia and in the tetrahedral form of the spores, though the latter feature he considers to be of secondary importance, as both bilateral and radial spores occur in recent Marattiaceae. He includes the genus in the Bennettiales but suggests that it should be referred to a separate family as an indication of the possession of characters which mark it off from *Williamsonia*, *Weltrichia*, *Wielandiella*, and *Cycadeoidea*.

WELTRICHIA. Braun.

The name *Weltrichia* was given by Braun³ to some Rhaetic fossils discovered by Weltrich near Culmbach in Franconia which

¹ See the photographs reproduced in Nathorst's latest and most complete account (12²).

² Bower (97) B.

³ Braun (49). (I have not seen this paper.)

represent funnel-shaped structures, the lower part having the form of an incomplete cup made of the concrescent bases of about 20 broadly linear segments which in the upper part are separate lanceolate lobes each with a midrib and slightly curved inwards at the apex. The whole, nearly 10 cm. long and 9 cm. in diameter at the upper edge, is very similar to the specimen of *Williamsonia spectabilis* reproduced in fig. 551. Braun described three species, but he realised the possibility that the different forms may be different stages in the development of a single type *Weltrichia mirabilis*. He assigned the genus to the Rhinanthæe. Saporta¹ drew attention to the resemblance of Braun's species to some examples of *Williamsonia* from Yorkshire which he considered to be portions of a sterile appendage borne at the apex of the flower. Some account is given of two types of funnel-like structures connected with *Williamsonia* flowers on a previous page²: one of these has been shown by Nathorst to be a whorl of microsporophylls, and it is with this that *Weltrichia* agrees. An important feature of *Weltrichia* is the occurrence of short linear segments, 5—8 mm. long, attached to the inner face of each of the free portions of the linear lobes: the lobes, or more correctly the free apical portions of the fertile leaves, and their slender appendages are compared by Nathorst³ to the microsporophylls and relatively long synangia-bearing appendages of *Cycadocephalus*. These, presumably fertile, segments of *Weltrichia* project in the flattened impressions beyond the edges of the free lobes of the campanulate flower and look like marginal teeth, though they are actually attached on each side of the midrib and originally extended, as in *Cycadocephalus*, towards the centre of the funnel-shaped flower. The examination of one of the type-specimens acquired by Nathorst⁴ for the Stockholm Museum enabled him to confirm his earlier conclusion that *Weltrichia* represents the male portion of a flower, whether unisexual or bisexual cannot be definitely determined, of a Bennettitalean plant. There is, as Nathorst states, a close agreement in plan between *Weltrichia*, *Cycadocephalus*, and *Williamsonia*, and indeed it is not clear in what respects *Weltrichia* is sufficiently distinct

¹ Saporta (91) p. 191, Pls. 253—255.

³ Nathorst (09) p. 28.

² See page 428.

⁴ *Ibid.* (11²); (12²).

from *Cycadocephalus* to be retained as a separate genus. Our knowledge of *Weltrichia* is, however, less complete than in the case of *Cycadocephalus* and *Williamsonia*. It is noteworthy that Braun's specimens and those on which *Cycadocephalus* was founded were obtained from Rhaetic rocks. An account of *Weltrichia* has also been published by Schuster¹ who differs from Nathorst in his interpretation of the type-specimens: he considers that another fossil described by Braun and named by him *Palaeoxyris microrhombea* is the central, female, portion of a *Weltrichia* flower, a view that is not supported by any substantial evidence. The specimens referred by Braun to *Palaeoxyris* and afterwards transferred by Schimper² to the genus *Lepidanthium* are too obscurely preserved to be determined with any degree of confidence, and their connexion with *Weltrichia* is purely hypothetical. With *Weltrichia* Schuster also connects the fronds known as *Otozamites brevifolius* Braun and some impressions of stems, combining all in a restoration of a complete *Weltrichia* plant which rests more on imagination than on fact. Attention has elsewhere³ been called to some wholly misleading and incorrect statements made by Schuster which vitiate the value of his descriptions.

Saporta⁴ described a species of *Weltrichia*, *W. Fabrei*, from French Rhaetic strata at Mende (Lozère) which bears at least a close superficial resemblance to *Williamsonia spectabilis*, and the same author founded another species, *Weltrichia oolithica*, on a drawing by Zigno of a specimen from Jurassic rocks in Italy; but this appears to be too imperfect for accurate identification.

All that can be said as to the nature of *Weltrichia*, as illustrated by the type-species, is that it represents a Rhaetic example of a verticil of microsporophylls very similar to those of *Williamsonia* and *Cycadocephalus*, if not generically identical with the latter form.

CHAPTER XXXVIII.

CYCADOPHYTA.

I. CYCADEAN STEMS OTHER THAN CYCADEOIDEA.

MOST of the stems now under consideration are represented by casts or impressions and afford no information with regard to anatomical characters. They are in many cases more slender and less tuberous than typical Cycadeoideas, and a few are characterised by an irregular form of branching, as is shown in some specimens of pith-casts from Wealden strata in Tilgate Forest figured by Mantell¹ and now in the British Museum. The genus *Wielandiella*² (fig. 566) is an altogether distinct type represented by flowers as well as vegetative organs. Several generic names have been proposed for Cycadean stems agreeing with those of many recent Cycads in the possession of an armour of persistent leaf-bases, but distinguished from *Cycadeoidea* in the absence of any fertile lateral shoots intercalated among the petiole-bases. It is, however, impossible in most cases to give any satisfactory definition by which these genera can be distinguished from one another; the characters employed by Carruthers³, Saporta⁴, and other authors are of comparatively little importance as trustworthy criteria and to a large extent are merely the expression of different states of preservation or of differences in age. Attention has elsewhere been called to the absence of any clear dividing line between stems referred to *Bucklandia*, *Yatesia*, *Fittonia* and *Cylindropodium*. The species *Cycadeoidea gigantea* described on a previous page affords an instructive example of the difficulty

¹ Mantell (27).

² See page 463.

³ Carruthers (70).

⁴ Saporta (75) A. pp. 256 et seq.

of drawing a generic distinction between certain types of Cycadean stems: in habit, in the form and structure of the leaf-bases, and in the ramenta this species is identical with other species of *Cycadeoidea*, but it differs in the absence of lateral fertile shoots, a feature that may have no morphological significance. It has already been pointed out that the absence of flowers intercalated among the leaf-bases may simply mean that the plant had not reached the stage of flower-production, or their absence may be due to some unfavourable conditions. Similarly the stems for which Saporta proposed the generic name *Clathropodium* agree in every respect with *Cycadeoidea* except in the absence, apparent or real, of lateral flowering branches. Such types as *Clathropodium foratum* Sap. and *C. sarlatense* Sap.¹, the latter probably from Upper Jurassic beds and the former from an unknown locality, should be included in the genus *Cycadeoidea*. The stem referred by Saporta to his genus *Platylepis* as *P. micromyela*² was originally assigned to *Cycadeoidea* and more recently Lignier has wisely adopted the original generic name. The generic term *Bolpopodium*, also instituted by Saporta³, is applied to small tuberous stems which appear to be identical with the *Cycadeoidea* type.

Having regard to the meagre data supplied by casts of stems preserved in various stages of defoliation, and in view of the impossibility of drawing other than purely arbitrary generic distinctions, it is preferable to employ one generic name in a liberal sense for stems that there is good reason to regard as plants that cannot reasonably be referred to *Cycadeoidea*. The name *Bucklandia* is thus employed, and a few examples are described in illustration of the external features of stems that are undoubtedly Cycadean but in most cases readily distinguished from *Cycadeoidea*. There are substantial grounds for stating that plants which bore flowers of the *Williamsonia* type possessed stems having the characters of *Bucklandia*. It should, however, be remembered that we cannot always draw a clearly defined distinction between flowers included in *Williamsonia* and *Bennettites*, or *Cycadeoidea*, particularly when they are represented only by detached ovulate strobili as in *Cycadeoidea* (*Bennettites*) *Morierei* and *Williamsonia scotica*.

¹ Saporta (75) A. p. 293, Pls. 123, 124. ² See p. 415. ³ Saporta (75) A. p. 256.

BUCKLANDIA. Presl.

Bucklandia was proposed by Presl¹ for a plant described by Mantell² from the Wealden of Tilgate Forest and compared by him to the Euphorbiaceae and arborescent Ferns; the same generic name was given by Robert Brown in 1832 to a recent member of the Hamamelidaceae. Stokes and Webb³ referred the same fossil to *Clathraria*, a name applied by Brongniart⁴ to certain types of Sigillarian stems and afterwards adopted by him for the Tilgate Forest species, *C. Lyelli*. Presl 'with remarkable discrimination' recognised the Cycadean nature of the specimen. Carruthers⁵ in his definition of *Bucklandia* includes a statement as to the nature of the carpellary leaves and suggests that a cone associated with the stems may be a staminate strobilus: the cone is undoubtedly a megastrobilus of an Araucarian plant and there is no evidence with regard to the nature of either the male or female reproductive organs in the material that he describes though, as already pointed out, there are reasons for believing that *Williamsonia* flowers were borne on branches of *Bucklandia* stems. The flowering shoots were not short and intercalated among the petiole-bases as in *Cycadeoidea* with the strobili barely projecting beyond the surface of the leaf-base armour, but they formed comparatively long branches, sometimes forked, at the apex of the main stem (cf. figs. 541—543).

Bucklandia is usually represented by casts, from Rhaetic to Lower Cretaceous strata, differing from *Cycadeoidea* in the absence of numerous axillary short fertile shoots, in the more slender form and greater length of the stems, and in the less uniform size of the persistent leaf-bases which assume various forms. Some of the specimens reach a length of 4 feet and afford evidence of occasional branching: the surface is covered with leaf-bases preserved as imbricate, broad, and obtuse or truncate scales (fig. 575), or as slightly convex polygonal areas in some cases showing a tendency towards an irregular zonal arrangement of larger and smaller leaf-bases (fig. 576). Within the armour of leaf-bases there may be a cast of the large pith the surface-features

¹ Presl in Sternberg (25) A. p. xxxiii.

² Mantell (27).

³ Stokes and Webb (24).

⁴ Brongniart (22) A. p. 209; (28) A. p. 128.

⁵ Carruthers (70) p. 682.

of which are practically identical with the cast of a recent pith reproduced in fig. 398. Casts of the pith preserved as separate fossils are included in the genus *Cycadeomyelon*.

There is evidence of the occurrence of more than one zone of vascular tissue in a stem from Lower Greensand beds of Bedfordshire described by Carruthers as *Yatesia Morrisii*¹ (= *Bucklandia Yatesii*), and Dr Stopes² has recently described a species, *B. buzzardensis* (fig. 578), with several zones of conducting tissue. This feature has not so far been satisfactorily demonstrated in *Cycadeoidea*. An Indian species, *Bucklandia indica*, shows that the secondary xylem is more compact than in typical *Cycadeoidea* stems, and the tracheids have multiseriate pitting.

Two long and narrow stems figured by Nathorst from the Rhaetic of Scania as *Bucklandia Saportana*³ differ from other species in the irregular arrangement of the leaf-bases which in certain regions are crowded as in the typical example of the genus shown in fig. 576, but in the intervening portions of the stem they are few in number and widely separated by the finely striated bark. This type, though similar to some specimens of English, Mexican, and Indian *Bucklandias* in the zonal differences in the leaf-bases, represents an extreme case of the alternation of smaller and crowded and larger and scattered leaf-scars. It is by no means unlikely that *Bucklandia Saportana* forms a transition between *Bucklandia* and the stem of *Wielandiella* described by Nathorst from the same region: in *Wielandiella* the leaf-scars are concentrated at the region of forking but a few occur elsewhere: in *B. Saportana* there is no evidence of branching and in this respect it differs from *Wielandiella*.

Bucklandia anomala (Stokes and Webb).

This species, from Wealden beds in Sussex, was first described by Stokes and Webb⁴ as *Clathraria anomala*, and the same type was figured by Mantell and other authors as *Clathraria Lyelli*. The specimens referred by Carruthers to *Bucklandia anomala* and *B. Mantelli*⁵ do not exhibit any well defined specific differences,

¹ Carruthers (67); (70) p. 688. ² Stopes (15) p. 309. See *postea*, p. 486.

³ Nathorst (86) Pl. xviii. fig. 5.

⁴ Stokes and Webb (24) Pls. xiv.—xvii.

⁵ Carruthers (70) p. 686, Pl. liv. See also Seward (95) A. p. 123.

and there would seem to be no reason for retaining both specific names. The petiole-bases are usually sub-rhomboidal in form and convex or flat, but in some stems more of each petiole is preserved and the surface is covered with broad imbricate scales (fig. 575) similar to some of the detached scales described under

FIG. 575. *Bucklandia anomala*. (British Museum, No. V. 3690; rather less than natural size.)

the generic name *Cycadolepis*. Pith-casts occur both in connexion with the *Bucklandia* stems and as detached specimens. The leaf-bases often show an irregular zonation of smaller and larger rhomboidal areas. The pith-cast in the lower part of the specimen from the Wealden of Cuckfield in Sussex shown in fig. 575 is 5×3.5 cm. in diameter.

Bucklandia Ruffordi Seward.

This species, from the Wealden beds on the Sussex coast¹, was originally described as *Fittonia Ruffordi*, but in the absence of any well defined distinctive features that can be regarded as of morphological significance it is better to include it in *Bucklandia*. The species affords a good example of a long and narrow type of stem, one specimen reaching a length of nearly 80 cm. with a breadth of about 10 cm.; the surface is covered with persistent leaf-bases 1.7 cm. in depth with a scar agreeing in size and shape with the base of a frond of *Otozamites Goepfertianus* (Dunk.)² found in the same beds. There is no indication of any alternation of large and small leaf-bases, and the species is characterised by the uniform size and relatively greater depth in a vertical direction of the leaf-base areas. In all probability the stem bore fertile branches similar to those of *Williamsonia gigas* with flowers of the *Williamsonia* type: the fronds may have been those known as *Otozamites Goepfertianus*, but this has not been demonstrated. A stem described by Carruthers from the Lias of Lyme Regis as *Yatesia gracilis*³ and afterwards included by me in *Cycadeoidea*⁴ is very similar to *B. Ruffordi* in its long and narrow form and in the shape of the leaf-bases; it should be transferred to *Bucklandia* as *B. gracilis* (Carr.).

Bucklandia Milleriana Carruthers.

This species was founded on a cast from Lower Oolite beds at Brora in Sutherlandshire⁵ characterised by leaf-bases very similar to those of *B. anomala* but smaller. Casts from the same locality were named by Carruthers *Yatesia crassa* and *Y. Joassiana*⁶, but an examination of specimens in the Dunrobin Museum leads me to regard these forms as indistinguishable from *B. Milleriana*. The specimen reproduced in fig. 576 from the Great Oolite of Brora illustrates the external characters of a typical stem and shows the variation in the size of the leaf-bases. A portion of the pith-cast is exposed in the lower part of the stem.

⁵ Carruthers (70) p. 687, Pl. LV. fig. 1.

⁶ Carruthers, p. 689, Pl. LV. figs. 7—9.

Bucklandia Yatesii (Carruthers).

This type from the Lower Greensand of Bedfordshire (fig. 577) was described by Carruthers as *Cycadeoidea Yatesii* and subsequently named *Yatesia Morrisii*¹. Ward expressed the opinion

FIG. 576. *Bucklandia Milleriana*. Brora, Scotland. (Manchester Museum, L. 7229. ca. $\frac{1}{2}$ nat. size.)

that the name should be *Yatesia Yatesii*, but as *Bucklandia* is now used to include *Yatesia* this combination is fortunately avoided. The stem is cylindrical, 20—30 cm. long and 12 cm. in diameter,

¹ Carruthers (67); (70) p. 688, Pl. LV. figs. 3—6. See also Seward (95) A. p. 166.

covered with rhomboidal leaf-bases separated from one another by a ramental reticulum. There are two concentric vascular cylinders as stated by Carruthers. In a recent account of this species Dr Stopes¹ adds further details: the xylem-cylinders are

FIG. 577. *Bucklandia Yatesii*. Type-specimen in the British Museum.

5—8 mm. wide and the tracheids occur in single rows or there may be bands 4—5 elements broad; the circular bordered pits are uniseriate or in two alternate series. The medullary rays

¹ Stopes (15) p. 299, text-figs. 93—97.

are broad but the cells are not preserved. The pith-cast is of the usual Cycadean type.

The type-specimen was presented by the Cirencester College to the British Museum.

Bucklandia buzzardensis (Stopes).

This species, from Lower Greensand beds at Leighton Buzzard and believed to be derived from Wealden strata, is described by Dr Stopes¹ as *Cycadeoidea buzzardensis*. Though agreeing generally

FIG. 578. *Bucklandia buzzardensis*. Rough sketch of a block of wood showing parts of at least eight concentric rings of secondary wood. (After Stopes; $\times \frac{2}{3}$.)

with *B. Yatesii*, the stem is specifically separated on the ground that the petiole-bases are more expanded laterally and because of the occurrence of several vascular cylinders (fig. 578), sometimes as many as eight, each with a maximum diameter of 1 cm. Dr Stopes thinks it possible that *B. buzzardensis* is an older form of *B. Yatesii*.

¹ Stopes (15) p. 309, text-figs. 98—100.

Bucklandia squamosa (Brongniart).

Sternberg first described this species as *Conites Bucklandi*¹ and regarded it as a cone bearing large imbricate cone-scales; it was named by Brongniart *Bucklandia squamosa*² and Carruthers³ retained this designation. The type-specimen, in the Oxford Museum, from the Stonesfield Slate is 18 cm. long, showing in the lower part a cast of the pith. The surface of the stem is covered with thick imbricate petiole-bases very like those on the stem of a recent *Encephalartos*.

Bucklandia (Fittonia) squamata (Carruthers).

Carruthers⁴ founded the genus *Fittonia* on a single specimen from the Wealden beds of the Isle of Wight, separating it from *Bucklandia* on the ground of the occurrence on a portion of the stem of large imbricate leaf-bases which are at first reflexed and then ascending; the stem is also broader and more tuberous than most species of *Bucklandia*. The type-specimen, in the Museum of the Geological Survey (Jermyn street), bears a close resemblance to a trunk of a recent *Encephalartos*, but the part of the stem from which the imbricate stumps have fallen is practically identical with a *Bucklandia*. As in certain recent Cycads the surface-features probably changed with the age of the plant; when the foliage-leaves were first shed a portion of the ascending petiole remained on the stem, and at a later stage this was cut off leaving a clean-cut rhomboidal scar like those on the *Bucklandia* shown in fig. 576. The difference between *Fittonia* and *Bucklandia* may, therefore, be a question of age. While substituting *Bucklandia* for *Fittonia* as the generic name the latter designation is added in parentheses to denote the possession of certain features which, though possibly of generic value, are not regarded as sufficiently important morphologically to warrant generic recognition.

The type-specimen of Saporta's species *Fittonia insignis*⁵, in the Paris Museum, from the Oxfordian of Poitiers, appears hardly distinguishable from *F. squamata* Carr. Another type with broader imbricate petiole stumps is described by Saporta from the Portlandian near Boulogne as *Fittonia Rigauxi*⁶.

Bucklandia indica sp. nov.

Oldham and Morris¹ and subsequently Feistmantel² described some specimens of Cycadean stems from the Rajmahal Hills of

FIG. 579. *Bucklandia indica*. A, side-view showing the leaf-bases and attached petioles of *Ptilophyllum*, also (to the left) a fragment of a detached *Ptilophyllum* leaf. B, transverse section showing the pith, xylem cylinder, cortex, and sections of petioles. (British Museum; nat. size.)

India of Lower Jurassic age: the latter author regarded them as stems of *Williamsonia* because of their association with flowers of that type, a conclusion fully justified by the evidence. Feist-

¹ Oldham and Morris (63) B. Pl. xxxiv.

² Feistmantel (77²) p. 78.

mantel also called attention to the resemblance of the Indian stems to specimens described from British strata as *Bucklandia* and *Yatesia*. Although the Indian examples are very similar to stems from Mexico discovered by Wieland¹ and to some of the English types, it seems desirable to refer to them under a specific name and I therefore suggest the institution of the specific name *indica*, the type-specimen being that represented in fig. 579. This specimen is particularly interesting because it affords some information as to anatomical features and is one of the few fossil stems preserved in organic connexion with leaves (fig. 579, B). A short account of it was published in 1900² and more recently Miss Bancroft³ has made a fuller investigation of this and other Indian specimens. The stem shown in fig. 579 from the Rajmahal Hills, and now in the British Museum, bears fronds of *Ptilophyllum cutchense* Morr., a type that appears to be indistinguishable from *P. pecten*; and with similar stems from the same beds are associated flowers of *Williamsonia*. Miss Bancroft describes a bract-covered shoot which agrees very closely with those of English stems reproduced in figs. 541, 542. In addition to the evidence based on close association, there is the more important argument furnished by the discovery of ramental hairs like those on the bracts of *Williamsonia scotica* and of anatomical characters in the bracts similar to those in the Scotch strobilus. The persistent leaf-bases are far from uniform in size; in this respect and in their form they agree closely with those on *Bucklandia* stems from English and Mexican localities. The secondary wood is more compact than in recent Cycads or in *Cycadeoidea*, though it resembles that of *Cycadeoidea micromyela*; the medullary rays are uniseriate and the tracheids have multiseriate bordered pits on their radial walls instead of the scalariform pitting in the majority of *Cycadeoidea* stems. Secretory canals are abundant in the parenchymatous ground-tissue; the cambium and phloem are not preserved⁴.

The transparent nature of the silicified material rendered very difficult the examination of the tissues, but enough was discovered

¹ Wieland (11) p. 440.

² Seward (00) B. p. 194.

³ Bancroft (13).

⁴ For illustrations and further details see Bancroft (13)

to show that these Indian stems are characterised by certain features, the more compact nature of the secondary xylem and the presence of multiseriate pitting, which distinguish them from the *Cycadeoidea* type. Further knowledge of the anatomical features of the *Williamsonia* (*Bucklandia*) stems from other localities might enable us to recognise these or other peculiarities as constant distinguishing characters of *Bucklandia* in contrast to the *Cycadeoidea* stems which bore the *Bennettites* type of flower.

Cycadeomyelon. Saporta.

Casts of the pith-cavity of Cycadean stems, like that shown in fig. 575 projecting beyond the armour of leaf-bases, are occasionally found as separate fossils and cannot always be referred to a particular species of stem. For such detached casts Saporta¹ instituted the name *Cycadeomyelon*: they are characterised by their comparatively large diameter and by the possession of surface-features similar to those on the corresponding cast from a recent Cycadean stem shown in fig. 398, namely spirally disposed, more or less prominent, lozenge-shaped areas formed by the sand or mud filling the cavities left on the decay of the parenchyma of the broad medullary rays of a manoxylic stem. Occasionally a slit at the lower end of a medullary ray area marks the position of the leaf-trace bending outwards from the lower angle of the mesh in the xylem-lattice². Lignier figures part of a pith-cast of *Cycadeomyelon Apperti*³ in which each medullary-ray area has a circular depression and not a slit extending from the lower angle: this may indicate that the surface shown on the cast is slightly external to the inner edge of the stele and in a plane where the leaf-traces were embedded in the parenchyma of the rays and free from the xylem-cylinder.

Large and branched examples of *Cycadeomyelon* were figured by some of the earlier authors from English Wealden beds as species of *Clathraria*⁴ and in many cases these are undoubtedly pith-casts of *Bucklandia* stems: a similar cast is figured under

¹ Saporta (75) A. p. 331, Pl. 119, fig. 3. ² Lignier (95) p. 11, fig. 1.

³ *Ibid.* p. 15, fig. 2.

⁴ Stokes and Webb (24) Pl. XLV.; Mantell (27), etc. See Seward (95) A. pp. 126, 130, etc., for other references.

this name by Schenk from the Wealden of North Germany. From Liassic beds in Normandy Lignier figures two species of *Cycadeomyelon*, *C. Apperti* and *C. densecristatum*. The surface-features of *Cycadeomyelon* resemble those of the Palaeozoic genus *Tylodendron* (see Vol. IV.), but in the latter genus the nodal swellings are a characteristic peculiarity. Though medullary casts of this type are of no great botanical importance and their specific distinctions are of little value, it is safe to assume that broad medullary casts with comparatively large lozenge-shaped areas belong to Cycadean stems, while narrower specimens with smaller lozenges are more likely to be pith-casts of Coniferous stems.

Lester Ward¹ instituted the genus *Feistmantelia* for some Lower Cretaceous casts from the Black Hills which he compared with an Indian fossil from Cutch described by Feistmantel as 'the stem of a Coniferous plant²,' and with pith-casts figured by Stokes and Webb as *Clathraria anomala*. It is impossible to determine the systematic position of such imperfect specimens as that on which Ward founded his species *F. oblonga*: they may, as Hollick and Jeffrey³ suggest, be casts of the bark of some Conifer; there is certainly no good reason for connecting them with Cycads.

COLYMBETES. Stopes.

Colymbetes Edwardsi Stopes. This genus⁴ is founded on the inner portion of a petrified trunk which was probably cylindrical and more than 12 cm. in diameter, consisting of a pith, 7.5 cm. in diameter, and part of a vascular cylinder of remarkable structure. The type-specimen is of Aptian age and may have come from Leighton Buzzard (Bedfordshire). The pith (fig. 580, *p*) consists of large parenchymatous cells and numerous secretory canals: the perimedullary zone, *pm*, is characterised by the occurrence of loosely disposed tracheids in groups and radial rows pursuing a sinuous longitudinal course in the accompanying parenchyma. The tracheids in this region are small in diameter and have oval, scalariform, or circular pits. Abutting on the perimedullary

¹ Ward (99) B. p. 693, Pl. 169, fig. 19.

² Feistmantel (76²) Pl. x. fig. 2.

³ Hollick and Jeffrey (09) B. p. 17.

⁴ Stopes (15) p. 314, Pls. XXXI., XXXII., text-figs. 101—111.

zone is the secondary xylem the inner edge of which forms bays, and this is composed of alternating zones of vertical and horizontal tracheids (fig. 580, y_1-x_5 ; fig. 581) with bordered, scalariform, pits on their walls traversed by medullary rays generally biseriata and from 4 to 30 cells deep. The disposition of the tracheids is such as to render transverse and radial longitudinal sections

FIG. 580. *Colymbetes Edwardsi*. Transverse section showing ten alternating zones of wood outside the perimedullary zone, pm ; y_1, y_2 , etc., vertically running xylem series; x_1, x_2 , etc., horizontally running xylem series; p , pith; lt , leaf-traces. (After Stopes; $\times 2$.)

practically identical in appearance; the first zone of secondary xylem with its bayed inner edge consists of vertically running elements; this is succeeded by a zone in which the tracheids pursue a horizontal course, and beyond this second zone is another band of vertical elements (fig. 581). 'Where the one zone passes

into the next, a curving of the elements is frequently evident, and in a few cases it is quite possible to trace a single radial series of tracheids through an angle of 90° running in the same section, first as a transverse and then as a vertical series. One and the same medullary ray also can sometimes be followed, first in transverse and then in radial longitudinal section, which later again turns to true transverse. The inference is therefore drawn that there was but a single cambium, which had periodic changes of

FIG. 581. *Colymbetes Edwardsi*. Diagram of stem in transverse (A) and radial longitudinal (B) section. *p*, pith; *pm*, perimedullary xylem; *b*, bays of first, vertically running, secondary xylem; x_1, x_2 , etc., zones of horizontally running secondary xylem cut transversely in the radial and radially in the transverse section of the stem; y_1, y_2 , etc., longitudinally running xylem cut transversely in the transverse and longitudinally in the radial section. (After Stopes.)

direction.' Leaf-traces (fig. 580, *lt*) are large and numerous; they are spirally disposed and pass nearly straight through successive xylem-zones: each trace consists of a small-celled ground-tissue including stone-cells and patches of tracheids in more or less regular radial rows. Tangential sections of the wood show that the tracheids follow a sinuous course forming loops enclosing numerous medullary rays.

As the pith and xylem are the only tissues preserved it is on their structure that any speculation as to affinity must be based. The close arrangement of the leaf-traces (about 1 cm. apart), as

Dr Stopes says, indicates small leaf-bases, assuming that each leaf received a single trace. In some respects the xylem and medullary rays resemble those of Cycads, and the author of the genus includes it in the Cycadophyta; but as she points out there are many peculiar features, and it is clearly impossible to assign the new type to a more precisely defined position. The possibility of any purely mechanical explanation of the course of the tracheids in the alternating zones is ruled out by the straight course of the outgoing leaf-traces, and it would seem that the cambium must have turned over at right-angles at regular intervals during the growth of the stem.

Cycadolepis. Saporta.

This name was used by Saporta¹ for linear-lanceolate scales from Upper Jurassic rocks in France which he compared with bud-scales of recent Cycads. The imperfect scale described as *Cycadolepis villosa* bears a striking resemblance to the hairy bracts of *Williamsonia* and may well belong to that genus. Saporta's term may be usefully employed in a more extended sense, including not only lanceolate scales but larger and much broader scales resembling the flattened petiole-bases on stems of *Macrozamia*, *Encephalartos*, and some other recent genera, as well as detached carpellary scales, other than *Cycadospadix*, and microsporophylls which cannot be assigned to a particular stem. Two qualifying subgeneric terms have been proposed²:

i. *Cycadolepis (Dory-Cycadolepis)*. Scales more or less linear-lanceolate like those described by Saporta and a specimen from Jurassic rocks of India named by Feistmantel³ *Cycadolepis pilosa*. This type of *Cycadolepis* may be identical with the bracts of *Williamsonia* flowers, though in the absence of any definite evidence of such affinity the provisional generic name is more appropriate.

ii. *Cycadolepis (Eury-Cycadolepis)*. Broadly oval or orbicular thick scales (figs. 582, 583), the broadest part being frequently nearer the distal than the proximal end. These larger scales though usually found as detached fossils have in one instance been obtained attached to an imperfectly preserved stem.

¹ Saporta (75) A. p. 200, Pl. 114, figs. 4—6.

² Seward (95) A. p. 96.

³ Feistmantel (76²) Pl. VII. fig. 5.

Eury-Cycadolepis sp.

This type of scale, represented by specimens from the Wealden of Sussex¹ (figs. 582, 583), reaches a length of 13 cm. and a breadth of 7 cm. and is sometimes almost orbicular. The lamina is convex but shows no definite venation and bears a close resemblance to the scale-like petiole-stumps on an old stem of *Macrozamia*. On

FIG. 582. *Cycadolepis* (*Eury-Cycadolepis*) sp. From the Wealden beds of Sussex. (Brit. Mus. No. V. 2799.)

FIG. 583. *Cycadolepis* (*Eury-Cycadolepis*) sp. Scale from the Wealden beds of Sussex. (British Museum, No. V. 2131a; nat. size.)

some of the smaller specimens (fig. 583) several forked veins extend vertically from the broad base. Since these specimens were first described additional examples have been discovered in the Wealden beds of Sussex, some of which are attached to a piece of stem² in such a manner as to give support to the view

¹ Seward (95) A. p. 98, Pl. v. figs. 2, 6; (03) B. p. 31.

² *Ibid.* (13) p. 101, Pl. XII. figs. 3, 4; Pl. XIV. fig. 6.

that they are leaf-bases very similar to those on such fossil stems as *Bucklandia (Fittonia) Rigauxi* (Sap.)¹ and *B. (Fittonia) squamata* (Carr.)². One partially carbonised scale yielded pieces of cuticle showing numerous stomata similar to those of recent Cycads and the outlines of very thick-walled epidermal cells³.

Eury-Cycadolepis Jenkinsiana (Tate).

The large and approximately orbicular or broadly ovate scales so named are believed to be identical with Tate's *Cyclopteris Jenkinsiana*⁴ from the Uitenhage series of Cape Colony (Wealden). The scales reach a length of 12 cm. and were attached by a broad base; the lamina, which may be strongly bent as though folded over some immature organ as a protective bract, shows numerous repeatedly forked veins of the *Cyclopteris* type and several anastomosing and irregular lines between the veins suggesting that the scales were tomentose.

II. REPRODUCTIVE ORGANS OF CYCADEAN PLANTS OTHER THAN THOSE OF THE BENNETTITALES.

The fact that practically all known Cycadean stems bore flowers either of the *Bennettites* or *Williamsonia* type prepares us for the scarcity of reproductive organs like those of recent Cycads. No specimens have been discovered in a petrified state affording any evidence of their close affinity to the cones, sporophylls, or seeds of the Cycadales. Such genera as *Cycadospadix*, *Androstrobos*, and *Zamiostrobos*, as the following descriptions show, are founded on material that is too imperfect to throw much light on their true morphological nature. The probability is that some at least of the specimens included in these genera are the reproductive organs of Cycadean plants more closely allied to the existing Cycads than to the Bennettitales. Among the numerous fossil seeds referred to such genera as *Cycadeospermum* and *Cycadinocarpus* there are but few that can confidently be assigned to the Cycadales rather than to the Ginkgoales or Coni-

¹ Saporta (75) A. Pl. 127.

² Carruthers (70) Pl. LVI.

³ I am indebted to Mr Edwards of the Geological Department of the British Museum for making a preparation of the cuticle.

⁴ Tate (67) Pl. VI. fig. 4; Seward (03) B. p. 29, Pl. IV. figs. 3—6.

ferales. While the seeds of the Bennettitales are clearly distinguished by their much smaller size from those of modern Cycads, many of the latter agree in size and form with those of some other Gymnosperms and in the absence of anatomical details could not easily be identified as fossils. Some of the examples included in the miscellaneous collection described by authors as species of *Carpolithus* or *Carpolithes* agree closely in external features with the seeds of modern Cycads, but it is seldom possible to accept them as undoubted records of Cycadalean plants.

The general conclusion is that such meagre evidence as we possess affords strong confirmation of the conclusion based on stems and foliage from Jurassic and Cretaceous strata, namely that the present representatives of the Cycadophyta are a relatively late product of evolution, though retaining in their anatomical features many survivals from a remote antiquity. The occurrence of Cycadalean characteristics in the vegetative organs of the Medulloseae and the recurrence of what may be called the Cycadalean seed-plan, with certain more or less striking peculiarities reminiscent of earlier stages of evolution, in several types of Palaeozoic seeds such as *Cycadinocarpus*, *Stephanospermum*, *Lagenostoma* and others bear testimony to the antiquity of the Cycadalean stock.

CARPOLITHUS¹. Linnaeus.

This generic name, as Nathorst² has recently pointed out, was used by Linnaeus in 1768 for 'Phytolithus fructus' and has therefore priority over Sternberg's genus *Carpolites* employed in 1825. Lester Ward³ attributes *Carpolithus* to Stokes and Webb (1824) and states that in the plural form the name was used by Walch in 1771. *Carpolithus* is a convenient term to apply to fossil seeds that cannot be assigned to a particular group of plants and which do not exhibit any peculiarities of form sufficiently striking to deserve generic recognition. Pomel⁴ proposed the genus *Ulospermum* but it never came into general use. Schimper's genus *Cycadinocarpus* and Saporta's *Cycadeospermum*

¹ For further reference to this generic name, as applied to Palaeozoic seeds, see page 364.

⁴ Pomel (49) p. 16.

(preferable in its morphological implication), though useful in the case of detached seeds of undoubted Cycadean affinity, can seldom be employed without an admission that they may imply a relationship that cannot be absolutely established. In the great majority of cases the better plan is to be content with the more non-committal term *Carpolithus* with the addition of a family-name when there are reasonably good grounds for a more definite reference. No useful purpose would be served by attempting a complete survey of the numerous casts and impressions of supposed Cycadean seeds recorded in palaeobotanical literature, but a few types are briefly described as examples of specimens with fairly well defined characters, which are in all probability Cycadean.

Carpolithus conicus (Cycadales?) Lindley and Hutton.

The original specimen figured by Lindley and Hutton¹ from the Coralline Oolite of Malton, Yorkshire, as *Carpolithes conica*

FIG. 584. *Carpolithus conicus*. The type-specimens in the Manchester Museum; nat. size. (a, No. 361; b, c, No. 360.)

FIG. 585. *Carpolithus conicus*. From a specimen in the Malton Museum; nat. size.

and now in the Manchester Museum, is represented in fig. 584. A second 'species,' *Carpolithus Bucklandi* Lind. and Hutt. ex

¹ Lindley and Hutton (36) A. Pl. 189. See also Seward (04) B. p. 124.

Will. ms.¹, from the same locality is no doubt specifically identical with *C. conicus*. The seeds are conical, broadly truncate at one end, presumably the base, and tapered to a blunt apex; the broad end is characterised by the presence of three ridges or in some specimens by a single median ridge illustrating an oscillation between the radiospermic and platyspermic form similar to that in *Ginkgo biloba*. As usually obtained the seeds are probably nucules or casts showing the surface-features of the inner wall of the sclerotesta, the sarcotesta having been destroyed before fossilisation: the irregular marginal teeth at the truncate end suggest casts of vascular bundles in the integument. The scattered tubercles on the sides of some of the seeds (fig. 584, *a*) are probably casts of holes in the shell bored by insects and comparable with those occasionally preserved on the casts of *Trigonocarpus*. A specimen in the Malton Museum shown in fig. 585 which may be an example of this species illustrates the occurrence of an internal cast enclosed by the remains of a thick testa. These Jurassic casts resemble the seeds of *Macrozamia Fraseri*, but it is impossible to determine their systematic position with confidence.

Carpolithus sp. (Cycadales?) Seward.

An unusually well preserved specimen from the Wealden beds of the Sussex coast described under this name in 1895² consists of a kernel and mould, 1.8 × 1.1 cm. The mould from which the kernel is readily removed is lined with a thin structure representing part of the testa and between this and the surrounding rock is a layer of coal. On the surface of the kernel, probably the cast of the seed-cavity, a reticulum of narrow grooves indicates the course of the vascular bundles over the surface of the nucellus.

Carpolithus (Cycadales?) *Pomelii* (Saporta).

The specimen from the Upper Corallian of Châteauroux (Indre) on which this species was founded by Saporta³ under the name *Cycadeospermum Pomelii* is a large ovate cast, 5.5 cm. long and 3.5 cm. broad, closely resembling some of the larger recent Cycadean seeds: it cannot be accepted as a true record of the group without reservation.

¹ Lindley and Hutton (36) A. Pl. 189, figs. 3, 5.

² Seward (95) A. p. 105, fig. 7.

³ Saporta (75) A. p. 242, Pl. 117, fig. 9.

Saporta describes other species of *Cycadeospermum* but none of them are of any real importance from a botanical point of view: the same remark applies to the seeds referred by Fontaine¹ from Potomac beds to the same genus, also to many other recorded examples of seeds that afford no decisive evidence of affinity.

Some specimens described by Compter² from the Lettenkohle of Apolda (Thuringia) as Cycadean fruits—too imperfect to be determined with accuracy—furnish an additional illustration of the slender foundation on which many of the records of supposed Cycadean reproductive organs are based.

CYCADOSPADIX. Schimper.

This name was proposed by Schimper³ for some French Jurassic fossils, described by Pomel⁴ as *Crossozamia Hennocquei* and *C. Moraeana*, on the ground that they bear a close resemblance to the megasporophylls of *Cycas*. Their occasional association with *Otozamites* fronds suggested a reference to the same parent-plant, but such data as we have point to *Otozamites* fronds having been borne by plants with the *Williamsonia* type of flower. Schenk⁵, who figured a specimen of *Cycadospadix* from France as the inflorescence of a Cycad, expresses the more probable opinion that it belonged to a plant with *Cycadites* fronds. A Permian species described by Renault as *Cycadospadix Milleryensis* is now transferred to the genus *Strobilites*⁶

Cycadospadix Pasinianus Zigno.

This species, first described from Jurassic strata in Northern Italy⁷, is recorded also from the Kimmeridgian of France⁸ and Scotland⁹. Zigno's figures give a fairly accurate representation of the type-specimens in the Padua Museum. The megasporophylls, almost identical in shape with those of some recent species of *Cycas* (figs. 381; 392, A—C), consist of a broadly lanceolate or triangular limb with deeply laciniate sides terminating a pedicel, or the distal expansion may be preserved without the

⁹ Seward (11²) p. 699, Pl. VII. fig. 18.

stalk from which it was no doubt easily detached as in certain recent Cycads (*cf.* fig. 392, A). In the specimen from Scotland there are no clear indications of veins in the lamina, which may have been woolly as in *Cycas*. In some of the specimens figured by Saporta¹ and now in the École des Mines, Paris, the stalk is absent, but in pedicellate examples scars occur on the sides of the narrow axis and casts of seeds are found in the same beds. A good example of *Cycadospadix Hennocquei* is figured by Saporta from a drawing supplied by Schimper showing two seed-scars near the base of the lamina: the same specimen, as figured by Saporta and Marion², bears a seed, but this is presumably a partial restoration. The occurrence of *Cycadites rectangularis* Brauns at Hettange in association with *Cycadospadix* strengthens the conclusion, based on the form of the megasporophylls, that some of the Jurassic Cycads bore megasporophylls very similar to those of existing species of *Cycas*.

Cycadospadix integer Nathorst.

This Rhaetic species from the south of Sweden³ was instituted for an imperfect broadly lanceolate lamina recalling the distal end of the megasporophyll of a *Cycas*: the discovery of a more complete example⁴ justifies Nathorst's use of the name *Cycadospadix*, though without further evidence one hesitates to regard the species as a thoroughly trustworthy record of a Cycadean fertile leaf. The species is characterised by the entire margin of the broad and relatively short and thick terminal limb borne on a broad stalk with alternate lateral projections presumably marking the position of the seeds.

These species of *Cycadospadix* are particularly interesting as evidence—though not amounting to demonstration—of the production by some Jurassic and Rhaetic plants of fertile leaves agreeing closely with those of *Cycas*. It would seem from the abundance of Bennettitalean flowers and the very scanty remains of fertile leaves or cones like those of modern Cycads that the existing type was exceptional in Mesozoic floras.

³ Nathorst (86) p. 80, Pl. xvii. fig. 7.

⁴ *Ibid.* (02) p. 6, Pl. i. fig. 11.

BEANIA. Carruthers.*Beania gracilis* Carruthers.

The generic name *Beania*¹ was given to a branched fertile shoot (fig. 586) from the Middle Jurassic beds at Gristhorpe, Yorkshire, characterised by loosely disposed sporophylls bearing two sessile seeds: each sporophyll is given off at a wide angle from a fairly stout axis and the seeds are borne on the adaxial side of a peltate distal expansion. Carruthers compared the type-species with a cone of *Zamia* with which it agrees in the general plan of construction but differs in the more open habit and in the longer and more slender seed-bearing pedicels. The same type of shoot was figured by Lindley and Hutton² as *Sphaereda paradoxa*. *Beania* is generally regarded as a Cycadean reproductive shoot, but there is no doubt that the majority of Jurassic Cycadophyta possessed flowers of the *Bennettites* types, and it is clear that *Beania* differs considerably from *Bennettites* and *Williamsonia*. Another suggestion is that *Beania* may belong to some member of the Ginkgoales³: though very different from the normal ovuliferous shoot of a *Ginkgo*, it resembles some abnormal forms (e.g. fig. 631, D) in which the ovules occur on elongated pedicels, but they are borne singly and the micropyle is directed outwards, while in *Beania* the ovules are attached in pairs to the inner face of a distal expansion. There is no conclusive evidence in support of either interpretation, though the general agreement between the Jurassic type and the cones of recent Cycads would seem to favour the inclusion of *Beania* among the Cycadophyta.

A specimen described by Nathorst⁴ from Upper Jurassic rocks in the North of Scotland as *Beania Carruthersi* closely resembles the type-species, differing chiefly in its smaller size and in the rather closer arrangement of the sporophylls. The seed-like bodies

⁴ Nathorst (02) p. 21, Pl. I. figs. 14, 15.

borne in pairs on the adaxial side of the terminally expanded pedicels are covered with small granulations which Nathorst thinks may be clusters of microspores, the apparent seeds being 'antherangia.' The granulations are, however, very similar to those on the larger detached seed-like bodies originally described by Nathorst from Rhaetic beds in Sweden as *Antherangiopsis rediviva*¹: subsequent examination of that species demonstrated that the granulations are due to the presence of resinous bodies in the tissues of true seeds², and it is not improbable that a similar interpretation may hold for the surface-features in the supposed male organs of *Beania Carruthersi*. Pending further evidence it may be suggested that *Beania Carruthersi* is like *B. gracilis* a seed-bearing shoot. The Rhaetic specimens described by Nathorst as *Stenorrachis scanicus*³ are similar in habit to *Beania* but differ in the forking of the sporophylls (fig. 656) and in the absence of any terminal swelling on which the seeds are borne: Nathorst considers that *Stenorrachis* may be the female organ of a *Nilssonia* and it is not improbable that that genus and *Beania* are closely allied types. We have no definite information with regard to the reproductive organs of the Nilssoniales: the closer resemblance which their fronds bear in the structure of the epidermal cells to those of recent Cycads is consistent with the view that their fertile shoots were also more like those of existing types. It is, however, still an unsettled point whether *Beania* is more closely allied to the Cycadophyta or to the Ginkgoales, but the balance of opinion is in favour of the former alliance.

Zamiostrobus. Endlicher.

Cycadeostrobus. Carruthers.

Though instituted by Endlicher⁴ for a cone figured by Lindley and Hutton as *Zamia macrocephala*⁵ which is almost certainly Abietineous and has no claim to be included in the Cycadales, the genus *Zamiostrobus* has been adopted by many authors for Cycadean ovulate cones, not only such as are believed to be closely allied to those of *Zamia* but for Cycadean cones generally.

¹ Nathorst (02) p. 20, Pl. I. figs. 22, 23.

² *Ibid.* (09²) p. 23.

³ See Vol. IV.

⁴ Endlicher (40) p. 72. See also Schimper (72) A. p. 201.

⁵ Lindley and Hutton (35) A. Pl. 125.

Carruthers¹ suggested *Cycadeostrobus* as a more suitable name on the ground that it is less limited in its implication of affinity; but, as Fliche points out, Endlicher's generic name has been widely adopted in a comprehensive sense as standing for Cycadean megastrobili, excluding the supposed *Cycas*-like megasporophylls, included under *Cycadospadix*.

Many of the specimens described as species of *Zamiostrobus* are of little or no value as records of Cycadean plants, e.g. *Zamiostrobus orientalis* Heer² from the Jurassic beds of Amurland. A Lower Cretaceous (Albian) species described by Fliche³ as *Zamiostrobus Loppinetti*, though not entirely satisfactory, is more likely to belong to the Cycadales. The type-specimen is an elliptical strobilus, 5.5 cm. × 3.2 cm., consisting of an axis bearing at right-angles numerous small, contiguous, peltate megasporophylls each with two small seeds on the lower surface. The figures given by Fliche are, however, not convincing. An examination of specimens in the British Museum, from Wealden and Jurassic rocks, described by Carruthers as species of *Cycadeostrobus*, convinced me that several are undoubtedly Araucarian cones⁴. Solms-Laubach⁵ called attention to the Araucarian appearance of *Cycadeostrobus Brunonis*, a cone from an unknown locality, and this with other species, e.g. *C. elegans*, *C. sphaericus*, *C. truncatus*, etc., may safely be referred to *Araucarites*. The specimen figured by Lindley and Hutton⁶ as *Zamia crassa* from the Inferior Oolite of Towcester (Northamptonshire) affords no satisfactory evidence of Cycadean affinity. The Lower Cretaceous Bohemian specimens described by Corda⁷ and Velenovský⁸ as *Microzamia gibba* should not be included in a genus implying Cycadean affinity: though Velenovský states that the megasporophylls bear a pair of seeds his illustrations do not afford any satisfactory evidence of this Cycadean character. Similarly the fossil regarded by Carruthers⁹

⁹ Carruthers (70) Pl. LIV. fig. 6.

as probably a male flower of *Bucklandia* is almost certainly an Araucarian cone. A small cone from the Lower Miocene of Armissan (Aude) named by Schimper *Zamiostrobus Saportana* and figured by Saporta and Marion¹ may, as Solms-Laubach says, be Cycadean, but we have no information with regard to the internal structure or as to the presence or position of the seeds.

Androstrobus. Schimper.

Schimper² instituted this genus for 'amenta, cycadeacea antherifera, cylindrica, e squamis imbricatis, latere postico antheras sessiles ferentibus efformata.' It may conveniently be applied to fossils which resemble the male cones of recent Cycads sufficiently to justify the use of a name implying relationship. As so defined, *Androstrobus* is used in a more restricted sense than the word suggests, just as *Masculostrobus*³ has been employed for fossils that are believed to be the corresponding organs of Conifers. Among the few species assigned to Schimper's genus reference may be made to *A. Balduini* Sap., originally named by Schimper *A. zamioides*, from the Upper Bathonian of Etrochy, and *A. Guerangeri* (Brongn.), another French type⁴. Heer's species *A. sibirica*⁵ of Jurassic age is represented by a slender axis bearing numerous appendages which in surface-view have the form of polygonal discs: there are no indications of microsporangia and the evidence of Cycadean affinity is far from convincing. Nathorst's Rhaetic species *A. borealis*⁶ is no more satisfactory as a record of a Cycadean strobilus. A fossil from the Lower Cretaceous of Bohemia described as *Zamites familiaris* and regarded by Corda⁷ and Carruthers⁸ as a male flower of a Cycad though not above suspicion may be included in *Androstrobus*.

Under the name *Fričia nobilis* Velenovský⁹ described some cones from the Lower Cretaceous plant-beds of Bohemia which

⁹ Velenovský (85) B. p. 8, Pl. III. figs. 1—3, 6, 11.

he regards as male strobili of some Cycadean plant: the cone, as shown in Velenovský's restoration, is 10 cm. long and 5 cm. in diameter; it bears a close superficial resemblance to a large cone of *Zamia* and consists of a stout axis bearing contiguous peltate, hexagonal, scales gradually contracted towards the proximal end, similar to those of *Androstrobos*. The evidence on which this species is identified as a male cone rests on the occurrence of numerous pits on the surface of the scales; but no spores or sporangia were found and the pits as shown in the published figures do not present the appearance of scars of sporangia.

The Rhaetic specimen originally named by Nathorst *Androstrobos Scotti* and afterwards transferred to the genus *Lycostrobos* was described in Volume II.¹

Androstrobos Nathorsti Seward.

The type-specimens were obtained from the Wealden beds of Sussex: they were referred to the genus *Androstrobos* on evidence which cannot be regarded as decisive². A fairly stout axis, 6.5 cm. long, bearing spirally disposed sub-triangular scales hexagonal in section and attached to the axis by a broad base; the scales, or sporophylls, are 1—1.5 cm. long and gradually tapered towards a pointed or slightly rounded apex. Near the proximal end of some of the sporophylls there are regularly arranged polygonal depressions which may be impressions of microsporangia. The regular disposition of the depressions is a striking feature and in contrast to the less regular reticulum exposed after the removal of the sporangia from the microsporangium of a recent Cycad. An examination of the cuticular membrane of the microsporangia shows that the epidermal cells have thick and straight walls³, characters consistent with the supposed Cycadean affinity of the strobilus.

³ I am indebted to Mr W. N. Edwards of the British Museum for the cuticular preparations.

CHAPTER XXXIX.

CYCADOPHYTAN FRONDS.

OCCASIONAL reference is made to Cycadean fronds in the account of flowers and stems but it is seldom that genera or species founded on leaves can be definitely correlated with particular types of reproductive organs or stems. As in the case of Ferns and Pteridosperms so also with detached leaves believed to be Cycadean, a large number of generic names have been employed for impressions which afford no information with regard to anatomical characters except, in some of the more favourably preserved specimens, a few facts as to the epidermal cells. Though association often suggests original connexion it is inadvisable except in well established cases to extend to fronds generic terms based on reproductive shoots. The designation *Zamites* has long been used for fronds that are clearly not closely related to recent species of *Zamia*, and were it not an old established genus the significance of which is not likely to be misunderstood, it would be wiser to substitute for it some name implying no affinity with any existing type. On the other hand the employment by some authors of such generic names as *Encephalartos* and *Ceratozamia* is not warranted by the evidence furnished by the imperfect material. Prof. Newberry¹ described as *Encephalartos? denticulatus* a piece of a frond from Rhaetic beds in Honduras characterised by lanceolate pinnae (30 × 6 mm.) gradually narrowed towards the acute apex and abruptly contracted at the base: the method of attachment of the pinnae appears to agree with that in the genus *Zamites*. In this case there is no

¹ Newberry (88) p. 346, Pl. VIII. fig. 5.

valid reason for assuming a relationship with *Encephalartos* or with any recent type. An impression from Lower Cretaceous, Dakota, beds in Kansas described as *Encephalartos cretaceus* Knowlt. ex Lesq. MS.¹ consists of a piece of lamina, 9 × 4 cm., obovate-oblong and with a cuneate base, a serrate margin and thick diverging veins: the specimen is too incomplete to serve as a record of any Cycadean genus. The generic name *Encephalartopsis* was applied by Fontaine² to some imperfect pinnae from the Potomac beds characterised by a linear-elliptical lamina with a spinous margin and slightly diverging and occasionally anastomosing veins. The figured examples of the type-species, *E. nervosa*, suggest pinnae like those of *Ctenis*; but in the absence of a rachis the method of attachment of the segments cannot be ascertained. Saporta³ named a specimen from the Miocene flora of Koumi, Greece, *Encephalartos Gorceixianus* because of its resemblance in habit to some species of the recent genus; but the designation *Zamites* would be more appropriate. Ettingshausen recorded an imperfect impression of a pinna from Tertiary rocks in Styria as *Ceratozamia Hofmanni*⁴ although it is by no means certain that the fragment is even Cycadean. The genus *Taeniopteris* was described in the second volume of this book as probably a Pteridophyte, though of uncertain systematic position: it has, however, been shown by Mr Thomas⁵ that the Jurassic species *T. vittata* was almost certainly borne on a stem with reproductive organs constructed on the Bennettitalean plan. Further research may enable us to fix the position of other species but as yet *T. vittata* is the only representative of the genus which there is good reason for assigning to the Bennettitales.

It is undoubtedly true that Cycadean plants, using the term in a wide sense to include the Bennettitales as well as the Cycadales, bulked largely in Upper Triassic, Rhaetic, Jurassic-Wealden floras; the Bennettitales probably reached their maximum development as regards wealth of form and geographical range

¹ Lesquereux (91) p. 29, Pl. I. fig. 12.

⁴ Ettingshausen (88²) p. 272, Pl. III. fig. 10.

⁵ Thomas, H. H. (15²).

in the latter part of the Jurassic period and in the earliest phase of the Cretaceous epoch. In Triassic floras Cycadean plants are represented almost solely by fronds but the very close resemblance between Keuper species and forms that in Jurassic rocks are found in association with fertile shoots leaves little doubt as to the affinity of Keuper and Rhaetic species.

The evidence obtained from Permo-Carboniferous strata is much more meagre, at least as regards Cycadean leaves: the occurrence of certain morphological Cycadean features is revealed by petrified vegetative organs of Palaeozoic plants, and the Cycadean plan of organisation is conspicuous in many Carboniferous and Permian seeds. The discovery of frond-impressions identical in external characters with Mesozoic genera may be accepted as a substantial indication that genera already existed possessing foliage of the Cycadean type, though we have no certain information with regard to the nature of the other organs of the parent-plants. A few examples of Palaeozoic species are included among those selected in illustration of the different genera, namely *Plagiozamites Planchardi*, *Sphenozamites Rochei*, *Pterophyllum Fayoli*, *P. Cambryi*: among other recorded instances of Palaeozoic species are *Pterophyllum Cottaeum* Gutb.¹, a Permian type similar in habit to *Ctenis* but without anastomosing veins, a feature in which it resembles *Pseudoctenis*; the Carboniferous species *Pterophyllum inflexum* Eich.² from the Altai mountains, transferred by Zeiller to *Dioonites*; *P. blechnoides* Sand.³ from the Stephanian of Oppenau; *Pterophyllum Grand'Euryanum*⁴ from Upper Carboniferous beds in France, and *P. gonorrhachis* Goepp.⁵ from Silesia. An examination of the type-specimens of the Carboniferous species *Cycadites gyrosus* Goepp. and *C. taxodinus* Goepp.⁶ in the Breslau Museum led me to regard the material as too imperfect to determine.

A conclusion that is forced upon us by a consideration of the geological range of Cycadean fronds is that at the close of the

⁵ Goeppert (44) Pl. I. fig. 6.

⁶ *Ibid.* (66) Pl. II.

Wealden period, a period very closely linked in the character of the vegetation with the preceding Jurassic floras, there appears to have been a relatively sudden decrease in the number of members of the Cycadophyta: the decline in the fortunes of Cycadean plants is coincident with the rise and remarkably rapid extension of the Angiosperms. From Middle and Upper Cretaceous and from Tertiary beds very few Cycadean remains have been obtained and many of them are represented by fragmentary fossils that afford no definite evidence of affinity to recent genera. The antiquity of the Cycadales, that is the section represented by existing Cycads, cannot be determined; but it would seem probable that if the Cycads apart from the Bennettitales existed in Jurassic and Lower Cretaceous floras they occupied a very subordinate position in comparison with the extinct Bennettitales. There are no data pointing to any widespread occurrence of the Cycadales in the Northern Hemisphere in Tertiary times at all comparable with the geographical range of Tertiary ancestors of the solitary survivor of the Ginkgoales.

The following records of Tertiary Cycadean fronds illustrate the paucity of the records. Reference has already been made to *Encephalartos Gorceixianus* Sap. of Miocene age, a species that has no claim to be regarded as an example of the recent South African genus. The specimen described by Saporta and Marion as ? *Zamites palaeocenicus*¹ from the Eocene of Gelinden is too imperfect to serve as a trustworthy record. A more satisfactory species, similar in habit to *Zamites gigas*, is that on which Saporta founded the species *Zamites epibius*² from Lower Miocene beds at Bonnieux (Vaucluse), France. Another Tertiary species is mentioned by Krasser³ from Pliocene strata in Brazil as *Zamia praecedens* Krass. ex Ett. ms. Ettingshausen has described a Tertiary species from New South Wales, either Lower Miocene or Upper Eocene in age, as *Anomozamites Muelleri*⁴, characterised by truncate segments with simple veins and set obliquely to the rachis.

• While certain form-genera of fronds can only be referred to

¹ Saporta and Marion (78) Pl. I. figs. 4, 5.

² *Ibid.* (85) fig. 61, A, p. 116.

³ Krasser (03) p. 852.

⁴ Ettingshausen (86) Pl. VIII. figs. 19—21; (88) Pl. VIII. figs. 19—21.

the Cycadophyta, in other cases it is possible to assign fronds to a section of this comprehensive group characterised by a particular type of fertile shoot and by certain well defined epidermal features.

The investigation of the cuticular structure of various Cycadean fronds by Nathorst¹ and especially by Mr Thomas² has supplied a basis of classification which affords the best criterion of affinity so far available. The majority of fronds are placed in the Bennettiales while the three genera *Ctenis*, *Nilssonina*, and *Ctenopteris* (or *Ptilozamites*³) are placed in the Nilssoniales.

I. **Bennettiales.** Epidermal cells characterised by sinuous walls and generally rectangular; the cuticle is thin; the stomata, confined to the lower surface of the pinnae, tend to be arranged at right-angles to the veins and are on a level with the epidermis or very slightly depressed; two large laterally placed subsidiary cells more or less surround the guard-cells and these are provided with thickenings of a definite shape (figs. 594, 609).

Genera: *Ptilophyllum*, *Zamites*, *Otozamites*, *Dictyozamites*, *Pterophyllum* and *Anomozamites*, *Taeniopteris*, *Pseudocycas*.

II. **Nilssoniales.** Epidermal cells with straight walls, not sinuous, irregular in form, rounded, hexagonal, or rectangular; the stomata are below the level of the epidermis; the cuticle may be thin or thick. There is no regular arrangement of the stomata; the guard-cells are surrounded by 6—8 subsidiary cells (fig. 625) which often form an overarching canopy; thickening lamellae like those on the guard-cells of the Bennettiales are seldom present.

Genera: *Nilssonina*, *Ctenis*, *Ctenopteris*.

It is a noteworthy fact that the representatives of the smaller group, the Nilssoniales, in their cuticular features, are more akin

¹ Nathorst (12³) p. 36.

² Thomas and Baucroft (13).

³ The genus *Ptilozamites* described briefly in Volume II. has recently been fully investigated by Antevs* who had access to the rich material in the Stockholm Museum from the Rhaetic beds of Scania. He thinks that the genus is intermediate between *Anomozamites* and *Ctenopteris*; its systematic position has not been definitely established but, as Antevs says, there seems to be no reason why it should not be a member of the Cycadophyta. In some species, e.g. *Ptilozamites fallax* Nath. and *P. Nilssoni* Nath., the rachis is forked, while in *P. Heeri* Nath. with linear fronds reaching a length of 53 cm. the rachis is undivided.

* Antevs (14²).

than the Bennettiales to modern Cycads. Until definite evidence is obtained as to the nature of the reproductive organs of *Nilssonia*, *Ctenis*, and *Ctenopteris* it is impossible to say how closely these genera agree in essential characters with existing members of the Cycadales. If, as has been suggested, the fertile shoots known as *Beania*¹ belong to *Nilssonia* their resemblance in plan of construction to the cones of recent genera, much greater than in the case of the flowers of the Bennettiales, is in accordance with the evidence of the epidermal characters.

Reference was made in the second Volume of this book to several genera founded on fronds which through lack of evidence as to the nature of the reproductive organs cannot be assigned with certainty either to Ferns or Cycads: it was stated that the genera *Ptilozamites* and *Ctenopteris* are probably Cycadean, and the structure of the epidermal cells in the latter genus lends support to this view². Among other genera of doubtful position not included in the following descriptions of fronds is *Zamiopsis* of Fontaine³ founded on large compound fronds from the Potomac formation: the venation and form of the pinnae are more Fern-like than in *Ctenopteris*, but in general habit the two genera are not very dissimilar. The generic name *Zamiopsis* is misleading as the species bear no resemblance to *Zamia* or *Zamites*.

I. BENNETTIALES.

PTILOPHYLLUM. Morris.

The generic name *Ptilophyllum* was instituted in 1840 for some specimens of pinnate fronds from Cutch: in this genus Morris⁴ included with the Indian leaves the English Jurassic species *Pterophyllum pecten* Lind. and Hutt.⁵ (figs. 587, etc.) and some other forms. He defined *Ptilophyllum* as follows: 'Fronds pinnate; pinnae closely approximated, linear, lanceolate, more or less elongate, imbricate at the base, attached obliquely; base semicircular or rounded; veins equal, slender, parallel.' Morris adds that he instituted a new genus in preference to *Zamites*

¹ See page 502.

because of the 'oblique insertion of the pinnae and their overlapping each other at the base.' In a later paper Morris¹ states that the pinnae of *Ptilophyllum* fronds are 'sometimes auricled in the upper and sometimes in the lower part' of the base of the

FIG. 587. *Ptilophyllum pecten*. (British Museum, V. 3795; $\frac{1}{4}$ nat. size.)

lamina. In his catalogue² he adopted Endlicher's genus *Palaeozamia* instead of *Ptilophyllum*. Without discussing the generic nomenclature adopted by various authors for the Indian types and similar fronds it is important to refer briefly to the treatment

¹ Morris (41) p. 116.

² *Ibid.* (54) p. 15.

of Morris's species by Oldham and Morris and by Feistmantel. In the first of the series of Memoirs on Gondwana floras¹ *Ptilophyllum* is retained for a section of *Palaeozamia* together with *Otozamites* and *Sphenozamites* as other sectional subdivisions:

FIG. 588. *Ptilophyllum pecten*. A, C, specimens figured by Feistmantel as *Ptilophyllum cutchense*. B, Feistmantel's *Otozamites angustatus*. ($\frac{1}{8}$ nat. size; Calcutta Museum.)

in the subgenus *Ptilophyllum* are included *Palaeozamia acutifolia* and *P. cutchensis* (fig. 588, A, C), also *P. affinis*, *P. rigida*, and *P. bengalensis*. The last species is in all probability an *Otozamites*:

¹ Oldham and Morris (63) B. p. 27.

P. affinis and *P. rigida* are almost certainly indistinguishable from *P. cutchensis*. Feistmantel¹ dealt in detail with the genus *Ptilophyllum*: he wrote, 'with Schimper and Schenk I therefore look upon this genus as an Indian type especially characterised by its...more or less slender leaves, angustate towards the apex and base, and petiolate, with regularly adfixed leaflets....The leaflets are equal to each other, for the most part elongate linear, and *auriculate and free at the upper angle at the base*, but adfixed at the lower angle, and each is decurrent behind the upper angle of the leaflet next below it, thus the leaflets are almost imbricate. The veins are rather numerous, simple, and forked, and more or less divergent².' Feistmantel distinguishes certain varieties of *P. cutchense* (fig. 588, A, C), none of which appear to be well defined. A specimen from the Rajmahal Hills with unusually long pinnae, the frond having a breadth of 8 cm., is described as *Ptilophyllum acutifolium* var. *maximum*³, but it differs in no important feature from the smaller and commoner form. The next point to be considered is the variability of certain species referred by Feistmantel to *Otozamites*. He figures specimens from the Jabalpur group as *O. Hislopi* Feist. ex Old. ms., *O. gracilis* (Kurr), *O. angustatus* Feist. (fig. 588, B) and *O. distans*⁴. An examination of the figured specimens leads me to regard *O. Hislopi* and *O. gracilis* as identical with the *Ptilophyllum* fronds: the pinnae exhibit no distinguishing features and there is no reason for a specific, still less a generic, separation. *Otozamites angustatus* is indistinguishable from *Otozamites* sp. as figured from the Madras coast and from *Ptilophyllum cutchense*, *P. cutchense* var. *curvifolium* and var. *minimum*. The drawings reproduced in fig. 6a, Pl. x. of the Madras flora⁵ and in fig. 8a, Pl. vi. of the Jabalpur flora⁶ showing auriculate bases are inaccurate: in all the fronds named the pinnae are straight with rounded edges precisely as in *Ptilophyllum*. The conclusion forced upon me by a comparison of the actual specimens is that the Indian fronds are not separable into well-defined species and should all be included in *Ptilophyllum cutchense*. Moreover in this compre-

¹ Feistmantel (76²).

³ *Ibid.* (77²) Pl. XL. figs. 1, 2.

⁵ *Ibid.* (79).

² *Ibid.* (76²) p. 42.

⁴ *Ibid.* (77²) p. 94, Pls. v. vi.

⁶ *Ibid.* (77⁴).

hensive species should be included the specimens described by Feistmantel as *Otozamites Hislopi* (fig. 589), *O. angustatus*, and *O. gracilis*. It may well be that a more detailed investigation of the numerous forms comprised in this protean species, particularly if specimens are obtained from which cuticular preparations can be made, may lead to the recognition of additional species or well-defined varieties. The resemblance between the

FIG. 589. *Ptilophyllum pecten*. A frond figured by Feistmantel as *Otozamites Hislopi*. A, $\frac{5}{8}$ nat. size; B, enlarged (Calcutta Museum).

various forms of *P. pecten* from the Jurassic strata of Yorkshire and those of *P. cutchense* from India is very striking, and at least in many cases no specific separation is possible so far at least as the form of the fronds and pinnae is concerned. The occasional close association of *Ptilophyllum* fronds and *Williamsonia* flowers is an important agreement between the English and Indian fronds (fig. 590).

In the first part of the Catalogue of Jurassic plants from York-

shire the opinion was expressed¹, based on an examination of Morris's type-specimen of *Ptilophyllum cutchense* and of a large number of English and other fronds identical with or closely allied to *Pterophyllum pecten* Lind. and Hutt., that the Indian and European fronds belong to the same genus. In a later paper² it was maintained that *P. cutchense* and *P. acutifolium* are probably identical with the English type, and a drawing was published—reproduced in fig. 591—of Morris's type-specimen. Dr Halle³ has discussed the genus *Ptilophyllum* and his investigations lead him to a different conclusion; he, like Zeiller and some other

FIG. 590. *Ptilophyllum pecten* (*P. cutchense*) and *Williamsonia Blanfordi*. [Drawn from a specimen figured by Feistmantel (76²) Pl. XII. fig. 6.]

authors, employs *Ptilophyllum* in Feistmantel's sense. The pinna-base is said to agree in its asymmetrical form with that in *Otozamites*, while it differs from the symmetrical base of *Zamites* pinnae. In *Ptilophyllum* both edges of the pinna-base are said to bend down in joining the rachis; at the upper corner the base thus becomes rounded and for some distance free from the rachis; it is also sometimes a little auriculate; at the lower edge the pinna is decurrent on the upper surface of the rachis. In a subsequent

¹ Seward (00) B. p. 193.

² *Ibid.* (03) p. 227.

³ Halle (13²).

paper Halle¹ repeats the view that the decurrence of the pinnae by their lower edges is an important distinguishing feature of *Ptilophyllum*, thus agreeing with Feistmantel whose illustrations appear to be confirmatory. The drawings in Feistmantel's memoirs are, however, misleading and in some cases incorrect. An examination of a photograph of Morris's type-specimen of *P. cutchense* led Halle to conclude that the two edges of the pinna-base bend downwards on joining the rachis as described by Feistmantel. This feature is not shown in the drawing reproduced in fig. 591: it is clear that either the drawing is incorrect

FIG. 591. Part of the type-specimen of *Ptilophyllum cutchense* Morris. (British Museum; $\times 3$.)

or that there has been some mistake in the interpretation of the photograph. Through the courtesy of Dr Halle I have been able to examine the actual print: when viewed in its correct position the two edges of the pinnae appear to bend down as described by Halle, but if it is examined in the reverse position the lower angle of the pinnae is seen to be slightly rounded as in fig. 591, the apparent decurrence being due to a confusion between the appressed lower edge of one pinna, which is faintly shown, and the stronger downward trend of the upper edge of the pinna next below. The upper edges of the pinnae are more prominent

¹ Halle (13²).

because they are less appressed to the rachis while the lower half of the base is closer to the rachis and is frequently, though not in Morris's specimen, overlapped by the upper edge of the next lower pinna. A re-examination of the type-specimen in the British Museum confirms this interpretation. The pinnae of *Ptilophyllum* are characterised by their attachment to the upper face of the rachis which they almost completely cover; the upper angle is rounded and in a few cases auriculate (fig. 592); the lower angle of the base is slightly rounded and not infrequently hidden by the imbrication of the adjacent pinna; it is occasionally auriculate (fig. 593). The pinnae are attached by nearly the whole base, but the upper angle is free. The veins are parallel, sub-parallel or, especially in the proximal portion of the lamina,

FIG. 592. *Ptilophyllum pecten*.
(Manchester Museum, Williamson Coll. 3726.)

FIG. 593. *Ptilophyllum pecten*. From the Lower Estuarine beds, Cleveland, Yorkshire. (After Thomas; nat. size.)

oblique. The pinnae are linear, varying considerably in relation of length to breadth and in the form of the apex; they are straight or more or less falcate. The epidermal cells of such *Ptilophyllum*

fronds as have been examined are characterised by strongly looped or sinuous walls; the stomata, confined to the lower surface, are roughly circular and the guard-cells are at right-angles to the veins and not appreciably sunk. Fig. 594 represents the appearance of a stoma in surface-view: 'on either side of the central slit-like pore are two elliptical or hemispherical structures; they are somewhat flattened when they abut on the pore, and have rounded ends....Between these and the subsidiary cells lie two other thickened patches, more or less hemispherical in shape, and apparently overlying the central structures.' On the analogy of similar appearances in recent Cycads Mr Thomas¹ interprets

FIG. 594. *Ptilophyllum pecten*; stoma. (After Thomas and Bancroft.)

the two pairs of thickened patches as belonging to the upper and lower sides of the highly inclined guard-cells. This author calls special attention to the abundance on some of the fronds included in the aggregate species *P. pecten* of regular rows of circular hair-scars preserved as small annulate projections, .03—04 mm. in diameter. A comparison of the cuticles of different forms of *Ptilophyllum pecten* enabled Thomas to recognise more than one type: for one of these the name *Ptilophyllum hirsutum* is proposed. It is by such work as this that we may hope to discover differentiating characters.

The different forms of *Williamsonia* flowers found in association with fronds of the *Ptilophyllum* habit also point to the inclusion of more than a single species under the group-species *P. pecten*. As additional evidence is obtained further analysis will be possible, but in dealing with impressions which include specimens transitional from one form of frond to another, the most convenient and to my mind the most logical course is to treat a species as an aggregate- or group-species. Some authors believe that the two fronds described by Phillips as *Cycadites pecten* and *C. pectinoides* are distinct species², but there would seem to be no adequate reason for this view. The fronds described by Heer³ from the Lower Cretaceous of Greenland as species of *Zamites* and similar

¹ Thomas and Bancroft (13) p. 184.

² Phillips (29) A. Pl. vii. fig. 22; Pl. x. fig. 4.

³ Heer (75) II.

leaves from Graham Land included in that genus by Halle¹ are in my opinion inseparable from *Ptilophyllum*, and this applies equally to *Otozamites Hislopi* (Old.) (fig. 589) and *O. abbreviatus* as figured by Feistmantel and by Halle. The nomenclature of Cycadean fronds having the habit of *Ptilophyllum pecten* is a great difficulty: after carefully reconsidering the whole question and comparing Feistmantel's figured specimens with the large series of English fronds the conclusion reached is that the characters exhibited by ordinary impressions do not admit of any satisfactory grouping under well-defined specific types. In the first place, as already indicated, the use by some authors of the generic names *Ptilophyllum*, *Otozamites*, and *Zamites* creates a false impression of the degree of difference between the numerous forms of frond agreeing more or less closely with the specimens on which were founded the species *Ptilophyllum acutifolium*, *P. cutchense*, *P. pecten*, and *P. pectinoides* (figs. 587, 591, 595, etc.). In his important memoir on the Jurassic flora of Graham Land Halle² discusses the limitation of *Ptilophyllum*, *Zamites*, and *Otozamites*. He employs *Zamites* for fronds with linear pinnae attached to the upper face of the rachis by a base which is more or less, but often very little, rounded and always asymmetrical, with or without a basal callosity: fronds of the type *Z. gigas* he includes in the section *Euzamites*, while *Z. borealis* and similar forms (fig. 597) are referred to a second section, *Subzamites*. It is in the sense of Halle's section *Euzamites* that the generic name *Zamites* is employed in this chapter. On the other hand the fronds grouped by Halle as *Subzamites* have pinnae with the basal angles of the lamina very slightly rounded precisely as in *Ptilophyllum* as seen in fig. 596 (cf. fig. 598 which represents fronds referred by Halle to *Zamites*); and they are not distinguished by any feature of generic importance from *Ptilophyllum* as defined on page 519. The species *Zamites pusillus*, *Z. Anderssoni*, and *Z. antarcticus* (fig. 598) described by Halle from Graham Land as well as Heer's Arctic forms³ *Z. borealis* (fig. 597), *Z. speciosus*, *Z. brevipennis*, and others are transferred to *Ptilophyllum* as types agreeing very closely with *P. pecten* and in some cases not clearly distinguishable from it even specifically.

¹ Halle (13²).² *Ibid.*³ Heer (75) II. Pls. XIV.—XVI.

Otozamites is the name employed by Halle for fronds with pinnae having contracted, asymmetrical and auriculate, bases, the anterior lobe being more developed than the posterior. The asymmetry of the pinna-base is considered an essential feature. As Halle states it is very difficult in some instances to draw a distinction between *Otozamites* and *Ptilophyllum*. As used in this chapter *Otozamites* signifies fronds with pinnae characterised by an auriculate base, a lamina usually broader than in *Ptilophyllum*, and by more spreading veins (fig. 604). The not infrequent occurrence of auriculate pinnae on fronds (fig. 603, A) which cannot be separated from typical examples of *P. pecten* illustrates the narrow dividing line as regards the form of the pinna-base between *Ptilophyllum* and *Otozamites*. The Indian species *O. Hislopi* (fig. 589) and *O. abbreviatus*, to which Halle refers some Antarctic fronds, cannot be distinguished from the English *P. pecten* or Feistmantel's and Morris's Indian fronds described as *P. cutchense* and *P. acutifolium*: these forms are therefore included in *Ptilophyllum*.

Ptilophyllum (*Williamsonia*) *pecten* (*Phillips*).

This designation is employed in a wide sense for a group of fronds exhibiting a considerable range in size, in the relative breadth and length of the linear pinnae, and in other features. Under *P. pecten* are included (i) the English fronds from Yorkshire first described by Phillips¹ as *Cycadites pecten* and *C. pectinoides*, the former from the Middle shale, the latter from the Lower shale of the Yorkshire coast, together with the Stonesfield slate specimens named by Sternberg² *Polypodiolites pectiniformis* (fig. 595) and by Brongniart³ and Lindley and Hutton⁴ *Zamia pectinata*; (ii) the Indian specimens already considered and (iii) numerous examples recorded under different names from Jurassic strata in many countries. Fronds from the Yorkshire coast named by Brongniart⁵ *Zamia Goldiei*, though regarded by some authors as examples of *Otozamites*, are probably referable to *P. pecten*.

⁴ Lindley and Hutton (35) A. Pl. 172.

⁵ Brongniart (28) A. p. 94.

Andrae's *Pterophyllum rigidum*¹ (fig. 596) from Steierdorf is almost certainly a form of *Ptilophyllum pecten*. The specimen shown in fig. 587 is one of the few examples of fronds apparently preserved in their original position attached in a cluster to a *Williamsonia* (*Bucklandia*) type of stem. The range in size and form of the pinnae is illustrated in figs. 588, 592, 593.

FIG. 595. *Ptilophyllum pecten*. The specimen figured by Sternberg as *Polypodiolites pectiniformis*. (Oxford Museum; $\frac{5}{8}$ nat. size.)

FIG. 596. *Ptilophyllum pecten*. Andrae's *Pterophyllum rigidum* from Steierdorf, Banat. (British Museum, No. 41438; nat. size.)

Fronde linear, tapering gradually towards the base and apex, often characterised by a marked uniformity in breadth. The pinnae, short or comparatively broad or long and narrow, are straight or more or less falcate; the apex is obtuse or acute or the upper margin of the lamina may be almost straight and the

¹ Andrae (53) A. Pl. XI. fig. 1.

lower edge curved abruptly upwards at the apex; the pinnae are usually attached obliquely to the rachis but may be almost at right-angles; with the exception of the upper angle, the whole of the base is attached to the frond-axis; the base of the lamina may be symmetrical, both angles being slightly rounded, or asymmetrical, the upper or less frequently the lower corner being auriculate (figs. 592, 593). There is no basal callosity on the lamina nor is there a median sinus. The veins are more or less spreading at the base but for the most part parallel. The features of the epidermal cells and stomata are mentioned in the general account of the genus. Fertile shoots of plants with this type of frond are described under *Williamsonia*. Very little is known of the stems which bore *Ptilophyllum* fronds, but as stated on page 488 Indian specimens show leaves of *Ptilophyllum cutchense* attached to a piece of stem (fig. 579) having the characters of *Bucklandia* and characterised by a xylem-cylinder denser than in recent Cycads; the structure of the wood at least in the Indian stem is rather pycnoxylic than manoxylic.

The fronds grouped under *Ptilophyllum pecten* are very widely distributed in Jurassic floras; they are recorded from many localities in Europe, from Turkestan¹, India, Graham Land², Patagonia³, and elsewhere.

As thus defined this 'species,' or more correctly this group of forms, undoubtedly includes more than one species in the strict sense, but without additional data it is maintained that the recognition of clearly defined specific types or varieties is beyond our power. It may be urged that in view of the wide geographical range of the *Ptilophyllum pecten* type of frond and the admitted probability that several species in the narrower sense are represented, distinctive specific names should be retained even though under such designations are included forms that, so far as can be seen from impressions, exhibit no constant distinguishing features. My purpose is to emphasise the futility of attempting to found well-marked species on the available material. The student must decide for himself what course to pursue, whether to retain such a specific name as *cutchense* for the Indian fronds

¹ Seward (07²) p. 29.

² Nathorst (04²) B; Halle (13²).

³ Halle (13).

or to employ that and other specific names as designations of geographical types differing in no clearly defined or constant characters from examples of the English *Ptilophyllum pecten*. A comparative examination of the cuticular membranes in the comparatively few cases where that is possible would probably furnish a basis for a satisfactory subdivision of the group-species.

The names *Ptilophyllum Anderssoni*, *P. boreale*, and *P. antarcticum* are retained for certain forms selected from a number of closely allied types partly on the ground that these fronds exhibit some more or less well-marked distinctive characters and in part as a recognition of the existence of geographical forms.

Ptilophyllum boreale (Heer).

Heer¹ described numerous well-preserved impressions of pinnate fronds from the Lower Cretaceous plant-beds of Kome, Greenland, which he referred to several species of *Zamites* though the differences between them are hardly of specific rank. An inspection of several of the figured specimens in the Stockholm Museum showed that Heer's drawings are in the main accurate. *Zamites borealis* (fig. 597) is characterised by small linear pinnae attached to the upper face of the rachis, the stoutness of which is a noteworthy feature; the veins are parallel and simple. In the shape of the pinnae, including the base-characters, this species agrees closely with *P. pecten*. The slightly falcate or straight pinnae are 1.7—2 mm. broad and reach a length of 15 mm.; in *Z. speciosum* Heer, probably specifically identical with *P. boreale*, the pinnae are relatively longer, and in *Z. brevipennis* Heer they resemble the shorter pinnae of some of the narrow fronds of *P. pecten*.

A preparation of the cuticle of a pinna of *P. boreale* made by Mr Thomas from a specimen in the Stockholm Museum shows a marked difference between the upper and lower epidermis: the cells on the upper surface of the lamina have very thick and sinuous walls precisely as in *P. pecten*, but the cells are often broader than long and not elongated parallel to the long axis of the pinna; those of the lower epidermis are thinner and less clearly preserved:

¹ Heer (75) II. p. 66, Pls. XIV., XV.

FIG. 597. *Ptilophyllum boreale* (Heer). Drawn from one of the specimens from the Lower Cretaceous beds at Ekkorfat, Greenland, figured by Heer. (Stockholm Museum; nat. size and a few pinnae enlarged.)

the stomata, which appear to be like those of *P. pecten*, are scattered and not in rows.

Ptilophyllum antarcticum (Halle).

The fronds from the Jurassic rocks of Graham Land, described by Halle as *Zamites antarcticus*¹, are very similar to some forms of *P. pecten* and to *P. boreale* and other Greenland forms; the linear subacute pinnae are attached to the upper face of the rachis at a wide angle and the base of the lamina is truncate and may be very slightly constricted. The veins are dense, as many as 5 in 1 mm., and they are occasionally forked near the base (fig. 598, A).

FIG. 598. A, A', *Ptilophyllum antarcticum*. B, *P. Anderssoni*. (After Halle.)

Ptilophyllum Anderssoni (Halle).

This Graham Land species (fig. 598, B), referred by Halle to *Zamites*², is of the same general type as *P. pecten*, but is characterised by a coarser venation and by the wider angle of attachment of the pinnae.

Ptilophyllum Dunkerianum (Goeppert).

Goeppert³ proposed the name *Pterophyllum Dunkerianum* for some specimens from the Wealden of North Germany which were

¹ Halle (13²) p. 58, Pl. VII.

² *Ibid.* p. 56, Pl. VII.

³ Goeppert (44) p. 52.

afterwards figured by Dunker¹. Miquel² included the species in his genus *Dioonites* and this name has been adopted by other authors. Attention has been drawn to the inconsistent use of the title *Dioonites*³, and I have previously employed the name in a sense similar to that in which it has been adopted by Nathorst, that is for fronds with long and narrow pinnae without any basal constriction and not auriculate, attached more or less at right-angles to the upper face of the rachis; but so defined *Dioonites* differs in no essential particular from forms of *Ptilophyllum* or from fronds referred by authors to Schimper's genus *Ctenophyllum*. The name *Ctenophyllum*⁴ was instituted for certain fronds differing in some points from *Otozamites* and *Dioonites*. One such type is *Ctenophyllum* (*Ptilophyllum*) *pecten* (Lind. and Hutt.): this is quoted in Zittel's *Handbuch* as a typical representative of the genus. Schimper followed Feistmantel in his definition of *Ptilophyllum*, a definition which is not in accordance with the characters of the fronds on which it was founded by Morris. Fontaine, on the other hand, has applied *Ctenophyllum* to fronds of a different type which are now included in the genus *Pseudoctenis*. There would seem to be no adequate ground for the retention of *Ctenophyllum* as a generic designation.

The Wealden species *P. Dunkerianum* is characterised by the following features: rachis fairly stout, pinnae approximate, linear 2—3 mm. broad and reaching a length of 11 cm. or more, gradually narrowed towards the apex, attached in two almost contiguous rows to the upper face of the frond-axis: the lower margin of the lamina may be slightly decurrent, *e.g.* in the apical part of the frond or very slightly broadened and bluntly rounded. The pinnae are attached at right-angles or, near the apex, obliquely; veins 5—6, parallel. The epidermal cells as figured by Schenk⁵ have very sinuous walls and are identical with those of the English and Indian forms of the group-species *P. pecten*; the stomata are confined to the lower surface. If Schenk's drawings of the stomata are correct they differ from those of other species of the genus in their simpler structure; there are no subsidiary cells and the

¹ Dunker (46) A. p. 14, Pl. II. fig. 3; Pl. VI. fig. 4.

² Miquel (51) p. 212.

³ Seward (95) A. p. 38.

⁴ Schimper (70) A. p. 127.

⁵ Schenk (71) B. Pl. XXXVI.

guard-cells show no cuticularised bands. In habit this species resembles *Encephalartos Ghellinckii* Lehm. (fig. 382). The superficial resemblance of the narrow linear pinnae to those of *Cycadites* led Dunker and Schenk to refer to that genus some specimens which have since been described as identical with *P. Dunkerianum*.

ZAMITES. Brongniart.

In the first instance the generic name *Zamites* was used in addition to *Zamia* for certain pinnate fronds including species¹, such as *Z. Bechei*, which are now regarded as typical examples of *Otozamites*. Subsequently Brongniart gave up *Zamia* for fossil fronds and applied *Zamites* to fronds with entire pinnae, not truncate at the apex and not decurrent but slightly constricted at the base. Braun's two genera *Podozamites* and *Pterozamites* were relegated to the position of subgenera. The name *Podozamites* has been employed by Schenk² for specimens now included in *Zamites*, and *Zamites* is used by him³ for some fossils which are examples of *Podozamites* as generally understood. Goeppert's definition⁴ of *Zamites* includes fronds with pinnae of the *Otozamites* type, and this author pertinently compares *Zamites* with recent *Encephalartos* leaves. Pomel⁵ proposed the name *Crossozamia* for certain fronds of the *Zamites* type, but this genus with several others instituted by the same author has not been adopted. Bornemann⁶ described *Zamites* as comprising species with a greater or less resemblance to the fronds of recent *Zamias*.

As defined below, *Zamites* fronds may be compared with those of some species of *Encephalartos*, *Ceratozamia*, and *Macrozamia*. There has been considerable difference of opinion with regard to the range of form in the pinnae that it is advisable to include in *Zamites*. The name *Zamiophyllum* was proposed by Nathorst⁷ for a Wealden species, described by Ettingshausen as *Pterophyllum Buchianum* (fig. 601, A—C), characterised by a decrease in the breadth of the linear pinnae towards the point of attachment and, according to Nathorst's description, by the lateral attachment of the pinnae. An examination of specimens of this type

⁶ Bornemann (56) A. p. 54.

from English rocks¹ enabled me to show that the pinnae are attached to the upper face of the rachis. Zeiller² has also included *Zamiophyllum* in *Zamites*, but Halle's recent definition³ of the latter genus excludes fronds of the *Zamiophyllum* type. Schimper instituted the name *Glossozamites*⁴ for fronds bearing pinnae with rounded and slightly contracted bases and borne on grooves on the upper surface of the rachis (fig. 601, F). In venation the pinnae agree with those of *Otozamites* but the base is not auriculate. Kurr's Liassic species *Pterophyllum oblongifolium*⁵ included by Schimper in *Glossozamites* is probably an *Otozamites*. Another species referred to this genus is Schenk's *Podozamites Zitteli*⁶ from the Urgonian of Austria (fig. 601, F): in this species the slightly falcate pinnae with obtuse apices have rounded and not auriculate bases and there is some evidence of a basal callosity. This species agrees so closely with such a typical *Zamites* as *Z. gigas* that it is difficult to see on what grounds the retention of *Glossozamites* is desirable. A Portuguese specimen referred by Saporta⁷ to *Glossozamites*, *G. brevis*, is founded on a single specimen very like a leaflet of *Otozamites Klipsteinii* (Dunk.); and *G. parvifolia* Yok.⁸ from China has no claim to be included among Cycadean fronds. Feistmantel's *Glossozamites Stoliczkanus*⁹ is almost certainly a leaf of *Cordaites*. For certain fronds originally described as *Zamites* Zeiller¹⁰ has instituted the genus *Plagiozamites*. An important question as to the type of frond which may conveniently be included in the genus *Zamites* was raised by the application of this name by Heer to some Lower Cretaceous fronds from Greenland, *Z. borealis* (= *Ptilophyllum boreale*, fig. 597), and others which differ in the form of the pinnae from species usually regarded as typical of the genus. Halle¹¹ accepts the Greenland species as examples of *Zamites* though he distinguishes them by a sectional name *Sub-Zamites*; he defines *Zamites* as including

¹⁰ Zeiller (94) B. p. 174.

fronds with pinnae attached to the upper face of the rachis with a contracted and always symmetrical base though in some cases the basal contraction is exceedingly small; there is a more or less distinct basal callosity. He recognises two types, (i) *Euzamites*, e.g. *Zamites gigas* (fig. 599), in which the pinnae are strongly contracted basally and have a callosity, and (ii) *Sub-Zamites*, e.g. *Z. borealis*¹, etc., in which the pinnae are not so broadly rounded at the base and retain the same breadth to the point of insertion where they are 'very rapidly and very little contracted,' with or without a basal callosity. The basal callosity in these forms is not shown in many of the pinnae and is at most but a slight rounding of the angles of the truncate base. The specimens referred by Halle to *Sub-Zamites* do not appear to differ in any feature worthy of generic rank from *Ptilophyllum*.

In the following definition *Zamites* is employed in a sense more or less in accordance with Brongniart's usage but with the inclusion of such forms as *Z. Buchianus*, the type of Nathorst's *Zamiophyllum*, and the exclusion of Heer's Arctic and Halle's Antarctic fronds referred by them to *Zamites*.

Fronde broadly lanceolate reaching a length of over 60 cm.; pinnae more or less oblique or at right-angles to the rachis (fig. 599), attached to the upper surface but not completely covering it, linear or linear-lanceolate, acuminate or obtuse, usually abruptly contracted at the rounded base and more rarely (e.g. *Z. Buchianus*, fig. 601) gradually tapering to the proximal end, with or without a callosity at the symmetrical base; veins divergent at the base, simple or dichotomously branched, for the most part parallel to the edges of the lamina and slightly divergent in the apical region. The presence of a basal callosity, such as is best seen in the pinnae of recent species of *Macrozamia*, is not a feature of great importance and cannot be easily recognised in many impressions. In the process of fossilisation the pinnae are often flattened against the surface of the rachis and this may produce transverse wrinklins of the lamina suggestive of a basal thickening. In some cases stems of the *Bucklandia* type occur in connexion with *Zamites* fronds (fig. 541). An account of these stems, and of inflorescences of *Williamsonia* which were borne by some at least of the plants

¹ See page 525.

with *Zamites* leaves is given in Chapter XXVIII. In such examples of *Zamites* as have been examined the epidermal cells have sinuous walls and the stomata¹, confined to the lower face of the lamina, occur in rows with their long axis at right-angles to that of the pinnae.

Zamites ranges from Rhaetic to Lower Cretaceous strata.

Zamites truncatus Zeiller.

A Rhaetic species from Tonkin² characterised by oval linear pinnae given off at a wide angle, alternate and not contiguous; apex obtusely truncate, gradually narrowed to a cuneate base which is rounded or elliptical and has a more or less definite callosity. The pinnae vary from 3 to 5 cm. in length and from 5 to 13 mm. in breadth.

Zamites gigas (Lindley and Hutton).

The specific name *gigas* is retained in preference to that of *Mantelli* employed by Brongniart³ on the ground that he afterwards discarded it in favour of the designation proposed by Lindley and Hutton⁴, and because their name has been generally adopted.

Fronds large, exceeding 60 cm.; broadly linear lanceolate; the comparatively slender rachis bears alternate linear lanceolate pinnae with a rounded and usually slightly swollen base and an acuminate apex. At the apex of the frond the pinnae are narrow and linear (fig. 599) and almost parallel to the rachis; in the lower part they are shorter and relatively broader and attached approximately at right-angles. The numerous veins diverge from the centre of the base but for the most part are parallel to the edge of the lamina. The form of the epidermal cells and the structure of the stomata have recently been described by Mr Thomas. The external features of the stem (fig. 541) are described under the genus *Williamsonia*. In the case of fronds of this type from English Jurassic rocks it would be legitimate to speak of them as *Williamsonia gigas*, but in view of the fact that such

⁴ Lindley and Hutton (38) A. Pl. CLXV.

fronds usually occur as detached specimens and without any associated flowers it is advisable, as Nathorst maintains, to retain the non-committal genus *Zamites*.

This type of frond is widely distributed in Jurassic strata. The occurrence of many forms agreeing generally with the type-specimen but differing from it in features that are not constant

FIG. 599. *Zamites gigas*. (British Museum, V. 2723a; $\frac{1}{2}$ nat. size.)

or of real morphological importance renders accurate specific delimitation very difficult. Species that appear to be indistinguishable from *Zamites gigas* by any well-marked characters are, *Zamites Feneonis*¹ Brongn., *Z. Moreaui*² Brongn., *Z. Renevieri*³

¹ Saporta (75) A. Pls. LXXXVII.—XCII.

² *Ibid.* Pls. LXXXIV., LXXXV.

³ *Ibid.* Pl. XCIII.

Heer, and *Z. claravallensis*¹ Sap.; similarly *Z. Schmiedelii* And.² is probably identical with *Z. gigas*. The Lower Cretaceous species *Zamites bohemicus*³ Vel. and *Z. iburgensis*⁴ Hos. and von d. Marck represent very similar forms.

Zamites recta (Tate).

This species was originally described by Tate⁵ as *Palaeozamia* (*Otozamites*) *recta* from Wealden strata in South Africa and subsequently transferred to *Zamites*⁶; it bears a very close resemblance to *Z. gigas*. The fronds bear alternate linear pinnae attached to the upper face of the rachis by a slightly contracted and swollen base. The lamina has an acuminate asymmetrical apex and the upper edge is slightly falcate; the larger pinnae are over 6 cm. long and nearly 1 cm. broad; the veins are frequently forked as they converge towards the base of the lamina. No clear evidence of association of these fronds in the Uitenhage series of South Africa with *Williamsonia* flowers has been discovered, but a specimen⁷ in the Tate collection in the British Museum may be a badly preserved cluster of bracts belonging to a *Williamsonia*. The rachis of this species shows some peculiar features in the form of two rows of alternate cushions in some partially decayed specimens. One of these is shown in fig. 600; the cushions are raised oval projections with a flat top, and pieces of the rachis without pinnae might easily be mistaken for a Coniferous stem.

FIG. 600. *Zamites recta*. (Uitenhage series, S. Africa.)

Zamites Carruthersi Seward.

A species founded on specimens from the Wealden of Sussex⁸ and recorded from Kimmeridge beds in Scotland⁹, characterised

by linear or linear-elliptical pinnae attached obliquely to the outer part of the upper surface of the rachis, somewhat abruptly narrowed at the proximal end but slightly broadened at the

FIG. 601. A—C, *Zamites Buchianus*. D, E, *Zamites Carruthersi*. F, *Zamites Zitteli*. (A—C after Seward; British Museum; A, V. 2363; B, V. 2123a; C, V. 2227; F, after Schenk.)

actual base (fig. 601, D, E). The pinnae appear to have been caducous and, as in fig. 601, D, the position of an abscission-layer

is occasionally visible. In habit the fronds bear a close resemblance to those of *Encephalartos longifolius* Lehm. The veins diverge from the base and are for the most part parallel, though divergent at the bluntly rounded apex. If, as may be the case, a specimen figured by Hugh Miller¹ from Scotland as *Zamites* and subsequently named by Richards² *Podozamites Milleri* is identical with *Z. Carruthersi*, the specific name *Milleri* has priority.

Zamites Buchianus (Ettingshausen).

A Wealden and Lower Cretaceous species³ (figs. 601, A—C; 602) represented in several European localities, also in North America and Japan, reaching a length of over 70 cm.; in habit very similar to *Ceratozamia mexicana*, *Macrozamia Macleayi* and some other recent Cycads. The rachis has a fairly broad median groove on the upper surface; pinnae alternate, opposite or sub-opposite, from 3 to 20 cm. long and from 1.5 to 2 cm. broad, linear, generally narrowed towards the base, but in the more slender segments the reduction in breadth is less obvious; attached obliquely to the rachis, slightly thickened and broadened at the base (fig. 601, C), separated from the rachis by a distinct absciss-layer and leaving an elliptical scar; usually inclined at about 45° but

the angle varies considerably in different parts of a frond (fig. 602); apices generally tapering to a point, or more or less obtusely rounded; veins numerous, parallel, and not as a rule prominent. It is by no means unlikely that specimens figured by Goeppert¹ and some other authors as *Pterophyllum saxonicum* or *Dioonites saxonicus* are examples of this species. Fontaine² speaks of *Dioonites Buchianus* as one of the most widely distributed and characteristic members of the Potomac flora and it is described from Japan by Yokoyama³ and Nathorst⁴. This type appears to be especially characteristic of Wealden strata.

OTOZAMITES. Braun.

Braun⁵ proposed the name *Otozamites* for certain Mesozoic fronds formerly included in *Zamites*, one of his types being *Otozamites obtusus* (Lind. and Hutt.) (fig. 603, B) originally regarded by Brongniart as a Fern and named *Filicites Bucklandi*⁶. The auriculate form of the base of the pinnae and the spreading veins were emphasised in the definition of the genus. As in the case of many other Cycadean fronds the limits of the genus are not always easy to define, but as described below the genus is on the whole fairly distinctive. It is a very widely spread Jurassic type and extends from Triassic to Lower Cretaceous rocks. The supposed Cretaceous species from Greenland, *O. groenlandica* Heer⁷, is probably not a plant-impression but a polished groove in the rock.

Fronds pinnate, reaching a length of 50 cm. or more in some species; pinnae alternate, separate or contiguous and imbricate, attached by a portion of the base to the upper surface of the rachis, long and narrow (fig. 603, A), broadly oval or almost orbicular, apex acute or obtuse, base auriculate and asymmetrical⁸, the anterior lobe being more prominent than the posterior edge of the lamina which is usually rounded. The veins radiate from the base and pass obliquely with occasional branching to the

⁸ Halle (13²) p. 55.

edge of the pinna; in the more linear pinnae the veins may be parallel or nearly so. Zigno¹ figured a piece of an *Otozamites* frond from Jurassic Italian strata in connexion with a *Williamsonia* and the actual specimen in the Padua Museum amply justifies the impression produced by the published drawing. Wieland's investigations² in Mexico have brought to light many cases of association of *Otozamites* fronds and *Williamsonia* flowers.

B

FIG. 603. A, *Otozamites Goepertianus*. B, *Otozamites obtusus* (= *O. Bechei*); type-specimen. (A, British Museum, V. 2360; B, Oxford Museum.)

The structure of the epidermis is partially described by Schenk³ and more fully by Thomas⁴: the epidermal cells have sinuous

¹ Zigno (85) Pl. XLII. fig. 9.

² Wieland (13).

³ Schenk (67) A. Pl. xxxiv. fig. 7.

⁴ Thomas and Bancroft (13) p. 186, Pl. XIX. figs. 3, 4.

walls and the stomata, apparently confined to the lower surface, have guard-cells with hemispherical or spindle-shaped thickened patches like those of some *Zamites* fronds. In one species, *O. Feistmanteli* Zig., Thomas found about 100 stomata in 1 sq. mm. of lamina forming almost contiguous lines between the veins. In the account of the genus *Ptilophyllum* reference is made to the occurrence of pinnae with asymmetrical and auriculate bases, and it is only by the comparison of a large number of specimens that a distinction can be drawn between fronds that should be assigned to *Otozamites* and forms of *Ptilophyllum* which exhibit a well-marked tendency towards the *Otozamites* type of pinna (cf. figs. 592, 593). The variation in the form of the apices of pinnae and the relative position of the pinnae in different parts of the same frond are features worthy of notice in the determination of species¹. The different appearance presented by an

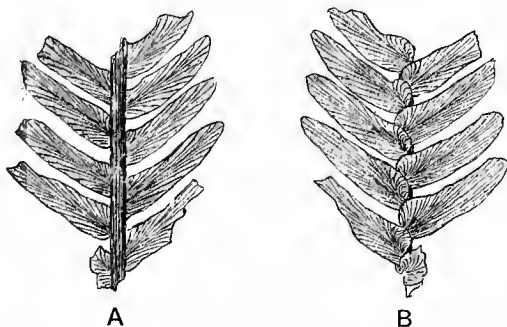

FIG. 604. *Otozamites Bechei*. A specimen in the Bristol Museum seen from below (A) and above (B). M. S.

Otozamites frond as viewed from the upper and lower face is illustrated in fig. 604. There are no recent Cycads in which the segments have auriculate bases, but in this feature as in the sinuous epidermal walls *Otozamites* agrees with some species of the Fern *Aneimia*, e.g. *A. rotundifolia* Schrad. (fig. 223, Vol. II. p. 288).

Otozamites Bechei Brongniart.

There is considerable confusion in the nomenclature of this species described by Brongniart² from Jurassic strata as *Filicites*

¹ Seward (95) A. Pl. I. figs. 1, 2.

² Brongniart (25) Pl. XIX. fig. 4; Seward (00) B. p. 219; (04) B. p. 39.

Bechei: in it Brongniart included a specimen from the Lias of Axminster (Dorsetshire) previously figured by De la Beche as a fossil Fern. It was on the Axminster specimen that Lindley and Hutton founded the species *Otopteris obtusa*¹, and as there is no doubt as to the specific identity of their type-specimen (fig. 603, B) and De la Beche's fossil, Brongniart's designation has prior claim². *Otozamites Bechei* is, perhaps, best regarded as a comprehensive type or a group-species in which numerous *Otozamites* fronds described by authors, on inadequate grounds, as distinct species may well be included. Fronds agreeing generally with *O. Bechei* were very widely spread in Rhaetic and Jurassic floras.

Specimens from the Middle Jurassic rocks of Yorkshire have been described as *Otozamites obtusus* var. *ooliticus*³ to denote a slight difference in the form of the pinnae from the Liassic fronds from Dorsetshire; but the distinctive features of the variety *ooliticus* are unimportant and hardly worthy of consideration in a general account of the species interpreted in a wide sense.

Fronds pinnate; pinnae usually more or less falcate, occasionally straight and with parallel sides, attached obliquely to the upper side of the rachis; imbricate or separate, the upper edge of the base of the lamina strongly auriculate, the lower edge rounded; apex obtuse; veins strongly divergent especially in the lobed base and extending obliquely to the upper and lower edge of the lamina.

The specimen, from the Lias of Lyme Regis, drawn in outline in fig. 605, is an almost perfect frond: the pinnae are obtusely pointed, slightly falcate, and there is a prominent lobe on the upper edge of the base of the laminae.

The Jurassic species *Otozamites graphicus*⁴ (Leck. ex Bean MS.), *O. vicetinus* Zig.⁵, *O. Hennocquei*⁶ (Pom.), *O. recurrens* Sap., *O. Terquemi*⁷ Sap., *O. linearis*⁸ Halle, are some of many examples of fronds agreeing closely with *O. Bechei*, or in the case of *O. Terquemi* with *O. graphicus*. The fronds described by Halle

⁷ *Ibid.* Pl. 99.

⁸ Halle (13²) Pl. vii.

from Graham Land as *O. linearis* afford a good illustration of the range of variation in the pinnae: a characteristic feature is the considerable length, exceeding 20 cm., of the narrow linear fronds. The impressions from the Kome (Cretaceous) beds of Greenland described by Heer as *Glossozamites Schenkii*¹ are probably closely allied to *O. Bechei*. The Rhaetic species *O. Bucklandi* Schenk², *O. indosinensis* Zeill.³, and *O. Polakii* Krass⁴, illustrate older examples of closely allied types. Zeiller records *Otozamites* pinnae similar to those of *O. indosinensis* from Rhaetic beds in Persia⁵.

Otozamites Beani (Lindley and Hutton).

Founded on a specimen in the Scarborough Museum from the Middle Jurassic of Yorkshire⁶ which is indistinguishable from Leckenby's type-specimen of *Otopteris mediana*⁷ in the Sedgwick Museum, Cambridge. Long and narrow fronds exceeding 20 cm. in length, characterised by the broadly oval, deltoid or sub-orbicular pinnae, separate or partially imbricate and attached by a broad auriculate base; apex bluntly rounded; veins numerous and spreading from the base of the lamina. The pinnae, which may be 3.5 cm. long and nearly 2 cm. broad, are narrower and longer in the distal part of the frond (fig. 606).

The Italian Jurassic species *Otozamites molianus* Zig.⁸, recorded also from Bornholm, is a very similar type. The generic name *Cyclozamia* suggested by Pomel for this form of frond has not been

adopted though it is applied by Schimper to *O. Bunburyanus* Zig.

Otozamites Bunburyanus Zigno.

A Jurassic species¹ similar in the long and narrow form of the frond to *O. Beani* but distinguished by the much smaller segments

FIG. 606. A, *Otozamites Beani*. B, *Otozamites Bunburyanus*.

FIG. 607. *Otozamites bengalensis*.
(Indian Geological Survey, Calcutta; $\frac{2}{3}$ nat. size.)

¹ Zigno (53) p. 11; Seward (00) B. p. 211.

and by their more orbicular lamina (fig. 606, B). In habit the fronds agree closely with the Fern *Nephrolepis Duffi*. Leckenby's species, *Otopteris tenuata*¹, is probably the same as Zigno's *O. Bunburyanus*, the type-specimen of which in the Padua Museum consists of a long and narrow frond with leaflets not exceeding 8 cm. in length; the rachis is hidden by the imbricate auriculate bases of the leaflets. Feistmantel² refers to this species some pieces of very narrow fronds with overlapping pinnae from Upper Gondwana beds in India. A still smaller form is described by Möller³ from Bornholm as *O. tenuissimus*, and *O. Bunburyanus* is recorded from the same flora. *O. Feistmanteli* Zig.⁴ agrees in the form of the frond and in its short and broad pinnae with *O. Bunburyanus*.

Otozamites bengalensis (Oldham and Morris).

This Indian species from the Rajmahal Hills⁵ and specimens of the same type from the Cutch flora described as *O. contiguus* Feist. afford another illustration of long and narrow fronds with short and relatively broad pinnae. The drawings published by Oldham and Morris accurately represent the specimens: the longest frond is 21 cm. long and neither end is complete (fig. 607); it is 9 mm. broad at the narrower end and 1.5 cm. at the broader end. The rachis is represented by a deep and broad groove; the actual bases of the leaflets are not preserved, but their position shows that they were attached to the upper face: this is clearly seen in the specimen described by Feistmantel as *O. contiguus* which shows also that the lamina is auriculate at the upper edge of the base. The pinnae vary in shape; the smaller ones are characterised by a strongly curved lower margin and the upper edge is slightly curved or straight, while the larger leaflets have more parallel edges and blunter rounded apices: the latter form is well shown in the specimens unnecessarily distinguished by Oldham and Morris as var. *obtusa*.

⁵ Oldham and Morris (63) B. p. 27, Pl. XIX.; Feistmantel (76²) Pl. VII. fig. 4.

Otozamites Klipsteinii (Dunker).

This Wealden species, first described by Dunker as *Cyclopteris Klipsteinii*¹, is remarkable for the large pinnae. The rachis is fairly stout; the broadly oval or oblong pinnae vary considerably in size and in the relation of breadth to length, in rare cases reaching a length of over 8 cm. and a breadth of 2.4 cm.; apex obtuse, base slightly auriculate and asymmetrical; veins numerous, radiating from the point of attachment to the margin of the lamina. The occurrence of finer lines between the more prominent veins may indicate the presence of hypodermal stereome strands. Fig. 608 illustrates the striking variation in the size of the pinnae on a single frond and their attachment to the upper face of the rachis. In the breadth of the segments *O. Klipsteinii* resembles *O. Beani* (Lind. and Hutt.), *O. decorus* Sap.², *O. lagotis* Brongn.³ and two species from South Russia described by Thomas⁴ as *O. Izumensis* and *O. giganteus*. The pinnae of *O. giganteus* exceed 10 cm. in length and 3 cm. in breadth, thus surpassing the largest segments of *O. Klipsteinii*. Some pinnae from the Jurassic flora of Oregon made by Fontaine the type of a new species, *O. oregonensis*⁵, may be fragments of *O. Klipsteinii*. Nathorst⁶ records the occurrence in Lower Cretaceous or Wealden beds in Spitzbergen of Cycadean leaflets very like those of *O. Klipsteinii*.

Otozamites Goepfertianus (Dunker).

This Wealden species, named by Dunker⁷ *Pterophyllum Goepfertianum*, agrees in habit with some of those to which reference is made under *O. Bechei*, e.g. *O. linearis* Halle, and represents a type of the genus with unusually narrow pinnae (fig. 603, A). The auriculate form of the lamina is feebly developed; the linear-lanceolate pinnae are occasionally falcate and have acute apices; as in many other species they were apparently deciduous. It is by no means easy to distinguish some of these fronds from specimens included in *Ptilophyllum pecten*.

FIG. 608. *Otozamites Kliptsteini*. (British Museum, V. 3709; nat. size.)

DICTYOZAMITES. Oldham.

This generic name was instituted¹ for pinnate fronds from the Rajmahal series of India, assigned by Feistmantel to a Lower Jurassic horizon, but probably nearer in age to the Middle Jurassic series. Morris, joint author with Oldham of the Memoir on the Rajmahal plants, adopted the name *Dictyopteris*. *Dictyozamites* agrees very closely with *Otozamites* but is readily distinguished by the anastomosing veins (fig. 609), while the absence of a midrib differentiates it from the Palaeozoic genus *Dictyopteris*. The genus is recorded also from Jurassic strata in England, Bornholm, Japan², Korea³, and from a locality 60 nautical miles N.W. of Cape Horn in Tierra del Fuego⁴: the specimens from these localities differ only in unimportant details from the Indian type. *Dictyozamites* is confined to Jurassic floras and appears to be especially characteristic of Middle Jurassic floras. In India⁵ fronds occur in close association with stems of the *Bucklandia* type and, although there is no proof of any connexion with stems or flowers, it is probable that the fronds of this generic type were borne on stems similar to those of *Bucklandia* and that the flowers were constructed on the *Williamsonia* plan.

Dictyozamites falcatus (Morris).

Morris⁶ described this Rajmahal species under the names *Dictyopteris falcata* and *D. falcata* var. *obtusa*; the specimens were included by Feistmantel under the designation *Dictyozamites indicus*, the original term *falcata* being discarded without adequate reason. An examination of several of the figured fronds enables me to confirm the accuracy of the published drawings and to extend the description in a few particulars. Fronds pinnate of the habit of *Otozamites*; pinnae comparatively thick, broadly linear, alternate, varying considerably in size and in the form of the apex which may be obtuse or acute. The pinnae are attached by the middle part of the lamina only; the upper edge of the base is slightly rounded or auriculate; the lower angle

¹ Oldham and Morris (63) B. p. 37.² Seward (03).³ Yabe (05) B. Pl. II. figs. 2—7.⁴ Halle (12); (13) p. 9, Pl. v. figs. 29—33.⁵ Bancroft (13).⁶ Oldham and Morris (63) B. Pl. xxiv. figs. 1, 2; Feistmantel (76²) Pls. IV.—VI. (77) Pl. II.

is generally more definitely lobed. The imbricate bases completely cover the upper face of the comparatively slender rachis. The longest pinna seen on an Indian frond is 6 cm. with a breadth of 2 cm. Some of the pinnae on magnification exhibit a finely tuberculate appearance, due no doubt to the presence of papillae on the epidermal cells like those on the pinnae of English and Bornholm specimens. This species is recorded by Yokoyama¹ from Japan as *D. falcatus* var. *distans*, and a similar form, referred by him to a distinct species, *D. grossinervis*, may be more appropriately named *D. falcatus* var. *grossinervis*². The Indian type occurs also in Jurassic rocks of Korea, and Halle has discovered some *Dictyozamites* leaves in Tierra del Fuego³ which he describes as *Dictyozamites* sp. cf. *D. falcatus*: this record is of special interest from a phytogeographical point of view.

Dictyozamites Johnstrupi Nathorst.

This species⁴, from rocks usually spoken of as Liassic but not improbably Middle Jurassic in age, differs from *D. falcatus* in the slightly more falcate form of the pinnae and in the more strongly auriculate upper angle of the base of the lamina. The stomata⁵ are confined to the lower epidermis and the strongly cuticularised guard-cells frequently lie at right-angles to the course of the veins. The epidermal cells have very sinuous walls (fig. 609, C) and in the middle of each is a prominent papilla.

Dictyozamites Hawelli Seward.

This Middle Jurassic type from Marske⁶, Yorkshire, differs from *D. falcatus* in the relatively broader segments, their straighter form (fig. 609, B), and in the attachment to the rachis being slightly below the middle of the pinna base. Fig. 609, A, shows the base of a pinna and an oval scar similar to those on the rachis of some recent Cycads (cf. fig. 387). The epidermis is like that in *D. Johnstrupi* and as in that species the stomata are confined to

¹ Yokoyama (89) B, Pl. VII. fig. 10; Pls. x., XI.

² Seward (03) p. 217.

³ The statement made by me [Seward (11⁴) p. 3] that *Dictyozamites* occurs in the Falklands is incorrect.

the lower surface. There are approximately 120 stomata per square millimetre; each with two subsidiary cells (fig. 609, C) of elongated form, and the guard-cells have small thickened outgrowths or papillae as in *D. Johnstrupi*.

The epidermal features are described under *D. Johnstrupi* and *D. Hawelli* (fig. 609, C). a fuller account of those in the latter species will be found in the paper by Mr Thomas and Miss Bancroft.

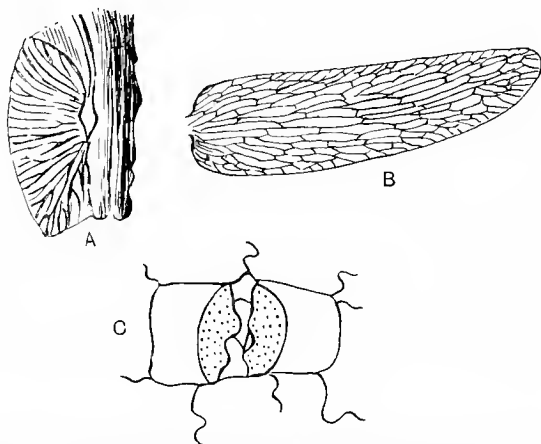

FIG. 609. *Dictyozamites Hawelli*. (A, B. British Museum; C. after Thomas and Bancroft.)

PTEROPHYLLUM. Brongniart.

The name *Pterophyllum* was first applied by Brongniart¹ to some fronds from the Lias of Hör, which he named *P. majus* and *P. minus*, species subsequently removed by Nathorst² to Schimper's genus *Anomozamites*. Brongniart³ defined *Pterophyllum* fronds, e.g. *P. Jaegeri* (fig. 610), as pinnate, bearing pinnules of almost equal breadth attached by the whole width of the base and with a truncate apex; veins slender, equal, simple and slightly arched. There has been considerable confusion and laxity in regard to the application of the name *Pterophyllum* and in many cases no clear distinction has been recognised between this genus and *Nilssonia*. In *Nilssonia* the distinctive feature is the complete absence of any rachis uncovered by the lamina

¹ Brongniart (25).

² Nathorst (81) p. 61.

³ Brongniart (28) A. p. 95.

on the upper face of well-preserved specimens, while in *Pterophyllum* the continuity of the lamina is broken by a greater or less breadth of rachis in the middle line of the frond; the lamina does not cover the rachis but is attached laterally, or at least the two laminae of the frond, whether entire or deeply dissected, do not meet in the middle of the rachis. A specimen from the Cretaceous of Greenland described by Heer as *Pterophyllum concinnum*¹ and now in the Stockholm Museum is probably a piece of a *Nilssonia*; the rachis is not exposed on the surface of the frond. In *Nilssonia* the veins are with few exceptions simple; in *Pterophyllum* they are often branched especially near their origin from the rachis: in *Nilssonia* the segments are of unequal breadth; in *Pterophyllum* they are usually equal. It has been the practice of several authors to follow Schimper² in the employment of the generic name *Anomozamites* for fronds

FIG. 610. *Pterophyllum Jaegeri*. From the Keuper of Lunz; part of a frond 23.5 cm. long and incomplete. (British Museum, V. 1044; nat. size.)

with a more or less entire or irregularly pinnatisect lamina which bear a very close resemblance to *Nilssonia* except that a portion of the rachis is exposed on the upper face. Potonié³ used *Pterophyllum* in a wider sense including both fronds with equal pinnae and those of the *Anomozamites* type: this more extended use of *Pterophyllum* is adopted by Zeiller⁴ who prefers to retain *Anomozamites* only as a sub-genus. It is in this sense that the following definition is framed.

Fronds pinnate; pinnae linear, attached by the whole base, which may be enlarged; the apex is truncate, rounded, or occasionally pointed; the veins are simple or dichotomously branched and parallel to the edge of the lamina. In some fronds (sub-genus *Anomozamites*) the segments are unequal (fig. 615), short, broad

¹ Heer (75) ii. Pl. xv. fig. 11.

³ Potonié (99) B. p. 281.

² Schimper (72) A. p. 140.

⁴ Zeiller (03) B. p. 174.

and truncate, and the lamina may be entire or divided into a few very unequal segments. The surface of the rachis is never completely covered by the lamina on the upper face of the frond and is often characterised by transverse wrinklings, possibly due to the presence of ramental scales.

Some interesting xerophilous features have recently been described by Halle¹ in the lamina of *Pterophyllum* (*Anomozamites*) *marginatum*, a Rhaetic species figured by Schenk and Nathorst from Franconia and Scania. The pinnae were thick and succulent. Stomata are confined to the lower surface and the edges of the upper face of the lamina form a rounded curve causing the thick upper cuticle to abut on the thinner stomatiferous lower cuticle, thus producing in impressions the appearance of thickened margins.

There is no satisfactory evidence as to the nature of the reproductive organs or stems of the plants which bore fronds of the type represented by *P. Jaegeri* (fig. 610) and other forms with equal segments. A stem referred by Heer² and by Leuthardt³ to *Pterophyllum* was not found in connexion with leaves, and there is the same absence of any convincing evidence in the case of the imperfect specimens from the Keuper of Basel believed by Leuthardt to be male and female inflorescences. On the other hand leaves of *Anomozamites* are known to have been borne on comparatively slender stems with dichasial branching, and the reproductive shoots are of the same general type as those known as *Bennettites*. This discovery is due to Nathorst who founded the genus *Wielandiella*⁴ on fertile stems with *Anomozamites* fronds. Mr Thomas⁵ has recently obtained evidence from Yorkshire Jurassic material pointing to a similar connexion between *Anomozamites* fronds and *Wielandiella* stems. *Pterophyllum* is further distinguished from *Nilssonia* by the folded walls of the epidermal cells and by the presence of two crescentic subsidiary cells (fig. 611, A) instead of the ring of cells which surrounds the guard-cells in *Nilssonia* (fig. 611, B). Schenk⁶ figured a few pieces of cuticle from fronds referred to *Pterophyllum* in which the walls are more or less sinuous, but the cells of *Pterophyllum crassinerve* Goepf.⁷ appear to have straight walls: this

species is, however, probably a *Nilssonia*. The stoma represented in fig. 611, A, is from the lower epidermis of *Pterophyllum* (*Anomozamites*) *Nilssoni* (Phill.)¹

Pterophyllum extends from Upper Carboniferous to Lower Cretaceous strata and is especially characteristic of Keuper and Rhaetic floras. A possible representative of the sub-genus *Anomozamites* is described by Ettingshausen from Tertiary beds in New South Wales as *Anomozamites Muellerei*².

FIG. 611. A, *Pterophyllum Nilssoni*; B, *Nilssonia mediana*. (After Thomas and Bancroft.)

Pterophyllum Fayoli Renault and Zeiller.

This species³ was founded on a large frond from the Commeny coalfield with a stout rachis bearing linear pinnae, attached along a narrow groove on its outer edge, reaching a length of 12 cm. and a breadth of 1 cm.; adjacent pinnae are united at the base. The apices are pointed and there are 10–12 unbranched veins in the lamina. Fig. 612 shows a small piece of the large specimen in the Natural History Museum, Paris.

Pterophyllum sp. Arber.

The only representative of a Carboniferous frond of Cycadean habit discovered in Britain is that recorded by Arber⁴ from Westphalian strata at a depth of 1834 ft at Barfreston in Kent. A fairly stout rachis bears incomplete pinnae the longest of which is slightly more than 1 cm. in length and 1–1.5 cm. broad; each segment, very slightly contracted at the base, has 3–4 occasionally

¹ Thomas and Bancroft (13) Pl. XIX. fig. 5.

⁴ Arber, E. A. N. (12²).

forked veins. Arber compares the fragments with *Pterophyllum blechnoides* Sand. from Germany¹.

Pterophyllum Cambryi Renault.

This Permian species from Autun² is similar to *P. Fayoli*, but differs in the more slender rachis and in the finer venation of the linear, acute, pinnae. The pinnae in Renault's specimen reach a length of 4.8 cm. and are from 3.5—4 mm. broad; they are slightly confluent at the base and the veins occasionally fork.

FIG. 612. *Pterophyllum Fayoli*. (From the type-specimen, Paris; $\frac{1}{3}$ nat. size.)

Among other Palaeozoic species are *Pterophyllum Grand'Euryanum* Sap. and Mar.³ discovered by Grand'Eury in the Coal Measures of France, *P. blechnoides* Sand.⁴ from the Upper Coal Measures of Oppenau and recorded by Geinitz⁵ from the Middle Permian of Germany, *P. Cottaeantum* Gutb.⁶, a similar type, also from Permian rocks, but with coarser venation. The specimens figured by Geinitz as *P. blechnoides* and *P. Cottaeantum* are in the Dresden Museum: the former species is represented by a

⁶ Geinitz fig. 8.

good impression on shale which shows the generic characters very clearly.

Pterophyllum Jaegeri Brongniart.

Brongniart¹ founded this species (fig. 610) on material from the Keuper of Stuttgart. The fronds are characterised by the relatively narrow parallel-sided pinnae with rounded or truncate apices and little or no basal contraction; the pinnae may be contiguous or separate. There are 14—16 veins in each pinna. Leuthardt², who figures several examples of this species from Keuper strata at Basel, speaks of the breadth-index of the pinnae as 12, a term employed to denote the relation of the breadth to the length of a segment. *Pterophyllum longifolium*³ is a very similar Keuper type: in this species the pinnae are rather shorter and broader than in *P. Jaegeri* and contracted at the base; the apex is truncate or obtuse. The differences between these species is, however, very trifling. The imperfectly preserved fossils figured by Leuthardt⁴ as the inflorescences of *Pterophyllum* have not been found in connexion with fronds and their nature is problematical. This and other species are recorded by Krasser⁵ from the Lunz beds in Austria.

Pterophyllum Bronni Schenk.

A Keuper species⁶ from Raibl in Carinthia distinguished by its large pinnae, 15 cm. or more in length and 0.5 cm. broad, and by their almost digitate disposition on the rachis. The fronds appear to be relatively short: the upper pinnae are highly inclined while the lower are given off at an obtuse angle; they are obcuneate or more or less oblanceolate, with a truncate asymmetrical apex and rounded angles; the base is slightly contracted. Arber⁷ has figured some specimens from the Munich Museum in one of which there are five spreading pinnae and a portion of the rachis; one pinna is undoubtedly attached and the others, though probably in place, are not in actual connexion

⁷ Arber (07).

with the axis. There is a close resemblance between this species and *Sphenozamites Rogersianus* Font.¹: in the American type the fronds must have been 1 met. long; the leaflets, 19×9 cm., are elliptical, broadest near the apex and attached by the middle of the rounded base. Between the divergent and forked veins there is a fine granulation probably due to the presence of papillae. *Pterophyllum Bronni* and *P. Rogersianum* might be placed in Schimper's genus *Macropterygium*², though another Raibl species, originally described by Schenk as *Pterophyllum giganteum*³ and referred by Schimper to *Macropterygium*, has much longer and relatively narrow pinnae and agrees more closely with *Pterophyllum* as the genus is usually defined. In order to emphasise the distinctive features of *Pterophyllum Bronni* and Fontaine's Virginian species they may conveniently be spoken of as *Pterophyllum (Macropterygium) Bronni* and *Pterophyllum (Macropterygium) Rogersianum*.

Pterophyllum Braunianum Goepfert.

In this Rhaetic species⁴ (fig. 613) the narrow linear pinnae, contiguous or more or less distant, are 1—2 mm. broad and may exceed 5 cm. in length though they are usually shorter; they are attached more or less at right-angles to the sides of a transversely wrinkled rachis. The base of the lamina is broadened and the veins are parallel, simple or forked. The epidermal cells have sinuous walls.

Pterophyllum Tietzei Schenk.

A Rhaetic species founded⁵ on specimens from Persia and described also by Zeiller⁶ from Tonkin represented by fronds

FIG. 613. *Pterophyllum Braunianum*. (A, nat. size; B, enlarged; after Schenk.)

1 met. long and at least 15 cm. broad. The segments, 3—7 cm. long and 8—18 mm. broad, are often set at right-angles to the rachis; the edges are parallel but the lower edge bends upwards at the apex. The veins are simple or forked and approximately 0.3 mm. apart.

Pterophyllum Bavieri Zeiller.

This Rhaetic species from Tonkin¹ and Persia² is interesting as affording an example of a frond with exceptionally narrow and contiguous pinnae. The frond is narrow and lanceolate, 15—20 cm. long with pinnae normal to the rachis, .5—1 mm. broad and 7—25 mm. long attached by the whole base which is sometimes slightly enlarged. The veins are simple or forked, .15—25 mm. apart: the apices of the segments are rounded or truncate and the form of the whole is similar to that of *Pterophyllum aequale* but narrower.

Pterophyllum (Anomozamites) inconstans Braun.

In habit this Rhaetic species³ resembles *Nilssonia compta*. The linear-lanceolate fronds, as described by Zeiller⁴ in his Tonkin memoir, attain a length of 20 cm. and a breadth of 4 cm. The rachis, characterised by numerous transverse ridges, bears alternate or subopposite leaflets often at right-angles; they are almost rectangular and hardly longer than broad, attached by the whole of the base, which may be broadened, to the upper face of the rachis, but the lamina does not cover the whole of the rachis as in *Nilssonia*. The pinnae vary in breadth on the same frond and occasionally the lamina is continuous as in some forms of *Nilssonia*. Schenk⁵ figures examples from the Rhaetic of Franconia in which the lamina is very irregularly dissected and may be entire for a considerable distance. The epidermal cells have slightly sinuous walls. A similar type is represented by *Pterophyllum (Anomozamites) Schenki* Zeill.⁶, but the segments are contracted basally and become wider towards the apex where, as in *P. inconstans*, the edges are parallel. Feistmantel's species *Platypterygium*

⁶ Zeiller (03) B. Pl. XLIII. fig. 7.

*Balli*¹, though superficially similar to *Pterophyllum*, appears to agree more closely with *Pseudoctenis*.

Pterophyllum Nathorsti Seward.

This species, founded on a specimen in the Sedgwick Museum, Cambridge, from the Middle Jurassic beds of Yorkshire, was formerly referred to the genus *Dioonites*², but since the Yorkshire specimens were supplemented by material from Kimmeridge strata in Scotland³ affording more definite information with regard to the attachment of the pinnae it has been transferred to *Pterophyllum*. Pinnae laterally attached to the rachis which in some specimens shows a transverse wrinkling, narrow, linear, 3—4 mm. wide and reaching a length of 9 cm. The base of the

FIG. 614. A, B, *Pterophyllum Nathorsti*; A from below; B from above. C, *Nils-sonia tenuicaulis*. (A, B, Gunn Collection, British Museum; C, Arber Coll. Sedgwick Museum, 539; nat. size.)

segments is slightly expanded; the apex is acuminate or bluntly pointed: there are approximately three veins in 1 mm. of lamina. This type (fig. 614, A, B) is similar to *Pterophyllum aequale* Brongn. as figured by Zeiller⁴ from the Rhaetic of Tonkin and agrees closely with some of the large Rhaetic specimens referred by Schenk to *P. Braunianum*. The Jurassic fronds from Oregon described by Fontaine⁵ as *Ctenophyllum angustifolium* are similar

Pterophyllum (Anomozamites) Nilssoni (Phillips).

The type-specimen, from the Jurassic beds on the Yorkshire coast and now in the York Museum, was described by Phillips¹ as *Aspleniopteris Nilssoni* and placed in *Pterophyllum* by Lindley and Hutton and many other authors². The fronds are linear; the lamina may be almost entire or divided into unequal deep truncate segments; the veins are simple or dichotomously branched (fig. 615). The leaves are very similar to those of *Nilssoniana*; they were probably borne on stems similar to those described by Nathorst as *Wielandiella*. Reference is made to the structure of the epidermal cells in the account of the genus.

Pterophyllum (Anomozamites) Lyellianum (Dunker).

This Wealden species, originally referred by Dunker³ to *Pterophyllum*, was afterwards transferred to *Anomozamites*⁴. The fronds, in habit resembling the larger Rhaetic species *P. Braunianum* Goepf., are characterised by the narrow linear pinnae of almost equal breadth attached approximately at right angles; there is a narrow line of rachis separating the two rows of segments (fig. 616).

{ **CYCADITES.** Sternberg.

{ **PSEUDOCYCAS.** Nathorst.

The generic name *Cycadites* was first used by Sternberg⁵ though it has since been shown that the specimens for which he proposed it belong to other genera. As employed by Brongniart⁶ and other authors *Cycadites* stands for fossil fronds agreeing in habit with the pinnate leaves of recent species of *Cycas* (fig. 387, A); the presence of a single median in the linear pinnae is generally regarded as an essential feature. *Cycadites* may be defined as follows: Fronds pinnate; pinnae alternate or opposite, linear entire, with a midrib and no lateral veins, attached to the rachis by the entire base, the lower margin of which may be slightly decurrent or narrowed near the point of attachment. Epidermal cells with straight walls and stomata agreeing in structure with

those of the recent genus. As thus defined, including the characters of the epidermal cells, the genus has no representatives; but the generic name should also be applied, as Miss Holden¹ has recently suggested, to fronds of the *Cycas* form which afford no information with regard to the structure of the epidermis. The resemblance of *Cycadites* fronds to those of *Cycas*, coupled with the fact that impressions superficially resembling megasporophylls of the recent genus are recorded from Mesozoic strata, was considered sufficient justification for the employment of a name implying close affinity to or even generic identity with *Cycas*. A fuller knowledge of the epidermal characters of some of the fronds hitherto included in *Cycadites* has necessitated the substitution of a new genus for *Cycadites*. An examination by Nathorst² of Heer's Lower Cretaceous Greenland species *Cycadites Steenstrupi* and of other fronds showed that the epidermal cell-walls are sinuous and the stomata arranged differently from those of *Cycas*. For these and other reasons Nathorst proposed a new name *Pseudocycas*. He also pointed out that the pinnae in the fossil fronds have as a rule a double 'midrib.' Nathorst's discovery raised the question whether other fronds described as *Cycadites* should be transferred to *Pseudocycas*. Miss Holden's investigation of other supposed Mesozoic representatives of *Cycas* leads to the conclusion that 'it is not impossible that all Mesozoic specimens of *Cycadites* will turn out to be *Pseudocycas*.' This observer shows that *Cycadites Saportae* Sew. and *C. Roemeri* Schk. agree in the sinuous walls of the epidermal cells with *Pseudocycas*; and so far no species of *Cycadites*, in which it was possible to examine the cuticular membrane, has been found that does not conform to Nathorst's definition of *Pseudocycas* at least as regards the structure of the epidermal cells. Nathorst defined *Pseudocycas* in the following sense: Fronds similar to those of *Cycadites* and *Cycas* but with pinnae characterised by a double 'midrib,' the stomata being confined or almost confined to the groove between the two 'midribs.' Nathorst also notes that in *Pseudocycas* the bases of the pinnae are not contracted as is often the case in *Cycadites* and *Cycas*, but this is a feature of secondary importance. Miss Holden has, however, expressed the opinion

¹ Holden, R. (14²).

² Nathorst (07⁸).

that the double 'midrib' is an untrustworthy character and that the stomata are not always arranged as in the fronds examined by Nathorst. Nathorst states that in *Pseudocycas Steenstrupi* and *P. insignis* the midrib though usually double may be single: the same variation occurs in *P. Saportae*. Miss Holden found that an impression made from a pinna of *Cycas siamensis* showed a double line on the upper face and a single rib on the lower; that is *Pseudocycas* and *Cycas* characters occur on a single pinna. On drying, the ridge on the lower face of the lamina collapses and a groove is formed bounded by two ridges.

In a recently published and interesting paper on 'Some Xerophytic Leaf-structures in Mesozoic Plants,' Dr Halle¹ makes some important additions to our knowledge of *Pseudocycas*. He agrees with Miss Holden's views with regard to the use of the generic names *Pseudocycas* and *Cycadites*, but dissents from her interpretation of the median groove as the result of shrinkage of a midrib. Part of the evidence presented by Halle is based on the structure of the leaf-cuticle as shown in microtome sections². He found that a distinct median groove is always present on the pinnae of *Pseudocycas insignis* and other species. If the groove were due to collapse of the tissue of a true median rib the presence of stomata—which in *P. insignis* are confined to the middle line of the lamina—below the vein would be an unusual feature. He found no indication of a median vein or of any vascular tissue. All that is revealed by an examination of the cuticle is that the lamina has a well-defined groove bounded by prominent ridges, and in *Pseudocycas Roemeri* the groove is deeper and is formed by the bending-back of the lamina. The stomata are practically confined to the groove and in *P. insignis* and *P. Steenstrupi* an additional protection against excessive transpiration was afforded by elongated papillae.

In the sinuous walls of the epidermal cells and in the structure of the stomata *Pseudocycas* agrees with the Bennettitalean type as defined by Thomas and Bancroft³. The 'midrib' of the pinnae marks the position of a pronounced groove and we have no information with regard to the venation. As Halle says, protection

¹ Halle (15).

² Pls. XII., XIII.

³ Thomas and Bancroft (13).

against drought is afforded by 'other means than those usual among existing Cycads,' which provide against excessive transpiration by the sinking of the individual stomata below the surface. The epidermal features of *Pseudocycas* afford a striking example of the danger of basing conclusions on mere impressions and they further emphasise the great difference between Mesozoic Cycadean fronds and those of recent genera.

We have no knowledge of the nature of the reproductive organs of the plants which bore *Pseudocycas* fronds, but the agreement of the stomata and epidermal cells with those in some Bennettitalean types favours the inclusion of the genus in that class. It has previously been pointed out that the impression figured by Heer¹ in close association with the Greenland specimens of *Pseudocycas Steenstrupi* as a carpellary leaf of the *Cycas* type is much too imperfect to be identified and has no claim, as an examination of the actual specimen in the Copenhagen Museum convinced me, to be compared with a megasporophyll of *Cycas*. This view is shared by Nathorst.

In some cases the name *Cycadites* has been applied to fragments that might equally well belong to Conifers or other plants, and not infrequently a careful examination of fossils referred to *Cycadites* shows that the pinnae afford no evidence of a true midrib. Casts of revolute pinnae like those of the recent species *Encephalartos Ghellinckii* (fig. 382) would present an appearance closely resembling a strong midrib. Heer's Siberian Jurassic species *Cycadites sibiricus*² is probably a piece of a *Taeniopteris* or *Nilssonia* frond, and *C. gramineus* Heer³ should be referred to *Taxites*. An examination of the Indian fronds described by Oldham and Morris and Feistmantel as species of *Cycadites* leads me to discard all of them as trustworthy records of the genus: in *Cycadites confertus*⁴ and *C. Blandfordianus*⁵ there appear to be several veins in the pinnae and not a single midrib. *Cycadites constrictus*⁶ is almost

⁶ Feistmantel (79) Pl. VII. fig. 10; Nathorst (09) p. 5, note 2.

certainly a Conifer as Nathorst has also suggested. No satisfactory example of *Cycadites* has been described from Palaeozoic strata; Goeppert's *Cycadites gyrosus*¹ is founded on material too imperfect to determine, and an examination of his Culm species *C. taxodinus* in the Breslau Museum led me to refer it to a Conifer. The specimens figured² by Zeiller from Lower Gondwana rocks

FIG. 617. *Pseudocycas insignis*. From the Lias of Hör. A, $\frac{2}{3}$ nat. size; B, ca. $\times 2$. (After Nathorst.)

in India as *Cycadites?* sp. are portions of linear leaves or leaflets 5 mm. broad with a median rib but they can hardly be accepted as evidence of the presence of a Cycadean plant.

Pseudocycas insignis Nathorst.

The fronds of this Cenomanian species from the West of Greenland reach a breadth of 16 cm.; the rachis, 1 cm. broad, has two

¹ Goeppert (66).

² Zeiller (02) B. Pl. VII. fig. 4.

parallel ridges on the upper surface and to these are attached at a wide angle the broad bases of narrow linear pinnae reaching a length of 9 cm. and a breadth of 2—3 mm. (fig. 617). The pinnae are thick and separate and each has a double 'midrib' consisting of two parallel lines (fig. 617, B) which are occasionally replaced by one. The so-called double 'midrib' represents the two prominent ridges bordering the groove. The stomata, confined to the median groove, are approximately circular and the short epidermal cells have sinuous walls¹.

Pseudocycas Steenstrupi (Heer).

Nathorst refers this species, described by Heer as *Cycadites*, from the Cenomanian of Greenland, to *Pseudocycas* on the ground that the epidermal cells are like those of *P. Steenstrupi* and the stomata are confined to a median groove. Heer figures an impression in close association with the frond of this species which he identifies, without any adequate reason, as a carpellary leaf like that of a *Cycas*.

Pseudocycas Saportae (Seward).

It has recently been shown by Miss Holden that this Wealden English species² has the epidermal characters of *Pseudocycas*. In external form it agrees closely with *Cycadites tenuisectus* Sap.³ from Lower Cretaceous rocks in Portugal, but nothing is known of the epidermal features of the latter type. The rachis is broad and flattened and bears alternate or sub-opposite pinnae of uniform breadth attached at right-angles or obliquely to its upper surface (fig. 618). The pinnae are 6—7 cm. long and about 1 mm. broad; their bases are slightly expanded and the apices sharply pointed. Miss Holden⁴ finds that the median rib is sometimes double and that the middle region of the lamina is covered with stomata; the epidermal cells have sinuous walls and stomata occasionally occur on each side of the main median stomatal area. Dr Halle⁵ of Stockholm, who has examined cuticular preparations made from English specimens, confirms Miss Holden's

¹ Nathorst (07^a Pls. I.—III.

² Seward (95) A. p. 29, Pl. II. fig. 7; Pl. VI. fig. 5; Pl. VIII. fig. 2.

⁴ Holden, R. (14^a).

⁵ Halle (55), p. 502.

observations as regards the stomata, but he shows that there is no evidence of the existence of a midrib in the strict sense, the appearance of a single or double median vein being due to the presence of a dorsal stomatiferous groove, the edges of which would produce an impression on the matrix of a double vein or, if the

FIG. 618. *Pseudocycas Saprotae*. From the Wealden, near Hastings.
(British Museum, V. 2777; $\frac{1}{2}$ nat. size.)

groove became narrower, the impression would suggest a single midrib.

Pseudocycas Roemeri (Schenk).

This Wealden species recorded from North Germany¹ and the Sussex coast² has broader pinnae laterally attached to the

¹ Schenk (71) B. Pl. xxxii. fig. 1.

² Seward (95) A. pp. 2—7.

rachis. Miss Holden describes the stomata as covering the whole lower surface of the pinnae except over the midrib. This description must be revised in the light of Halle's results obtained from an examination of the cuticle of the type-specimen of the species in the Berlin Museum. He finds that the edges of the pinnae are strongly revolute and thus form a deep dorsal canal which is almost closed¹, a form of lamina, as seen in section, very similar to that of an *Empetrum* leaf. The stomata are confined to the groove. It may be that the specimen examined by Miss Holden is specifically distinct or, as Halle also suggests, the cuticle obtained from the English fossil may not represent the whole surface but only the walls of the canal with possibly a portion of the cuticle of the outer dorsal surface. This type of leaf described by Halle is similar to that of *P. insignis* with the xerophilous character intensified.

Cycadites Saladini Zeiller.

This species was founded by Zeiller² on fronds from the Rhaetic of Tonkin reaching a length of 40 cm. and 2—8.5 cm. broad with a rachis 3—4 mm. wide bearing contiguous linear pinnae 1.5—4.5 cm. long and 1.5—3 mm. broad with a more or less contracted base and a rounded or obtusely pointed apex. The pinnae are attached almost at right-angles or at an angle of 60°—80°. There is a clearly defined midrib.

It is not improbable that were the structure of the epidermal cells known this species would be found to be another example of *Pseudocycas*.

Cycadites rectangularis Brauns.

This species³, first recorded from Rhaetic strata in Germany, differs in the narrower and more acutely pointed pinnae from *C. Saladini*. Miss Holden describes the midrib as double, but until specimens are found which admit of an examination of the cuticles it is impossible to decide whether it should be transferred to *Pseudocycas*. The species is widely distributed in Rhaetic

and Jurassic strata and specimens are recorded from the Lias of Lyme Regis on the south coast of England.

Cycadites Renaulti Lignier.

This species, from the Middle Lias of Normandy¹, is founded on fronds 2.2—2.6 cm. broad with a rachis 3 mm. in breadth bearing laterally-inserted pinnae almost at right-angles 11—12 mm. long and 1.25—1.50 mm. broad; it is very similar to *C. rectangularis* which occurs in the same beds.

II. NILSSONIALES.

NILSSONIA. Brongniart.

This genus² was named after the Swedish naturalist Nilsson who had figured certain plants from the Lias of Hör referred by Fries to the Ferns: these were named by Brongniart *Nilssonia brevis* and *N. elongata* and classed with the Cycads. The type-specimens of the latter species are regarded by Nathorst as a form of *N. brevis*. The history of the genus is fully discussed in Nathorst's able monograph³. *Nilssonia*, founded on fronds which with one exception are known only as casts or impressions, may be thus defined: Fronds with circinate vernation, at least in the type-species *Nilssonia brevis* (fig. 619, C, D), similar in shape to the leaves of *Scolopendrium vulgare* and *Polypodium irioides* and to such unusual forms of *Cycas* fronds as those reproduced in figs. 384, 387, I⁴, in which the laminae of the pinnae are concrescent and form a continuous or deeply cut lamina. They may reach a length of 60 cm. and a breadth of 10 cm. and some specimens are known in which the leaf is less than 1 cm. in width. The lamina is occasionally entire, but in the great majority of cases it is more or less deeply cut into segments of unequal breadth varying considerably in size and shape even in the same species, usually deep and truncate and sometimes long and narrow (e.g. *N. pterophylloides*, fig. 619, B). An important distinguishing feature is the attachment of the lamina to the upper face of the rachis which it covers: the extension of the lamina over the surface of the frond axis and the rare occurrence of branching

¹ Lignier (13) p. 90, Pl. ix. figs. 18, 19.

³ Nathorst (09²).

⁴ Pages 13, 16.

FIG. 619. A, seed (*Nilssonia*?); B, *Nilssonia pterophylloides*; C, D, *Nilssonia brevis*; E, *N. polymorpha*. (A—D $\frac{1}{2}$ nat. size; E, slightly enlarged; after Nathorst.)

of the veins are characters in which *Nilssonia* differs from *Taeniopteris*. The veins are given off at right-angles or obliquely from a very narrow groove occupying the median line of the rachis; they are nearly always simple and in some of the more fleshy leaves, e.g. *N. brevis*, they are seldom visible. The surface of the lamina may be smooth or transversely corrugated. The rachis forms a prominent rib on the under surface of the frond (fig. 620, A) and may be continued beyond the lamina as a short petiole. Epidermal cells polygonal or rectangular, with straight walls in contrast to the sinuous walls of *Taeniopteris*; some of the cells bear strongly cuticularised papillae, possibly the bases of hairs (compare the hairs on the fronds of *Acrostichum crinitum*, a Fern with leaves similar in shape to some of the large entire fronds of *N. orientalis* though relatively broader and with anastomosing veins). Stomata usually confined to the lower epidermis and not very numerous; guard-cells of rounded contour and without any special thickening surrounded by 6—8 accessory cells with thickened walls (fig. 611, B) forming a chimney slightly raised over the stomatal pore¹. In *Nilssonia* the guard-cells do not exhibit that regularity of orientation which characterises the stomata of *Ptilophyllum*, *Otozamites*, and other Bennettitalean fronds. Little is known of the anatomy of the leaves: in a petrified leaf of *N. orientalis*² from Upper Cretaceous rocks in Japan there is no palisade-tissue and small groups of sclerenchyma occur above and below the veins. The xylem appears to be centripetal, but the preservation is far from satisfactory. A few secretory canals were found near the edge of the leaf. We have no certain knowledge of the reproductive organs. The small circular projections figured by Schenk³ on some leaves of *Nilssonia polymorpha* as sporangia have no claim to be so regarded. In the description of *N. brevis* reference is made to some seeds discovered by Nathorst which may belong to that species. Nathorst suggests the possibility that the Rhaetic fossil *Stenorrachis scanicus* Nath. may be the seed-bearing shoot of a *Nilssonia*, either *N. brevis* or *N. polymorpha*, and if this surmise is correct it almost necessarily involves the genus *Beania*⁴ which has been tentatively referred to the

¹ Nathorst (09²); Thomas and Bancroft (13).

³ Schenk (67) A. Pl. xxix. figs. 1, 2.

² Stöpes (10²).

⁴ See vol. iv.

Ginkgoales though without any convincing evidence to support such connexion. Nothing is known of the stems: the occasional occurrence of leaves converging towards a common support points to a Cycadean habit. It is possible, as Nathorst suggests, that the Rhaetic species *Bucklandia Saportana*¹ may be the stem of a *Nilssonia*.

Nilssonia is especially characteristic of Jurassic and Rhaetic floras; it occurs also in Triassic beds and extends into Cretaceous floras.

Nathorst instituted the genus *Nilssoniopteris*² for some specimens from the Yorkshire coast which he believed to be examples of *Nilssonia tenuinervis* on the ground that the veins are dichotomously branched and the epidermal cells have sinuous walls. Mr Hamshaw Thomas³ has, however, shown by an examination of the specimens in the Stockholm Museum that they belong to *Taeniopteris vittata*, and Prof. Nathorst agrees with this conclusion. The name *Nilssoniopteris* must therefore be abandoned. Miquel⁴ proposed the name *Hisingera* for some *Nilssonia* fronds, but it has not been adopted.

Nilssonia polymorpha Schenk.

Linear fronds varying considerably in breadth and in the degree of dissection of the lamina, which may be entire; the margin may show broad and shallow crenulations or there may be a few narrow and deep sinuses cutting the otherwise entire lamina into long and narrow segments. More usually the lamina is divided to the rachis into numerous truncate segments traversed by parallel, simple, veins extending from a narrow groove in the middle of the rachis on the upper surface of the frond (fig. 619, E). The veins run in very narrow grooves in the generally flat but occasionally corrugated lamina⁵.

This species agrees very closely in habit with *N. compta* and *N. brevis* and, as Nathorst points out, it is in some cases almost impossible to distinguish *Nilssonia polymorpha* from *N. brevis*.

¹ Nathorst (86) Pl. xviii. fig. 5.

² *Ibid.* (09²) p. 28.

³ Thomas (13²) p. 241; Thomas and Bancroft (13) p. 193.

⁴ Miquel (42) p. 61.

⁵ Schenk (67) A. p. 127, Pls. xxix., xxx.; Nathorst (09²) p. 10, Pl. v. figs. 9—13, etc.

Some of the fronds from the Rhaetic of Franconia described by Schenk as *N. polymorpha* are examples of *N. brevis*. In *N. polymorpha* the distal ends of the segments are blunter, the lamina is much less folded and when folds or corrugations occur they are less regular than in *N. brevis*. The epidermal cells are polygonal and have thick, straight, walls: oval or circular papillae occur both on the lamina and rachis. The stomata, confined to the lower surface, are between the veins and each is accompanied by a ring of subsidiary cells (*cf.* fig. 611, B). *N. polymorpha* is a member of Rhaetic floras and is recorded also from Liassic rocks at Hör¹.

Nilssonia brevis Brongniart.

This species² (fig. 619, C, D), one of those from Hör on which the genus was founded, has been very fully investigated by Nathorst³ whose researches have cleared up many obscure features.

FIG. 620. A, B, *Nilssonia brevis*; A, section of the frond; B, section of the lamina parallel to the rachis. C, *N. saighensis*. (A, B, after Nathorst.)

The young fronds are circinate like those of Ferns and *Cycas*. The linear fronds agree generally in habit with those of *N. polymorpha* and *N. compta*, but the lamina is thicker and is characterised by regular transverse corrugations; the veins are very rarely visible except in young leaves which have not reached their full thickness. The fronds may be 50 cm. long and vary in breadth from 1.5 to 12 cm.; the petiole is very short or the frond may be

FIG. 621. *Nilssonia rajmahalensis* (= *Cycadites rajmahalensis*). (Indian Geological Survey, Calcutta; nat. size.)

sessile. Between the regular grooves on the upper surface the lamina is more or less convex; seen from below the grooves are represented by ridges and between each pair of ridges there are parallel folds, sometimes three (fig. 620, B) or as many as six; and where the segments are narrow, that is the strips of lamina between two grooves (or ridges), there may be only a single fold which gives the appearance of linear segments with a single midrib as in *Cycadites*, a misleading resemblance of special interest in reference to the *Nilssonia* fronds described by Oldham and Morris¹ and by Feistmantel² as *Cycadites rajmahalensis*. Owing to the fleshy nature of the leaf the difference between the upper and lower side is particularly well marked in this species. The lamina may be more or less entire, but is usually divided by deep sinuses extending to the rachis into truncate or distally tapered segments varying in breadth (fig. 619, C, D), the narrow segments being characterised by a more pointed apex than in *N. polymorpha*. The structure of the stomata and epidermal cells is of the type described in the definition of the genus. Strongly cuticularised papillae, incorrectly described by Schenk³ in *N. polymorpha* as stomata, occur on some of the epidermal cells: these may be the bases of hairs. In some preparations Nathorst found patches of a resinous substance, an interesting discovery in view of the occurrence of secretory canals in the petrified leaf of *Nilssonia orientalis* described by Dr Stopes⁴.

Nilssonia brevis occurs in Upper Rhaetic and Lower Liassic strata.

Nilssonia pterophylloides Nathorst.

A Rhaetic Scanian species originally referred by Nathorst⁵ to *Nilssonia* but later removed by him to *Dioonites*⁶ and in 1909 reinstated in *Nilssonia*⁷ on the ground that the lamina covers the upper face of the rachis. The segments are fairly uniform in breadth and linear; they reach 10 cm. in length and are usually 5—7 mm. broad; the lamina is slightly tapered towards the apex (fig. 619, B). There are 3—10 parallel grooves on the upper

⁴ Stopes (10²).

⁶ *Ibid.* (02) p. 18, Pl. I.

face of the segments and between each pair is a single unbranched vein. In close association with portions of three fronds of this species Nathorst found several oval bodies, 1 cm. \times 7 mm., which he at first regarded as 'antherangia' comparable with the sporocarps of the Hydropterideae, but an examination of the carbonised tissue demonstrated that the small rounded bodies contained in each of the 'antherangia,' originally believed to be pollen-sacs, are grains of resin internal to a cuticle of thick-walled cells and probably formed by secretory sacs in a fleshy tissue. Internal to the resin-bodies is a second cuticle which may be the remains of a nucellus, the outer cuticle and the resin belonging to the sarcotesta. Nathorst's careful examination of these fossils shows that they are seeds (fig. 619, A) and were probably borne on plants of *N. pterophylloides*, though an accidental association is not improbable.

Nilssonia compta (Phillips).

Broadly linear fronds varying considerably in size and in the breadth and number of the truncate segments. In some cases the fronds exceeded 40 cm. in length and had a breadth of 9 cm. (fig. 622). The veins are simple, parallel, and fairly prominent and the lamina shows clearly the attachment to the upper surface of the rachis which is covered by it as in all species of the genus¹. The structure of the epidermis and stomata has recently been described by Thomas². Brongniart mentioned in the *Prodrome* a species from the Lower Oolite of Yorkshire under the name *Pterophyllum Williamsonis*³, but in a later work this is given as a synonym of *N. compta*. *Nilssonia compta* bears a close resemblance in habit to *N. polymorpha*; it agrees also with the large fronds described from the Upper Gondwana of India as *Pterophyllum princeps*⁴. Since attention was first called to this similarity an examination of several of the figured specimens has convinced me that the Indian fronds are either identical with or at least

¹ Phillips (29) A. p. 148, Pl. VII. fig. 20. See Seward (00) B, p. 223, Pl. IV. fig. 5; text-figs. 39, 40.

⁴ Oldham and Morris (63) B. Pls. X.—XIII.; Feistmantel (77) Pl. XLVII.

closely allied to the European leaves. The apparent lateral attachment of the lamina in the drawings published by Oldham and Morris and Feistmantel is due to imperfect preservation; the lamina ends in two raised ridges, and the discovery of a specimen in which the lamina completely covers the rachis confirmed the impression made by the other specimens. The Amurland Jurassic species *Nilssonia Schmidtii*¹ Heer though probably not identical

FIG. 622. *Nilssonia compta*. (Whitby Museum; nat. size.)

with *N. compta* is a very similar type; it was originally described by Heer as *Anomozamites Schmidtii* and transferred by Nathorst² to *Nilssonia*: the veins are occasionally forked near the rachis and are rather farther apart (.5 mm.) than in *N. compta* and the segments are broader and deeper than in the English species. *Nilssonia nipponensis* Yok.³ a Jurassic species recorded from Japan and North America is another similar type.

¹ Heer (78) ii. Pls. xxiii., xxiv.; Seward (12³) p. 27, Pl. II.

² Nathorst (97) p. 13.

³ Yokoyama (89) B. Pls. v., vii., xli., xliii.; Ward (05) B. Pl. ¹xvii.

Nilssonia orientalis Heer.

In this Jurassic and Lower Cretaceous species, founded on material from Jurassic rocks in Siberia¹, the lamina is generally entire. The fronds exhibit a wide range in size and shape; they may have the form of very narrow linear leaves barely 1 cm. across or may reach a breadth of nearly 10 cm. The leaves from Middle Jurassic British strata named by Nathorst *N. tenuinervis*² are probably identical with Heer's type, and *N. Johnstrupi*³ Heer from the Lower Cretaceous of Greenland may also be referred to *N. orientalis*.

The veins are at right-angles or oblique to the rachis and are very numerous, three or more in a breadth of 1 mm.⁴ A species recently described by Halle⁵ from Graham Land as *N. taeniopteroides* agrees closely in habit with *N. orientalis*: in the southern form the frond may have a length of 40—50 cm. and a breadth of 3 cm. The entire lamina of *N. taeniopteroides* tapers gradually towards the base and is more rapidly narrowed in the distal region; the petiole is at least 6—7 cm. long: the simple or branched veins, 15—20 in 1 cm., are given off from the axis at a wide angle. The more crowded veins in *N. orientalis* constitute one of the few features in which it differs from Halle's species, but the fact that the degree of closeness of the veins is inconstant within the same species renders this distinction of doubtful value. Halle compares his species also with *N. densinervis* (Font.) originally described as *Platypterigium densinerve* from the Potomac beds⁶ and afterwards transferred by Berry⁷ to *Nilssonia* and considered by him to be identical with Fontaine's *Platypterigium Rogersianum*. An examination of some of Fontaine's specimens in the Washington Museum led me to refer the fronds to *Nilssonia*⁸.

It is impossible to speak with confidence as to the absolute specific identity of *N. orientalis* Heer, *N. Johnstrupi* Heer, *N. taeniopteroides* Halle, and some similar forms; but it is clear that the linear fronds of this type characterised by an entire

or occasionally pinnatisect lamina were widely distributed in Jurassic and Lower Cretaceous strata and persisted to the Upper Cretaceous series in Japan. This form of frond is recorded from England, Scotland, North America, Greenland, Spitzbergen¹, Siberia, Russia, Afghanistan², Japan³, Graham Land, and elsewhere. Reference has already been made to a petrified specimen of *N. orientalis* described by Dr Stopes from Japan⁴.

Specimens described by Salfeld⁵ from the Corallian of Germany as *Taeniopteris* sp. may be *N. orientalis*; Bartholin's *N. polymorpha* from Bornholm, Velenovský's Lower Cretaceous *N. bohémica* and Yokoyama's *N. ozvana* from Japan are other examples of fronds which may be identical with *N. orientalis*⁶.

Nilssonia tenuicaulis (Phillips).

This Jurassic species, while agreeing generally in habit with *N. compta*, is characterised by the narrow and numerous linear segments with a more acuminate apex. The fronds reached a length of more than 20 cm.⁷ Leckenby's name *Pterophyllum medianum*⁸ was given to a specimen from the Yorkshire coast and now in the Sedgwick Museum, Cambridge, which, with *Pterophyllum angustifolium*, is clearly identical with *Cycadites tenuicaulis* Phillips. The specific name *mediana* frequently used⁹ for this type should be given up in favour of the older term *tenuicaulis*. A species of similar habit is described but not figured by Krasser¹⁰ as *N. Sturii* from the Lunz beds. *N. tenuicaulis* is fairly common in the Middle Jurassic beds near Scarborough and is recorded from the Kimmeridgian of Scotland under the name *N. mediana* (fig. 614, C)¹¹.

Nilssonia princeps (Oldham and Morris).

Oldham and Morris speak of *Pterophyllum princeps*¹² as one of the commonest plants in the Rajmahal beds in India. The

fronds are characterised by their large size and by the very broad oblong and distally truncate pinnae with parallel and occasionally branched veins. In the specimens figured by Oldham and Morris and Feistmantel the pinnae are cut off at their bases (fig. 623), which form ridges parallel to the rachis: this feature is not clearly shown in the published drawings. By breaking some pieces of

FIG. 623. *Nilssonia princeps*. (Slightly reduced; Indian Geological Survey, Calcutta.)

rock from a slab containing figured specimens other pieces were found in which the laminae of the bases of segments meet in the middle of the upper face of the rachis. The pinnae vary in breadth from 1 cm. to 3.5 cm. and reach a length of 8 cm.; the distal end is truncate, the lower edge being strongly curved: the segments are slightly broadened at the base. The veins are prominent and parallel, from 0.5 to 0.8 mm. apart. The Rajmahal

fronds described as *Pterophyllum Morrisianum*¹ appear to be indistinguishable from this species.

Nilssonia Schaumburgensis (Dunker).

This species, first described as *Pterophyllum Schaumburgense*² from the Wealden of Germany, affords a good illustration of a small type of frond closely resembling the much larger species *N. compta*. Examples from English Wealden rocks seldom exceed 1 cm. in breadth and are often much narrower; the linear lamina is almost entire or divided into short and broad truncate segments of unequal breadth: the veins are parallel and simple. For figures of this species, recorded from different European localities and from Japan, reference should be made to the accounts by Schenk³, Nathorst, Yokoyama, Yabe, and Fontaine.

CTENIS. Lindley and Hutton.

The genus *Ctenis*⁴ was founded on a piece of pinnate frond from the Middle Jurassic rocks of the Yorkshire coast previously figured by Phillips as *Cycadites sulcicaulis*. Lindley and Hutton regarded the plant as probably Cycadean and proposed to apply the name *Ctenis* to all leaves having the general characters of Cycadeae, but with 'the veins connected by forks or transverse bars.' While many authors have accepted *Ctenis* as a Cycadean genus, by others⁵ it has been placed among the Ferns, on the ground that some small circular elevations on the lamina of the segments of certain species are believed to be sori or sporangia. Since Ettingshausen⁶ and Schenk⁷ first noticed this feature Raciborski⁸ has figured several examples from Poland and Staub⁹ records similar circular bodies on a Liassic Hungarian species. In no single instance have sporangia been found. Nathorst¹⁰ proposed the designation *Anthrophyopsis* (because of the resemblance of the lamina in form and venation to the leaves of the Fern

Anthrophyum) for some Rhaetic specimens from Scania, but as they were subsequently found to be segments of a pinnate frond he adopted the name *Ctenis*. An example in the Manchester Museum¹ (fig. 624) from Yorkshire, mentioned by Nathorst in

FIG. 624. *Ctenis* sp. Single pinna. (Manchester Museum, No. 53.)

FIG. 625. *Ctenis* sp. The epidermis of the pinna shown in fig. 624. A, surface-view; p, papillae; s, stomata. B, side-view. (Manchester Museum, No. 53.)

an early paper as probably a new species of *Anthrophyopsis*, afforded good preparations of the cuticle (fig. 625) which revealed the existence of circular elevations on the outer walls of the epidermal cells: these may explain the nature of some at least

¹ Seward (00) p 21; (00) B. p. 232, figs. 42, 43.

of the supposed sporangia. The walls of the epidermal cells are straight. The name *Ctenis* is applied to pinnate fronds which are probably Cycadean though we have no evidence as to the nature of the stem or the reproductive organs. *Ctenis* fronds are among the largest Cycadean leaves from Mesozoic floras; in *Ctenis hungarica* Staub the frond is said to have reached a length of 2 met. and in other species the dimensions exceed those of most pinnate leaves. The stout rachis bears linear or broad-oblong pinnae attached at a wide angle and varying considerably in size and shape; the pinnae are attached by the whole base which is usually broadened and decurrent but in a few cases slightly contracted (e.g. *C. Zeyschneri* Rac.¹). For some fronds bearing broad and basally narrowed segments Raciborski proposed the name *Ctenidiopsis* in distinction from *Eructenis* which he applies to the typical forms. The pinnae may be long and narrow reaching a length of over 12 cm., or short and broad: in some cases the frond would be more correctly described as deeply pinnatisect; the apex of the segments is acute, bluntly rounded or truncate. Several veins pass into the base of each pinna and pursue a course approximately parallel to the edge of the lamina; a characteristic feature is the occasional occurrence of oblique cross-connexions between the veins. It is possible that in some species the pinnae had spinous margins as in the pinnae of uncertain affinity figured by Fontaine² as *Encephalartopsis nervosa* from the Potomac series. Our knowledge of the epidermal cells is very meagre: in the specimen represented in fig. 625 the epidermal cells have straight walls and a central papilla. The genus extends from Triassic to Upper Jurassic rocks.

Ctenis lunzensis Stur.

This species, first recorded by Stur from the Lunz Upper Triassic flora, has recently been examined by Krasser³ and compared with the Jurassic species *Ctenis sulcicaulis* (Phill.) (= *C. falcata* Lind and Hutt.) and *C. Potocki* Rac. No figures or detailed descriptions have been published.

¹ Raciborski (94) A. Pl. XVI.

² Fontaine (89) B. p. 174, Pls. LXX.—LXXII.

³ Krasser (09) p. 113.

Ctenis fallax Nathorst.

This Scanian Rhaetic type¹, including *Anthrophyopsis crassinervis*, *A. Nilssoni*, and probably *A. obovata* Nath., is characterised by very large obtusely pointed pinnae reaching at least 20 cm. in length and over 3 cm. in breadth. The veins are often 2 mm. apart and form long polygonal meshes. Nathorst figures small circular patches on the surface of the lamina. Raciborski², on slender evidence, refers a fragment from the Jurassic of Cracow to this species.

Ctenis hungarica Staub.

A species³ characterised by very large fronds reaching 2 met., bearing broad linear pinnae almost at right-angles and attached to the rachis by decurrent bases, attaining a length of 21 cm. and a breadth at the base of the lamina of 3.5 cm. and 4 cm. a short distance from the acute apex. The veins are parallel to the edge of the lamina, but Staub does not appear to have seen distinct anastomoses. It is not improbable that Staub's species may be identical with *C. asplenoides* (Ett.) from the Lias of Hungary, specimens of which are preserved in the École des Mines, Paris.

Ctenis asplenoides (Ettingshausen).

This species was first described by Ettingshausen⁴ from Liassic strata in Austria as *Taeniopteris asplenoides* and compared by him to large simple fronds of *Asplenium nidus* but distinguished by a deeply dissected lamina. Schenk⁵ found that the veins anastomose and adopted the name *Ctenis*. In habit very similar to *C. sulcicaulis*, but the pinnae are much broader, exceeding 4 cm., and the veins are 3—5 mm. apart. Only the basal part of the segments is figured by Ettingshausen. Specimens in the École des Mines, Paris, from Hungary have pinnae nearly 40 cm. long and 2.5 cm. in breadth, the parallel veins being connected by a few oblique branches. Both Ettingshausen and Schenk speak of small circular sori on the lower epidermis, though these are not figured nor were any sporangia obtained. This species

³ Staub (96)

⁴ Ettingshausen (51) Pls. XI., XII.

⁵ Schenk (68²).

and other examples of large *Ctenis* fronds are described by Raciborski from Lower Jurassic rocks in Poland. He figures part of a leaf of *C. Zeyschneri*¹ 40 cm. long bearing alternate pinnae approximately 10 cm. long and nearly 4 cm. broad, characterised by obtuse apices, a decurrent lamina, and anastomosing veins closer together (16—24 per 1 cm.) than those of *C. aspleniooides*. In one Polish specimen, *C. remotinervis*², with pinnae 5 cm. broad the lamina is represented in the upper part of the frond as continuous over the face of the rachis, and—if the drawing is accurate—the frond in this respect differs from typical examples of *Ctenis* and agrees with *Nilssonia*. A species of *Ctenis* with broad pinnae is described by Yokoyama³ from the Jurassic of China as *C. Kaneharai*.

Ctenis sulcicaulis (Phillips).

This type⁴ is more familiar under the name *Ctenis falcata* given to it by Lindley⁵, but if we follow Lester Ward⁶ in strict observance of the rule of priority, a course from which I have frequently deviated on the ground of long usage, the less familiar designation must be adopted. Fronds pinnate; long and tapered linear pinnae sometimes exceeding 12 cm. in length and 1 cm. in breadth attached obliquely or almost at right-angles to a fairly broad rachis (fig. 626). The lamina is broadest at the base and the lower margin is strongly decurrent, tapering distally to an acute apex. The parallel and frequently anastomosing veins diverge slightly in the basal region of the pinnae. Though usually separate to the base, the laminae of adjacent pinnae may be continuous as in a pinnatisect leaf⁷. This species is recorded also from North America, and fronds of similar habit are figured by Fontaine⁸ from the Jurassic of Oregon as *Ctenis orovillensis*: a fragment recorded from Jurassic rocks in Afghanistan as *Ctenis* sp. may belong to *C. sulcicaulis*⁹.

⁹ Seward (12) Pl. III. fig. 43.

Ctenis latifolia (Brongniart).

This species¹, originally referred to *Taeniopteris*, was transferred to *Ctenis* as the result of the discovery of anastomosing veins in the type-specimen in the Oxford Museum. The segments are shorter and broader than in *C. sulcicaulis* and very similar to those of *C. orovillensis* Font.

FIG. 626. *Ctenis sulcicaulis*. (British Museum, V. 9012.)

Ctenis sp.

The pinna shown in fig. 624 from the Jurassic beds in Yorkshire² is interesting as one of the few examples of the preservation of the cuticular membrane. The straight or curved walls of the epidermal cells agree with those of recent Cycads except *Stangeria*, and each cell bears a large central papilla that gives to the lamina the finely punctate appearance which has been regarded as evidence of sporangia. The gaps in the cuticle probably mark the position of sunken stomata.

¹ Seward (04) B. p. 115.

² *Ibid.* (00) p. 21.

PSEUDOCTENIS. Seward.

This genus¹ was established for certain pinnate fronds agreeing in habit with *Ctenis sulcicaulis* but distinguished by the almost complete absence of any cross-connexions between the veins. Some of the forms with narrow pinnae closely resemble species of *Zamites*, the distinguishing feature being the decurrent lower margin of the leaflets. Though such fronds might not unreasonably be included in *Ctenis*, it is more convenient on the analogy of the occasional occurrence of *Glossopteris* fronds with very few anastomoses to employ a distinctive designation.

FIG. 627. *Pseudoctenis eathiensis*. (British Museum, No. V. 2744; $\frac{1}{2}$ nat. size.)

Pseudoctenis eathiensis (Richards).

Some of the specimens on which this species² is founded were originally figured by Miller³ from Upper Jurassic strata in Scotland and afterwards named by Richards⁴ *Zamites eathiensis*. The general appearance of the fronds is very like that of *Ctenis sulcicaulis*; the pinnae vary in breadth from about 3 mm. to 1.5 cm.; they are attached at right-angles or, in the apical region,

¹ Seward (11²) p. 691.

² *Ibid.* p. 792, Pls. IV., VII., VIII., X.

³ Miller (57) B. figs. 133, 135.

⁴ Richards (84) p. 117.

may be almost parallel to the rachis. The longest pinna recorded is 17 cm. and the lamina tapers to a slender apex; the veins are parallel and occasionally forked, but cross-connexions are rare. The partially petrified rachis of one specimen showed hypodermal stereome and some secretory canals as in recent Cycads. The specimen from Wealden rocks near Hastings (fig. 627), originally described as *Zamites* sp.¹, is probably specifically identical with *Pseudecten* *eathiensis*. The South African Wealden species, originally described by Tate as *Palaeozamia Rubidgei*², agrees closely with *Pseudecten* and is probably an example of that genus. This type bears a close resemblance in the form of the frond to *Ctenophyllum grandifolium* Font.³ and *C. Wardi*⁴ Font. from American Trias and Jurassic rocks respectively. *Pseudecten crassinervis* Sew.⁵ is another Scotch form with coarser veins.

A frond very similar in habit to *P. eathiensis* is represented by *Pseudecten ensiformis* Halle⁶ from the Jurassic strata of Graham Land originally referred by Nathorst to *Pterophyllum*. An examination of the type-specimen in the Stockholm Museum revealed its resemblance to the Scotch species *P. eathiensis*: a single anastomosis was noticed in one of the pinnae. The broadly ensiform obtuse pinnae, reaching a length of 7 cm. with a maximum breadth of 3 cm. at their expanded bases, vary in breadth and are attached at right-angles to a slender rachis. The veins, 1—1.5 mm. apart, are parallel and strong. The varying breadth of the pinnae irrespective of their position on the rachis is a distinctive feature. Halle draws attention to a resemblance of this Antarctic species to *Ctenophyllum latifolium* Font. a Potomac type referred by Berry⁷ to the genus *Ctenopsis* on the rather slender ground that the veins are arranged in pairs. Berry in a footnote expresses the opinion that *Ctenopsis* is very closely related to or possibly identical with *Pseudecten*.

If the bases of the pinnae in the specimen of *P. ensiformis* figured by Halle are complete, as they appear to be, the frond

¹ Seward (95) A. p. 89, fig. 5.

⁵ Seward (11²) Pls. IV., VII.

⁶ Halle (13²) p. 51, Pl. VI. fig. 8.

⁷ Berry (11) p. 349.

agrees very closely with *Pterophyllum Carterianum* Old. and Morr.¹ from India. A comparison of the Rajmahal specimen with Halle's figure leads me to regard the two fronds as probably identical. The veins in the Indian species, which should also be referred to *Pseudoctenis*, are prominent and from .5 to 1 mm. apart; the base of the lamina is slightly broadened and the veins curve downwards towards the rachis in the lower decurrent portion. The other Indian type, *Pterophyllum Morrisianum*², with which Halle compares his species is, however, not a *Pseudoctenis* but should be included in *Nilssonia* and is probably identical with *Pterophyllum princeps* Old. and Morr.

Pseudoctenis Lanei Thomas.

This species³, recently described from Middle Jurassic beds at Marske, Yorkshire, has narrower linear lanceolate pinnae. The linear pinnae reach a length of 10 cm. and a breadth of 9 mm. The veins are numerous, 10 in a breadth of 6 mm., and only one cross-vein was noticed. In the decurrent lower edge of the laminae the fronds are identical with *Ctenis sulcicaulis*. A very good example of this species⁴ in the York Museum is reproduced by Mr Thomas in his account of Cleveland Jurassic plants.

Pseudoctenis Balli (Feistmantel).

A species described originally by Feistmantel⁵ as *Anomozamites Balli* from the Barakar group of the Damuda series and afterwards transferred to the genus *Platypterygium*, characterised by broadly linear segments of unequal breadth attached obliquely or at right-angles to a slender rachis. The apices of the segments though usually imperfect appear to be truncate; the bases of the pinnae are decurrent by their lower edge. The veins are approximately 3 per millimetre; they are generally forked at the base and in one or two places show cross-connexions. In the middle of the frond the narrow rachis is exposed but in the apical region it is covered by the laminae. The occurrence of two divergent pinnae at the apex of the frond is a feature met

with also in *Otenis sulcicaulis*. This description is based on an examination of the specimens figured by Feistmantel.

III. CYCADEAN FRONDS WHICH CANNOT BE ASSIGNED TO A FAMILY-POSITION.

SPHENOZAMITES. Brongniart.

This name was proposed by Brongniart¹ as a subgenus of *Otozamites* denoting pinnate fronds bearing leaflets without an auriculate base: he suggested that the subgenus might eventually be raised to generic rank and this was done by Zigno² though in too wide a sense. In the case of *Otozamites Beani* (Lind. and Hutt.), quoted by Brongniart in illustration of *Sphenozamites*, the latter designation is inapplicable as the pinnae are auriculate. Another species, *Zamites undulatus* Sternb., to which Brongniart applied his new subgeneric term, is probably identical with *Otozamites acuminatus* (L. and H.)³.

Although the distinction between *Sphenozamites* and *Otozamites* is often ill defined the former name may be conveniently adopted for pinnate fronds similar to those of *Zamia Skinneri* and some species of *Encephalartos* characterised by leaflets of an asymmetrical, obovate, or rhomboidal form with a contracted or cuneate base and numerous branched divergent veins. Nothing is known of the structure or reproductive organs of *Sphenozamites*, and the genus, though serving a useful descriptive purpose, is founded solely on form, and in the absence of other data it would be rash to assume that its use implies close natural affinity. In the case of many other genera of Cycadean fronds there is additional evidence of relationship, but this is not the case with *Sphenozamites*. The pinnae resemble those of such recent Cycadean fronds as *Zamia Skinneri* and *Z. muricata*. The genus ranges from Lower Permian to Jurassic rocks.

Sphenozamites Rochei Renault.

This species⁴, from the Lower Permian of the Autun district, is founded on a pinnate frond bearing alternate pinnae, 2.5 × 1 cm., with an asymmetrical oblong lamina attached obliquely near

¹ Brongniart (49) A. p. 61.

² Zigno (85) p. 105.

³ Seward (00) B. p. 215.

⁴ Renault (96) A. p. 327; (93) A. Pl. LXXXI. fig. 1.

the edge of the rachis with a cuneate base slightly decurrent below and a broadly rounded apex; the veins dichotomise once or twice as they diverge from the narrow base (fig. 628). The pinnae resemble the leaflets of *Noeggerathia foliosa* Sternb. and are similar in shape to those of the Jurassic species *Sphenozamites Geylerianus* Zig.

Sphenozamites Belli Seward.

This Middle Jurassic species from Stonesfield¹ is founded on detached pinnae possibly identical with a specimen figured by Buckman as ?*Naiadea obtusa*². The pinnae are wedge-shaped, tapering gradually to an acute apex and attached by a narrow base: the leaflet shown in fig. 629 is 9 cm. long; the veins are numerous and more divergent than in some leaves of similar form referred to the genus *Podozamites*. With this species may

FIG. 628. *Sphenozamites Rochei*.
(After Renault; nat. size.)

FIG. 629. *Sphenozamites Belli*. (Oxford Museum; nat. size.)

be compared several Italian Jurassic specimens described by Zigno³ as four distinct species but more appropriately assigned to a single type *S. Geylerianus*. An examination of Zigno's fronds in the Padua Museum, which he named *S. Rossii*, leads

¹ Seward (04) B. p. 119, Pl. XI. fig. 4, text-fig. 12.

² Buckman (45) Pl. I. fig. 2.

³ Zigno (85) Pls. XXXIX., XL.

me to regard the irregularly serrate edge of the pinnae as the result of tearing of an originally entire lamina and to compare the specimens with *Otozamites Beani* (L. and H.). An imperfect ovoid pinna recalling *S. Belli* is figured by Newberry from the Rhaetic of Honduras as *Sphenozamites robustus*¹. A French Upper Jurassic species figured by Saporta as *Sphenozamites latifolius* bears a very close resemblance in the form of the leaflets to the Wealden plant *Sewardia latifolia*². Kurtz records the occurrence of *Sphenozamites*, *S. Geinitzianus*, from Rhaetic strata in Argentina³, but I have not seen any figures of this species.

PLAGIOZAMITES. Zeiller.

The name *Plagiozamites* was proposed by Zeiller⁴ for some pinnate fronds and detached leaflets from the Stephanian of Commeny and the Lower Permian of the Vosges. The better preservation of the Vosges material enabled him to recognise certain features which led to the substitution of *Plagiozamites* for *Zamites*, the name originally employed by Renault for the Commeny specimens. *Plagiozamites* bears a superficial resemblance to *Zamites* and *Otozamites* and differs but little from *Sphenozamites* and *Noeggerathia*; it stands for pinnate fronds bearing ovate pinnae with a sub-amplexicaul oblique attachment to the rachis as is clearly shown in the species *P. Planchardi* (Ren.)⁵. In the case of Palaeozoic fronds assigned to the Cycadophyta on the ground of the resemblance of their pinnae to those of undoubted Cycadean species, it is particularly important to recognise the fact that decisive evidence as to systematic position is lacking. We know nothing of the stem, the reproductive organs, or the epidermal and stomatal characters of *Plagiozamites*, and it is by no means certain that the genus is a true representative of the group in which it is provisionally included.

Plagiozamites Planchardi (Renault).

Fronds pinnate; pinnae ovate-lanceolate reaching 5 cm. in length and 1.6 cm. in breadth, inserted obliquely on the rachis,

¹ Newberry (88) Pl. VIII. fig. 14.

² See vol. IV.

⁴ Zeiller (94) B. p. 174, Pls. VIII., IX.

⁵ Renault and Zeiller (88) A. p. 614, Pl. LXVII. fig. 8.

³ Bodenbender (02) p. 40 of the reprint.

but not along a line parallel to the long axis of the rachis as in *Zamites*, and partially embracing it: the edge of the lamina is finely denticulate; veins slightly divergent and occasionally branched. The leaflets are narrow and more acute than those of *Noeggerathia* and *Sphenozamites Rochei* Ren. *Plagiozamites* is recorded from the Stephanian of Commeny, the Coal Measures of Manchuria¹, and the Lower Permian of the Vosges. Renault described six species of *Zamites* from Commeny all, except *Z. carbonarius*, based on detached pinnae. The type-specimen of *Z. carbonarius* consists of a piece of stout rachis bearing ovate acute pinnae, 2.2 × 1 cm. Potonié², who refers a piece of pinnate frond from the Permian of Thuringia to *Z. carbonarius*, includes the other species of Renault under that name. Whether or not the differences in the venation and form of the pinnae are of specific significance cannot be definitely settled without better material, but the important point is that these Permo-Carboniferous fronds are sufficiently distinct from *Zamites* to be placed in a separate genus. *Plagiozamites carbonarius* is recorded also by Zalessky³ from the Permian of Manchuria though the examples figured do not afford satisfactory evidence of the mode of insertion of the segments on the rachis. *P. Planchardi* has recently been recorded from the Coal Measures of Maryland; the discovery is interesting both on phytogeographical grounds and as the first satisfactory record of a Palaeozoic Cycadophyte from North America⁴.

Cycadorachis. Saporta.

The employment of this generic name may serve a useful purpose if used for specimens, whether preserved as petrifications or impressions, believed to be portions of Cycadean frond-axes, but which in the absence of pinnae cannot be assigned to one of the recognised genera of fronds. Saporta⁵ describes two species from Kimmeridgian beds in France, *Cycadorachis abscissa* and *C. armata*: the first may be the winged base of a Cycadean petiole, but it agrees equally well with the broad base of an Osmundaceous

¹ Zalessky (05²) p. 401, fig. 13.

² Potonié (93) A. p. 210, Pl. xxix. fig. 5.

³ Zalessky (05²) p. 403, figs. 14, 15.

⁴ Bassler (16).

⁵ Saporta (75) A. p. 193, Pl. 114, fig. 3; Pl. 117, fig. 1.

leaf and should not be referred to a genus implying affinity with a particular class. The other species, *C. armata*, is probably a piece of a spinous axis like that of the Wealden plant *Sewardia latifolia* (Sap.). A fragment figured by Fliche and Bleicher¹ from the Jurassic of Nancy as *C. tuberculata* is another example of a fossil which cannot be referred with any certainty to the Cycads.

Dr Stopes², inadvertently overlooking the previous institution of *Cycadorachis*, has recently proposed the name *Cycadeorachis* for pinnately branched rachises of Cycadeanfronds which, 'while indicating the general character of the frond, do not show the shape of the pinnae well enough to be associated with any of the many foliage-genera.'

¹ Fliche and Bleicher (82) p. 21, fig. 4.

² Stopes (15) p. 53.

LIST OF WORKS REFERRED TO IN THE TEXT
(VOLUMES III. AND IV.)

[With a few exceptions this list does not include books and papers
given in the Bibliographies in volumes I. and II.]

The following are some of the Bibliographies which students will find useful for additional references:—Geological Literature added to the Geological Society's Library, published from time to time by the Society; Prof. Zeiller's lists in the 'Revue Générale de Botanique' (Paris); lists given by Arber in the 'Progressus Rei Botanicae' (Leiden), vol. i. Heft i. p. 218, 1907; Jongman's 'Die Palaeobotanische Literatur' (Jena), 1910-13; also the International Catalogue of Scientific Literature (Botany and Geology). For the Literature dealing with Cretaceous plants the student should refer to Dr Marie Stopes' 'Cretaceous Flora' I. and II. (British Museum Catalogues, 1913, 1915).

The dates of books published in parts given in the footnotes to this volume are as a rule those of the concluding part. For the dates of separate parts of books relating to Palaeozoic floras the student is referred to Prof. Zeiller's valuable list at the end of the 'Flore Fossile du Bassin Houiller de Valenciennes.' Useful bibliographies of the writings of Saporta, Heer, and Ettingshausen have been compiled by Zeiller (96), Malloizel and Zeiller (N.D.), and Krasser (97).
