Midwife education has been completely neglected by the teachers in the medical colleges of the country and there is no generally accessible data concerning them. The reports of the Commissioner of Education contain no information about midwife schools, although nearly every other branch of education has been made the subject of investigation and the subject of training schools for nurses is quite fully considered. The Commissioner of Education replied to an inquiry of mine, that there was no information in the possession of the department. Until recently the subject has been quite outside of the notice of the State boards of health. Recently the boards of health of a few States have made certain requirements of midwife schools, as to length of term, teaching facilities, etc., as requisites to recognition. Both Illinois and Missouri demand that a midwife school shall require a student to attend two terms of five months each. They also have an examination of all midwives before giving them licenses to practice. Ohio has a law requiring the State Board of Examiners to examine and license midwives. Formerly, however, there was no control of the schools, a condition that still obtains in many States; the result was that an utterly irresponsible midwife or an unknown or disreputable physician was able to establish a midwife school for the sake of the fees and for the illegal and immoral business that would come from such a source. Of course such a school has no teaching facilities and little or no clinical material. I know of poor women who could with the greatest difficulty raise the required fees, going to such a swindling institution, taking the so-called course, and graduating without having seen a single case of labor. It is not necessary to go into further detail to show that these so-called midwife schools were very often frauds of the worst description.

In importance second only to a good education of midwives, is an efficient system of midwife control or regulation. Without it the best trained midwives are liable to degenerate in their practice and overstep the balance of their legitimate work. With it much may be done to insure the community against the dangers to which it is exposed from poorly trained midwives. The general and almost complete neglect, in America, of a system of midwife recognition, has led to the following results: Inefficiency in the details of their legitimate obstetric practice, especially in the line of asepsis, with a consequent excessively large rate of puerperal infection; assumption of the management of abnormal labors; assumption of medical and surgical practice quite outside of obstetrics, and the illegal and immoral practice of the induction of abortion.

The failures of midwives in asepsis are due both to imperfect teaching and to lack of control of their legitimate practice. The dangers from this source are well illustrated by a study of the mortality records of Chicago. In a paper presented to the Chicago Gynecological Society last year, I gave the results of a study of the mortality from puerperal infection in Chicago for the last forty years. In these tables I have obtained the average annual mortality rate from puerperal infection for the decennial periods 1866 to 1875, 1876 to 1885 and 1886 to 1895. In the first period there were one hundred and twenty-seven deaths from puerperal infection for every 1,000 deaths from all causes of women of childbearing age, namely, women from 15 to 45 years old. In the second decennial period there were ninety-seven deaths and in the last period seventy-three deaths. The rate based on the number of confinements shows about the same rate of decline. In the three periods, for every 1,000 confinements the rate was 7.6, 5.5 and 4.1 respectively. These figures show indeed a decline, and so far are encouraging. The decline corresponds in time to the spread of the teachings of Lister, and is no doubt due to the excellent teaching of asepsis and antisepsis in our medical schools. The fact remains, however, that the mortality rate from puerperal infection is still very much too high, and indeed has increased during the last four years. In 1891 it was sixty-two per 1,000 deaths of women of childbearing age; in 1892 it was sixty per 1,000; in 1893, sixty-five per 1,000; in 1894, seventy-one per 1,000; and in 1895, sixty-nine per 1,000. In other words, puerperal infection still kills more women in the prime of life, women of the greatest worth to their families and to the state, than any other cause except consumption. While it is impossible, from the imperfect records of the registrar's office, to say whether physicians or midwives are responsible for this large continuing mortality, it seems very certain that the improvement for the last decades is due to the better training of medical students, and that the bad results of the last few years are largely due to midwife practice which has not made corresponding advance.

The management of abnormal labor is everywhere recognized as outside the scope of the legitimate work of midwives. It demands not only a trained technic, but a careful study of indications and conditions which is only possible to one trained in all branches of medicine and surgery. How can a woman of limited education, in a course of study of four to six months, learn to appreciate the indications for operative interference, to say nothing of the technic of difficult and

dangerous operations? The most she can do is to learn the progress of normal labor and to recognize such deviations therefrom as to require her to call for assistance. Yet in the absence of control, midwives have come to assume their right and ability to do the most important and dangerous operations. They often oppose the calling of physicians for assistance, and with an amazing audacity and a lack of comprehension of their responsibility, assume the gravest risks with greatest indifference. Among many interesting instances now being collected by the health department of Chicago, I may cite one which illustrates this statement. One of the confident domineering midwives had a case of primipara in whom she considered forceps indicated. With the help of the husband to give chloroform, she attempted the extraction of the child, but after a somewhat lengthy struggle with the half anesthetized woman was compelled to desist. The husband then wished to send for a physician, but was opposed by the midwife, who at last, to carry out her will, locked the door of the room and put the key in her pocket to prevent the exit of the husband. The poor man was then compelled to assist again in the anesthesia until, after two hours of fruitless struggle, the midwife relented and allowed the husband to call a physician. A serious puerperal infection afterward developed, which ended fatally. Such cases might be many times multiplied, were it necessary to further illustrate the dangers of uncontrolled medical practice.

The assumption by midwives of medical and surgical practice is not uncommon. Not long since I saw a young girl with an ulcer on the knee, three by six inches, which under the care of a midwife had gradually reached these dimensions from a very small sore. The assurance of midwives in treating such cases is another proof of the necessity of controlling them.

The practice of abortion has become a very great evil, largely as a result of a lack of midwife control. Its prevalence is so generally known to all physicians that it is only necessary to refer to the fact; the amount of disease that results therefrom is also universally recognized. The number of deaths that results from this cause is a not unimportant element of puerperal mortality. Some of these cases in Chicago were the immediate cause of the movement which led to the establishment of the system of midwife regulation that now prevails. Dr. Reilly, the assistant health commissioner and the originator of the movement, in the monthly report of the health department for June, 1896, calls attention to the fact that a recent brief search of the coroner's office shows thirty-four deaths due to the criminal practice of midwives. The details of many of these cases were simply sickening. In one case, a midwife admitted in the criminal court that she had used the catheter found on postmortem pushed through the uterus and lying in a bed of pus in the omentum. The fact that in this case as well as in all others the midwife escaped punishment, showed that our criminal laws are powerless to remedy the evil. An efficient control of midwife practice may be expected to prevent such a condition, since in those countries where midwife regulation prevails, such cases are altogether wanting or extremely rare.

In other countries the great difficulties that may arise in securing midwife regulation by law are illustrated by the futile attempts made in England to secure the passage of the Midwife Registration Bill. Here we may often secure, through the boards of

health, quite as important results as are obtained by laws. The comparative ease with which similar regulations may be obtained in this country through the powers of the boards of health is illustrated by the history of the midwife regulation rules of Chicago. The city health department obtained permission from the Illinois State Board of Health to formulate rules governing midwives which, on approval by the State Board, should have the force and effect of the State Board's rules. Under this permission the rules were framed which were approved by the State Board July 9, 1896. These rules, twelve in number, follow in general the lines of the Austrian regulations. Rule 1 defines midwives to be only those authorized to practice midwifery by the State Board of Illinois. Rule 2 provides that all midwives must register with the medical inspector of midwives in Chicago. Rule 3 provides that midwives shall attend only cases of natural labor, which is defined to be cases of head presentation at term, where no specified abnormal condition is found. It is also provided that in cases of unnatural labor a physician must be called, and if the patient be too poor to pay a physician, a department obstetrician shall be called. Rule 4 enumerates the abnormal cases where a physician must be called. Rule 5 specifies the general duties of a midwife to the patient as respects her visits, nursing, etc. Rule 6 forbids a midwife to come in contact with cases of contagious disease or attend a case of puerperal fever. Rule 7 gives details for preventing puerperal fever. Rule 8 forbids a midwife having medicines or instruments for operations. Rule 9 provides for keeping a case-book. Rule 10 provides for reporting births. Rule 11 concerns the management of the apparently dead-born. Rule 12 concerns the confidences of patients.

For the purpose of assisting in the execution of these rules, the obstetric staff of the help department was organized, consisting of seven honorary consultants, fifty-one department obstetricians and three pediatricians. Each obstetrician has charge of a district. The most eminent men in the city consented to serve on the staff without pay. The duties of the staff are to attend cases when called on by the midwives, to inspect her book and outfit and in general to help in carrying out the regulations. The staff perfected its organization by electing officers and arranging for regular bi-monthly meetings. In the meetings thus far held the subject of the prevention and treatment of puerperal infection has been especially discussed as well as the reports of cases by the registrar.

It is still too early to say much of the results obtained. The Board has been organized only about seven months and it has been the policy of the department to go slow and consider carefully the difficulties to be met rather than to arouse much opposition. A fairly complete registration of midwives has been obtained and sent to the various district obstetricians. The midwives are keeping their books fairly well. The department obstetricians have assisted in a number of pathologic cases to which they have been called by the midwives; they have also investigated a number of cases of deaths from puerperal fever with the result in some cases of thoroughly impressing the offending midwife with new ideas of their responsibility. The punitive part of the regulations is still in doubt, as no test case has yet been made, in the courts, of the legality of the rules. We believe that

the revocation of licenses by the State Board will be sufficient to accomplish all the ends aimed at.

The foregoing description of the condition of the midwife class in America suggests the needs of the future:

1. It may be reaffirmed that the midwives are needed. There is a demand for them that is not filled in any other way. There is a large class of people who can not afford to employ a doctor, even if they could obtain his services for a very low fee, for they would still be in need of a nurse. The lying-in dispensaries are not equivalent, for the patients are not paupers who demand gratuitous services and they will not allow themselves to be used as clinical material. Moreover, the prospects of the future show no hope for a decrease in the number of the poorer classes who must depend on midwives, but a study of the social condition makes it probable that their numbers must greatly increase.

2. There is a need for a general and efficient regulation of midwife practice and midwife education. This can best be secured by the State boards of health if they are supported by the physicians of the State. The attacks recently made on the health departments can be efficiently met by organization, and the need of thorough local organization to support the State medical boards is becoming generally recognized.

The need of efficient medical education is so apparent, although heretofore so strangely neglected, that it needs no discussion. It should be of such a character as to enable a woman of average intelligence and a common school education to perform the legitimate functions of a midwife, that is, to conduct a normal labor safely and care for the puerpera and child. Such an education can be given in the course of ten months by a school that has proper teaching and clinical facilities. In this connection, I take the opportunity to suggest that a midwife school can be carried on best in conjunction with a medical college. A college has the facilities for teaching anatomy, physiology, mechanism of labor, asepsis, etc., by means of preparations, manikins, charts and laboratories, and its clinical material can be utilized by the midwife students without detriment to the medical students. Indeed, I believe that the clinical teaching of midwife students, which consists very largely in a drill in obstetric nursing in conjunction with medical students, will be very valuable to the former in showing them their especial function, and to both in indicating and establishing their popular relations. The midwife will come to regard the physician not as her enemy but as her counsellor and helper in difficulties, and the physician will learn to appreciate and respect the properly qualified midwife.

In conclusion I will say that in planning a new system of midwife education and regulation we should take account of the history of the midwife class in Europe, recognize its bad features and the causes that have produced them, and avoid the mistakes that have been made in dealing with them. I believe that Professor Fritsch is right in ascribing, as a very important cause of the unsatisfactory condition of the midwife class in Germany, the poor material from which it is recruited, but that he does not go to the root of the matter when he proposes his remedies. He suggests as a remedy, the attraction of students from a better class of the community by making the condition and work of the midwife students less repulsive

and allowing them to study in all obstetric hospitals, not confining them to the midwife schools. It seems to me that Dr. Dietrich, formerly of Liebenswuerda, has a much more efficient plan in his restriction of the number of midwives and providing for a fair living compensation for each. He divided Liebenswuerda into a number of districts, each having a fair number of births annually for one midwife to attend. In a district only one midwife is allowed, who is chosen in such a way as to provide against favoritism and secure only a competent and responsible woman. She must keep an account book in which is recorded all her income from patients. A minimum charge is established which she must hold to. In case her income at the end of the year falls below a certain amount the State must make up to her the balance. By this plan a woman is insured a fair living if, by proper training, skill and faithfulness, she proves herself a good midwife. It would hardly need the test of experience to convince one that this plan will attract a much better class of women to study midwifery and secure a much higher average of midwives. While such a scheme may sound quite utopian or revolutionary when proposed for adoption in democratic America, where free competition and the widest individualism holds sway in theory, yet the history of our trade unions on one side and the protective organization of capital in trusts, etc., on the other, shows that at least the voluntary limit of competition may prove very efficient. I suggest that those who have at heart not the improvement of a class for its own benefit, but through this improvement the betterment of a greater mass of society, should not neglect to study the question thoroughly and fearlessly.

DISCUSSION.

Dr. E. H. M. SELL of New York—Dr. Bacon does not propose to have such a class of midwives as has been referred to, believing that they are uncalled for. I agree with him that not even in the darkest corner of this widespread country is such a class of midwives called for. We should endeavor to get rid of this uneducated class, and if we are to have midwives they should be properly educated.

Allow me to say a few words regarding what I have seen in European cities, as I have spent considerable time abroad. The midwives of Vienna have to pass an examination in regard to their general education first; then they have to pursue a thorough course of instruction under one of the best obstetricians, and after a thorough examination they get their certificates to practice. After passing this examination in midwifery they are only permitted to accept normal cases and are obliged to call in assistance in every abnormal case, or else have it transferred to the hospital. While there is room for the educated midwife in some of our large cities, among the poorer classes, there is no room for such midwives as we have in New York, and I presume you have them here (Philadelphia) and in other cities. I was once called in consultation by a physician, and what did I find? I found a midwife pulling and pulling, trying to deliver the child. What the presentation was originally I could not say. It was transverse, the arm out of the vagina, and it was a wonder to me that it was not pulled out of its socket. The woman was exhausted. I proposed to perform the only operation, namely, decapitation and deliver, and I told them it was necessary to get the woman into the hospital at once or else she would die undelivered.

Dr. JOHN M. DUFF of Pittsburg—I have seen the evils of midwifery as other practitioners have, but we have to take the conditions as they are, and I can not see how we can avoid having midwives to practice. One of the great evils is that they reach beyond the line: they invade the field of practice in other directions. But with the present condition in this State, where they are not licensed to practice, they practice clandestinely, notwithstanding the fact that we might wish them out of the way altogether. As a medical body, we should encourage the education and licensing of them, so that they will not practice clandestinely and therefore do a great deal of harm which they would not otherwise do. Of the two evils we should choose the lesser. If clandestine midwives were compelled to leave

the field it would be a godsend. When properly educated they will take care of the clandestine ones; they will see that they are brought before courts of justice for invading other fields. But it is astonishing how many abortions are being produced by these same women. Within three months I traced a number of abortions, I have forgotten the exact number, but I believe it was in the teens, to one midwife in my neighborhood. In the position we are in today the wisest thing for us to do is to make the best of the matter and secure the best possible material we can.

Dr. RACHEL BENN of Philadelphia—I believe that we have no use for midwives in America; that we have too many physicians who can do this work properly, and the midwife need not be recognized by the profession. Another point is, How can we tell when pregnancy is going to terminate in a normal birth? In a case of postpartum hemorrhage after a normal birth, the midwife would hardly know what to do. It seems to me accidents during childbirth are sometimes so serious that we should have the services of skilful physicians, who ought to be allowed to take charge of obstetric cases. I have been working in China, where midwives originated. There are no physicians there, that is, real physicians, but there are those who call themselves such, and these are not allowed to attend women, and it is here that midwives flourish. They are not educated.

Dr. JAMES F. BALDWIN of Columbus, Ohio—I think there is a field in this country for the educated midwife. I know of no work which the doctor does that requires as much time, which interferes so much with his other work and for which he is so poorly remunerated, as his obstetric work, and that too in well-to-do families. In this country we have comparatively few of the very poor, as they have in Germany, and these must go to hospitals or be treated by charity physicians. We have a large class, which is increasing in number, who are too poor to pay a physician even a moderate fee for his services, and are unable to pay a nurse. The physician in these cases must go unpaid; there is perhaps no nurse, and the woman is left to the mercy of some neighboring woman to assist her in the interval. The midwife in my city is in the habit of attending a woman in her confinement and visiting her daily for a week or ten days thereafter, looking after the mother and washing and dressing the child. This is a labor which the doctor should not perform. In country districts or communities this work is done perhaps five or ten miles from the physician. The physician in some of these cases may be obliged to remain ten or twenty-four hours to attend to a patient, and as he has other patients to attend to he can not afford to go this distance to attend a case of this sort. We should have educated midwives to take care of these cases of normal labor. The truth is that formerly our midwives were not educated, and almost without exception they were dirty. A year or so ago I traced three cases of death to a single midwife. I reported the matter to the health officer and succeeded in suppressing her. When our State law went into effect, requiring the examination and registration of midwives, we hoped something would be done. But the examination was little better than a farce. Acting on suggestions from physicians and others, in connection with the Ohio Medical University, we started a department of midwifery, requiring an attendance of two years of six months each. We intended to give instruction not only in midwifery, but instruction as regards the anatomy of the pelvis, the physiology of menstruation, gestation, etc., and perhaps a little in regard to the therapeutics of the most commonly used drugs, and teach them that ergot should not be used under any circumstances. We advertised the matter in our annual circular, which went to about twenty thousand physicians. We thought the action of the State Board of Health would aid the matter a little, but I am sorry to say that we did not get a single application for midwifery. After trying this for one year the matter was discontinued by a vote of the faculty at its annual meeting at the close of the year. We must look to the State Board of Examiners and Registration for the enforcement of such rigid requirements, compelling midwives to have a sufficient amount of education to do fair work. I do not see why the midwife should not be educated so as to look after cases of postpartum hemorrhage.

Dr. T. M. BURNS of Denver—I believe there are only two reasons for midwives, and these are a small fee and because some women would rather have women than men to attend them. Both of these can be done away with. We have plenty of female physicians, and we have a large number of dispensaries. I think the solution of the midwifery question will be done by the dispensary. In New York City, at present, one dispensary has handled seventeen hundred cases in one district, and it is only a short time when the midwife there will be a thing of the past. One of the speakers said that the

physician could not make daily calls in the country districts on account of the distance. In the more important cities we have charity nurses to make calls daily, taking care of the patients.

Dr. HENRY P. NEWMAN of Chicago—We are greatly indebted to Dr. Bacon for this contribution, for he is one of the co-workers in this work, in that he has organized the method he has given you here to-day; and we are still further indebted to him for having carried it to a greater perfection, and I think we all acknowledge the good which will come from it in time. The midwifery evil is one which we have to contend with, and according to some of the suggestions that the doctor has enunciated, he has solved the problem to a certain extent.

What the last speaker said in regard to cities will apply to a certain extent, but there are districts which can not be reached even by the charity nurse. Outside of cities we have very few of them; neither have we women physicians, particularly among the foreign element, and I am afraid we will have this to contend with for all time. However, I believe it can be met in the manner referred to and judiciously disposed of, if others will take the interest in it that Dr. Bacon has, and use means for supervision.

Dr. BACON, closing the discussion—In reply to the remarks made by Dr. Burns, with reference to establishing a charity for confining poor women, it seems to me an unwise proposition from a social standpoint, and if it were practicable, it would not work well. The patients who employ midwives are not paupers, and should not be made so. They should not receive the attention of dispensaries and charity nurses. We all know that the dispensary is to a certain extent abused. Let us not carry that so as to make a very large part of society paupers. The fact is that from two-fifths to three-fourths of the labors in some of our large cities are attended by midwives. Is it possible that there is no demand for midwives when such a state of affairs exists? They must be recognized and the condition met in a manner not to pauperize such a large number of women.

THE TREATMENT OF CIRCUMSCRIBED PELVIC HEMORRHAGE.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY M. ROSENWASSER, M.D.

CLEVELAND, OHIO.

When fluid blood escapes into the normal pelvic cavity it can not be palpated, because it forms no distinct resisting mass. The hemorrhage is *free* and unlimited.

If the patient survive, the blood soon coagulates; the clots gravitate to the lowest part of the pelvis; the dependent intestinal loops are floated up above the clot, and all other pelvic viscera are displaced in the direction of least resistance. The unabsorbed blood serum, together with the lymph poured out by the surrounding peritoneal surfaces, covers the blood clot, fills the interstices between the intestinal coils, fills the gaps between the displaced viscera and, becoming organized, constitutes a false membrane of varying thickness, which more or less effectually shuts off the blood mass from the rest of the peritoneal cavity. This blood mass together with whatever debris may be enclosed within, can be readily palpated both externally and internally. The longer the lapse of time between the hemorrhage and the examination, the more distinctly palpable is the mass.

The mass can be palpated earlier when the hemorrhage takes place between the layers of the broad ligament, or into a space formed by pre-existing adhesions, because the blood is surrounded by a limiting resistant wall.

Whenever the symptoms warrant a diagnosis of intrapelvic hemorrhage, and there is present a peculiarly resilient, immovable, fairly defined mass, the case is one of *circumscribed* hemorrhage.

Free hemorrhage is always intraperitoneal. Cir-

circumscribed hemorrhage is practically extraperitoneal, because the false membrane or the layers of the broad ligament shut off the mass from the rest of the peritoneal cavity.

Rupture of the false membrane or broad ligament may convert a circumscribed into a free hemorrhage. Both forms of hemorrhage would then be present at the same time.

When seen a few days or weeks after its occurrence the most astute clinician can not say whether a hemorrhage was originally intra- or extraperitoneal, whether hematocele or hematoma. But he can positively say whether it is a case of circumscribed hemorrhage. The graduate fresh from the class-room will find no difficulty in distinguishing circumscribed hemorrhage from free hemorrhage, no matter what the pathology may be.

To avoid confusion and to cut loose from misleading terms, such as pelvic hematoma, pelvic hematocele, extra- and intraperitoneal hematocele, the suggestion has been made and is now repeated, to distinguish but two forms of pelvic hemorrhage in plain, unmistakable terms: namely, *free* and *circumscribed* hemorrhage.

Pelvic hemorrhage may be due to injury, to rupture of diseased or dilated blood vessels, to reflux of menstrual blood, to rupture or perforation of a viscus, or of a tumor; but in most instances the cause is either tubal abortion or ruptured ectopic pregnancy.

It is all but universally conceded that abdominal section for early removal of tubal gestation is safer and more rational than the use of electricity or the injection of morphin.

No one today questions the propriety of opening the abdomen to check free hemorrhage, if the symptoms warrant even the suspicion of such an accident.

But the cases which we are called upon to see early, whether before tubal rupture, or soon after hemorrhage has set in, comprise but a small proportion, not more than one-fourth, of all cases of pelvic hemorrhage. The bulk of these cases are seen days, often weeks after the initial symptoms. Many are not recognized, and many more are not brought to our notice because the symptoms had not been severe and recovery has taken place. They are seen by us as circumscribed pelvic hemorrhage.

The encysted blood from ruptured vessels or from tubal reflux, when not infected, nor in quantity too large for absorption, will disappear in a few weeks to a few months without detriment to the patient. The only treatment necessary is absolute rest.

The same is true in the majority of cases of circumscribed hemorrhage due to ectopic gestation; not only the blood clot, but even the early product of conception (two to three months), are capable of absorption.

Not more than 40 per cent. of cases of circumscribed hemorrhage due to ectopic gestation require active surgical interference.

I have seen in my own practice forty-six typical cases of hemorrhage due to extra-uterine pregnancy. Of these, eleven were of the free variety requiring emergency operations, and thirty-five were cases of circumscribed hemorrhage. Of the latter variety twenty-three have been previously tabulated,¹ and the remaining twelve are herewith submitted in similar form.

When called to a case of this kind, unless there is

a distinct indication for immediate operation, I order absolute rest under reliable supervision—so-called *vigilant delay*. This close supervision must be in the hospital whenever practicable, or at the home of the patient in charge of a competent attendant. While this precaution for the safety of the patient has been insisted on in every instance, I have not in a single case of the thirty-five so treated been flurried, or compelled to do an emergency operation. When an indication arose forbidding further delay, there was always ample time for deliberate action.

Two cases are submitted in detail to bear out these statements:

Case 1.—Dr. D. S. Hanson requested me to see Mrs. A. S. on Feb. 22, 1895. She was 30 years old, had been married six years and had had three children. The last was one year old and still at the breast. The mother's previous health had been excellent. She had menstruated for the first time since the birth of the child on January 15, the flow being scant and lasting only two days. Two weeks later she began flowing and has continued since. There have been no clots, but shreds of membrane. She has had three attacks of sharp pain within the past week, resembling the attack of today, though not so severe. While sitting, holding the baby on her lap, she was taken suddenly with a severe chilly sensation, accompanied by intense, agonizing pain in the abdomen, and became faint. She was carried to bed. Dr. Hanson found her looking blanched, as if internally bleeding, with small pulse, impressing him as if she was a very sick woman. At the hour of consultation the patient had rallied. Her pulse was 96, her temperature 100 degrees. The pain had been relieved by morphin. A large globular, elastic, somewhat tender mass filled the right side of the pelvis and the Douglas *cul-de-sac*. The cervix was pushed forward against the symphysis. The abdomen was slightly distended, but not tender. Her pendulous, fat abdominal wall made me shrink from attempting immediate operation. Supervision was advised. Though prepared to hear from the patient at any time, I did not see her again until April 8, six weeks later. Dr. H. reports that during this interval she had had an occasional rise of temperature (not over 100 degrees): that the flowing had stopped for a week, to return again, first a dark blood with clots and shreds and since April 4 a red fluid blood. After the first week of her sickness he had seen her at intervals of a few days, now he saw her for the first time in a week. Her temperature is normal, pulse 100. She has no pain, good appetite and sleep and would like to get up. The cervix is still slightly forward, though easily reached. The enlarged uterus is plainly outlined against the globular tumor in the *cul-de-sac*. The tumor is of the size of a small cocoon. There is now no tumor in the right side, but a slight tenderness. After two weeks she was allowed to get up and has enjoyed excellent health since.

Case 2.—I saw the second case July 5, 1896, at the request of Dr. A. J. Cook, who had correctly diagnosed it before sending for me. The woman was 28 years old, had been married five years, had had two children, the last three years ago. Menstruation had been regular until May 1, since which time there had been no flow, excepting a few drops three days ago. She thought herself pregnant, though she did not feel the usual nausea. She had felt quite well until twelve days ago, when she had some colicky pains. These continued until a week ago, when she was taken suddenly with violent pains in the right side of the abdomen and with nausea. She had to go to bed at once, but got up the next day and the following days, being compelled however to lie down daily on account of weakness. This afternoon (July 5) she was again seized with pain similar to that of a week ago, but worse. She also had some rectal tenesmus. Though under morphin when seen by me, she was suffering sharp pain in the hypogastrium. Her lips and conjunctiva were pale. Her pulse was 88; temperature 100 degrees. The hypogastrium, especially the right, was quite tender. The cervix was large and was pushed forward by a mass lying at the right of and behind the uterus. On account of the tenderness of the abdomen the mass could not be well outlined. Her pulse being good, I did not deem immediate interference necessary, but had her removed to the hospital for careful watching. By July 11 she was free from pain, had a pulse of 74 and a normal temperature. The mass in the right could now be well defined, filling that side of the pelvis. July 14 she was again taken with sharp, peritonitic pain through the right abdomen, and there was increased tenderness behind the uterus; pulse 108; temperature 100.2 degrees. She was

CASES OF CIRCUMSCRIBED PELVIC HEMORRHAGE.

No.	Medical attendant.	Age.	Number of children.	Last child.	Disease continued from	Disturbance of menstruation.	Size of Tumor.	Indication for operation.	Operation.	Duration of disease.	Result.
1	M. R.	37	4	5 yrs.	Nov. 16, '94, to Feb. 15, 1895.	Missed two periods. Attack sudden with collapse after having flowed five weeks.	From iliac fossa to liver.	Sepsis.	Dec. 22, 1894.	Previous to operation five weeks.	Recovery.
2	Dr. D. S. Haunson, Cleveland.	30	3	1 yr. ing	Feb. 15 to April 22, 1895.	Last menses five weeks ago. Flowing past three weeks. Attack sudden. Flow continuing six weeks after attack.	Filling right pelvis, and pouch to 3 in. above brim.	None.	July 27, 1895.	Previous to operation five weeks.	Recovery.
3	Dr. F. W. Herbersmau, Cleveland.	25	0	0	June 23 to Aug. 24, 1895.	Missed one period. One month later seized with sharp, cramp-like pains and fainted; two weeks later, similar attack; flowing since first attack.	Within 2 1/2 inches of umbilicus.	Recurrent hemorrhage.	July 27, 1895.	Previous to operation five weeks.	Recovery.
4	Dr. B. E. Sager, Cleveland.	37	1	16 yrs.	July 17 to Oct. 1, 1895.	Menses stopped suddenly, having lasted three days, usually six days. Two days later sudden agonizing pain, collapse; flowing five weeks.	Douglas' pouch to brim of pelvis.	None.	July 27, 1895.	Ten weeks.	Recovery.
5	Dr. D. S. Haunson, Cleveland.	32	3	3 yrs.	Apr. 25, '95. Absolute rest, May 19 to June 24.	Repeated attacks of pain from time of menses, and tenderness of abdomen. Then sudden violent pain with formation of tumor in pelvis pushing uterus forward.	Size of three months' pregnancy.	None.	July 27, 1895.	Five weeks' rest.	Recovery.
6	Dr. J. M. Friend, Cleveland.	30	2	3 yrs.	June 7 to July 30, 1895.	Last menstruation only one day, then continued flowing a month with pain in left side. Seen June 28; no collapse.	First size of fist, later increas'd to double.	Growth of tumor.	July 1, 1895.	Previous to operation four weeks.	Recovery.
7	Dr. A. Pav, Cleveland.	30	3	1 yr.	Jan. 28 to Mar. 15, 1896.	Taken at time of menstruation with intense pain and found in collapse on kitchen floor. Flowed for several weeks.	Reaching near umbilicus.	None.	July 1, 1895.	Two months.	Recovery.
8	Dr. R. E. Skeel, Cleveland.	28	5	2 yrs.	Mar. 15, '96, but abt' 1 st rest June 13 to July 16.	Menses due March 15; came with gush and labor-like pains; continued two weeks. Second attack with sharp pain in April. May 17 third attack and flowing since; no collapse.	Cocoonut in right pelvis.	None.	July 1, 1895.	Four weeks in hospital.	Recovery.
9	M. R.	30	2	1 1/2 yrs.	June 13 to July 11, '96, when she left h'spit' 1	Flowing one week when seen; labor-like pains past two weeks.	Reaching midway between umbilicus and symphysis.	None.	July 1, 1895.	One month when she left the hospital.	Improved.
10	Dr. A. J. Cook, Cleveland.	26	3	3 yrs.	June 23 to August, 1896.	Missed two periods; taken suddenly with violent pains in right abdomen; more violent attack one w'k later and again nine days later.	Filling right side of pelvis and cul-de-sac.	Recurrent hemorrhage.	July 16, 1896.	Previous to operation two weeks.	Recovery.
11	M. R.	33	3	1 yr.	Nov. 15, '96, to March 20, 1897.	One week over time; intermittent flow two weeks at a time; severe bearing-down pain.	Size of orange in left pelvis.	None.	July 16, 1896.	Four months.	Recovery.
12	Dr. G. R. Feil, Cleveland.	33	2	5 yrs.	June 23, '96, to Feb. 22, 1897.	Missed two periods; sudden violent pain; syncope; peritonitis.	Size of eight months' pregnancy.	Peritonitis after missed labor.	Feb. 22, 1897.	Previous to operation 18 mon'hs.	Recovery.

REMARKS.

Case 1.—Late operation resulting from mistaken diagnosis. Convalescence from sepsis two months after operation. No fetus found. Health good. No trace of disease except scar and pleuritic adhesions. Reported in "Transact. Amer. Asso. Obstetric and Gynecol.," 1895, Vol. viii.
 Case 2.—Seen a week ago. Enjoying excellent health. See first case in present article.
 Case 3.—First seen by me July 19, 1895. Sent to hospital for observation. Pain, increase of tumor and rise of pulse from 76 to 104 after rest of five days, lead to operation. No fetus found. Only blood clot and ovarian hematoma. Left hospital August 24; well since.
 Case 4.—First seen by me Sept. 8, 1895. Case complicated by fibroid size of small cocoonut in right pelvis. Elastic tumor bulging out Douglas's pouch in left. March 4, 1896, examination shows oval tumor in right broad ligament size of cocoonut, not tender. Patient quite well.
 Case 5.—First seen by me May 19, and ordered absolute rest. Recovered without a bad symptom. "Uterus is now movable as that of a virgin."
 Case 6.—Seen by me in consultation. Had had no strict rest. Tumor

increasing. Dr. F. operated, assisted by me. No fetus. Recovery complete; had baby eleven months later.
 Case 7.—Seen by me Feb. 20, 1896. Large, somewhat tender, elastic tumor, bulging in vagina and rising above symphysis. Said to have been much larger. No fever. Absolute rest. Feels perfectly well.
 Case 8.—Uterus pushed to left by boggy mass in right pelvis size of cocoonut. Operation advised when first seen in hospital, June 13. Operation declined. Rest ordered. Recovery complete; no trace of tumor.
 Case 9.—Seen by me June 27 at hospital. Slavonic nationality. Information meagre. Pulse 108, temperature 99.7. Cervix pressed against symphysis by soft mass bulging into vagina and extending beyond fundus above, on left side. Patient very anemic. Could not be held at hospital as soon as she felt better.
 Case 10.—Reported in second case in this article.
 Case 11.—Came to dispensary. Would not go to hospital, not even to bed. When last seen uterus was movable. Mass only size of walnut. Appendages could be outlined.
 Case 12.—Character of case not recognized at time of rupture. Went three weeks beyond term. Fetus died after spurious labor. Reported in full in "Transactions of Ohio State Medical Society," 1897.

now closely watched, anticipating necessity for operation. July 15, her pulse was 88, temperature 100 degrees. She felt easy. July 16, though the temperature was lower, being 99.8 degrees, her pulse had been rising since midnight, being 108 in the morning. There had at no time been any tympanites or vomiting. To my mind the rising pulse indicated active hemorrhage. Operation was now decided on.

Operation: Present Drs. Cook, Dutton, Barnes and Skeel. Chloroform. Incision four inches. Abdomen full of free and clotted blood. The tumor consisted of the enlarged ruptured right tube, enlarged ovary and the greater upper portion of the right broad ligament. These were ligated with catgut, chain stitch. Behind and below the uterus was a mass of loose, coagulated blood. After this had been scooped out, another mass was found filling the cavity of the rectovaginal pouch. This was separated from the layer of loose blood above by a thin spider-web membrane, which had to be broken up before the lower layer of blood could be removed. The abdomen was flushed with sterilized water and a glass drain introduced. No fetus. The rupture, with ovum and placental tissue, was in the outer end of the tube. Excepting abscess from constricted suture, her recovery was uneventful.

Of the twelve cases included in this report, five recovered by rest, one left the hospital before full recovery, one took only snatches of rest, and five were operated on for cause; two for growth of tumor, one for recurrent hemorrhage, one for sepsis, and one for fetus beyond term. All recovered.

Following the plan of vigilant delay I have succeeded in restoring to perfect health, without operation, eighteen women out of thirty-five, not one of whom has been left an invalid. All consider themselves as well as they ever were and attend to their households as well as previous to their sickness. Of the remainder one refused operation, one left the hospital before recovery and fifteen were operated on, with four deaths. Three of the deaths were due to far advanced sepsis previous to operation, in cases not recognized by the attendants. Eliminating the three hopeless cases, there would remain a mortality of one in twelve. If the eighteen women who have recovered had been submitted to operation, according to my results, at least one would have died; one or more would have had a ventral hernia, and nearly all ventral scars.

In the papers above referred to and in discussions elsewhere published² I have given my reasons for the faith that is in me. It would unnecessarily prolong this résumé to repeat them. The technique of some of the operations,³ and the choice of the abdominal or

³"A Contribution to the Technique of Intraligamentary Operations,"

vaginal route⁴ have also been considered on previous occasions. My experience with cases of circumscribed pelvic hemorrhage leads to the following conclusions:

1. That, unless they require immediate operation for cause, when first seen, they can be submitted to careful supervision in a hospital or home without danger.

2. That, when thus watched, more than one-half will get well without operation by keeping them at absolute rest for an average period of six to eight weeks.

3. That, when they can not be watched, or refuse to rest, early operation is to be recommended.

4. That operation is necessary only for special indications, of which the most important are sepsis with or without suppuration; recurrent hemorrhage; growth of tumor; non-absorption after a reasonable time, and compression of the pelvic viscera (rectum, or ureters).

5. Abdominal section is to be preferred to vaginal incision in most cases.

722 Woodland Avenue.

DISCUSSION.

Dr. LEWIS S. McMURTRY of Louisville, Ky.—The subject presented by Dr. Rosenwasser is a very important one, and as I take it, it is a further contribution to the study of pelvic hemorrhage, as Dr. Rosenwasser has favored the profession with several papers on it. In studying the subject, it seems to me we can reach it best by analogy; just in proportion as our knowledge becomes accurate in regard to pathologic conditions so do they become simplified. For the sake of analogy let us look at the subject of appendicitis. It used to be known as perityphlitis, typhlitis, etc., and now it is appendicitis. Our knowledge of the subject has been greatly increased. The subjects of pelvic hematocele and intrapelvic hemorrhage, encysted, circumscribed and diffuse, these terms have mystified us and should be dispensed with just as the terms that were formerly used in regard to appendicitis. So far as I know, all cases of intrapelvic hemorrhage are ruptured tubal pregnancies. In all of my personal experience, it has been entirely a confirmation of the pathology that was a long time ago defined by Bernutz and Goupil, and as we study the pathologic condition more and more we find but one condition obtains in these cases. I wish to state that the pathology will be very greatly cleared up when we realize the fact that these cases are nothing but ruptured tubal pregnancies, and this lesion presents itself in the same great variety, using the same analogy, as appendicitis does. The operation for this condition is not always immediately fatal. The patient may recover without operation, but these cases are few, that is, proportionately few. In considering the treatment, it would seem best to operate on all of them. There is greater safety in an abdominal section skilfully performed than there is in waiting and taking chances and avoiding sepsis.

Dr. A. GOELET of New York—I wish to dissent from the statement made by Dr. McMurry, that all of these cases are due to ruptured ectopic gestation. From my own experience, I can not believe that is the case. I have seen a number of cases of intrapelvic hemorrhage in which there was no possible chance of making a diagnosis of pregnancy. Again, a hemorrhage having occurred in the pelvis, the proper thing to do, if it is not absorbed immediately, is to remove the blood clot or clots. Objection to operation is invading the peritoneal cavity. We must remember, if the hemorrhage is beneath the peritoneum, the peritoneal cavity is not involved. If hemorrhage takes place in the peritoneal cavity it is shut off by the exudation and inflammatory action; therefore, we may say, after a certain length of time, it is extraperitoneal to all intents and purposes. Some two years ago I advocated treating these cases by vaginal section, and I rise today to reiterate statements I made at that time, that in cases of ectopic gestation if, after a sufficient length of time is allowed for the vessel to close, there be a recurrence of hemorrhage, the operation of incision into the mass through the vagina is simple and safe, and there need not be any fear of abdominal section.

Dr. CHARLES P. NOBLE of Philadelphia—So far as my experience goes, I have never seen a case of intrapelvic hemorrhage that was not due to ectopic pregnancy. I think everyone agrees that if we have a rapid violent hemorrhage in these cases, the only thing to do is to operate. This point is not debatable. In the circumscribed cases, especially in my own practice, where the diagnosis was made early, I have not seen one that died after abdominal section and removal of the clots and affected tube. That has been my experience and I heartily favor operative interference. I have seen a number of late cases, after suppuration has taken place, and in those it is best to operate *per vaginam*. In operating *per vaginam* in a case seen early, I think it is risky, as there have been numerous cases reported where active hemorrhage took place, and so in the old suppurating cases I would prefer to operate from above.

Dr. RUFUS B. HALL of Cincinnati—The time to operate in extra-uterine pregnancy is when you have made a diagnosis. According to the Doctor's own statement of waiting for nature to cure the patient after organization of the blood clot, etc., he has five cases suffering from sepsis. These were operated on, four got well, and one died. This alone should prompt him to operate as soon as he has made a diagnosis in these cases. The method of operating is open to question; I grant each man the method he prefers. Personally, I prefer the abdominal route, and operate when I make a diagnosis.

Dr. L. H. DUNNING of Indianapolis—I heartily agree with the last speaker (Dr. Hall) that we should operate as soon as the diagnosis is made, and yet there will arise cases in which the specialist alone has the privilege of examining the patient weeks after the hemorrhage has occurred. It has been my privilege to see two such cases within the last two weeks. In these cases there was a circumscribed, immovable tumor, bulging into the vagina. The tumors were large, were incised through the vagina, and the blood clots and debris were removed. The patient made an excellent recovery. It is necessary to discriminate in these cases. We know that if we have hemorrhage early in the period of gestation, that frequently peritoneal inflammation will shut off the clot from the general peritoneal cavity, that the blood may remain there without change, and infection may take place if fermentation occurs, and then it would be almost impossible for us to remove the mass by an abdominal operation, while in such cases we can incise them from below and the patients will invariably recover. We should consider the time that pregnancy has elapsed until the time of rupture. At several months, pregnancy would have supervened before rupture occurs, and, of course, we have a condition not likely to be absorbed, and suppuration is more likely to occur. If it does occur in these cases, it is absolutely necessary to remove the tube, or we will have a protracted case and perhaps death in the end.

Dr. DUDLEY of New York—The subject under discussion is the treatment of circumscribed intrapelvic hemorrhage, but the discussion has drifted largely to the treatment of extra-uterine pregnancy. That does not include the entire scope of this paper, in my judgment, because there are other causes of circumscribed pelvic hemorrhage than extra-uterine pregnancy. I have seen it in many cases. Granting all that has been said concerning extra-uterine pregnancy, I will mention other conditions. One of the most prolific causes of circumscribed pelvic hemorrhage is interference by the midwife in producing abortion. I have found more than half a dozen cases in my practice, and I would like to say a few words relative to a case that came to my clinic last week. A patient came to me saying that a midwife had operated on her, and she came into the hospital septic. I made a diagnosis of fibroid tumor which filled the pelvis, and in opening the abdomen I discovered what was apparently a triple uterus, the larger portion being central, a part of the tube extending from two lateral portions of the uterus. A puncture was made through the top of the central one, and from which was removed about a pint of clotted blood. The patient died. The puncture had been made near the circular outlet. The hemorrhage was so great and sepsis so profound that the patient lost her life. I was able to get a postmortem and to prove the truth of my statements.

Another cause of circumscribed intrapelvic hemorrhage is ulcerative processes which attend diseases of the tubes. The treatment of circumscribed pelvic hemorrhage depends entirely upon the diagnosis, and in my judgment the proper method of treatment in the majority of such cases is by the abdominal route.

I am willing to confess my mistakes. On last Friday I did a laparotomy for diseased appendages, and as is always my custom I everted the uterus, and knowing the condition of the patient I did so very carefully. I then opened the abdomen, found one ovary filled with blood, the opposite side of the tube filled with water and a little bunch of hair close to the horn

⁴Annals of Gynecology, March, 1891.

⁴Comparative Merits of Abdominal Section and Vaginal Incision in Extraperitoneal Hematocele," Annals of Gynecology, September, 1889.

of the uterus beneath the tube. In pulling the gauze up through the uterus and incision, I did not recognize that I had punctured the uterus. There was the gauze and I drew it out through the abdominal cavity, having punctured the uterus in packing it close to the horn.

Dr. JOHN M. DUFF of Pittsburg.—In the vast majority of cases in which we have evidence of sudden hemorrhage I think it is the result of extra-uterine pregnancy. But I will not take time to discuss this phase of the subject. I have heard on one or two occasions the statement made that there was very little danger in puncturing the uterus. I have a specimen in my possession at the present time concerning the case of a woman who had whittled a skewer that had been used for beef and had passed it up through her uterus and broke it off in the uterus, it having passed through the walls of the organ, and she died from the hemorrhage resulting therefrom. This case shows that we may have immediate fatality from puncture of the uterus.

Dr. A. H. CORDIER of Kansas City, Mo.—I am of the opinion that the paper of Dr. Rosenwasser is going to be the cause of doing some mischief in this country. He is a recognized authority on this subject, and a great many practitioners in treating these cases would do so very much along the line they would treat cases of appendicitis. I fully agree with Dr. McMurtry in regard to the hemorrhage being due to extra-uterine pregnancy. I have never seen a case but what the hemorrhage was due to it. If a patient is shot through the uterus or receives a stab wound in this organ, there is no reason why it should not cause hemorrhage in this locality as in any other part of the body. Cases present themselves with a history of hemorrhage in the pelvis without any foreign substance having been passed into the uterus, or without a definite history of traumatism. I am unable to understand how (and I hope the Doctor will tell us in closing the discussion) he makes the diagnosis and how he knows the hemorrhage is going to remain circumscribed. A most intelligent practitioner two weeks ago, in my city, made a correct diagnosis of extra-uterine pregnancy with primary rupture. One week later the woman presented herself with secondary rupture. There was a tear in the tube either from a blow from the child or extravasation of blood from this locality. The doctor gave the patient a hypodermic injection of morphin to relieve the pain, and in so doing he made a fatal mistake in that he masked all the symptoms. The patient turned over in bed and said that she felt very easy. The doctor presumably thought she was going to sleep, but at the end of an hour's time she was dead, having died from a concealed hemorrhage without a single drop making its appearance through the vagina. Dr. Dunning has called attention to the duration of pregnancy as an operative indication. It is absolutely impossible to tell the duration of pregnancy. Most of these cases rupture before the twelfth week of pregnancy and we can not get a straight history as to when pregnancy began. Whenever the diagnosis is made, then is the time to operate. If the cases are operated on early and thoroughly, the mortality will be extremely low. I prefer the abdominal route in operating on these cases; you remove the suppurating or diseased tube.

Dr. HOWARD A. KELLY of Baltimore—I heartily agree with Dr. Rosenwasser in some of his conclusions and we are indebted to him for his paper. It will to some extent modify my own practice. Dr. Rosenwasser has been following out this subject in a scientific manner by taking a radical departure from previous methods, hinting at the deductions drawn by Tait many years ago, who showed that the majority of cases of extra-uterine pregnancy ruptured early and disappeared without anything being heard of them other than a severe attack of pain. Where the hemorrhage is circumscribed, in case it is held down by adhesions or is in the broad ligament, it is perfectly safe under such circumstances to watch the patient to see if the blood will not be absorbed. In case the patient should have repeated hemorrhage I would prefer to operate.

Dr. ROSENWASSER (closing the discussion)—I have been in the habit of making careful notes of cases, taking a few of them into the hospital, and recording the results from time to time. I shall continue these reports until we can draw further conclusions. The title of my paper says exactly what I mean—the treatment of circumscribed pelvic hemorrhage. I have nothing to do with free hemorrhage which comes from injury or anything else. I simply wish to make the point that we should distinguish between the two kinds of pelvic hemorrhage. In reading a paper before an association like this a great many points are misunderstood, and I hope the gentleman who asked the question how to differentiate between circumscribed and other forms of hemorrhage will read the paper carefully and I think in it he will find the information he asked for.

One of the speakers is afraid that my paper will cause the pendulum to swing too far in a certain direction. If it will set it back in the right direction I shall be well pleased. The pendulum has swung too far one way, and we want to get it back. If the truth is going to set us back, I want it to do so. There was a misstatement in the discussion with regard to septic cases. I reported four cases of death, these cases came to me at a time when they were hopelessly septic and I made a forlorn operation. They all died. I lost one such case seen in the morning and operated the same day.

THE ANTISEPTIC VERSUS THE ANTITOXIN TREATMENT OF DIPHTHERIA.

Presented to the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY O. W. BRAYMER, M.D.

CAMDEN, N. J.

I am much interested in the subject of diphtheria and its treatment, and from what I have been able to observe, it would seem that the point at issue at the present time is this, viz., is or is not antitoxin the best treatment yet offered for the cure of diphtheria?

I have had very limited experience with the remedy, but as yet can not feel that it is worthy of the advertising it has received at the hands of the profession. This conclusion has not entirely been arrived at from the few cases in which I have used the remedy, but from all the information I have been able to obtain from reading the arguments *pro* and *contra*, in medical literature. Let us consider a few published facts.

Producers of antitoxin are urging the profession to use the serum in the very early stages of the disease and in suspected cases, even before any bacteriologic examination can be made (on which they are great sticklers) and even before one could decide from clinical diagnosis.

They would have this admittedly dangerous remedy injected into those suffering from the slightest sore throat, even into the well persons of the household. These actions naturally swell the number of cases reported and lower the percentage of deaths. Yet statistics show that, in reality, as many people are now dying from diphtheria and its *sequela*, in proportion to the population, as there were before the serum treatment was introduced. Then, granting that sometimes you have almost a zero death rate when using the antitoxin, you must give those who use other treatments like concessions, because all who have met with many cases of diphtheria know how different in fatality it is. You also know what a difference in vital force there is in individuals. These points have much to do with the results from any remedy in this disease.

I believe all will agree that diphtheria is primarily a local disease; then we ask the question, why not treat it as you would any other like condition, why not treat it successfully by antiseptics? If antitoxin does any good at all, it is only to counteract the effects of the absorbed toxin of the disease. Why not as well destroy the bacillus while it is yet doing the local work before great absorption has taken place? Surely this can be done in those cases that are amenable to treatment, when seen early. And those that have been of several days standing without treatment are admittedly not so much benefited by antitoxin, perhaps no more than by any other rational treatment. Then again the use of antitoxin causes great pain and fright, especially in small children, and this alone might be a cause of death.

I feel that a local antiseptic treatment, properly applied by skilled hands, and an internal supporting treatment pushed to the limit indicated by the individual case is as good a treatment as we have yet found. I feel that the reason the results from this line of treatment have not been more generally successful, has not been because of weakness of remedies, but in unskilfulness in their application, and inadequate care to the general surroundings of the patient.

My experience with diphtherial cases has been divided into three periods and methods of treatment.

During the early years of my work the old chlorate of potash and iron, and the calomel treatment, were adopted. Thirty-six cases were treated during this time, and seven deaths were the result. During the second period thirty-two cases were treated very carefully by local antiseptic applications, a 1 per cent. solution of creolin was the principal remedy used, either by spray, gargle or applicator, as indications warranted, together with the internal use of strychnia, stimulants and foods. In this list there were no deaths. The third group contains only six cases, all treated with antitoxin, and the result was two deaths. These seventy-four cases were not selected ones, but all that came under my care in a series of years.

They were all children except four, who were adults aged respectively 19, 20, 22 and 32 years; the latter being the mother of two children, suffering from the disease in the same house.

The youngest patient among my list was eleven months, all were white excepting one, a colored girl aged 11 years. No record of bacteriologic examination has been recorded in this paper for various reasons, viz.:

1. In the beginning it was not convenient to have such examinations made, and it seems best to report all cases on a clinical diagnosis, giving all the same standing.

2. Since in some of the very marked cases of diphtheria no bacilli are found in the throats of those affected and since many bacilli are found in some persons not sick with the disease, it seems to me that we have just reason to doubt the utility of bacteriologic examination for practical medical work. I do not feel that the well qualified physician of ordinary attainments is any the less able to make a correct diagnosis in diphtheria than he is in measles, enteric fever or like diseases, and it seems that it is only since antitoxin has come to hand, that such attainments have been denied the general practitioner. This paper is not presented with the intention of giving tabulated statistics; it is an expression of my own private opinion, based upon the knowledge gained from careful practical experience and study, and as yet I can not grant to antitoxin as offered today the powers that some claim for it. I feel that it is yet *sub judice*.

I look at it in the same light as I do the proprietary medicines and foods so much advertised in our day; while it undoubtedly has some virtues, yet it is no better than other judicious treatment, and is being greatly pushed to swell the coffers of those firms who are manufacturing the remedy. I believe that what we are the most in need of at present is more truthful statements from the profession at large, who are using different remedies. That man who claims to cure all of his cases of diphtheria by any one line of treatment, is either one of two things, not partial to the truth or else a very poor diagnostician.

The friends of antitoxin claim especial benefits from its use in laryngeal cases, yet we all know that excellent results have been obtained from other remedies, and no doubt still better would follow if we could always have the best nursing in these cases so that remedies ordered would be applied according to our instructions and as the individual case indicated.

THE SERUM THERAPY OF DIPHTHERIA, THE "ANTITOXIN QUESTION."

Presented to the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWIN KLEBS, M.D.

CHICAGO, ILL.

It is a matter of great importance not to neglect the question of the origin and nature of antitoxins. While clinical facts and statistics seem to give sufficient reason for approval or disapproval of the therapeutic application of antitoxins, it must be borne in mind that laboratory research alone can give exact data, and by its methods can be perfected. Science and humanity will derive more benefit by not only accepting the rough facts, which the statistics give us of the results derived from clinical observations, but by exact investigation of the nature and origin of those bodies, which from their probable action, we call "antitoxins."

The first investigations toward discovering the relation of toxins and antitoxins were made by Smirnow (*Berl. klin. Wochenschrift*, 1895, 1896), d'Arsonval and Charrin (*Comptes rendus de la Société de Biologie*, 1896), Bonome and Violo (*Centralblatt für Bacteriologie*, B. 19, 1896), who thought to have transformed toxins into antitoxins by means of different forms of the electric current. Other observers had not the same results in the different methods of application; sinusoidal currents of high voltage seemed to be less detrimental to the easily destructible albumoses which probably form the toxins and antitoxins.

In what way the electric current may cause such transformation has not been clearly demonstrated, but one may accept the oxidation theory, expressed by one observer, whose work will be referred to later.

Nearer to the solution of this transmutation question comes Dr. Dzierzowsky (*Archiv f. exp. Path.*, B. 38, p. 186, 1897), who tried to ascertain the quantity of diphtheria antitoxin in the different organs of immunized horses. He found that the highest quantity, seventy Behring's units, was contained in the blood serum and blood plasma and in a Graafian follicle; then follows the kidney with forty-five, the ovaries, the mammary and renal glands, with thirty; the heart and lymphatic glands contained twenty; liver, spleen and spinal chord ten; brain, marrow of bones, *white and red blood corpuscles only one*.

This shows clearly, as correctly deduced by the author, that the antitoxin is not found in any organs or cells but that it is generally a *product of transmutation of the injected culture fluid*. But it seems to be very questionable, if, as he concludes, the toxins are changed into antitoxin.

Having demonstrated experimentally that the culture fluids of tubercle, diphtheria and typhoid bacilli (for the last not yet published) contain two different albumoses, very well separable chemically, the one with healing or bactericide properties (soalbumoses), the other with poisonous properties (toxalbumoses),

it seems that only the last are destroyed in the body of the animal, into which the whole culture-fluid was injected.

It seems not difficult to explain why it is so, the toxic substances provoking the febrile reactions, that is the higher oxidation, which also destroys the toxins when electric currents are used. The immunization is probably obtained by the active poison-destroying property of the leucocytes, trained in the struggle against the toxins.

Behring concluded from the observed lack of bactericide properties in his serum, that the curative principle of the serum must lie in new products formed in the immunized body. But Pfeiffer has shown that these properties can be demonstrated in the sera of animals immunized against cholera Asiatica and typhoid fever. It is improbable that it should be different in diphtheria. If diphtheria contained only antitoxic substances, why should the efficacy of it be less in the latter stages of the disease, in which toxic effects are most prominent and so in all cases, even of true uncomplicated diphtheria. That the best results with serum are obtained in cases where, in the first days after infection, the treatment was begun, is generally accepted. And furthermore the loosening of the membranes after the injections of serum can not be well explained as produced by antitoxic influences.

In conclusion I wish to say that in the serum there must be contained not only antitoxic but also bactericide principles. It is therefore most probable that not only antitoxic but also bactericide principles work together to produce the curative effect of the serum. Furthermore these bodies are not new products formed in the immunized animal, but transformed from the injected culture fluid. This leads to the possibility that we are able to transform the culture as such directly, without the passage through the body of an animal, and my experiments in this line seem to emphasize this theory.

SUCCESSFUL TREATMENT OF DIPHTHERIA AS COMPARED WITH ANTITOXIN.

Presented to the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY JOHN H. COUGHLIN, M.D.

NEW YORK, N. Y.

This is certainly the age of medical and surgical progress, and there is a constant desire for something new. The wonderful advances which have been made in medicine and surgery during the past decade would seem to warrant us in looking for newer remedies in every department of medicine, and, indeed, the number of these which of late years have been pressed upon us by writers in medical journals and manufacturers, are so great that much confusion of thought and purpose is often induced thereby. It is well, therefore, to stop, consider and try to estimate the value or worthlessness of the new, and to see what of it should be added to our stock of old, and thus recognize where true advance has been made. It would be really amusing, were it not so sad, to read and record carefully all that is written in journals and publications relating to the treatment of diphtheria, and then in time carefully note the true value of this and that remedy as developed by the experience of others than the one presenting it. We are not so much in need

of new remedies, but a better understanding and adaptation of the old ones.

Isolate your patient in a separate room, preferably in the upper part of the house, having the sick-room divested of all unnecessary furniture; remove the carpets, curtains and upholstered fixings. There should be plenty of fresh air and sunlight without draughts. Draughts are dangerous, as they often cause the diphtherial process to extend into the larynx. The clothes and bed linen should be kept scrupulously clean and pure, being well exposed to the sun and air.

Great precaution should be taken that cups, saucers, spoons and other utensils should be kept apart for the absolute use of the sick. The cups, saucers and the clothing necessary to be returned to other parts of the house, should be boiled and washed in the following solution before being taken from the patient's room: Zinci sulph. 3 iv, sodii chlorid. 3ij, boiling water 1 gallon.

Nurses or attendants upon the sick should be separated as much as possible from the rest of the household. They should wear a loose gown or wrapper, and upon leaving the room should remove and hang it up in the chamber of the patient.

Mothers nursing a child and often having the care of the sick, should use extra precautions in paring her nails very close, scrubbing her fingers, nails and hands with soap and water and soaking them from three to five minutes in a solution of 1 to 5000 bichlorid of mercury before nursing her baby, as she is very prone to infect her child in using her fingers in placing the nipple in the nursing child's mouth.

A towel, wrung out after being soaked in 1 to 1000 bichlorid of mercury solution, should be pinned by its two upper borders over her bosom by a safety pin under the gown or wrapper which is worn in the room of the patient, and should be removed before each nursing or handling of the baby.

Importance of diet and feeding.—Trousseau says: "Alimentation occupies the first place in the general treatment." I have observed that the severer the attack, the more imperative is the necessity for sustaining the patient with nourishing food. Diphtheria debilitates, and as recovery often depends on the strength and staying power of the patient, it is obvious that the greatest care must be taken from the commencement of the illness to keep up nutriment. It is much easier to prevent the disturbances of the digestion by proper feeding than to allay them when they have been excited. Administration of nourishment should be carried on on the principle of the little and often plan.

Patients are sometimes allowed to sleep too long without nourishment, it is often the sleep of toxemia, the commencement of that long sleep which knows no awakening. They should be aroused and fed. Failure of the appetite, that is, disgust for every kind of food, is justly regarded as a very unfavorable prognostic sign. We must try to overcome the loathing of food by every possible means; we should first coax, bribe with toys and make promises to our little sufferer; failing in these, I would not hesitate sometimes to threaten the child with punishment. While the child retains its appetite for food there is good hope for recovery. We are apt too rely too much on drugs in this disease and overlook a very important part of our treatment, the supporting of our patient's strength with proper nourishment. It is not wise to defer too much to the whims and fancies of the child.

The physician should not permit himself to give vague and indefinite directions about diet; he should dictate a diet list with as much care and precision as he prescribes the medicine and should at each visit satisfy himself that his directions are being carried out. Many children treated after the most scientific and improved methods, have been neglected in this essential and allowed to perish, when they could have been otherwise saved.

The power of digestion is greatly diminished in all febrile diseases, due to the locking up of the gastric juices; hence, our anorexia. Puddings, jellies and ice-cream are liable to disturb the digestion and had better not be used. Avoid solids, as a rule. Use beef tea, meat juice, beef extract, chicken broth, oatmeal made with plenty of milk and strained, white of an egg beaten up in water or diluted milk; but our main reliance must be placed on pure fresh cow's milk, as it is the most natural food for the child. In infants and young children it can stand dilution with lime-water. All drugs which interfere with proper digestion and assimilation of food, are harmful and should not be given.

Forced feeding is often necessary, owing to dysphagia due to sepsis, stupor, severe pharyngitis, paralysis of the soft palate; or a child sometimes becomes so obstinate as to decline all food and there is great danger from inanition. In infants up to 18 months old we should employ gavage, in older children we should use nutrient enemas.

Stimulation.—The common practice of some is to prescribe an enormous quantity of alcohol for infants suffering from diphtheria, justifying their course by pointing to the fact that these little sufferers tolerate and some survive its use in such large quantities.

Permit me here to make quotations from the two leading text-books of the English-speaking nations:

The American Text-book of the Diseases of Children (p. 283) says: "Alcohol should be given freely from the beginning, and there is more danger from giving too little than too much."

Ashby and Wright's (of England) Text-book of the Diseases of Children (p. 274) says: "Alcohol in the form of brandy and port wine must be given with a free hand."

The vast majority of text-books and modern writers on this subject speak of alcohol as though it was harmless and a specific in the treatment of diphtheria; such teaching and practice certainly does much harm. The early and continual administration of large doses of alcohol must certainly result in the same disastrous effects as observed when liquor is taken in excess.

The active intoxicating ingredient of the alcoholic drinks used by mankind is ethyl alcohol. We will take it for granted in our observations that these drinks are pure and free from fusel oil and other base, vile and more poisonous ingredients of liquors, leaving out of consideration the secondary effects of adulterated alcoholic drinks.

From a pathologic standpoint, even, the chemically pure ethyl alcohol must be regarded as a poison to the organism of the child. Literature records the death of a 3-year-old child after a single dose of two and one-half ounces of ethyl alcohol.

Various alcoholic drinks in use contain it from 3.5 to 55 per cent. by weight, and that which is usually used in sickness is whisky or brandy, and they contain an average 50 per cent. of ethyl alcohol. Alcohol is conveyed to the blood through the veins of the

intestines and to a less degree through the lymphatics.

The excretions of alcohol from the organism, according to Binz and his disciples, occurs through the intermediate formation of aldehyde and acetic acid. The final products are carbonic acid and water. If the blood is overcharged with alcohol, a portion is eliminated by the skin, the expired air and especially by the kidneys. It has been proven by the French writers, Duroy, Perrien and Lallemand, that unchanged alcohol has been found in the urine.

Physiologic action of alcohol.—Alcohol applied to the skin is an irritant, and if persisted in will cause ulceration of the skin.

The brain gives way the most quickly after the reception of alcohol, as instanced in drunkenness; it is capable of producing the stupor of anesthesia, and this anesthesia may be deepened unto death.

Nerve destruction is the well-recognized action of alcohol brought into the system, even in repeated small doses, as Kerr and Strümpell have proven.

Heart and arteries.—The first influence of alcohol is to cause the action of the heart to be accelerated and the pulse to become increased in frequency, but the tension of the arterial walls and the blood pressure are, on the contrary lowered. The distention and fulness of the blood vessels are produced by paralysis of the vasomotor influences. Wood of Philadelphia says: "Alcohol whipped the heart into furious activity at first, and then produced paralysis, so that death took place in the relaxation."

Digestive organs are increased in their action like other functions of the body, but digestion itself is not promoted by alcohol; on the contrary, it causes a catarrhal condition of the mucous membrane by irritating its surface, resulting in an insufficient supply of digestive fluid and an abnormal secretion of mucus, thus seriously interfering in the assimilation of food, as has been proven by the investigations of Little of London, Limanowsky of Munich and others. Demme of Berne says: "According to the majority of investigators absorption and assimilation are diminished in rate even by small doses of alcohol."

In diphtheria there is usually albumin in the urine, showing that there is a disturbance in the nutrition of the epithelium of the capillaries of the tufts or of the cells surrounding the glomeruli.

The presence of albumin in the urine under all circumstances must be regarded as kidney changes. The severer the attack of diphtheria the more pronounced the albuminuria usually is. Modern writers urge that in just such cases large quantities of alcohol are indicated. Now, how in the face of this unquestionable condition of the kidneys can such large doses of alcohol be given, when it is known to irritate the delicate epithelium of the kidneys and to aid and cause nephritis and other renal complications?

Uremia is one of the most important of local maladies pertaining to diphtheria and is produced by diphtheritic poison, it is also brought on by large doses of alcohol; therefore, we can ask those who use large doses of alcohol in diphtheria, when their cases end in uremia, how much has alcohol to do with this termination?

In septic or toxic conditions of diphtheria an enormous quantity of alcohol is used; we can here ask when the child has passed over to the majority if it was the toxemia of diphtheria or alcohol? The toxic symptoms of diphtheria and alcohol are closely allied.

Acute alcoholic insanity and melancholia are produced by even small doses of alcohol, and those disorders come on suddenly without visible prodromes.

Acute alcoholic multiple neuritis, acute alcoholic gastritis and delirium tremens are the result of large doses of alcohol.

The "Twentieth Century Practice of Medicine" (Vol. iii, p. 11) mentions an acute pneumonia induced by alcohol. Is this the pneumonia that so often accompanies so many fatal cases of diphtheria and is known as a septic or broncho-pneumonia?

Certainly these are open questions waiting for investigation. Diphtheritic paralysis caused by the toxin of the Klebs-Loeffler bacilli is not prevented by alcohol, no matter how large a quantity is given, but that we may assist a myo-carditic heart muscle to do its work is believed by many. I question it, considering that Strümpell claims to have seen degeneration of the myo-cardium from habitual moderate doses of alcohol. Is it not possible that large doses aid the diphtheritic virus in increasing the degeneration here, where we expect to aid instead of hinder?

There is a corresponding depressing reaction following over-stimulation from large doses of alcohol, in exact proportion to the amount of alcohol used, in every instance in the healthy human body, and also during diphtheria, leaving the centers guarding the heart certainly not in an improved condition. It is in the stage of depression that the heart is apt to fail and death ensue from heart failure; here, we bring about a serious or fatal depression from over-stimulation of the heart, from our large doses of alcohol, when we are endeavoring to assist and prevent heart failure; large doses are beyond doubt cardiac depressants.

I have seen in the last year a case of acute mania, from large doses of brandy, in a child, and I have also seen a case of acute alcoholic multiple neuritis, and both of these children were suffering from diphtheria and were being treated with large doses of alcohol.

I maintain that such a powerful toxic capable of producing those serious complications, if used at all, should be used with great caution, as it is very difficult, if not impossible, to determine the amount of harm it is doing when its toxic effects are so closely allied to the disease as in diphtheria.

Alcohol, if used, should always be ordered in drop doses to children, as it impresses the attendant having charge of the child that it is not harmless in its use in diphtheria, and prevents the errors likely to be made with other measurements.

I believe the amount of alcohol used in diphtheria, by many physicians, can be safely reduced, and the indications for its use materially lessened if not entirely stopped, if thorough, prompt, and efficient local measures are practiced with proper feeding and hygienic requirements.

The number of successful cases which I present for your consideration have not had one drop of alcohol, except one where I gave it late in the disease and had to stop its use on account of the harm it did, showing that cases of diphtheria get along just as well without alcohol. To suppose that any present theory of alcohol is settled because it is accepted by the general medical profession is not the spirit of the age.

Cardiac stimulation can be had from such accepted and useful stimulants as strychnia, digitalis, caffeine, camphor: hot milk, cocoa, coffee, and from judicious feeding.

Local treatment.—The universally accepted theory is that diphtheria is a local affection, and gives rise only secondarily to constitutional symptoms, by the absorption of the toxalbumins generated by the Klebs-Löffler bacillus. It has been proven that the membrane deprived of its germs produces the diphtheria by the action of its ptomain, a ptomain so poisonous that one-three-hundredth of a grain is fatal to a full grown guinea-pig. If we can, therefore, detect the disease clinically at the point where the infection is just taking place; that is to say, at its strictly primary seat, where the thin hazy film of fibrous exudate is just beginning to form, and slight constitutional symptoms exist, much can be done to stay its progress; we may expect thereby to check the local progress of much of its infective potency and limit its capacity for extension and constitutional effects. Local treatment, to be of service, should begin at the onset of the disease; we can have but little hope of influencing the disease by topical applications in the last stage, but something can be accomplished even then by thoroughly cleansing the parts of fetid and decomposing matter.

In the success of local treatment we must remember that many microbes are in the secretions and also on the epithelium, while others are imbedded in the fibrinous membrane, and the surrounding parts are covered with a myriad of bacilli, ptomains, septic and necrotic material. Systemic poisoning occurs from absorption through the lymphatics and blood vessels which are in immediate relation with the under-surface of the pseudo-membrane. The best and most satisfactory result in diphtheria are obtained by sprays, gargling, irrigation, and inhalation in the form of medicinal vapors. To keep diphtheritic membrane at bay the applications must be thoroughly and frequently applied at regular intervals until the chance of fresh formation of membrane altogether passes.

Patients are injured by irritating lotions or instrumental treatment designed to remove the pseudo-membrane which immediately reappears in greater extent and thickness than at first, on account of the increase in the inflammation in consequence of the severe measures employed.

Pharyngeal diphtheria.—The tonsils, uvula and the pillars of the fauces are the favorite site for the false membrane in diphtheria. In the treatment arrest the spread of the false membrane from extending into the larynx or nares, promote liquefaction, or removal of the false membrane, and prevent sepsis. These indications are best met with local measures and should be combated with vigor, promptness and frequency, by thoroughly cleansing these parts *every two hours, night and day* with a fifteen volume solution of the peroxid of hydrogen used from a hand spray for about two minutes, it being the most useful drug for the removal of broken down membrane, pus and necrotic tissue.

It should be used from 33 $\frac{1}{3}$ to a 75 per cent. solution, on an average of a 50 per cent. solution diluted with water; this often irritates and causes pain, but can, however, be in a measure overcome by following with a salt solution, thereby neutralizing the excess of acid.

A solution of the chlorid of sodium, of the strength of a teaspoonful to a pint, can be given to the child to gargle if old or strong enough to gargle; if not we should use it every four hours, day and night, from a fountain or Davison syringe, using at least from one

to two pints; the mechanical removal of the septic material is a valuable aid.

Nasal diphtheria.—From its concealed position it is easy to perceive why the disease is so frequently overlooked, and a simple nasal catarrh is suspected to be present when there is no inflammation or membrane in the fauces to aid the diagnosis. Invasion of the nasal tract may be suspected when nasal respiration is obstructed, giving rise to a bubbling or sniffling sound especially during sleep; and when a thin ichorous, muco-purulent discharge appears, with small excoriations and ulcerations at the entrance to the nares and upon the upper lip.

It always involves great danger, since it is very liable to give rise to systemic infection, from the large number of lymphatics lodged in the connective tissue of the nares. It may be primary or secondary; when secondary the inflammation extends up the posterior nares from the pharynx.

It is here where the greatest care and attention must be given to local treatment; it must be thoroughly and frequently repeated, gentle douching from a fountain or glass syringe with a rubber tip, with a warm bland 1 per cent. solution of the chlorid of sodium, alternating with a warm, saturated boric acid solution to be used *every two hours, night and day*, while at least one pint to a quart of the solution should be used at each application.

Laryngeal diphtheria may be primary or secondary. The onset is recognized by a harsh, dry, shrill or hoarse muffled cough; the voice is weak, husky and sometimes inaudible; the breathing is embarrassed, intermittingly at first, constantly afterward; associated with the metallic or brassy cough is a spasmodic closure of the glottis and a temporary increase in the dyspnea. In this form of diphtheria our main reliance must be placed on steam inhalation; the vapor should be medicated with some disinfectant; the following will be found highly serviceable: *Oleum eucalyptus*, 2 drams; *spirits of turpentine*, 1 ounce to each pint of water. Carbolic acid is still used, but the risk of absorption and the damage it may do to the already affected kidney should make us careful about using it for any length of time.

With regard to the value of emetics in diphtheria, there has been considerable difference of opinion; one should hesitate before administering a powerful depressant in a disease the danger of which is depression. Calomel fumigations, vapo-cresolin, also the burning of tar in the room, have their advocates. If obstruction to the breathing increases, as evidenced by the restlessness of the child and aggravation of the above symptoms with recession of the intercostal and the supra- and infraclavicular spaces, it becomes our duty to interfere, and to relieve the obstruction mechanically, if possible; first by intubation, later by tracheotomy if necessary. Do not wait for intermitting pulse nor for the child to become cyanotic before intubating, nor allow our patient to drift along into an almost moribund condition before you operate, if you expect any good results from the operation.

Constitutional treatment.—Commencing our treatment we should invariably move the child's bowels with calomel in the form of one-tenth grain tablets, one every hour or half-hour; if diarrhea is present during the illness, it is a conservative process on the part of the intestine to rid itself of noxious and toxic matter and nature should be aided by castor oil in a 1 or 2 dram dose, followed later by salol, beta-naphthol,

bismuth, or pulv. Doverii; this not controlling it, irrigation of the rectum will prove most efficient.

It is of the utmost importance to remember that diphtheria is a disease that leads to anemia and great exhaustion. We are all familiar with the pallor, loss of appetite and strength before the close of the first week, in severe cases, which are always symptoms indicating rapid and progressive deterioration of the blood.

Iron is at once suggested as the proper medicinal agent to check the blood changes from its well known effect in increasing the number of red blood corpuscles and the amount of the coloring matter in these corpuscles; by its effect on the red corpuscles, which are the carriers of oxygen, it increases the functional activity of the organs and improves general nutrition.

Iron in the form of the *tr. ferri chloridi* is indicated. The tincture of iron or the muriatic tincture of iron is prepared by adding alcohol to the officinal liquor ferri chloridi and contains the sesqui-chlorid of iron, muriatic acid and alcohol; from the reaction of the alcohol and the acid, chloric ether is produced; hence, this preparation of iron has a variety of actions that meets the indications in the treatment of diphtheria, making it the theoretic and clinical remedy.

The chloric ether contained in this preparation of iron is a diuretic and aids us in combating the albuminuria. The chlorin which it contains is a local and constitutional disinfectant. The iron is also an astringent, antifermentative, disinfectant, and a vascular stimulant. To be of service it should be used in large doses, from 10 minims to 1 dram; it is best given in glycerin and water each hour or two, night and day, according to the severity of the diphtheria and the age of the child.

The title to my paper may be somewhat misleading; I simply intended that my paper should be compared to those papers presenting their arguments in favor of antitoxin in the treatment of diphtheria before this meeting. I had not intended to touch on the subject of antitoxin, but one can not discuss the treatment of diphtheria without giving their opinion or experience with its use. With serum-therapy I have had but very little experience. I used it for the first and only time on a clergyman, and immediately after its use he commenced to vomit and continued vomiting for some twelve hours. After using many remedies to check the vomiting without success, I finally stopped all medication and gave the stomach absolute rest, when he commenced to vomit mucus streaked with blood; at this stage I used morphia and atropia hypodermically, which stopped the vomiting at once. The vomiting was probably simply a coincidence and had nothing whatever to do with the injection of the antitoxin; but the vomiting, starting so promptly after its use, left me in doubt as to its value.

We are treated to statistics which show without doubt, to those who make them, that antitoxin reduces the death rate in diphtheria. These figures would certainly be convincing were it not that these observers so universally rely upon the Klebs-Löffler bacilli as the sole test for the presence of the disease. Dr. Gross has lately made the statement that in the Children's Hospital at Boston the diphtheria bacillus was found in 8 per cent. of the throats examined, when there was not the slightest clinical symptom of the disease. In one of these cases the bacilli were found for 103 days; in another they were found in the discharge from an otitis media.

A prominent physician, now serving the City of New York as a coroner's physician, informed me that he made a culture from his throat and sent it to the Board of Health while he was up and around and attending to his official duties in the best of health, without a single local or constitutional symptom of the disease, and the report was returned that it was a true case of diphtheria. Yet the tendency is to allow the Board of Health to make the diagnosis of diphtheria, making the opinion of the physician and the clinical symptoms unconsidered trifles.

Prof. Joseph E. Winters, visiting physician to the Willard Parker Hospital for Contagious Diseases, in New York City, and having a number of clinics for children, a large consulting and private practice to draw his conclusions from, fails to find any value in antitoxin as a remedy in diphtheria, after observing the experiments of himself and others. Dr. John Dorning, consulting physician to St. Joseph's Hospital, visiting physician to St. Frances' Hospital, also having a large children's clinic and consulting and private practice, having in seven consecutive cases treated with antitoxin, some as early as thirty-six hours after the commencement of the illness, every one of these seven children died; each one of those were treated in private practice.

Dr. Alexander Dallas of Bayonne, N. J., a shrewd, careful practitioner of large experience, used antitoxin on eleven cases in private practice and ten died.

Dr. Francis Huber, chief of the Vanderbilt Clinic, the largest children's clinic in New York City, and a gentleman with large practice and experience, was forced to discontinue the use of antitoxin, failing to find the brilliant results claimed from its use. My single experience with the use of antitoxin, the observations of my personal friends and of the above gentlemen, and others, has not encouraged me in using antitoxin or advocating its use.

Convalescence.—Diphtheritic paralysis is an affection of the convalescent, usually making its appearance after two or three weeks after the commencement of the illness. We should guard against fatigue, excitement, exertion or moisture, for even in mild cases there is great danger of paralysis and sudden death from involvement of the heart or diaphragm, a month after the disappearance of the membrane and when all signs and symptoms of the disease have disappeared. Tonics with nourishing food, with sunshine and air, is indicated during convalescence.

Cases.—In each of these twelve successive successful cases, the clinical diagnosis was confirmed by bacterial cultures made by the Board of Health of the City of New York; they are from my private practice, and I present them for your consideration as a criterion of what we might expect from such management of diphtheria.

Many gentlemen within my hearing are using practically the same line of treatment, probably not as vigorously carried on, and have no doubt had their confidence in its usefulness somewhat disturbed on account of such glowing statistical reports from the use of *antitoxin* and *alcohol*.

The brilliant results claimed from such treatment, unfortunately, have not proven so effective in the hands of others who are just as competent to determine their value in the treatment of diphtheria.

Case 1.—William McA., age 13 years. Pharyngeal. Patches partly covered both tonsils. No antitoxin or alcohol used. Recovery.

Case 2.—Mary McA., age 7 years. Pharyngeal. Patches on both tonsils and small one on uvula. No antitoxin or alcohol used. Recovery.

Case 3.—Jennie B., age 10 years. Pharyngeal. Several discrete large patches on tonsils. No antitoxin or alcohol used. Recovery.

Case 4.—Maggie B., age 5 years. Pharyngeal. Several discrete patches on tonsils and soft palate. No antitoxin or alcohol used. Recovery.

Case 5.—William B., age 2½ years. Pharyngeal. Thin patches on tonsils. I was the fifth physician called in to see child suffering from abuse of alcohol with acute mania and acute alcoholic multiple neuritis. Child received 3ss of brandy every three hours with approval of physicians; stopped alcohol, used no antitoxin; child commenced to improve at once. Recovery.

Case 6.—Mannie C., age 4 years. Nasal and pharyngeal. Ulceration about anterior nares; snuffing and thin ichorous discharge from nostrils. Large patches running upon tonsils along uvula and soft palate. No antitoxin or alcohol used. Recovery.

Case 7.—Vincent D., age 7 years. Pharyngeal. Both tonsils covered with large patches and running along on uvula. No antitoxin or alcohol used. Recovery.

Case 8.—Charles H., age 5 years. Laryngeal and pharyngeal, with great difficulty of breathing, with slight recession of intercostal spaces. Did not intubate, no antitoxin or alcohol used. Recovery.

Case 9.—Mary M., age 3½ years. Pharyngeal. Several large patches on both tonsils and at side of uvula. No antitoxin or alcohol used. Recovery.

Case 10.—Alice M. Pharyngeal. Large patches on both tonsils, several discrete patches on soft palate; came to office to be treated for chronic diarrhea and bronchitis. Child very much emaciated.

Case 11.—Gertrude R., age 11 years. Pharyngeal. Several large patches on tonsils and soft palate. No antitoxin or alcohol used. Recovery.

Case 12.—Eleanora R., age 5 years. Laryngeal primarily; diagnosis also confirmed at Vanderbilt clinic; severe depression at commencement of illness, difficult breathing with recession of intercostal spaces; did not intubate. Gave whisky, twenty drops every two hours; had to stop the alcohol because the child became irritable, restless and unmanageable. No antitoxin used. Recovery.

Inhalation and exhibition of a croup kettle.—Inhalation to be of service, our patient should be placed under a tent; an improvised one can be made by placing several vertical slats beside the cradle or crib with several horizontal pieces tacked upon these, and a covering of rubber sheet or a blanket. An umbrella or parasol with a sheet about it will also make a good tent, but I am in the habit of taking the hoops from off a barrel and tying the ends with string or tape to the opposite side of the cradle or crib, and placing my coverings over them, leaving a small opening at the side when the child is not sleeping. The better the tent, the more satisfactory are the results in inhalation.

The use of steam inhalation is very beneficial because it increases mucous secretions and favors the removal of the membrane.

The air in the tent should be kept saturated by means of a tube from a croup kettle. Care should be taken that the nozzle which conveys the steam is not allowed to come too close to the child, because burns and scalds come from neglect of this precaution.

The apparatus most commonly used is the croup kettle, with its alcohol lamp causing innumerable accidents from fire. It is a clumsy arrangement and is not always to be had in small villages, so they are obliged to send to the town or city for it, causing the loss of considerable valuable time. In the cities you will not always find one to suit at the drug stores. We do not always have gas in the houses of the poor and it is not found in the country, so that gas stoves can be used.

I am in the habit of using in my practice an oil

stove and a kettle, which is commonly called an oil stove kettle, and a piece of gas stove tubing or a piece of garden hose, as nozzle for carrying the steam.

The stove cost forty cents, the kettle ten cents and the rubber tubing ten cents; this outfit costing less than half of what an ordinary croup kettle would cost. The cost of kerosene to be used as fuel will be five cents, while the cost of alcohol for fuel will be seventy-five cents to one dollar for each twenty-four hours.

Oil stoves are found in the houses of the poor, especially during the summer; we can thereby save time and the cost of a croup kettle, besides the saving of the cost of fuel in burning kerosene instead of alcohol, and there is very little danger of accidents from fire.

I may not be the first to present this idea, or the originator of this very convenient, efficient arrangement for use in inhalation; if not, it will do no harm in bringing it to your notice again, thereby refreshing your memories that such a cheap, easily managed, efficient arrangement can be found everywhere. It can be placed on a chair or stool at the side or foot of the bed and the tubing carried on the covering of the tent by pinning pieces of tape around the tubing and to the coverings over the tent.

In getting the rubber tubing see that the ends are a composition which is not affected by the heat from the kettle; the rubber ends will shrivel up and loosen. It is well to place a piece of sponge, held by a bent hair-pin, to catch any drippings of water. We can use a double oil stove if desired, and carry the tubing along the coverings on either side of the child or crib.

THE THERAPEUTICS OF DIPHTHERIA, WITH SPECIAL REFERENCE TO ANTITOXIN.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY W. M. W. GRAY, M.D.

BRIDGEPORT, CONN.

In preparing this paper I have necessarily drawn somewhat upon the articles of eminent men in the profession, which have been published in our medical journals from time to time, so I now express my thanks in general for the aid thus derived, and confess to any plagiarisms that may be noted, without referring specifically to any article or authority, except to emphasize some particular or disputed point.

The therapeutic agents which have been used and have obtained reputation in the treatment of diphtheria are many.

Locally: Iron, the tincture of the chlorid being considered the most effective; lactic acid; bichlorid of mercury; carbolic acid; the digestive ferments, the theory being that they digested the membrane; peroxid of hydrogen; Loeffler's solution, and inhalations of calomel.

Internally: The tincture of iron; large doses of mercury; turpentine; bromin; pilocarpin; benzoate of soda, and sulphate of calcium.

The remedies which have stood the test of time and next to antitoxin are of most value, are alcohol and tinctura ferri chloridi combined with a spray and nasal douche of normal salt solution, and perhaps hot vapor and inhalations of calomel. Of course in tracheo-laryngeal diphtheria intubation at times is necessary,

although its use is greatly lessened by the early administration of antitoxin.

The treatment of diphtheria with antitoxin has been a medical question of high interest and first importance ever since Roux delivered his address at Budapest in September, 1894.

In a typical case of severe diphtheria the diagnosis can be made without difficulty. It is in those cases where the symptoms are non-typical and where the membrane covers but little surface, that at times it is almost impossible to distinguish a true diphtheria from ulcerative tonsillitis.

It is in this class of cases that we reap such a vast benefit from a bacteriologic examination, and for which the whole profession, aye, the whole civilized world owe a deep debt of gratitude to the discoverers of the Klebs-Loeffler bacillus, and the same heartfelt thanks should be bestowed on the discoverer of antitoxin. The name of Behring should be engraved, by the side of that of Jenner, in the hearts of the profession, for by their labors we are enabled to control and combat two death-dealing scourges.

In speaking of antitoxin as a remedy for diphtheria, I take it as a foregone conclusion that all admit that the disease is caused by the Klebs-Loeffler bacillus. I can not believe there are any who will fail to recognize this bacillus as the cause of the disease.

In a given case we first have the lodgment of the Klebs-Loeffler bacillus, the parts are infected and the bacilli by their multiplication cause the local inflammation observed, which may vary from a mild erythematous angina to the gravest pseudo-membranous inflammation. The systemic symptoms and lesions of internal organs occur from the absorption of toxic substances formed by the Klebs-Loeffler bacillus. But it is important to remember that in diphtheria we may have severe complications and secondary and mixed infection due to other bacteria, the most frequent and dangerous of which is the streptococcus pyogenes, over which antitoxin has no control.

Admitting these facts, it seems to me that the theory of serum-therapy as applied to diphtheria rests on a sound scientific basis, absolutely proven by experiments on animals and from the results obtained by its administration to human subjects.

Experimentally, an animal is inoculated with the Klebs-Loeffler bacillus or its toxins. The antitoxin is administered and the animal recovers, because the serum arrests the local process, stopping the multiplication of the bacillus and the absorption of its toxins by neutralizing these poisonous substances.

William H. Welch, in 1895, said, "the evidence derived both from experiments on animals and from observation on human diphtheria is decidedly in favor of the view that antitoxin does not directly neutralize the toxin in a chemie sense, but rather that each of these substances acts in an antagonistic manner upon the living cells of the body. It follows, that in order to secure the beneficial effects of the antitoxin treatment the cells must be able to respond to the introduction of the antitoxin serum. This responsive power may be partly or completely annulled by intense or prolonged action of the diphtherial poisons or by other previous or co-existent disease." This is the generally accepted view as to the action of antitoxin, although the results obtained by Ehrlich in some recent experiments as to the *modus operandi* of the antitoxin seems to favor the theory that the antitoxins neutralize the toxins by direct chemical action; for a detailed

account of these experiments I must refer you to his article in the *Fortschritte der Medicin*, Jan. 15, 1897.

I believe the only way to decide as to the value of a particular line of treatment is to carefully weigh the evidence for and against it, which evidence is of three kinds:

1. Statistical evidence; that is, reliable mortality tables showing the percentage of fatality in a large series of cases treated with and without it.

2. The individual opinion of men of the foremost rank in the profession, noted as careful observers and clinicians—these men giving their opinion after carefully observing and treating a large number of cases.

3. The evidence of the members of our profession who have used antitoxin to some extent and kept records of a fair number of cases.

Certainly all evidence gathered from these three sources is overwhelmingly in favor of antitoxin as being the best remedy for diphtheria, giving better results than any other known treatment. As Professor Welch of Johns Hopkins Hospital remarked, "It is highly significant that the testimony in favor of antitoxin is the strongest and most positive among those who have had the largest experience in its use; whereas, the doubtful and uncertain opinions come mainly from those with limited experience in the employment of antitoxin."

Statistics.—I have collected the following statistics from various sources, trying to cover as large a field as possible. The statistics of antitoxin are not as great in number as those of cases treated without it and do not cover so long a period, still there have been enough cases treated of all types to warrant the drawing of final conclusions.

Bosworth, in his admirable article on diphtheria, in his text-book on "Diseases of the Nose and Throat," prints statistics obtained from Stern, Martin, Agnew, Lovett and Monroe, these authors having collected them from all quarters. Fifty-four thousand six hundred and sixty-five cases were laryngeal; on all of these tracheotomy was performed, with a death rate of 72.86 per cent. He collects from reports by Stern, Dillon, Browne and Waxham, 4,336 cases, which were intubated, death rate 72.8 per cent. These were not treated with antitoxin.

In the first report of the American Pediatric Society's collective investigation from private practice, we find 533 cases of laryngeal diphtheria in which intubation was performed. These cases treated with antitoxin, giving a death rate of only 25.9 per cent. I quote from the report of the committee, as follows: "The most convincing argument, and to the minds of the committee an absolutely unanswerable one, in favor of serum-therapy, is found in the results obtained in the 1,256 laryngeal cases. In one-half of these recovery took place without operation, in a large proportion of which the symptoms of stenosis were severe. Of the 533 cases in which intubation was performed, the mortality was 25.9 per cent., or less than one-half as great as has ever been reported by any other method of treatment." In the second report for 1896-1897, we find 1,704 cases of laryngeal diphtheria. Of these, 1,036 cases were not operated on, 178 died, a mortality of 17.18 per cent.; 668 required operation, and of these 182 died, a mortality of but 27.24 per cent.

From the report of the German Board of Health (*Arbeiten aus dem Kaiserlichen Gesundheitsamte*, 1897, Vol. xiii, p. 254) relative to the use of antitoxin

in the German hospitals, I find the following: From April, 1895, to March, 1896, 9,851 cases were treated with antitoxin; of these 1,489 died, a mortality of 15.5 per cent. In the same report is found the fatality of diphtheria occurring in German hospitals from 1883 to 1894; these cases not being treated with antitoxin; during this period 157,721 cases were treated; of these 42,176 died, giving a mortality of 26.7 per cent.

I think we can be certain that these various reports are correct, and no matter what may be said against statistics, I believe the foregoing to amply show that the death rate in diphtheria is reduced, by the use of antitoxin, from an average of 26 to 15 per cent. in ordinary cases, and in laryngeal diphtheria from 72 to 26 or 30 per cent.

I select for my own report a series of twenty-three cases which I have treated during the last eighteen months. I have made a careful study of each case and have been able to keep them all under observation. Diphtheria was proved bacteriologically in every case.

Twelve of these cases were laryngeal; three were of an extremely severe type, the remainder not severe, in that the nasal passages and larynx were not involved at the time of my first visit.

The twelve cases of laryngeal diphtheria occurred in children from the ages of 1 to 6 years. Nine were treated with antitoxin, three were not. Of the nine treated with antitoxin nine recovered; of the three treated without, three died; of this number one was moribund and died within two hours after I saw the case.

Group 1.—The child that was moribund on my arrival was 3 years of age and had been sick four days. Her brother, a little over a year old, had been sick two and one half days and the membrane involved the fauces, larynx and nasal passages. I gave 1,000 units, repeated in eight hours, and gave 800 units twelve hours subsequently. The child recovered.

Group 2.—Three children in the same family, respectively 6, 3 and 2 years of age. They were affected with diphtheria nearly simultaneously, and I saw them at the beginning of the third day. Owing to strong objections on the part of the parents I was unable to give antitoxin, although I urged that the delay would be dangerous. On my visit on the following morning I found that the 3-year-old child had died during the night. The parents now requested me to use antitoxin, which I did, giving three injections to each remaining child; both recovered.

Group 3.—Two children in a family; one 3 years of age, one 2 years old. On my first visit I found the older child suffering with laryngeal diphtheria, the other child having diphtheria also, the fauces being alone involved. I was called to the case late in the evening and was unable to secure any antitoxin for thirty-six hours. In the interval the older child died. By this time the membrane in the throat of the other child had extended to the larynx. I administered 1,200 units, repeated in eight hours and gave a final injection of 800 units twelve hours afterward. The child recovered.

All these cases occurring as they did within a month of each other, and being as it were in groups of twos and threes, I can not help believing that if the two children dying had received the serum treatment two human lives would have been saved. No one can *positively* state in a case of death that recov-

ery would have taken place if a certain remedy had been administered. Nor on the other hand can we absolutely affirm that recovery was due to a remedy given, and that death would have taken place if it had been withheld; but we can reason from probabilities and if we see case after case of an extremely fatal disease recover by the use of a certain line of treatment we must assign to it something more than chance. The whole basis of our therapeutics rests on this principle.

The remaining five cases of laryngeal diphtheria occurred in children between the ages of 2 and 6 years. Three cases I saw at the close of the second day; one on the third and one on the fourth. I can simply state that all of them showed symptoms of severe stenosis and all were profoundly sick children. All received large doses of antitoxin and all recovered, and in no case has a single unfavorable symptom presented itself. But I have noted that in these cases, within five or six hours after the first injection of antitoxin, the breathing became easy and the voice less harsh and croupy and the general condition improved.

Baginsky remarks that "cases of laryngeal stenosis and more especially those which do not come to operation, speak to me more forcibly than statistical figures. The surprising regression of the laryngostenotic respiratory phenomena, the disappearance of the harsh voice and the croupy cough, the euphoria of the children the change in their general condition, so that in two days after an injection they were sitting up in bed playing contentedly and observant of their surroundings, all of these things produces in him, who has had before his eyes for years the hopeless picture of continually progressing laryngeal stenosis, in very truth ineffaceable impressions."

Of the remaining cases of my own, none were laryngeal; eight occurred in children between the ages of two and nine years; three in adults between twenty-three and forty years of age. Six of these presented the disease in a severe type, not being seen till the third day. The other five received the initial dose within the first twenty-four hours.

Some of the advocates of antitoxin try to prove by a number of cases that more recovered by the use of antitoxin, and that all would have died without its use. These statistics are not of themselves sufficient, but there should be an analysis of the number of cases, the age of the patient, the number of days the disease has been in progress, its type and variety; then by reasoning from past experience, we can draw conclusions. I have only given statistics of cases treated with antitoxin that were analyzed in this manner, and as such, in my judgment, they are reliable.

Welch says: "A most convincing demonstration of the human power of antitoxin is supplied by the experience of Baginsky during an involuntary pause in the serum treatment, caused by failure of supply of serum. Between March 15, 1894, and March 15, 1895, there were treated in Baginsky's service in Berlin, by antitoxin, 525 children, with a fatality of 15.6 per cent. During the period of enforced interruption of the serum treatment, this period being chiefly the months of August and September, 126 children were treated *without* antitoxin, with a fatality of 48 per cent. There was absolutely no selection of cases in either group." In his comments on this experience, Baginsky says: "It is all the more remarkable as the ratio of mortality of those treated with the serum, both

before and after the period of interruption varied in very small percentage. If one will permit figures to speak at all, there has scarcely been made on human beings a more demonstrative test of the curative power of a therapeutic agent. It was an experiment forced upon us, but it proved to us how numerous would have been the victims without the use of healing serum."

A similar experience has been reported by several other writers. Korte noted a rise in fatality from 33.1 per cent. during the serum period to 53.8 per cent. when the supply failed.

Ganghofer, under similar conditions, noted a rise from 12.7 to 52.2 per cent. Hein, from 22 to 65.6 per cent.

A good deal of controversy has arisen in a few fatal cases occurring from the use of antitoxin. I think it a conservative estimate to say that over one hundred thousand injections of antitoxin have been recorded. I believe the treatment speaks for itself in the few accidents that have happened. I distinctly remember the case of a girl of 11 years, who died of diphtheria in 1892. She had an attack of diphtheria, the membrane not involving the larynx or nasal passage. The second day of the disease she sat up in bed and asked her mother who was in the adjoining room to bring her something. Before her mother reached her bed, she was dead. The medical opinion given was, that death was due to cardiac paralysis. If this patient had received, just before death, a dose of antitoxin, the serum would have been blamed. May it not be that some of the few sudden deaths laid at the door of antitoxin were due to a like condition, and *not* to the use of the serum?

There is a right and a wrong way to administer antitoxin. The admitting of a quantity of air with the injection, a dirty needle, the filling of the syringe with a strong solution of carbolic and failing to expel it all before refilling it with serum—all of these blunders may cause symptoms and results for which antitoxin should not be blamed.

It is impossible, in any case of diphtheria, to say whether the case will improve or laryngeal stenosis develop, or what complication will arise or sequelæ occur from the action of the diphtheritic virus or streptococcus sepsis.

It is the opinion of the most noted men and of the majority of physicians that antitoxin is the best agent at our command to prevent these unfortunate results from supervening by neutralizing the effects of the Klebs-Löffler bacillus, thus putting the patient in a position where he is not so susceptible to secondary invasion. It takes a definite quantity of antitoxin to neutralize a definite quantity of toxin; we can not tell, in the human subject, just how much of the toxin has been formed by the diphtheria bacillus, therefore antitoxin must be given in large quantities, and the earlier the better; administered early it will arrest the diphtheritic process, and it is the duty of every physician to use it in mild as well as in severe cases. It offers the best chance of saving life in the latter, and as we know not how soon a seemingly mild case may turn into one of a severe type, we should by giving the serum cure the disease and prevent its assuming a dangerous character.

In making a diagnosis of diphtheria I believe we should note all the clinical features presented and form our judgment from these. At the same time a culture should be taken and a bacteriologic report

obtained as soon as possible. If the physician believes the case to be one of true diphtheria, let him treat it as such, using antitoxin, giving the patient the benefit of the doubt and every chance of recovery. If this is done and the case proves to be one of true diphtheria, much valuable time will be saved and many grave complications be warded off. If, on the other hand, the case is not one of diphtheria, the tentative dose of antitoxin will have done no harm, notwithstanding a few opinions to the contrary. I do not believe properly prepared antitoxin, administered in a proper manner, can cause bad results.

We must consider the discovery and application of the antitoxin treatment as an advance in our glorious profession. It is not a sudden and brilliant find, but it is the outcome of persistent work in the laboratory. The investigators in this field had a set problem to solve, and finally have done so, but only after patient toil and labor.

DISCUSSION OF THE PAPERS ON DIPHTHERIA.

Dr. FREDERICK A. PACKARD of Philadelphia—When asked if I would open the discussion on the antitoxin treatment of diphtheria, I wrote to Dr. Tuley and told him I thought it would hardly be worth while to discuss the antitoxin treatment of diphtheria with any man who could not discover enough in the published statistics to convince him. I think this is true; the published statistics at our command must now convince any man who can be convinced at all; I have, therefore, prepared some statistics, which have been pretty well covered by Dr. Gray's paper. I admit that statistics and figures can lie. But statistics and figures differ somewhat from the human being, inasmuch as statistics and figures as they grow bigger lie less; human beings are likely to lie more. Hence, the greater the statistics are the more accurate they are. Dr. Gray has brought sufficient of them, I believe, to convince anybody who could be convinced. I would like, however, to know how it is possible for anyone who is skeptic to explain the experience of Baginsky and Roe. Their mortality increased so markedly when their supply of antitoxin was exhausted, and when they obtained a supply the mortality percentage ran rapidly down. I can not understand how anyone can get over this point made by Baginsky and Roe.

There is one point I was sorry not to hear brought out and that is the use of prophylactic doses of antitoxin. I am a staunch believer in the therapeutic use of antitoxin, but I am beginning to be a disbeliever in the prophylactic use of this remedy. Quite a percentage of fatal results have occurred after the prophylactic use of antitoxin. The death of the child of Professor Langenhaus, for instance, was after a prophylactic dose of antitoxin. So it is a question in my mind whether we have a right to use prophylactic doses of antitoxin in healthy people. I believe we should treat every throat exposed to diphtheria as every physician should treat his own throat when treating diphtheria, by using antiseptic washes to wash off all the Klebs-Loeffler bacilli collected there. I have seen some cases where I felt I had done something to prevent the spread of diphtheria, although they might not have had diphtheria if no preventive treatment had been resorted to.

Dr. WILLIAM P. NORTHRUP of New York—I wish to say something in regard to the prophylactic use of antitoxin. In the New York Infant Asylum they stopped a furious epidemic of diphtheria by prophylactic injections of small doses of the serum. It was so serious an epidemic that my telephone rang me out at 6 o'clock on Sunday morning to go to Mount Vernon in consultation. That is, the consulting staff was summoned in consultation, and when it was serious enough for that and for us to have to go, you know it was important. There were no deaths among the adults; there were plenty of deaths among the children, but the epidemic was stopped by prophylactic injections and there were no accidents from the injections.

With regard to the collective investigations, without rehearsing figures which are very familiar to me, as I hope they are to you, the Pediatric Society sought to place a crucial test on the value of the antitoxin treatment of diphtheria. In order to have a test they must first of all have a control. We looked back on the records of intubation and we said the statistics of intubation are sufficient to act as control and so we will lay our stress on intubation cases of laryngeal diphtheria, since anti-

toxin was well established, not in the experimental stage when the serum was uncertain and the dose not well understood. You will understand the nature of the work of the committee when I tell you there were 60,000 circulars sent out, from which we received 1,900 returns, 1,700 of which we could use, and of this number 600 cases such as we were looking for, intubated cases of laryngeal diphtheria, cases had enough to demand intubation. There might be differences of opinion about a child that is hoarse or croupy or that had stenosis, but if it was so bad they had to put in a croup tube or a tracheotomy tube, I assume we will all admit that it was a case of severe diphtheria. Altogether there were 668 such cases for the test of the value of antitoxin. In pre-antitoxin days if we got twenty-five recoveries in a hundred we did very well, and 27 per cent. of recoveries was about the best we could do. I have lived at the elbow of Dr. O'Dwyer and I know what his experience has been, and I have tried to guide my experience by his. At one time I had twenty-two successive deaths in private practice from laryngeal diphtheria after I had put in a tube, and not because I had put it in so badly for I had a very good record before that. On top of that Dr. O'Dwyer had twenty-five cases of death with all the best treatment we knew then. I only cite that to say that I have not heard of anybody having a series of deaths so distressing as that in the past year or two. These 668 cases then represent a severe type from all over the country. A large part of the returns came from west of the Hudson, all the way from around St. Louis and away up in Michigan, so there was no chance to cook the terms and very little opportunity for accidents. You will please note that in the best of the control cases the very best we could get was twenty-seven recoveries in a hundred, and in the last report of 668 cases there were twenty-seven deaths in the hundred. Whereas before there were twenty-seven recoveries in the hundred, now there are seventy-three. I would base my reasons for urging you to adopt antitoxin for the treatment of diphtheria on these figures.

Now a word about the dose. Some cases among the returns we received reported 200 units used in a bad case of diphtheria. A few cases were sent that even did not give the amount of antitoxin used, so carelessly were our circulars read by some. I would like to give you my convictions, because I have been thoroughly saturated with this work for four of five years. In the New York Infant Asylum we have about 800 children in one block, and that is rather a bad place to have diphtheria. We used to have rather bad times there when we got diphtheria, especially if we got it mixed up with measles. Now it is the prevailing feeling among the laity, among the nurses who take charge of these cases that diphtheria is shorn of its terror. They have more fear of measles. One of them said to me: "Why is it, Doctor, when the cases of diphtheria come back to the ward we do not have diphtheria in the ward?" She did not recognize the fact that we made many, many cultures, and did not permit the case to return until these were entirely negative.

At the Presbyterian Hospital we have a miserable, little, children's ward. This small ward has turned out eight cases of diphtheria among the nurses. None of the children had it, but they did have what from my standpoint I recognized as a little nasal discharge. There has been so much decrying of the bacteriologists' work that I mention this instance.

I believe antitoxin is just as much a specific for diphtheria as is quinin for malaria. I believe, thoroughly, if you were to inoculate a baby two years old, you could nullify 1,000 or 2,000 units with a relative proportion of the antitoxin. In other words, I believe it is a specific in the human just as much as in the guinea pig. In the guinea pig it is a true specific. Anything that disturbs that in the child takes nothing from the definition. A tuberculous temperature will stay a tuberculous temperature in spite of antitoxin.

As to the dosage of antitoxin, I believe we should inject not less than 2,000 units, and this dose should be repeated in twenty-four hours if there is no manifest improvement, and again in twenty-four hours if no further improvement takes place.

Dr. LOUIS FISCHER of New York—When I first saw the efficacy of antitoxin in 1894, I only had a repetition of what I learned from Professor Behring in 1891. We were then still skeptic regarding the antitoxin of diphtheria because of the failure of tuberculin. Last summer while going through his Children's Hospital, Professor Baginsky told me he had no more dread of diphtheria since he was using antitoxin than he would have had years ago from any simple ordinary constipation. In fact, he said he wished he had as strong a specific for the other infectious diseases as we have today for diphtheria. I watched the cases under his treatment and a case of malignant diphtheria would receive 1,000 to 1,500, in some cases 2,000

units, and in twenty-four hours be transformed into a case of simple sore throat. I think the question of the dose should not be answered definitely, for if I were to ask you the dose of castor-oil to be given in a case of constipation, you would have to say that would depend on the cause of the constipation. While one case might be relieved by a teaspoonful, another would require a tablespoonful. Also, we must look into the idiosyncrasy of the patient. I have seen some cases receive 6,000 units. But I believe a good round dose of 2,000 units would be a good beginning dose in a malignant case of diphtheria. I think we have gone over this subject quite thoroughly and we who have watched the work of the foremost men, especially on the other side of the Atlantic, will have no fear of the result with antitoxin. I have seen the membrane thrown off in so short a time that I have no hesitancy in saying a case will get well. I saw this afternoon, before leaving New York, a case with distinct septic symptoms, malignant diphtheria, temperature 100 degrees, that low temperature that I regard as so malignant, the child decidedly pale and anemic from the whole system being drenched with the septic element, besides the loss of sleep and the want of food, inanition, all of which goes to make diphtheria so malignant. The first thing to do was to relieve the asphyxia by putting a tube into the throat, and then we considered the further therapeutics of the case. We injected at first 2,500 units of antitoxin and I agreed with the physician that if the child's condition is not better by 9 o'clock tomorrow morning, to give the same dose again. Those are things we have seen so often it seems almost useless to talk about them.

As a rule, if the child is not moribund it must get well when treated with the proper dose of antitoxin. One case will require more of the antitoxin, when the system is overwhelmed with the toxin, and another will require less. I know, in talking this matter over with Professor Jacobus, he was not anxious to use antitoxin until he knew what others had done, but now he considers it a crime to treat diphtheria without the use of antitoxin.

Dr. H. A. WEST of Galveston—The idea I have had in regard to the *modus operandi* of the diphtheria antitoxin has been that it is a remedy, as the name indicates, that is especially active as an antidote to the toxin of diphtheria. Now when it is claimed that this serum acts upon the bacilli, that it has an effect upon the lesions produced by the bacilli in addition to its antidotal effect upon the toxins, it involves an entirely different explanation. I do not mean to doubt that it does accomplish this, because I think the facts go to prove it, but if it has been conclusively proven that the diphtheria serum will cure those cases of diphtheria, then it must be admitted it has an effect not only on the toxins but also on the bacilli. That is the question I wish to ask. What is the explanation of the action of the serum in the treatment of the cases of laryngeal diphtheria?

Dr. H. A. ARNOLD of Pennsylvania—On the advent of antitoxin I hailed it with as much delight as any one. I began its use early and for the time everything seemed auspicious. There were prompt manifestations. The membranes separated and it was possible to prognosticate changes and see those changes afterward. During the early part of the winter just passed, I was called to see a child that had been treated, by another physician, for tonsillitis. A bacteriologic examination revealed the presence of the bacillus and satisfied me as to the nature of the disease. I used the antitoxin, considering that I had a good chance of recovery, but the child died. About two miles from that place I had a child sick with diphtheria. I used the antitoxin. The membrane disappeared in the throat. There was an abnormally slow pulse, dropping to 50, 45 and 40 beats to the minute, and the boy died. About two miles and a half from there I used antitoxin in another case about the same age. I believe the children were six, seven and nine years of age. I had a disappearance of the membrane, but there was complete suppression of the urine and the child died. The point I wish to make is that this serum was procured from one of the most reputable makers in this country, but every bottle contained the same number and the same letter. I took the numbers to the manufacturer and asked an explanation. The proprietor appeared very anxious to give an explanation, but the bacteriologist in charge of the laboratory evaded me. I have had no other deaths; I have treated no other cases of diphtheria since.

Dr. Cook of Illinois—The doctor whose cases all get well is a poor diagnostician. As a matter of fact, I have a record of eighty-nine cases, microscopically diagnosed, without a death, without an intubation and without a second dose of antitoxin. They were as cases run in private practice.

THE CHAIR—Please state the number of units and the potency used; you need not mention the maker's name?

Dr. Cook—2000, I think; I have not my statistics in shape to give them. I only spoke of this, as the Doctor on the other side of the house spoke of his fatal cases, to balance the evidence on the other side if it is possible to do so. I made my first observations in Berlin, under Professor Baginsky. My first case I saw in the Charité and it was a marvelous thing to see the membrane disappear from the throat without a single thing having been done, further than the use of the antitoxin. The eighty-nine cases I have mentioned received, on an average, about 2,000 units. Once or twice I gave only 1,000 units, and as far as I could see they did as well, although they were mild cases. I always reserve the right to repeat the dose.

QUESTION—Will the Doctor state how many of those cases were cases of laryngeal diphtheria?

Dr. Cook—No, I can not exactly, but I should say ten or fifteen of them. I have the record of the cases but did not bring it with me because I did not expect to report the cases. There were some quite bad cases. In reference to the matter of intubation, and I do intubation occasionally, although I have never done it on my own cases, it seems to me intubation is a good deal like a boy whipping his horse when he has a whip. If you are at hand with your tools the child will often need intubation, whereas otherwise it would not.

Dr. C. GRAEFE of Sandusky, Ohio—I should like to bring up one point, the suspicion not only of the laity but of the profession at large in regard to these statistics. These statistics, as cited here, are principally those of hospitals, besides those of collective investigations. But they are so large and extensive that the general practitioner is likely to be suspicious of them. When the matter is brought home to him, there is so much made of one failure that he hesitates a long time before he will give the new treatment any consideration or will venture its use in private practice. Last winter I found myself in this position during an epidemic. After using the ordinary remedies for the ordinary types of the nasal disease, there developed suddenly a great line of laryngeal cases. They died very promptly under the ordinary treatment; only here and there one got well. According to the report of the health officer, the statistics of the epidemic show fifty-three deaths and forty-seven recoveries. These include my cases besides all the others reported at the health office. My cases, where I used antitoxin only for the laryngeal cases, show a record of fourteen recoveries out of sixteen cases of laryngeal diphtheria. In three other cases in the practice of other physicians, where I used it at their solicitation, there were three deaths. They neglected to do what I would have done, that is to repeat the dose in twelve or twenty-four hours. Some of those cases were better in twelve hours, worse in twenty-four hours and promptly died. I think these cases show about what they bring forth in hospital cases, but my reason for presenting them here is that the general practitioner should have impressed upon him that he can do what they do in the hospitals and his mortality can be made as good as that I have here presented.

Dr. McFARLAND of Philadelphia—My administrations of antitoxin number something over three thousand, but unfortunately they have been given to animals. It seems to me that in this whole discussion the antitoxin treatment of diphtheria has been treated as though it rested on an empiric basis, whereas in reality it rests on scientific principles worked out in the laboratory. Nobody doubts the utility of the hydrated oxid of iron in the treatment of arsenical poisoning, because he knows from laboratory experience that it is an antidote for the arsenical poisoning. Nevertheless, many cases die from arsenical poisoning notwithstanding the use of this antidote. So it seems to me it is foolish for us to condemn the use of antitoxin in diphtheria because some cases die notwithstanding its use. I will give you some cases to show that antitoxin will do some good. I have seen two horses die after the injection of one cubic centimeter. About six weeks ago, in the laboratory, I gave a horse 100 c.c. of antitoxin serum. I can not give you the strength of the serum, but it was I suppose a serum averaging 100 or 150 units to the cubic centimeter. The first day I gave 1 c.c., and the next day 150 c.c., and the horse showed no symptoms. A definite amount of serum will protect a guinea pig against an equal amount of toxin. Thus, 10 c.c. of the serum will protect against 10 c.c. of the toxin, and 100 c.c. of the serum will protect against 100 of the toxin. I have no theory of my own to present. I am rather inclined to that presented by Dr. Klebs, that the antitoxin is a toxin in a changed form, that the toxin is in some way oxidized or transformed. At any rate, it is an absolutely certain antidote, a neutralizing agent.

Dr. G. W. Cox of Chicago—One point very frequently overlooked is the selection of the serum. It has been my fortune to go around and inquire for diphtheria antitoxin a number of

times in Chicago, and when I would ask my druggist for it he would go to a room with a temperature of 75 or 80 degrees. When I would ask how long the antitoxin had been there he would perhaps say two or three months. It has been demonstrated that the antitoxin must be kept in a cool place or it will lose its potency in a short time. I have no doubt in the world that many of the failures in the use of antitoxin may be traced directly to this source, that antitoxin perfectly good and potent in the beginning has deteriorated by being kept at a high temperature.

Dr. MAYER of Johnstown—There are a few minor points brought out by Dr. Coughlin that should not go unassailed. They are minor points and do not touch on the value of antitoxin. To my mind, and to the mind of the majority present the remarks of Dr. Packard apply to antitoxin. But Dr. Coughlin spoke of punishing children with this disease. We all know the depressing influence of diphtheria on children, and anything which will depress the child further is so much against recovery, and anything in the nature of pain will be against recovery. Bribing and coaxing and anything else that is not punishing will be a good plan. Another thing he proposed was the use of ice cream. If ice cream is not too sweet, it will do no harm. I believe if we will instruct our nurses to make an ice cream without sugar it will do no harm and will do good. The Doctor assailed the use of whisky. There is no question in my mind but whisky is essential. The truism was brought out by Dr. Rosenthal that the doses and the limitations of antitoxin applies as well to that of stimulation in diphtheria.

Dr. H. H. WITHERSTINE of Rochester, Minn.—I wish to report twenty-five cases recently treated, with one death. In one family there were ten children. When called on to see the first child taken sick, I isolated the child and administered the antitoxin about 5 o'clock in the afternoon. The child seemed to me to be very sick and had been ill for three days. The pulse was 140. The next day the membrane came off the throat and the child was playing. I kept the child isolated from the rest of the family until the bacteriologic examination revealed no more germs. Then the child was permitted to go with the rest of the children. Unfortunately, a few weeks after that, another child was put to sleep in the same room where this child was sick. I speak of this to bring out the point and emphasize the importance of more thorough cleansing and fumigation. I want to emphasize the point, too, that fumigation as practiced in most cases is entirely useless. Another child was taken ill with diphtheria, and so on one after another, and I used antitoxin in every case, using only one dose of 2,000 units. Coming to the last children, I made up my mind they also would have diphtheria and I injected the prophylactic dose, and they did not have diphtheria.

I want to call attention to another point that I consider quite important in using antitoxin and that is having the antitoxin syringe thoroughly aseptic, thoroughly sterilized, and after it is used to thoroughly sterilize the point of injection and dress it as the surgeon does his wounds, in an aseptic manner.

Dr. EDWIN ROSENTHAL of Philadelphia—It is rather unfortunate in arranging these statistics that some stress is not paid to the mortality during the epidemic. The mortality in the epidemic I studied was not better than before the use of antitoxin. I say this with all due respect to the feeling of the Society. This afternoon I talked with a physician about an epidemic that had been raging for the past two weeks, during which 102 cases were treated and three deaths resulted. In only some five or six cases of this total was antitoxin used. Consequently, in estimating our statistics it is well to acknowledge that the mortality at different seasons of the year, at different institutions and in different constitutions differs materially. For example, had antitoxin been used in these 102 cases, the list would have gone to swell the good statistics of the antitoxin treatment.

Dr. HOUGHTON of Detroit—There are two points I wish to refer to. One is the statistics where antitoxin is used and where it is not used. During the twelve months preceding April last, in the city of Detroit, according to the report of the health officer, between eight hundred and nine hundred cases were treated. Nearly all of these cases were examined and diagnosed by bacteriologic examination. About 400 of these cases were not treated with antitoxin, the other 400 were treated with antitoxin. The mortality of those treated without antitoxin was 34.9 per cent., while in those cases treated with antitoxin the mortality was 12.5 per cent. That includes all the cases during the year.

In regard to the explanation of sudden death after the use of antitoxin, I would like to relate a case that occurred in Iowa. The doctor was called to a family where three members were suffering with diphtheria. After consultation with the family

he concluded to use antitoxin and that he would begin by injecting the older patient, a young man. The young man was walking around, suddenly he said he felt a little pain, lay down and died in a few minutes. No antitoxin had been used. The other two children were injected and both were saved. I have frequently noticed in immunizing animals, that after a large dose was given there sometimes follows diphtheritic paralysis and the animal dies suddenly.

As to prophylaxis, I do not believe antitoxin has been used as much and with as good success as it might be. During the past few years I have had to deal with diphtheria in the wards of the Children's Hospital. I was called in consultation two years ago, and most of the physicians and myself agreed that it would be a good plan to use diphtheria antitoxin as a prophylactic. Thirty four patients were injected. The house physician, however, was not injected. We had no more cases develop, except that the house physician developed a marked case of nasal diphtheria. Afterward we had an outbreak, and I was called again, but the epidemic was stayed. During November we had a third outbreak, which was also stopped, and during the month of February we had another outbreak, which was promptly stopped. Three of the children injected were under 3 years of age and no detrimental results were noticed in any of the cases, except there was a slight urticaria in nine cases.

Dr. LOUIS FISCHER of New York in reply to Dr. West—I believe the question is one which involves the basis upon which most scientific work has been done. We all know that in treating diphtheria we try to overcome the damage done by toxins, or poisons, created by the bacilli. Many experiments have shown that the bacilli will persist for weeks and months after the case is supposed to be well. That is to say, if a bacteriologic examination is made of a specimen taken from the site of infection, we can cultivate the bacilli for weeks after there are no macroscopic evidences of infection. Therefore we do not in this treatment attempt to attack the bacilli so much as the swelling and edema, the results of the invasion of the bacilli and their products, the toxins. The treatment of diphtheria, as has been stated here, is one of those positive treatments in which we inject a substance that is capable of controlling the disease just as we can control arsenic poisoning with the hydrated oxid of iron. We know that by injecting a sufficient quantity of antitoxin we merely neutralize the toxemia which causes destruction. I should like to be put on record, though, as not being one of those gentlemen who every time he sees a Klebs-Löffler bacillus in the throat or mouth insists on using antitoxin. I am not one of those bacillophobists. On the other hand, I believe in using the antitoxin in cases that eminently need it.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

XVII. DISEASES OF THE HEAD AND FACE.

(Continued from page 1065.)

We shall here give the supposed relations existing between the brain and the liver. Chopart, Desault and Mursinna interpreted abscesses of the liver as a consequence of a cranial injury, as well as a concussion of the liver; later, Desault considered the relation unknown and probably brought about by the nervous system. Pouteau caused more blood to enter the aorta descending than ascending by interrupting the arterial and compressing the venous circulation; in this wise the liver became more highly inflamed, being supplied by two vascular systems. Richter and Cheston were of the opinion that the ulcers of the liver resulted from the acidity of the bile and charged it to the consensus existing between the skull and the intestines; at times they believed them the effect of direct injuries to the liver. Gradually a reaction against trephining became apparent in France. It was known that within sixty years Mery had not saved the life of a single trephined patient in the

Hôtel Dieu of Paris. Likewise Maréchal, the head surgeon of the Charité, lost more than one-half of the patients he had trephined, while in Versailles and Fontainebleau, out of twenty operated cases scarcely one died. The consequence was that from about 1780, trephining was abandoned in the Parisian Hôtel Dieu. And so we enter upon the third period with Desault. First of all he disputed that trephining of itself was without danger; on the contrary. The admittance of air into the great cavity could in no wise be an indifferent matter especially in unhealthy hospitals. When Desault entered the Hôtel Dieu, he trephined like his predecessors, with the same unfortunate results. That the mere presence of a fracture did not indicate an operation, had already been established; yet, was one to trephine when without a depression it was accompanied by appearances of compression? Also, experience taught him, that he had to take the risk of an operation upon himself. Later, he trephined only in the most urgent cases of fractures with depression or with indications of compression. But he also gave up this method; because he usually attained the required results by grasping the fragments with forceps. Furthermore, he did not believe that suppuration of the brain indicated an operation, for one could never know whether there was any pus present and where located, if any. So during the last five years of his life Desault did away with trephining entirely on account of its dangers, its poor results and the great success of his new method. In all this time he safely treated more injuries of the head with depression without the trepan than with it. (It is an old story, yet it will ever remain new, that no one will believe until taught by experience. So we come across Dieffenbach, who underwent the same experiences as Desault. During the first years of his practice he trephined often and saw his patients die; then as his experience grew apace he restricted the operation to a few exceptions.) Desault treated fractures of the skull with blood-letting, stimulants and purgatives. Schmucker's cold compresses were unknown to him and to the rest of the hospital surgeons in Paris. He restricted himself wholly to the above general remedial agents. Among the stimulants, a cantharides plaster spread over the entire head at first appeared to him the best method of treating concussion of the brain; but the effect of the same not lasting and the patient relapsing into a stupor, he gave up this plan and used tartar emetic. This he prescribed more especially to stimulate than to evacuate in doses to be taken about every ten days without interruption; he also ordered enemas. The more he became convinced of the astonishingly favorable results produced by the use of the tartar emetic, the greater became his aversion to trephining. The inflammation of the brain and its membranes seemed to him to be either of a phlegmonous or a bilious nature; if the former was the case, repeated bleedings, leeches, rigid dieting, fresh air and enemas were required; if the latter, no bleeding, but tartar emetic and purgatives were resorted to. Inasmuch as the same symptoms shown by afflicted patients with cranial injuries indicated very different affections of the brain, those of compression, concussion and inflammation being more or less alike, so that the origin remained rather doubtful, the treatment was thereby rendered very difficult. Therefore, Desault, if there existed any doubt regarding the diagnosis, desired to employ such methods as would do no harm.

Another great opponent of trephining was found in Lombard at Strasburg (1796), after he had seen troublesome fractures heal without it with a strict mode of living. According to his ideas, out of twenty-five trephined cases only five would recover, and these could, perhaps, have been cured without an operation. The indications which had first given rise to the use of the trepan, namely elevation of depressed fragments, extraction of splinters and draining of extravasations, should constitute a limit beyond which no one is allowed to go. Arnemann (1799) expressed similar views against the malpractice of trephining, yet thought there were cases when operation was indispensable.

Speaking of the operative technique, we shall briefly remark that the instruments were gradually simplified. J. L. Petit invented an elevatorium, which was supported by a small block; Cheselden and Sharp again introduced the trephine, which since then has been the main instrument used by the English; Pott and B. Bell preferred the large trepan crown to the small one; Theden scraped the bones of children with glass; Richter recommended the old forgotten tripod instead of Petit's and Louis' elevators. The movable pyramids of the crowns were contrived by Bichat, and a saw by Hey, with which instead of the trepan he trusted himself to remove any fragment of bone. Hill opposed Pott's oval incision and advised the crucial, and unlike him applied the trepan to the side of the fissure, not on it. The removal of the oval-shaped piece of skin and the exposure of the entire fracture Richter also disapproved of, and he removed only as much as necessary. He first perforated where the skin was badly contused, while Bell trephined on the most depressed portion of the fracture, because he thought it the place where the blood would settle. Proceeding from the principle to heal all wounds by quickly joining, he contrived a new plan, by not wholly cutting away the piece of skin of the cranium, only loosening the same, putting the trepan on the periosteum, which was not scraped off on account of its insensibility, and then adjusting the flap by adhesive plaster and sutures. Regarding head-bands we will make use of the opportunity here afforded to rummage among the bandages so as to give an idea of their great size and at the same time promise never to stir up the dust among them again. Already Verduc had reduced the number of bandages, of which seventy different kinds were described by Gesner. Heister furnished twenty-one illustrations, and Henckel, in the year 1756, gave a description of seventeen bandages, as follows: 1. The large or four-cornered head bandage or cap, the large bandage of the head, capitium magnum or quadratum, tegumentum capitis quadratum or magnum, fascia capitis magna or quadrata or quadrangularis; le grand couvre chef, le couvre chef en quarré. This was the most frequently used bandage, especially after trephining. 2. The small or three-cornered head band or cap, like the above, but not so warm, consequently more appropriate for the summer. 3. The screw hat, mitra Hippokratidis; in cases of severe headaches, hydrocephalus and congestion. 4. Funda capitis, frondium; for cranial injuries. 5. The six headed bandage, the cancer of Galen; also used for cranial injuries, particularly in hot air. 6. The uniting head bandage; for wounds of the forehead and eyebrows. 7. Scapha; for wounds of the base of the skull. 8. Fascia stellaris, stella; for the compression of the temporal

artery, after the extirpation of the parotid and sub-maxillary glands. 9. Oculus simplex; for injuries to one eye, the eye-lids and cheek. 10. Oculus duplex capite simplici; for both eyes. 11. Fascia triangulæ ad oculos; in default of a fascia contentiva. 12. The four headed bandage hawk; for cut-off noses. 13. Discrimen in morbis nasi; like the preceding, also in fractures of the nasal bone. 14. Funda; for hare-lip. 15, 16, 17. Capistrum simplex, duplex, funda maxillaris: for fractures and luxations of the lower jaw.

Let us get out of this suffocating dusty rubbish chamber of bandages of a hundred years ago. During this short period of thirty years of strife among the best surgeons, what had become of trephining? From the luxuriantly growing tree fell one twig after the other until a rotten, almost dead trunk remained.

In case of *facial wounds* it was very desirable to avoid a disfiguring scar by means of sticking plaster or a suture. The latter did not readily gain favor, although it had already been highly recommended by F. Wuertz in wounds of the cheek, nose, ear and in hare-lip. Only the skin of the ear and nose were caught in sewing, not the cartilage. Even when the nose was nearly or entirely cut off, agglutination was tried and occasionally with success (Ravaton, Nannoni). In case of failure, an *artificial nose* had to be worn. Tagliacozzi's rhinoplastic (1597) was not understood nor any interest manifested for the same in the eighteenth century, not even by a single surgeon. When the Medical Faculty of Paris put the question, "An curtae nares ex brachio reficiendæ," it was unanimously answered in the negative. The art of the Italians, whose success Heister doubted, was like a ridiculous fairy tale to Dionis. Without having put rhinoplasty to a test, Camper, Richter, Chopart and Desault considered artificial noses of light wood, papier maché, silver or lacquered linen, which were fastened by means of two springs in the nasal cavities behind, preferable to those of flesh and blood. J. Hunter did not comprehend Tagliacozzi's method, for he believed that it concerned the transplanting of skin from one person to another. ("The joining of two parts belonging to different bodies is what Tagliacozzi advised.") Richter also spoke of a piece of skin taken from a stranger engaged for the purpose and thought that such a nose would not be as perfect a substitute as one of wood, which was often hard to detect. In 1794, a Madras paper reported the first new nose which had been grafted by a physician of India the year previous, from the skin of the forehead of a man, whose nose had been cut off as a punishment. Carpue of London, performed the first rhinoplasty in Europe in 1814 by transplantation. (Among the prothetic efforts made the past century, are also worthy of mention, besides the artificial noses and feet, the artificial eyes manufactured out of glass and enamel. The former were worth one florin each, the latter, one guinea. In 1782, there is also mention of an artificial chin which the Parisian mechanic Merklin contrived for a sailor, whose lower jaw had been shot off; he was thereby enabled to again speak distinctly.

The *nasal polypus* was either a flesh or mucous polyp, or a malignant one. B. Bell considered as more important the local nature of the former two, while Richter deemed it more essential whether their origin was due to syphilis and scrofula. In the treatment of the same, there was little that was new;

most of the modes had been known in ancient times. The flesh polyp, the most common of all, was generally torn out, that is, more correctly speaking, it was twisted off on account of the bleeding. In consequence many different kinds of forceps were invented. Richter's nippers for polypi, approved by many, could be taken apart at the screw, so that every spoon might be inserted severally. Sharp had notched the ends of his forceps; Garengot had roughened them with lattice work, to enable him to hold the swelling more easily. The bleeding was stopped by means of ice water, by making a plug of the finger, or by inserting a wad of lint, which was drawn up into the nose after the manner of the Bellocq tube with a catgut; the safest way, though, was to pull out the remaining piece of root. Richter did not favor the ligature; on the other hand he thought much of the hot iron in the form of a trocar, to be used in cases of polypus that bled but little or very freely, and with exhausted patients. The malignant polypus, for many a noli me tangere, he removed as soon as possible, and so contradicted Pott's statement that it was useless to treat many polyps which, although not cancerous, were accompanied with intense pains, continued to grow uninterruptedly, bled when touched, and had greatly grown, presenting a deep red color. The mucous polypus being a prolongation of the Schneiderian membrane, he treated with astringents (ice water, alum, lead), which, when ineffective, were changed for the ligature or incision; relapses were treated with the cautery. For swellings situated far back in a cavity, Theden constructed a special pair of forceps; on the other hand, Manne of Avignon was the first to cut through the palate (1747), an operation which Morand defended. An improvement in the treatment of polyps was brought about by Levret's improved ligature (1749). He taught how to remove polyps which had heretofore been inaccessible, from different cavities of the body with a double cylinder and silver wire. Desault favored this idea and invented a cleft sling fastener, using linen thread in the place of the silver wire, which easily tore, and with it operated on polyps in the nose, ear, uterus and rectum. Levret's method was considered by B. Bell for all polyps the best and easiest kind of treatment and less painful than the operative interference with the forceps. Hereupon Richter declared undisguisedly that he had not as yet been able to tie off a nasal polyp, therefore pulled them out; furthermore, he confessed that he once mistook a swelling for a polyp of the nose and a few months after the operation discovered that the swelling was the result of a fracture of a skull. On the other hand, he tied those polypi in the rectum, in the uterus and in the upper part of the esophagus. In cases of the last kind Bell lowered a wire ligature into the same, in which he tried to catch the swelling. But if this was too low down so that it was too difficult to succeed with the ligature, then he, as well as Richter, advised tracheotomy, "an easy and harmless operation," before tying off the polyp, which could until then lie in the mouth.

There existed a prejudice against operating children with *hare-lip* before they were two years old. Heister opposed this prejudice, because he successfully operated on children six months old, and Roonhuysen, children ten weeks old. The number of successful operations on new-born children increasing, Richter also became convinced that the most appropriate time was soon after birth, especially when com-

bined with a fissure in the roof of the mouth, which would close after the operation of hare-lip (Sharp, Levret, LaFaye). The age from 3 to 10 years he excluded, waiting until the children had become more sensible. All preparatory measures, like the drawing together of the lip by tying, etc., were rejected; on the other hand Desault recommended to clear the head of vermin by combing and application of mercurial ointment as a preliminary to the operation, and thus prevent the later moving of the bandage. When the fissure extended far up into the roof of the mouth, the upper lip with the frenulum was severed. The edges of the cleft were very carefully denuded with as little loss of flesh as possible, very narrow lips being held with a common pair of forceps, instead of the old clumsy nippers. One surgeon would operate with a pair of scissors, another with a knife. With exaggerated importance, Louis defended the latter and contended that the scissors gave more pain and bruised (1768). This was a sort of prefatory gossip to Percy's prize essay on the Scissors (1785), in which it was placed far behind the bistoury. The greatest cry was made in Paris, and Desault, although at first uncertain in his choice on account of Louis' fame, finally decided in favor of the scissors. Also Richter used a dressing scissors and allayed the gossip concerning the use of knife or scissors, or both, with the following words: "Moreover every surgeon may and can select the instrument he thinks the most convenient: both have been used with equally good results." Later Lucas of London, cut off one margin with the knife, the other with the scissors. All educated surgeons used the twisted suture and did away with the interrupted suture, on account of the irritation caused thereby. The apparatus for sewing was improved. Instead of the steel needles which Paré had already used, and which were apt to rust somewhat, silver ones (J. L. Petit) with steel points that could be unscrewed (Sharp, Richter), were employed, and even gold ones (LeDran, Desault). As early as Heister's time and later, a few quacks and wandering operators successfully employed two or three interrupted sutures, which were removed after three to six days. In former years Desault and Chopart preferred the same, but now Ollenroth was about the only one of the surgeons left who clung to the interrupted suture, after having learned how to sew it from the itinerant surgeon Köhring. Now also Pibrac and especially Louis rejected all forms of sutures and joined the wounds by ligatures and court plaster, like P. Franco did long ago. But Louis' success in France was only transient; abroad, he had no followers whatever and was severely criticised by Valentin, who supported the suture by two clasps which kept the lips against each other. The double hare-lip, in the treatment of which La Faye was very successful, was sometimes operated on in one sitting (Heister; Desault, always and usually successful) or within an interval of two weeks. While Richter and others cut away the intermaxillary bone on account of its uselessness, Desault pressed it back with a linen band several days before the operation, and on it joined the margins of the hare-lip. Two singular occurrences are recorded in this connection. One fatal case caused by hemorrhage, which Bichat reported, and one case of spontaneous recovery of hare-lip mentioned by Loder, who says: "The congenital cleft extended to the nostrils, but a thin membrane weakly joined it to the inner side of the lip; in the

tenth year the same began to contract without special inducement and finally there was only a narrow white line visible on the outside."

A *cleft palate* was joined, according to Paré's idea, by obturators, that is, with a sponge, to which, on the lower side, a piece of leather or silvered tin was fastened to prevent the admittance of moisture and to furnish a smooth surface for the tongue. Already it was advocated to definitely join the fissures in the palates of children. Therefore Jourdain wished to draw a band through the mouth and fasten the ends to the molars on each side, while Levret advised to compress the cheeks with a bandage. Richter did not share their views and thought of scarification of the bone fissure with the application of balsam ointments, but with children preferred to let nature heal the cleft after the operation, or rather, to insert a sponge. Surgeons were also afraid to venture an operation when the soft palate was cleft. It was likewise closed by a little sponge with a silver plate. There is something pathetic in C. C. von Siebold's remark: "When the mother implored me to help her suffering child, my sympathetic heart desired to make an operation. But sad to say I got no further than my honest wish. If one could only get at the palate with instruments, the joining of the fissure of this part could as easily be accomplished as that of any of the other parts of the body." Twenty-four years after this confession Gräfe made the first staphylorrhaphy (1816.)

Regarding the subject of *dentistry*, Germany was far behind France and England, where excellent and intelligent dentists could be found. In 1728 the Parisian dentist Fauchard created an epoch with his "Chirurgie Dentiste," the first complete scientific work on dentistry published. This work formed the basis for all the succeeding books issued. Among the better-known dentists were Berdmore ("Treatise," 1770) and Spence of London, and especially Jourdain of Paris. One of the most important works relating to dental anatomy as well as surgery was written by J. Hunter ("Natural History of the Human Teeth, Explaining their Structure, Use, Formation, Growth and Diseases," 1771). The pain in a carious tooth began when the air touched the bare nerve. Ever of an inflammatory nature, it was not directly dependent upon caries, but due to secondary caries, a disordered stomach, etc., and was so excruciating because the inflamed portions could not spread nor give like the panaritium. To prevent the advancement of caries by draughts of air, the cavity of the tooth had to be filled with gold or lead, or the decayed tooth was extracted, cleansed by boiling and then replaced, whereupon it again grew fast to the socket. Hunter was particularly successful in this mode of procedure, which he based upon his experiments. Having removed the spur of a cock and replaced it in the bird's crest, it again adhered; the human testicle having been cut out and returned to its place, likewise grew. If a sound tooth was knocked out by an accident, it was at once put back into the socket. Also the teeth taken from cadavers and set again remained intact for many years: they were fastened to a neighbor tooth by a thread. In this connection Littsom, a native of the West Indies who had freed his slaves and thereby lost much of his property, called attention to the transference of syphilis, which he had not observed to be the case when inserting artificial teeth (1787). These were constructed from hippopotamus teeth (Nuck, 1714) or of ivory,

and so skilful was the manufacturer that he made whole rows, even entire sets of teeth. When a patient refused to have his decayed tooth extracted the nerve was killed with a heated fine knitting needle or with mineral acids or caustic alkalis. The prejudice that a tooth must not be drawn during pregnancy was disputed by the Vienna dentist Serre. In case of an ulcerated tooth the only remedy was to remove it; but not until the inflammation had subsided so as to prevent its spreading. With painful and difficult eruption of teeth Hunter, as Paré had done, advised the cutting of infants' gums, but it was essential that the knife or lancet pierced through to the tooth, otherwise the operation was useless; the scar did not hinder its exit. The Erlangen professor, Isenflammer, contested this idea and therefore opposed this little operation. B. Bell, who early employed the cross incision, was of Hunter's opinion; also Richter, who had very accurately described the process of teething. Both recommended as a means of cleansing the teeth to rinse the mouth with lukewarm water after each meal, which method had already been advised by the French dentist, Guillemeau, in 1706, and wiping off the teeth with a sponge. Theden thought it necessary to clean the teeth also at night, so as to remove all particles of food. In treating sound teeth Richter discarded all powders, brushes and toothpicks, which ought never to be too pointed, nor made of soft wood, nor of metal, nor be made from quills. Even during his time Guillemeau considered it dangerous for the preservation of the teeth to drink beverages too hot or too cold; on the other hand, he thought well-baked bread, mutton and chicken conducive to good teeth; fought against the use of golden and silver needles as toothpicks and permitted only those of quills. Dirty teeth required the application of powder prepared from cream of tartar, chalk and cinchona, with a brush, used on the lower jaw in an inverted position and *vice versa* on the upper jaw. Tartar was removed with instruments; for filling the teeth zinc was also used, besides lead and gold. Hirsch of Jena advocated the use of tinfoil in 1796. According to Richter, the remedies for toothache depended upon the origin of the same. When inflammatory, caused by caries, leeches and poultices were applied; if rheumatic, tincture of cantharides, cajepout oil, camphor and electricity were prescribed, if caused by a disordered stomach, emetics and cream of tartar; in case the origin was not known, extract of poppy and the above anti-rheumatic remedies were used. The most common instruments for pulling the teeth, which was done toward the side on which the continuation of the socket was the thinnest, were the pelican, the English key and the dental elevator.

The suppuration and the operation for the opening of the *antrum of Highmore* were known. In 1675, Molinetti first opened the antrum directly through the cheek by means of a cross incision and by trephining, while Meibom in 1718 first laid the socket bare by extracting the teeth implicated. To this method Cowper and Drake added that of puncturing the alveolar processes. After the Bremen physician, Runge, had compiled the first work on the diseases of the antrum (1750), the French surgeons, Bordenave, Lamorier and Jourdain, gave their special attention to this operation and published their writings in the fourth volume of the *Memoirs of the Académie*. Bordenave recommended Meibom's method and extracted preferably the third molar, because its alveolus was

the thinnest, therefore, the easiest to perforate. He at once caused a large opening, which he kept from closing by inserting a silver tube. This procedure was opposed by Lamorier, because often a sound tooth had to be sacrificed, and instead trephined above the third molar and below the cheek-bone, the most prominent part of the antrum. Jourdain, however, deemed it useless as a rule to open the antrum in this way; he sought to find the connection with the nose, in order to free the closed passage and through this make his injections. This method was much too difficult and often impossible, consequently of no use. Lastly, Gooch is mentioned, who bored through the hard palate into the antrum, taking for granted that the same had been pushed forward by the pus. Most of the surgeons chose either Meibom's or Lamorier's method. B. Bell employed a curved trocar, in order to make a puncture from the alveolus; Desault opened from the mouth the lower portion of the fossa canina where the bone was the thinnest and where the operation and the after-treatment were most easily accomplished. These punctures and trephinings of the anterior wall are to be considered as the starting-point for the resection of the upper jaw.

In a similar manner was treated the suppuration of the frontal sinus, which Richter saw break through into the skull cavity. Either the anterior wall was trephined or injections were made into the nose as soon as the pus had found its way there, or if the outer wall was already decayed, the too small opening was enlarged, which, however, could remain fistulous for a long time. Bilguer was once very successful in taking a bullet out of the frontal sinus and Maréchal related the case of a wound in which the brain matter was mistaken for the mucus and pus.

(To be continued.)

SOCIETY PROCEEDINGS.

Southern Surgical and Gynecological Association.

Proceedings of the Tenth Annual Meeting, held in St. Louis, Mo., Nov. 9, 10 and 11, 1897.

(Concluded from page 1067.)

FIRST DAY—AFTERNOON SESSION.

Dr. J. G. EARNEST of Atlanta, Ga., reported a case of EXTRA-UTERINE PREGNANCY OPERATED ON AT THE SEVENTH MONTH.

The patient was 36 years of age, the mother of several children. Patient came under his care September 19, 1897. Five months before he had been called to see her on account of profound collapse which threatened life. A history of irregular uterine hemorrhages was elicited and a diagnosis of ruptured tubal pregnancy on the left side was made. Patient rallied somewhat, but her condition was such that it was feared she would die under the anesthetic if an operation was done. Operation was deferred, and nothing further was heard from her until the date mentioned. At this time the doctor found the abdomen distended by a tumor on the left side and in the center as high as the umbilicus. On the right was another and apparently distinct cyst filling that side of the pelvis and extending well up into the abdomen. The enlarged uterus could be felt in the center merging into a large tumor. Upon opening the abdomen a large tumor occupying the center and left side presented a surface somewhat irregular, very dark in color, and traversed in every direction by large blood vessels that stood out prominently on the surface, reminding the author of an enormous broad ligament cyst. The enlarged uterus was enclosed in this mass, and the shading off of the tissues was so nicely done that it had every appearance of a tumor springing from the uterus. The tumor of the right side was about the size of an adult head, about one-quarter of an inch thick, and seemed to be distinct from the large one, the dividing line dipping down between

them about half the diameter of the tumor. To the larger mass was attached several coils of intestine which were dark and changed in texture at the points of contact. The cyst on the right side peeled out without much hemorrhage. But with the work of peeling off the placenta from the pelvic and abdominal wall began the flow of blood so appalling. Pushing it as rapidly as possible the mass was loosened and iodoform gauze quickly packed in behind it. The cyst was still unbroken and had the appearance when lifted up of being a fibrocystic tumor of the uterus, the uterus following forming the stem from which it sprang. The author concluded to remove the uterus and drain through the vagina. As the uterine arteries could not be reached a wire attached to a serre nœud was thrown around the uterine body, tightened and the mass cut away. The patient was now in such a critical condition that the author abandoned draining through the vagina. He tied the uterine and ovarian arteries, and packed the cavity with iodoform gauze, which was brought out at the lower angle of the wound, and closed the abdomen with silk-worm gut. A large compress of cotton was firmly fastened over the abdomen by a very tight binder and the patient put to bed. Gauze removed on the sixth day. On the eighth day fecal matter passed from the drainage tract. From this time until she left the hospital, October 30, most of her feces passed by the fistula. Five days after she went home he was informed that she was having free rectal evacuations with a corresponding falling off of the discharge from the fistula. If the fistula fails to close spontaneously the patient will return to have it closed by operation.

The large tumor was covered entirely by an enormously expanded placenta beginning in the bottom of the pelvis, firmly attached to the pelvic and a portion of the abdominal wall, its villi reaching well down into the tissues. From the top it was deflected from the abdominal parietes over beyond the center everting the body of the uterus. In the cyst thus formed was found a fetus of about seven months.

Dr. L. McLANE TIFFANY of Baltimore, read a paper entitled
CYSTIC DISEASE OF THE MAMMÆ.

He said the occurrence of cysts as a confusing element in the course of solid tumors of the breast was not so uncommon and might greatly resemble the subject dealt with in his paper, yet the clinical history and anatomy of cystic adenomata were sufficiently clear and the prognosis sufficiently important to justify careful study. In most cases an accurate diagnosis could be reached before operation. Dr. Tiffany reported eleven cases that showed many symptoms in common.

CYSTIC FIBRO-ADENOMA OF BREAST.

He had examined three of these tumors, and as they agreed so closely both in microscopic and macroscopic appearances, a description of one would answer for all.

Macroscopically the breast is full and hard with numerous small nodules to be felt under the skin but not adherent to it. These nodules vary in size from a pea to a walnut. Some of them feel as though they contain fluid. On cutting through the breast normal glandular tissue is seen to be replaced by a hard, dense white tissue with innumerable cysts containing either glazy sticky fluid or a cheesy material. The fluid varies in color. In some cases it is white and transparent; in others green, red, yellow, or a dirty brown.

Microscopically. Sections were taken from various parts of the tumor, hardened in a 10 per cent. solution of formalin for twenty-four hours and in alcohol. They were imbedded in colloidin and stained by the ordinary method with hematoxylin and eosin. Under the microscope the sections presented the following appearance; there is a mass of white fibrous tissue including cysts, fat and tubules. The tubules are lined by several rows of cuboidal epithelial cells and are massed in discrete areas presenting somewhat the appearance of an intracanalicular growth. In some localities the tubules are seen to be much dilated in parts, completely filled with cells, while outside they are surrounded by a well marked area of round cell infiltration. Here and there in the tubules are to be seen loose desquamated cells, which are granular and swollen, presenting somewhat the appearance of the cells of sebaceous glands. These cells have very deep staining nuclei, and when seen in the smaller tubules are deeply pigmented, of a brownish color, as though blood stained, and as here and there one can find the remains of red blood corpuscles, this is probably the case. Many of the ducts are lined by papillary ingrowths made up of cylindrical cells which take eosin well. The tubules present all stages of dilatation up to large cysts; many of the cysts are lined with several layers of cells resembling pavement epithelium. The fibrous tissue which is too abundant is rather waxy, not very cellular, and well supplied with blood vessels. It stains very faintly with eosin.

The diagnosis of benign cystic fibroadenoma is perfectly clear.

Dr. A. V. L. BROKAW of St. Louis, Mo., made some remarks on

THE X-RAY AND ITS APPLICATION TO SURGERY.

He exhibited two hundred radiographs, and among them was a radiograph of a fractured dislocation of the cervical vertebra; one showing silver wire *in situ* that was used in wiring the segments of vertebrae together after operation upon this case. Another showed a rubber drainage tube used in a case of empyema. He also exhibited radiographs of the heart, the thorax in its entirety, fractures of the dorso-lumbar vertebrae, the pelvis, several fractures and lesions of the long bones.

In many hundred exposures that he had made, he had yet to see harmful effects following the use of the X-ray, such as cutaneous burns, loss of hair and lesions of varying intensity.

SECOND DAY—MORNING SESSION.

Dr. D. F. TALLEY of Birmingham, Ala., read a paper on
CHRONIC PROCTITIS.

The author dealt with two varieties of non-specific chronic proctitis: 1, those cases in which a diffuse, persistent inflammation, superficial ulceration and papillomatous vegetation are the prominent features: 2, those in which the submucous tissues are principally involved in the hypertrophic process, causing a proliferative stenosing proctitis. This latter condition is often engrafted on the first, and both conditions may exist in any case. The main symptoms of the first form of proctitis were dealt with.

In the treatment, rest in the recumbent position was referred to as being of paramount importance in the first form of the disease. The diet should be of a liquid character, bland and nutritious. In most cases it is best to divulse the sphincter muscle when the trouble is low in the rectum. Where there is no ulceration, but a diffuse chronic inflammation, the mucous membrane should be mopped with silver or copper of the strength of 30 grains to the ounce. The after treatment consists in putting the patient to bed, washing the rectum daily with warm boric acid solution and the use of suppositories of iodoform and boric acid. In very chronic cases, where the ulcers are extremely indolent, the solid stick of silver or crystal of copper may be used. In these cases it is necessary to make repeated applications before the ulcers become healthy and begin to heal.

The main feature of the proliferative stenosing proctitis is involvement of the submucous connective tissue in a fibrous hyperplastic process which causes a thickening of the rectal walls and subsequent contraction and stenosis of the rectum.

Dr. HOWARD A. KELLY of Baltimore read a paper on the

SOURCES AND DIAGNOSIS OF PYURIA.

He began by stating that if he were asked what subject in the entire range of medicine and surgery he considered it most important to bring prominently before the profession at present, he would probably reply pyuria. The subject is important on account of the great number of undetermined cases under treatment, and on account of the progressive nature of some forms of the disease, as well as on account of the facility with which the diagnosis can now be made with better means of investigation.

Pyuria, of course, signifies merely the presence of pus in the urine; this may be in large or in small quantities, and may proceed from any part of the urinary tract, from the external urethral orifice up to the cortex of the kidneys.

The investigation of a pyuria is an analytic one, taking the symptom and trying to trace its origin.

The best way to investigate a pyuria is to begin by making an examination of the urinary tract, following an anatomic order proceeding from below upward.

The history of the case, the microscopic and bacteriologic and chemic examinations of the urine must be carefully made, and all facts ascertainable by palpation must be elicited first.

The direct investigation then proceeds in an orderly manner, beginning with the external urethral orifice, where Skene's glands may be distended with a drop or two of pus; if the urethra may be in a state of intense inflammation and even ulceration affording sufficient pus to yield a decided sediment in the urine. Sometimes a suburethral abscess may pass unnoticed for many months, in spite of the fact that it contains from a teaspoonful to a tablespoonful of pus.

The vesical sources of pyuria are from a cystitis, including a trigonitis, or inflammation of the trigonum; foreign bodies, creating a cystitis; ulcers, associated with a cystitis or tubercular in their nature.

These affections will all be readily recognized by making a cystoscopic examination of the patient in the knee-breast position through a simple cylindrical speculum. By this examination the cystitis will often be found to be well localized and in

patches, which may be readily treated by direct topical applications, upon removing a foreign body, the cause of a cystitis, the pyuria disappears. Ulcers seen through the cystoscope may be treated with strong solutions of nitrate of silver, curetted or cauterized.

There are also a number of extra sources of pyuria, and these arise most frequently from tubal and ovarian abscesses breaking into the bladder, across the base of a broad ligament.

If the pyuria does not come from the lower urinary tract, it must then come from one of the ureters or kidneys: a telltale blush around a ureteral orifice often marks the side from which the pus issues. I have found pyurias from the upper urinary tract proceeding from strictures of the ureter with a gonorrhoeal, tubercular or other infection. The site of the stricture and the source of the pyuria may be readily located in these cases by passing a ureteral catheter, a metal one for the low strictures, or a flexible one for those above the pelvic brim.

Renal pyurias are after all the commonest, and he finds that these are most frequently caused either by a calculus in the pelvis of the kidney or by a tubercular pyelitis, or by a hydronephrosis which has become infected. Such pyurias are often the occasion of presence of large amounts of pus in the urine, appearing either continuously or intermittently. By passing a renal catheter well up into the pelvis of the kidney the pus may be evacuated and the pelvis washed out. If the pus is too thick to flow through the catheter it may be thinned out by injecting a little fluid.

By making an orderly investigation of this sort the pus is traced to its origin and the source of the disease discovered and treated and the cause eliminated, if possible, just as we would seek to investigate the source of the contamination of a body of water by taking a boat and traveling up the muddy stream until we had located the point at which it entered the main body and until we found that above this point the water was free from contamination. The methods proposed are safe in careful, practiced hands.

Dr. WM. H. MYERS of Fort Wayne, Ind., followed with a paper on

THE EARLY DIAGNOSIS AND TREATMENT OF CANCER OF THE UTERUS,

in which he first dwelt upon the various theories respecting the nature of cancer, the last theory being that the disease was in its origin purely local. If we adopt the view that cancer appears first in a certain locality, and that danger consists in its extension from that locality to remote organs, then we were in a position to advance arguments in support of early diagnosis and treatment. To make an early diagnosis the physician should observe closely and reflect upon the history of the case as detailed by the patient. He should encourage her to accurately describe every symptom, and insist and urge her with all the force which the strongest conviction of a necessity imparts on a local examination. How seldom do physicians have an opportunity of making an early diagnosis! Patients come to physicians after the disease has passed the limitations of surgical aid, their cases regarded as inoperable, so far as a permanent cure may be promised.

Physicians often treat symptoms as trivial, that appear to the patient as unworthy of special notice. For example, an abnormal menstruation, a vaginal discharge, or a trifling hemorrhage, seldom profuse.

The author then dwelt at length upon elements of diagnosis, and gave statistical results following operations by different authors for this disease.

The author considered the value of the microscope as an aid in clinical diagnosis of cancer to have been over estimated, and quoted several high authorities in support of this view.

He closed by saying that the knife had become the emblem of gynecologic treatment. It had supplanted the curette, intra uterine injections, caustic applications, the quaint conceits of monkish craft, and the brutal records of the cancer cure. The knife had become, in a surgical sense, the specific therapy of this particular disease.

SECOND DAY—AFTERNOON SESSION.

Dr. F. D. THOMPSON of Fort Worth, Texas, reported

A CASE OF TETANUS FOLLOWING A SURGICAL OPERATION.

The patient, a male, was 21 years of age, American, with good family history. A radical operation for extensive varicocele was performed on him. Asepsis was carried out in every detail in the usual way. The result of the operation was excellent; yet on the morning of the ninth day after operative interference the patient could not open his mouth very well, and there was more or less stiffness about the muscles of the neck. A diagnosis of incipient tetanus was made, and the patient died in less than three days after the first appearance

of this disease. Dr. Thompson could not account for the fact how this patient was infected with the bacillus tetani.

At this juncture the President, Dr. GEORGE BEN JOHNSTON of Richmond, delivered his address. He selected for his subject

THE PREVALENCE OF SPECIALISM AND WHO SHALL BE SPECIALISTS.

He said the tendency of the times was toward specialism in medicine. The science of medicine had grown to such gigantic proportions that no one mind could any longer thoroughly master every detail of it; hence the necessity for specialism. It was desirable because it gives to the profession and the people the most intelligent consultants and the most skilled attendants the art of medicine could supply. It was therefore not wise to hamper its legitimate growth. It should be regulated, however, and kept within proper bounds so that proper persons shall become specialists. He divided specialists into two kinds, the true and the pseudo-specialist. He defined a true specialist as one specially distinguished for learning and skill in a given pursuit; the false as one having merely a special occupation. He would make very clear the difference between these varieties, for one reached the distinction of a specialist by reason of his training, experience, skill and wisdom, whereas the other was made a specialist by the possession of a diploma, a door plate and a "kit" of special instruments. The profession recognizes the excellence and the value of the one, whilst the other derives his standing from the magic term specialist, which is so ill understood by the public. The professional qualities of the true specialist he likened to a massive pyramid, the finished capstone of which constituted the specialty. This pyramid of experience, learning and skill was a stable edifice, a pillar of strength which could not topple or reel. It was a mark by which all recognized superior design and masterful workmanship. In the case of the pseudo-specialist, this pyramid of learning was inverted. There was no base of a knowledge of detail, of general information, of professional attainments. The structure has no foundation in fact. It began with the specialty and its growth spreads as it ascends, over-shadowing what is below, thus rendering it an unstable, top-heavy structure, which is likely to fall before the winds of uncertainty and doubt.

Proper education, sufficient training, ability and special aptitude mark some men as fit subjects for specialists. These qualities are soon seen by their confrères, who, recognizing superior attainments in given lines, force such men into specialties by consultations and referring special cases to them. The self-constituted specialist needs no such recognition, but depends upon the title of specialist to win him patronage from an over credulous public.

The public has been improperly educated to the idea of specialism. Specialism means more to the lay mind than to the professional. In the public eye, all specialists stand upon the same footing, possessing all the needful requirements to give the best service. The profession has misled the public. It is responsible for this lack of discrimination on its part.

Lastly, medical colleges should vigorously discourage the practice of recent graduates becoming specialists. Teachers should point out to them the error they are about to commit. They should counsel them. Colleges should recognize only the real specialists. Reform is necessary in the present system of specialism. It must be accomplished through the instrumentality of medical colleges and societies, and when they take the matter properly in hand, the general profession and public will lend cordial support and the evil will perish.

Dr. A. M. CARTLEDGE of Louisville, Ky., read a paper on

OVARIOTOMY IN THE AGED.

The patient upon whom this operation was performed was born Oct. 29, 1816. Eighteen months before Dr. Cartledge saw her, her family noticed an abdominal enlargement, shortly after which she complained of pressure symptoms. Latterly the gastric and digestive disturbances from pressure had been very troublesome. Emaciation and ovarian expression appreciable, but not marked. Examination revealed the abdomen well filled with an encysted growth, which was diagnosed as ovarian. Naturally the great age of the patient, 80 years, 7 months and 15 days, made the decision as to operation a debatable one. However, an operation was deemed justifiable, urged and consented to, and was performed May 12, 1897. The ovarian cyst originated from the right ovary, was multilocular and weighed about forty pounds with fluid and omentum. Time of operation, fourteen minutes. Patient sat up fourteen days after operation, left the infirmary May 29, or seventeenth day after operation: has recently made three quilts, and is active and happy as a woman of sixty-five.

The author has operated seven times in women over sixty years old.

Dr. H. H. GRANT of Louisville, Ky., contributed a paper on

OPERATIVE TREATMENT FOR ENLARGED PROSTATE,

in which he drew the following conclusions :

1. In malignant diseases any operative step except palliative suprapubic drainage, even if based on an error of diagnosis, is a serious mistake.

2. That in myomas, fibromas and adenomas it is yet uncertain that good results will follow castration ; and, furthermore, that such conditions render enucleation by Alexander's method very difficult and perhaps not feasible ; hence when interference resists catheterization and is not remedied by the permanent catheter, as suggested by Kane, suprapubic section and removal of the projecting portion, if practicable, or the permanent fistula of McGuire instead, is the wisest course.

3. In conditions including stone in the bladder, suppuration in the gland, and the suspicion of intravesical growth, exploration by the suprapubic method offers the best insight into the nature of the lesion, as well as the most hopeful prospect of relief.

4. Inasmuch as castration is unsatisfactory, and is less acceptable to men under sixty-five years of age than later, it appears that in the commonest form of enlargement, the chronic parenchymatous, to which the operation of Alexander is especially appropriate, will be best treated by this method, provided it appears feasible or necessary after section, which, if it bears out the promise of the present, will surely take a high place in the future, as it has almost no objection, aside from the seeming gravity of the step.

It is to be borne in mind that desperate and long protracted suffering may influence a patient to consent to the mutilation of castration, when after relief regret may tend to grave dissatisfaction, and even melancholy ; hence though apparently a less serious and certainly a more easily executed operation than either the Alexander or McGill, it is to be looked on as less appropriate than either, other things being equal, before the sixty-fifth year, and perhaps not to be even suggested when the Alexander method can be applied.

Dr. JAMES A. GOGGANS of Alexander City, Ala., followed with a paper entitled

REMARKS ON EMPYEMA, WITH A REPORT OF TWENTY CASES.

He said that empyema was a disease of much more frequent occurrence than it was generally supposed to be ; that two-thirds of the cases were of simple origin and the disease developed as a sequel of pneumonia, and instead of being, as formerly held by Sir Astley Cooper and Dupuytren, always fatal when treated by surgical interference, it had under aseptic management become most amenable to treatment. He classified the mode of evacuating pus from the pleural cavity under two general headings : 1, the closed method, which consisted in evacuating the pus by simple puncture and allowing the puncture to heal at once ; 2, the open method, which consisted in making a more or less free incision for the removal of a piece of rib, and the introduction of rubber drainage tubes to maintain perfect evacuation of the fluids to permit of free ingress and egress of air that had passed through an antiseptic dressing. He said that the relative value of these methods could only be determined by statistics. The age of the patient and pathology of the disease present should have much to do with the character of surgical interference. The prognosis was unfavorable in cases where pyemic cocci were found in the pus. When the pus contained streptococci a free incision or Estlander's operation should be done. Simple incision and drainage only were necessary when the pus contained the pneumococcus of Fraenkel. He said that the statistic results in children could not favorably be contrasted with those obtained in adults, and that this was explained by the etiology and pathology of empyema in childhood, in that it was more favorable to recovery than when the disease was developed in adults. Aspiration offered many advantages in the empyema of childhood. The operation was simple and favored lung and thoracic expansion rather than contraction and deformity of the chest walls, and statistics proved that a vast majority of the patients recovered. He gave an analysis of twenty cases, eight of which were under 9 years of age, and twelve between the ages of 17 and 86 years. The first, aged 7 years, was cured after eleven aspirations ; the second, aged 8 years, was cured after three aspirations ; the third, aged 17 years, cured after one aspiration ; the fourth, aged 35 years, cured after two aspirations ; the fifth, a man aged 58 years, cured after three aspirations ; the sixth, aged 9 years, cured after three aspirations ; the seventh, a male aged 86 years, died after three aspirations. The ages of those cured by thoracotomy ranged as follows : Two, 3 years old,

two were 4 years old, two 7 years, one 10 years, two 17 years, one 22 years, one 25 years, one 30 years, and one 40 years of age.

In cases where the chest wall was opened by a free incision, or removal of a piece of rib or ribs, he emphasized the necessity of perfect ingress and egress of air, which should be heard at each act of inspiration and expiration. He advised that the fluid removed by any method should be allowed to flow away slowly, since the fluid acted as a wedge and made greater pressure than the atmospheric pressure.

The operations of Estlander and Schede caused more shock and produced greater deformity of the chest, and required general anesthesia, which should be complete. He advised against using washings in the pleural cavity, saying that they were harmful.

THIRD DAY—MORNING SESSION.

Dr. RUFUS B. HALL of Cincinnati, read a paper entitled

IMPROVED TECHNIQUE IN OPERATION FOR INTRALIGAMENTOUS CYST.

After reviewing the literature on the subject, the Doctor said he believes the mortality from operation for intraligamentous cyst is much higher than the statistics would lead one to believe. A large per cent. of the deaths are due to hemorrhage, either on the table or within a few hours after they are put to bed. He thought the operation he proposed would save many lives, as it was practically a bloodless one. It is applicable to those cases where the adhesions are very firm and the cyst can not be easily stripped from the pelvic floor.

The operation is as follows : First tap the cyst and empty it. Ligate the ovarian artery on the tumor side at the pelvic border ; ligate the ovarian artery on the opposite side, outside the healthy ovary. Divide the broad ligament. Divide the peritoneum above the top of the bladder and push the bladder down. Ligate the uterine artery on the healthy side. Cut across the cervix and clamp or ligate the uterine artery on the tumor side. The blood supply is then cut off and the patient has not lost a drachm of blood. The capsule of the tumor can now be divided above the top of the bladder and at a suitable point behind, and the tumor enucleated from below upward with very much greater ease than from above downward, and with corresponding safety to the ureter, the rectum and the iliac vessels. Close the peritoneum over the pelvic floor with a running suture of catgut. This method brings every part of the field of operation into view. The ureter can be seen, recognized and pushed aside. The adhesions are separated along the line of cleavage instead of against it as in the old method.

Then followed the presentation of a specimen and report of a case illustrating the operation and the class of cases to which it is especially applicable.

Dr. H. TUHOLSKE of St. Louis, Mo., read a lengthy and exhaustive paper entitled "Personal Observations in Abdominal Surgery."

Dr. GEORGE J. ENGELMANN of Boston, presented a paper on SYMPHYSEOTOMY AS COMPARED WITH OTHER OBSTETRIC OPERATIONS,

and illustrated his remarks by diagramatic sketches. Symphyseotomy was not as attractive an operation as is Cesarean section or the Porro operation, yet it was very successful as compared with Cesarean section. It was a successful all-around operation for the city and country. The mortality statistics of the different operations were given and compared. There has been no trouble in union of the pubic bone after symphyseotomy. Quite a number of women have been delivered by a second symphyseotomy and it has been found that while the pubic bone was slightly separated, it was nevertheless firmly united with connective tissue. There was no trouble in the locomotion of women so operated upon. A number of cases are also reported of normal labors having followed symphyseotomy. The first operation in this country was performed by Dr. Williams of Dennison, Texas. Dr. Englemann showed what had been accomplished by symphyseotomy and said that surgeons must be guided in a measure by that. It required good judgment on part of the surgeon to decide what operation to do in cases of contracted or deformed pelvis.

Dr. JOHN D. S. DAVIS of Birmingham, Ala., followed with remarks on "Plaster of Paris as a Universal Fracture Dressing." He finds that less than 3 per cent. of the physicians who use plaster of paris as a primary dressing, cut the plaster at the time of applying it. The object of incising the plaster of paris was to allow it to yield and at the same time fit the contour of the limb. For fractures of the shaft of the humerus, as elsewhere, he thinks plaster of paris is the best dressing.

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Continued from page 1071.)

METHODS OF MEAT INSPECTION

were considered by Prof. LEONARD PIERSON, V. D. M., Veterinary Department of the University of Pennsylvania. The existing systems in this country may be divided into two classes, national and local. For some years, the U. S. Bureau of Animal Industry has conducted a constantly improving meat inspection service that now extends to animals killed for export and for interstate trade in the principal meat-packing centers of the country. The work is performed by veterinarians, who examine all carcasses, stamp those that are sound and condemn those that are unfit for food. There is also a microscopic examination of pork for the detection of trichina, but this extends only to the products prepared for export. Some of the cities in the United States have also organized more or less complete meat inspection systems. The system in New Orleans, originated and developed principally by Dr. A. S. Wheeler, is perhaps as perfect as exists anywhere in the United States. It provides that all animals killed locally for food shall be inspected and the meat stamped. Moreover, all dressed meat brought into the city must be stamped in a similar way. It is unlawful for any butcher to sell meat that does not bear the stamp of the meat inspector. In Montgomery all meat-producing animals are killed in a central slaughter house under the supervision of a meat inspector. These systems and all those followed in European countries place the responsibility of deciding whether a given carcass is suitable for food upon an inspector who is trained in animal pathology. In some cities, as Philadelphia, the meat inspection system is based upon an entirely different system. There are laws prohibiting the sale of diseased or unwholesome meat, and it is assumed that the butcher is always competent to determine this point. Under this system detectives or police officers are appointed to visit slaughter houses, markets and butcher shops, hunt for diseased meat which is condemned by a veterinary adviser called in by them, and the seller is often prosecuted. It is scarcely necessary to say that this system is undesirable, because it does not include an inspection of all meat sold, and inevitably permits the consumption of much that is injurious, and because it assumes knowledge on the part of the butcher that he can not possibly possess, and makes him responsible for conditions that he can not recognize.

The system is therefore incomplete and as a permanent system is unjust. Its chief advantages lie in the fact that it tends to make butchers more careful, so that gross pathologic conditions do not reach their stalls and a portion of the diseased meat that would otherwise be placed upon the market is barred. However, such a system constitutes a beginning in the right direction, but no municipality should be satisfied with it if a better can be obtained. Municipal meat inspection is of more importance in the East than in the West because tuberculosis is more prevalent in this region and a great many worn out dairy cows are sent to the shambles. Many of these cattle are afflicted with tuberculosis and other diseases. They are frequently emaciated and constitute the most dangerous class of beef animals. Philadelphia is situated in the midst of a bountiful dairy region and is a large consumer of these animals. They are not killed in a large central abattoir, under constant supervision, but in numerous little slaughter houses scattered throughout the city and its suburbs. There are about one hundred such places in Philadelphia. Many of them are quite small, situated on back streets and surrounded by stables and dwellings. In these establishments cattle are frequently killed at night or very early in the morning and are not inspected at all. Occasionally, and as often as possible, the inspector drops in while the carcasses are being dressed, and his vigilance is often rewarded almost daily by the discovery of a diseased and dangerous animal. The business of these slaughter houses is conducted so irregularly, that it is not possible to properly control them without having almost as many meat inspectors as slaughter houses and if the force were enlarged to these dimensions the sanitary conditions and the surroundings of the slaughter houses would still be such as to injure the wholesomeness and keeping qualities of the meat dressed in them. A further reason for a better system of meat inspection here is that there is a constant and growing demand for many parts of carcasses which are more frequently diseased than the flesh and were formerly thrown away. Our ever increasing foreign population consumes viscera for which there was no market a few years ago, and meat inspectors frequently find that such organs are diseased to

such an extent that renders them unwholesome, while the rest of the carcass can be safely sold. As a result of the fact that inspectors are not constantly present a great many diseased carcasses are unquestionably sold and frequently without the knowledge of the butcher who handles them. His training is not sufficient to enable him to detect symptoms and lesions. In some cases, however, he does detect them and remove them so thoroughly that the suspicions of the meat inspector are not aroused. The conditions that prevail in Philadelphia are not unique. They exist in almost every city of the country and it is largely on account of the multiplicity of the slaughter houses that thorough systems of meat inspection have not been more generally established. An adequate control of the meat supply of Philadelphia can not be enforced without a great extension of the present force or a concentration of the business of slaughtering. The latter plan is supported by the experience of the older civilized countries, and is to be recommended not only because it would facilitate the inspection of meat, but for several other reasons as well. It would do away with all of the small, poorly equipped, badly managed slaughter houses which are in many cases nuisances in their respective neighborhoods. It would make it unnecessary to drive cattle through the streets, a practice that blocks traffic, frightens people, and at times occasions serious accidents. It would give small butchers the advantage enjoyed by wholesalers; they could use the facilities of the large slaughter house which are immeasurably superior to their individual establishment, and the cold storage system could be used by all with economy to the dealer, and advantage and increased wholesomeness of the meat to the consumer. The offal and the condemned organs and carcasses could be disposed of to better advantage. Local meat would gain in reputation if such a system were enforced, and trade could be built up on its merits, and competition with western meat would be less difficult.

Dr. E. P. LACHAPPELLE, President of the Provincial Board of Health of Quebec presented the report of the Committee on Transportation of Diseased Tissues by Mail. He gave in detail the plan agreed upon with the U. S. Postal Authorities by which such specimens might be carried in the mail and the danger of the transmission of disease be positively prevented.

Dr. EDWARD JACKSON, Professor in the Polyclinic of Philadelphia read a paper on "Eye Strain from poor Window Glass." He called attention to the influence of inequalities of thickness and irregularities in the index of refraction in window glass. Such defects necessarily cause the same eye strain when the glass is looked through as would be occasioned by regular or irregular astigmatism. The damage done is much more serious because the amount and kind of astigmatism so produced varies with every movement of the eye or objects looked at. Plate glass alone is of sufficiently uniform thickness to avoid any lens effect; but may present such inequalities of the index of refraction as to produce greater distortion of the rays passing through it, this distortion being greater in proportion as the glass is thicker. It was particularly urged that eye strain from this cause was an essential factor in car sickness, and that public conveyances should be freed from this source of annoyance. While some luxuries are harmful good window glass is one that is altogether beneficial in its effects.

Dr. ROBERT L. PITFIELD, Assistant Bacteriologist to the State Board of Health of Pennsylvania, read a paper on the "Official Control of Plants Yielding Biologic Products, particularly Vaccine Virus."

REPORT OF THE COMMITTEE ON THE NOMENCLATURE OF DISEASES AND FORMS OF STATISTICS

was made by Dr. CRESSY L. WILBUR, Registrar of Vital Statistics, Michigan.

Your Committee desires first of all to express its sincere regret that the multiplicity of other duties has made compulsory the resignation of the former able chairman, Dr. Samuel W. Abbott of Massachusetts, and to hope that his experienced counsel will still be available, so far as his other engagements may permit, in the service of this Committee while discharging its duties to the Association. The principal recommendations of this report, it may be said at the outset, especially those relating to the adoption of a standard system of nomenclature, are made possible by the labors of this Committee under Dr. Abbott's direction in recent years.

The time has come when it would seem desirable that this Association should pronounce definitely in favor of a standard classification of causes of death for use in the compilation of statistical reports. The Bertillon system, reported to the International Statistical Institute at Chicago in 1893, seems to have better prospects of general adoption at this time by regis-

trars generally in the three countries represented in this Association than any other, and therefore this committee submits as its chief recommendation for action by the Association at the present session that the Bertillon classification be declared the choice of the American Public Health Association.

The classification was printed in full in Vol. xx of *Public Health*, so that it is unnecessary to discuss it in detail at this time. It has already been put into practical use by the governments of Mexico and of the Province of Quebec in their reports, and several States of the United States will undoubtedly accept it when indorsed by the Association. Among those ready for the immediate adoption of a modern nomenclature are Massachusetts, Michigan, Ohio and Vermont, while all of the States included in the New England Registrars' Association will, it is hoped, conform. Besides the long classification printed in the volume of *Public Health* referred to above, there is a shorter and intermediate classification, each comparable with the longer one, so that the needs of the cities and of monthly reports from States, requiring less statistical detail, are fully provided for. It is especially desirable that the municipal reports adopt the same classification as those used by the State systems, and it is very fortunate that, owing largely to the efforts of Dr. Heckard, Registrar of Vital Statistics of Chicago, we have a large attendance of municipal registrars at this meeting of the Association for the purpose of obtaining greater uniformity in classification. It is not maintained that the Bertillon system is entirely perfect, nor that it may not properly be subject to revision after a reasonable time. It is believed, however, that its adoption in its present condition will afford a working basis of uniformity and lead to general improvement along the best lines. Much energy is dissipated and many valuable suggestions come to naught from the utter absence of co-ordination. Working together, with a broad basis of agreement, many improvements will be made by the associated registrars and come into general use that would not be possible if each State and city continue its development along individual lines. One of the principal advantages to be derived from the general adoption of the same formal classification of causes of death will be the possibility of reaching a better agreement on the inclusion of the terms employed, as related to the original returns. It is obvious that in even the most extended classifications in ordinary use there is considerable condensation, or "consolidation," as the term is technically employed, from the statements made in the certificates of death. This is well known to all who have been engaged in practical registration work, but is less obvious to physicians and others accustomed to accept implicitly the statistics as finally printed in the reports. Sometimes considerable discrepancies may arise from varying methods of compilation, and the necessity of a uniform code of rules for compilation can only be met by associated action.

Among the practical questions to be settled in connection with the adoption of a standard classification is the treatment of still-births. They are not included in the Bertillon classification as used in France, nor is it generally customary to state them among causes of death in the English classification. Nevertheless, both Quebec and Mexico, in their adoption of the Bertillon system, have so far changed it as to include still-births in the regular list of causes of death, thus rendering a correction necessary before comparison with the standard form of the classification. It is recommended that still births be separately stated from other deaths and that, in case it is considered necessary to include them in the classification, they be stated in connection with total deaths, so that errors from inclusion or non-inclusion of the same can be avoided in comparing reports of different countries. Premature births, living an appreciable time after birth, are not still births and are contained in No. 138 of the list, "Congenital debility, jaundice and seterema." Here also may be placed deaths of infants occurring a few days (less than three) after birth without assigned cause of death, whose inclusion under a separate caption was proposed at the last meeting of this Association. It will entirely defeat the object of the adoption of a uniform classification if each registration office introduces its peculiar modifications of the original classification.

Probably the most efficient method of carrying out the purpose of this Association, should it authorize an effort at this time to secure practical uniformity in the classification of causes of death, is the preparation of a circular containing the three alternative systems of classification presented by Dr. Bertillon to the Statistical Institute, with the recommendations of this Committee and this Association and the endorsement of as many State and municipal registrars as may be able immediately to promise the adoption of the system in their work; this circular should be distributed among the regis-

trars of the three countries. A set of working rules to secure uniformity in the practical work of compilation should accompany the same. It would be very gratifying if this proposed action should lead to a fuller representation of the official registrars at the annual meetings of this Association, with perhaps a formal organization for the discussion of questions of vital statistics and the settlement of practical details of registration. They might well meet as a section of the general body.

Leaving the matter of classification and nomenclature of causes of death, this Committee urges that steps be taken to secure the adoption of efficient systems of registration of vital statistics in those States that do not possess them at present, and especially in those populous and wealthy States that are well able to maintain efficient systems at present but do not do so. Among these States is Pennsylvania, and we sincerely trust that it may not be accounted discourtesy toward our courteous host if we emphasize this fact. It is not due to lack of interest, nor want of well directed efforts by Dr. Lee and his fellow-workers upon the Pennsylvania State Board of Health, who well appreciate how useful an efficient modern system of mortality statistics would be in their work of restricting disease. Pennsylvania should not lag behind New York and other progressive States in this respect, and if the earnest recommendation of this Association of sanitary workers, assembled within her borders from the farthest bounds of the three nations for the promotion of the public health, will be of any avail with her legislative body in causing it to take speedy action for the establishment of a satisfactory modern system of registration of vital statistics, such advice should be given freely and with unsparing reference to the condition of present neglect.

There are many States wherein efficient registration of deaths will be impossible for many years to come on account of the great sparseness of population. The sanitary authorities in such States should not be deprived of the benefit of reliable vital statistics, so far as the general government can reasonably undertake to supply the want. At every United States census since 1850 vital statistics have been collected for such States in this country, but the results under the discredited method of enumeration, have been imperfect and even misleading in many cases. It is possible to obtain accurate vital statistics of representative areas in all the non-registration States of this country, which, while not wholly exhaustive, will be invaluable for many important sanitary and sociologic uses. The collection of useful vital statistics by the United States census necessarily implies a permanent organization, such data requiring continuous collection from year to year. This Committee earnestly recommends that the Association exert its influence for the passage of a law by the approaching session of Congress to provide for a permanent census organization, and as an especially important feature of such a law, having a direct bearing upon successful public health work, to provide for the continuous collection of vital statistics in representative areas of non-registration States during intercensal years. Under the head of form of statistics, it may be said that the adoption of a standard classification of causes of death as recommended in the preceding part of this report, will pave the way for many reforms of value in our methods of presenting vital data. It is especially urged that greater attention be paid to establishing a suitable basis of population in the statement of death rates from the common infectious diseases, such as diphtheria, scarlet fever and others, whose chief incidence is upon a special age class of the population. Rates as a rule should be based only upon susceptible population. Similar precautions are necessary in the statement of death rates from all causes, a difficulty which the system of mortality indices devised by Korosi and adopted by the International Statistical Institute, has been employed to obviate. It is not expedient to enter into the discussion of these subjects in the present report, whose chief object has been to suggest measures whereby the general condition of the collection of vital statistics could be improved and data of fundamental importance be rendered comparable. Greater exactness and refinement of methods will properly come later on.

"On How to Practice Isolation from the Contagious Diseases" was read by Dr. J. M. MONJARRAS, Director of Health of the State of San Luis Potosi, Mexico.

In the evening the members were entertained at a banquet tendered by the City of Philadelphia.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 27, 1897.

CONGENITAL TUBERCULOSIS.

The question of the transmissibility of tuberculosis is one of great interest and importance. Before the discoveries of VILLEMEN and KOCH tuberculosis was regarded as a hereditary and constitutional disease due to a morbid condition of the tissues which was inherited from the parents. When it became established that tuberculosis is caused by a bacillus, the common occurrence of the disease in the members of the same family was generally explained on the score of the exposure to the inhalation of dried and pulverized tuberculous sputum. Others, however, would explain the many instances of tuberculosis among the children of tuberculous parents as due, in part at any rate, to a certain predisposition to the disease, the bacilli finding a favorable soil for their growth; these children are born, as PETER says, "tuberculisables, mais non tuberculeux." What this disposition really depends on is not known, but it has been thought to be due to the chemical nature of the tissues and fluids of the organism.

Inherited, or more properly congenital, tuberculosis may also have another mode of genesis—the tubercle bacilli may become lodged in or introduced into the tissues of the child before it is born. There are now so many unquestioned examples of this form of transmission that no one any longer denies its occurrence; but while the majority of the writers regard it as so exceptional and rare that it can not lay claim to any practical importance there are also those, as, for instance, BAUMGARTEN, who claim that tuberculosis is oftenest spread by means of prenatal infection, and their number is increasing.

The bacilli may be assumed to pass from the parents to the child either as the result of a germinative infection, which occurs at the time of fecundation, so that the embryo is tuberculous from its very beginning, or as the result of a placental or intra-uterine infection. In the case of germinative infection the bacilli might be assumed to be present in the unimpregnated ovum, or this may become infected on the way to the uterus, or the bacilli may be brought into the ovum with the impregnating spermatozoon. There exists, however, no reliable instance of conceptional infection. A few authors are inclined to urge the occurrence of infection through the spermatozoa. JAN¹ found bacilli in the testes of five out of eight phthisical persons without urogenital tuberculosis, sometimes in the interior of the seminal tubes and in some cases also in the prostate. SEMB,² SPANO³ and BUGGE⁴ have corroborated such findings, but WALTHER⁵ obtained negative results in nine cases. GÄRTNER'S⁶ well-known experiments speak against transmission by the father. He injected bacilli into the testicles of male guinea pigs and produced genital tuberculosis; seventy-four young pigs born of healthy mothers impregnated by the tuberculous males remained free from tuberculosis, while some of the female pigs—mothers—became infected. This part of the problem is therefore still open for discussion.

On the other hand, there are definite demonstrations at hand of congenital tuberculosis of placental origin. GÄTHER injected bacilli into the circulation of pregnant rabbits, and of fifty-one young rabbits five became infected; of nine mice injected with bacilli into the trachea seven brought forth tuberculous young. Here in this last set of experiments the conditions present in human pulmonary tuberculosis were as closely reproduced as feasible by experiment. The conditions necessary for transgression of bacilli in the maternal circulation to the fetal are but little known. In all cases of unquestioned congenital tuberculosis in the human the mother appears to have died soon after the birth of the child of phthisis. LEHMANN⁷ in two cases found tubercles in the placenta. SCHMORL and KOCKEL⁸ report three cases of placental tuberculosis. Two of the mothers died of miliary tuberculosis; the third of chronic pulmonary and laryngeal tuberculosis. In these three cases there were tubercles in the placenta, partly in the intervillous spaces, partly in the stroma of the villi. There were bacilli in the lumina of the fetal placental vessels. While a direct entrance of bacilli into the circulation of the fetus was thus demonstrated the author succeeded in finding bacilli in the liver and in a lymph node in the hepato-duodenal ligament of only one child. Inocu-

lation experiments gave negative results in all these cases. KOCKEL and LUNGUITZ⁹ found tuberculosis in the maternal and fetal parts of the placenta of pregnant tuberculous cows and lymphatic and hepatic tuberculous foci in the embryos. Further reports of placental tuberculosis are not at hand as yet.

The cases of human congenital tuberculosis are slowly increasing year for year. In one group tuberculous lesions are demonstrable at birth, in another group bacilli are found in the fetal organs. In many other cases bacilli have been sought for in vain. Thus CHARRIN, MERKEL, LANDARZY and MARTIN, ARMAUN, BIRCH-HIRSCHFELD and SCHMORL, AVIRAGNET, JACOBI, SARWEY, LONDE, LEHMANN,¹⁰ BUGGE¹¹ himself and the authors already mentioned, have described cases of more or less definitely demonstrated congenital tuberculosis. As to animals, BANG,¹² the well known Danish veterinarian, has found congenital tuberculosis in 13 calves. The first case of proven congenital tuberculosis is the widely known bovine case of JOHNE from 1885. While the number of instances of congenital tuberculosis is yet small it has been inferred that the transmission through the placenta of bacilli in the latter part of pregnancy occurs much more frequently than actually susceptible of demonstration and that they may remain latent in a lymph gland, a small lung or bone focus for many years. BAUMGARTEN and his followers urge this view and that the conditions are similar to those of tardy congenital syphilis. This view is in a measure supported by certain recent statistics which show that tuberculosis is more frequent in infancy than in any other period of life.¹³ Some of these statistics show that the tuberculosis is found most often in the peribronchial lymph nodes and the lungs, a fact which is difficult of explanation on the score of congenital infection pointing as it does to infection by inhalation. The champions of the congenital infection claim that the bacilli may circulate in the blood for quite a long time and become deposited finally in certain particularly favorable places, of which the lymphatic structures is regarded as one. Certain experiments with inoculated bacilli also point in this direction. On the whole it must be stated that the possibility of congenital infection with tubercle bacilli is becoming more and more widely recognized. At the congress for tuberculosis in Paris 1893, numerous and important arguments and facts in favor of congenital tuberculosis were brought forward. The frequent primary bone and joint tuberculosis in infancy are hard to account for by the theory of the doctrine of predisposition as long as there is no demonstration of any changes at the places of ordinary invasion from without.

From this fragmentary discussion of congenital

tuberculosis it may be gathered that the question is yet an open one and that there is a decided tendency toward, as well as considerable ground for, the belief that congenital infection, especially through the placenta, is of more common occurrence than generally believed.

THE ALLEGED DECREASE IN THE NATIVE AMERICAN POPULATION.

Every little while we read in the secular or other publications, what may be called jeremiads on the extinction of the native American stock, especially in the New England States. These are generally based upon reported statistics or analyses of reports of State boards of health, and to some extent upon pessimistic utterances of physicians who use the facts to point an argument against certain evil practices that they claim are too prevalent in that and other sections of our country. The author of a recently published series of lectures on medical jurisprudence with a strong sectarian bias uses these alleged facts, as it were, as a direct charge against a certain portion of the population whom he practically accuses of practicing criminal abortion as well as of other less flagrant immoralities.

The most recent authoritative statistics bearing upon the points in question are those contained in the twenty-eighth report of the Massachusetts State Board of Health, which are thus interpreted by the public press as bearing witness to the extinction of the native New England stock. They show that during the past forty years, from 1856 to 1896, the natural increase of population was only 463,419, or an average of something over eleven thousand a year, and that this birth rate was ever increasing amongst the foreign born. The decrease of native fecundity and the greater vigor and longevity of the foreign born and their children are held to inevitably point to the gradual extinction of the native American families in that State.

There is little doubt but that there is a certain degree of truth in this deduction and that neo-Malthusian practices are more general in that and other sections than is to be desired for the good of the country generally. This however is more or less the case in all civilized countries where general moderate thrift is the rule and it may be more so in some parts of New England than elsewhere. It is doubtful, however, whether any one who has had the opportunity to observe would claim that they are exclusively confined to the native stock; the division between the fecund and the comparatively sterile is drawn on economic more than racial lines, there as elsewhere, as is shown by the signification of the term "proletariat" in all parts of the civilized globe. Late marriages, urban rather than country life, the gradual selection of the most vigorous by emigration, and a forced celibacy of a larger

or smaller proportion of the female population ought all to be counted in calculations as to the causes of the phenomenon, instead of attributing it in a wholesale way to objectionable or criminal practices. And when we talk of the extinction of the New England stock we utterly ignore the fact that New England has furnished many times its own population to that of the newer sections of our country. Each generation of New Englanders sees its most energetic and active members migrate to the West, and the wonder is, not that the race should decrease in its original seat, but that it should continue to furnish, as it does, a steady supply of superior emigrants to all parts of the country and even to foreign lands. The native Yankee in his original New England home is still strongly in evidence in all matters of local or National importance, and however neurotic or degenerate some of them may be in some particulars, or sterile as compared with the foreign immigrant proletarian, there is hardly any sufficient reason to justify the belief that their extinction is at hand. Even were this probable, the New England blood is flowing in the veins of millions of Americans, a fact that certainly ought not to be left out of consideration; the partial transplanting of a race is not extinguishing it, and there is probably little danger of this even in its original soil. The original agricultural population of New England may perhaps largely disappear or be replaced by immigration from another region, but there will always be a leading element in that section that can trace its descent from the first settlers and which will mold the new comers to conform to a greater or less extent to the original type. At all events, however much we may regret that apparent comparative sterility of one of the best native stocks, we are not yet warranted in believing that it is in imminent danger of immediate extinction.

There is so much said upon this subject and almost exclusively from the pessimistic point of view in both medical and lay journals, that it is worth while occasionally to point out that bad as things may be, they hardly justify the extreme statements and deductions that are so often made. It is a misfortune if it is a fact that population is in even a static condition as regards one of its more desirable elements in any section of our country, but that does not justify intemperance of statement in regard to it. Taking the country as a whole it is questionable whether even the more moderate statements are correct.

INFLUENCE OF ENVIRONMENT ON MEDICAL MEN.

This subject has lately come into some prominence by the publication of the Smithsonian Lectures on "Environment in Civilization." The great difference of highly educated medical men in manners, habits of thought and personality, have always been the subject of comment and inquiry. At our ASSOCIATION

meetings from year to year these facts come out prominently, and ideal writers and authors are disillusionized and appear very different from previous conceptions. On one occasion, a noted man exhibited a wild fit of coarse passion; another was childishly stupid from spirits; and another was repulsive in his personal appearance. How far these personal differences are due to environment is often asked. Two men come from college equally polished and trained; years after one is a coarse egotist, the other a feeble, shrinking, doubtful man. One man becomes coarse in language and manners, another simpering and childish. One man reads a paper before the Section, and because it fails to attract attention, believes that he is the victim of prejudice. Another man who reads the paper of a rival in the JOURNAL, becomes angry and doubts the judgment and honesty of the editor. This list might be extended almost indefinitely, and is explained by environment and constitutional differences. This environment is both physical and mental. The physical is climate, hardship, struggle to secure a place and position in society and professional work. The mental is society, the people who surround him, and the thought atmosphere about him. Many medical men are able to form and keep up a mental environment about them; others are dependent on the men and women they come in contact with, and draw from this source mental stimulus and force. In this way many medical men reflect the coarseness and ignorance of the community and people they associate with; others exhibit opposite traits. In a certain city the medical men of half a century have been in constant conflict, and their weakness has come down, infecting every new class of physicians who settle in that place. This has given a distinct personality to physicians of that city, who are controversial, critical and intolerant. Many of these physicians, in a different atmosphere, would have been mild, quiet men. In another city the medical men vary widely in both personality and scientific attainments.

While it is clear to every one that the power of environment both shapes and makes the progress of individuals in all communities, it is not recognized in its influence over medical men and their work. Our ASSOCIATION meetings are admirable places to study these forces. Supercilious critics who sneer at these so-called great "mob gatherings," have no conception of the tremendous educational power which every meeting has on the personality of the men who attend. The narrow environments expand and disappear; the sordid egotism and pessimism is checked; the timid shrinking from intellectual contact is overcome. The one finds that his boasted power is feeble compared with others, and the other is roused to find that he is able to judge and compare his own opinions favorably. The man with coarse language and manners growing out of his environment, receives an impres-

sion of his weakness which is startling. The combative physician discovers the folly of personal conflict over points which the leaders discuss so placidly, and join in hearty friendships after. There can be no doubt that American medicine depends very largely on the AMERICAN MEDICAL ASSOCIATION meetings. The larger these meetings are, and the more widely they are held in different parts of the country, the greater and more beneficent their influence on the general profession. Each man in the profession needs a change of environment; he needs some standard of comparison by which he can estimate his own vantage-ground. The teacher with his admiring crowds of students, the specialist, the country practitioner and the village doctor, are all subject to the laws of environment, and reflect the mental and physical world they live in. They show this in every public gathering and in every ASSOCIATION meeting, and whether they take part or not, are immeasurably benefited by the contact with others who pursue the same calling in different fields. They take home a new dignity and new and wider conceptions of medicine in its best sense. The critics may decide that scientific medicine is not much advanced by these meetings, but this is a narrow view. The gain psychically appears later. Medicine is seen to be something more than diagnosis and therapeutics, and its daily drudgery more than the struggle to obtain a living. Each individual life will appear, from these contacts in National gatherings, larger and less bound down by the environments of home and home influences. The last meeting at Philadelphia should be the beginning of a larger field of medicine in America. The coming meeting at Denver should bring out two thousand physicians and more, each one of whom will go home better fitted to make his environments assist him to higher professional and social ranges of life and living. We are all subject to environments, but to make these environments help and not detract is the province of wisdom. The intense personalities, petty weaknesses and defects of our lives, require therapeutic study and treatment, and one of the great specific remedies is to cultivate a larger and more intimate acquaintance with the profession in both the local and National societies. In this way environments can be made helpful, and we can use what is now so often an obstacle.

THE DIXON CASE AND EXPERT FEES.

The Supreme Court decision in the Illinois case of Dr. DIXON furnishes one of the many instances where Supreme Courts support the dignity of inferior courts at the expense of general principles of law by deciding on an inferior point in such a way as to settle temporarily a general principle unconnected with the inferior issue. The DIXON case turned on two elements; in one, Dr. DIXON was a fact witness and

could be compelled to testify without compensation as such witness. He was asked his opinion, which a pettifogger might easily regard, under the circumstances, as the opinion of a non-expert and treat accordingly. Had Dr. DIXON declined to testify at all, a clear case of expert opinion would have been made out. It is exceedingly doubtful whether even in its excessive desire to preserve the sacred right of government by injunction, the Supreme Court would then have dared to have set itself against the trend of decisions in most of the English speaking countries, notoriously in Great Britain itself.

With the exception of Alabama and Tennessee, the decisions of the Supreme Courts of the various States have, in the absence of a code, been opposed to the taking of property in the shape of expert knowledge without compensation. While Indiana was working under the common law its Supreme Court held that the expert witness must be paid; a position which since its adoption of a code is no longer tenable, as the code makes explicit provision for the case. In Illinois the courts, except where limited by statute, work under the common law. The trend of decisions in Illinois has been to the effect that where a physician has testified to the facts, he can be compelled to give his opinion without promise of further compensation than that of an ordinary witness. This rule is based (according to the position held in *Wright vs. The People*, 112 Illinois 540) on the principle that the physician's opinion is that derived from his original relation of physician to his patient and hence a non-expert matter. This position indicates the desirability of separating fact and opinion witnesses, not merely because of the question of compensation alone but because, as has been previously pointed out by the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, the ends of forensic science can thus be better secured. The great difficulties in expert testimony have arisen from the confusion of fact and opinion witnesses. Of necessity under this confusion, the experts are able to secure one side of the case alone and hence apparent contradictions result, due to imperfect data. The introduction of the hypothetical case, free from any facts observed by the expert to whom it is put, would at once specifically limit the expert to expert functions and secure opinions which would really represent the judicial position of the expert. The expert would undoubtedly give contradictory opinions on different hypothetical cases, but this would enable the jury to see clearly the strength of the positions of the opposed parties. It could by deciding which hypothetical case represented the evidence most truly, avail itself of expert skill in a way most scientific and judicial. Furthermore, from the standpoint of the interest of the physician, the hypothetical case would prevent the confiscation of expert skill by judicial jugglery.

since even the most case-hardened stickler for court dignity would hardly dare to compel a medical man to testify on a mere hypothetical case.

The enactment of a statute such as was presented some years back by the united medical societies of Chicago, would undoubtedly settle the case beyond judicial jugglery. This statute provided for the selection of experts, not for each case, but at the beginning of the year, from whom the city attorney, State's attorney and corporation counsels were to draw in any case, to whom the facts in evidence on both sides were to be presented in hypothetical form while cross-examination was to be limited to these hypothetical questions. No interference could be made with a constitutional right of the individual of calling his own witness. Had the statute been enacted it would have guarded against expert evils on the side of the State, the side where they are greatest and the side which exacts most with least compensation. It would have destroyed the power of an irresponsible county board to use an expert fund as a means of patronage, as has been done by more than one state's attorney of his own accord and at the dictation of the county board whence he draws his funds. It would also have established a precedent for expert compensation, which would have settled the question in Illinois. The physician has an easy redress against private individuals in the matter of expert evidence, but he has none against judges armed with the contempt of court dodge and replete with power to legislate by the great writ of injunction.

The problem before the profession of Illinois is therefore a double one on the expert compensation question. The first thing to be done is the passage of a statute along the lines mentioned. The second is to secure a proper test case on pure opinion evidence and carry this to the United States Supreme Court if necessary. The JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION has repeatedly urged action along these lines. The DIXON case adds special emphasis to its warning that special organization for political power of the physicians as physicians is needed.

CORRESPONDENCE.

Asiatic Plague and Cholera Centers.

ESCHENZ, CANTON THURGAU, }
SWITZERLAND, Oct. 26, 1897. }

To the Editor:—My second letter on the above subject has been unavoidably delayed while rustivating on the shores of the Swiss lakes and among the Alps, emulating the goat in mountain-climbing and other praiseworthy pursuits. Of my observations and experiences at European health resorts, I shall write at length on some future occasion. I must now get back to Mesopotamian epidemics and Turkish quarantines.

On May 28, 1893, cholera was reported to have broken out in Bassorah and among the Bedouin tribes of Lower Mesopotamia. A quarantine was forthwith established about half way between Bagdad and Bassorah, with a military cordon extend-

ing from the Persian frontier to the Euphrates; but in spite of government vigilance and red tape, a battalion of comma bacilli advanced boldly up stream, passed the guards unchallenged, and then attacked a town on the bank of the Tigris just above the quarantine station. Quarantine officers and comma bacilli now began a race, alternately gaining on each other, until the latter finally entered Bagdad unobserved and in advance of the former, making their presence known in the "City of Peace" on August 24. The quarantine station was now removed to some distance above the city, and communication with the Persian gulf region was re-established. Never shall I forget the rejoicing of fifteen hundred Bagdad Jews who had been on a pilgrimage to Ezra's tomb, when they learned cholera had invaded their homes; jubilant they entered the city after nearly three months of enforced exile, which but for the Arabs of the desert would also have been three months of enforced fasting. Shouts of joy rent the air, as the steamer approached, shrill dissonant trills from a thousand throats drowning for a time the sound of mourners' doleful dirges sung to frantic time-beating on naked breasts. Except forbidding the sale of watermelons nothing was done to stay the ravages of the epidemic; and when one morning some sixty or seventy cuffahs (round boats built of basketwork and covered with bitumen) loaded with melons came down the river and a couple of hundred soldiers were sent to empty their contents into the middle of the stream, some two thousand Arabs swam out, gathered in the spoils, and sat down on the river bank filling their bellies with the forbidden fruit. Whenever I looked out of the window, my eye dwelt on an enlivening, security-inspiring scene.

Within my range of vision was the U. S. Consulate and the health offices. The space between the two being filled with donkeys and men and their excrements. Near by and up stream a row of water-carriers were filling their skins from the river, and just above them a row of men defecating on the river bank, while above the latter was a row of men washing clothes soiled with cholera dejecta. A wall projected into the river below and near the water-carriers, admirably adapted to arrest all floating bodies coming down stream near the shore, and here dead sheep, camels, dogs, solid excrements, etc., were floating. Further up stream a bridge crossed the Tigris and from this are emptied the privy contents from mosques along the bank.

Truly an invigorating sight! Jews and Christians fled to the deserts as soon as the first cholera bulletin was issued; but the Mohammedans remained, hoping *inshallah*—"if God willed it"—that the death angel would pass them by, and, if not, satisfied that fleeing would not save them. The epidemic raged furiously for about four weeks, but lingered on until toward the end of November, typhoid fever and diphtheria following in its wake. One peculiarity of this epidemic was the unusually high child mortality. The fatality of epidemics in Turkey can only be guessed at, and not even approximately, as the number of deaths recorded bears no relation whatever to the actual number. Many deaths are concealed by surreptitious burial in cellars; only comparatively few of the total number are reported, and from those reported the daily mortality bulletins are boiled down by the Wálé and health officer in secret council.

Early in 1893 the U. S. Treasury Department and Hospital Marine Service seem to have had a severe paroxysm of epidemiphobia, and a number of laws and regulations, some no doubt wise and some otherwise, were framed and sent out to confound consular and quarantine officers, lead merchants and shippers into temptation to conceal, deceive and prevaricate, perhaps even to bribe the local health officer into outright lying, or attempt to induce U. S. Consuls to inspect American-bound ships through the bottom of champagne glasses heavily gold-framed (the most convenient official spectacles invented)

and finally, failing to accomplish this, to bring influence and pressure to bear on the Department itself, forcing it to break its own regulations. Dark and slippery the ways of the burrowing offshoots from the root of all evil, and tighter their grasp than that of the arms of the octopus!

Early in 1894, the Sublime Porte decreed that cholera must not be permitted to enter Bagdad that year: hence it happened that an epidemic of some mysterious malady, clinically indistinguishable from the epidemic of the previous year or the national epidemic of Bengal, received no official recognition: but this slight did not pass unrevenge, as one of the clerks in the health office was made to feel the invader's grip and gripe. Foolish doctors and undertakers whispered among themselves the name of the tabooed guest, and an honest but indiscreet physician in Bassorah came near being mobbed for daring to pronounce it above breath.

There are three very holy cities in this region, where good Shiah Mohammedans choose to be buried, and thus it happens that some eight or ten thousand defunct immigrants, some of whom have already been dead two or three years, pass annually through Bagdad on the way to their final resting place. The coffins being leaky, putrid cadaveric liquid pours out through the seams and drops on the road to there dry and scent the dust. Thus one smells the approach of a funeral caravan with its three or four hundred corpses for miles to leeward. They come mostly from Persia and bring also with them great loads of the finest Persian carpets and rugs. From Bagdad these rugs, which have perhaps for twenty or more years been exposed in inconceivably filthy homes to the contagion of every known disease germ and other abominations, are now shipped to Europe and America to henceforth adorn the parlors of the rich and undermine the health and shorten the lives of their children. Let the quarantine authorities take due notice thereof and govern themselves accordingly.

Every spring the rapid melting of the snow in Armenia and Kurdistan, causing the rivers to swell and overflow their banks, gives rise to devastating floods, sometimes of long duration, and followed by epidemics of malignant miasmatic fevers, dysentery, etc., and often by an outburst of the plague. The most destructive inundation of this century occurred in 1831, when 7,000 houses fell in one night, in Bagdad, burying the inhabitants under the crumbled masses of brick. Two-thirds of the population died that summer of the plague. In 1849 there was another great flood, and the city was decimated by fever. Early in the spring of 1894 the Tigris rose suddenly, twenty-six feet, and converted the desert into an immense ocean with an average depth of from ten to twelve feet and a clear horizon all around, except for a little island here and there marking the sites of buried ruins. The walls of Bagdad strengthened by earthworks and matting, and the houses skirting the river banks kept the streets, though considerably below water level, fairly dry: but the cellars were mostly flooded. Fishing from parlor windows was among the idle sports in this lazy fishermen's paradise. Verily, I could say with Jeremiah: "The sea is come up upon Babylon; she is covered with the multitude of the waters thereof."

As the waters subsided, a rank and luxuriant vegetation sprang up, soon again to wither and dry, pools of stagnant water, greenish, semigelatinous, ammoniacal from decomposing animal and vegetable matter, charging the atmosphere with their poisonous effluvia. The fellahin along the river banks, as also the Arabs of the desert, sickened and died by the hundreds. Wandering from hut to hut and from tent to tent I put into each fever-parched patient's mouth an orthodox Texas river bottom congestive-chill powder consisting of forty grains of quinin and twenty grains each of calomel and Dover's powder, which they washed down with muddy Tigris water. Dysentery patients were made to swallow forty grains of ipecac, and under this treatment those who did not die got

well, *Hakim Balois'* fame spread wide and far, and procured me the freedom of the desert, which soon again regained its usual salubrity. The pure dry desert air is, even though fiery hot as the blast from a furnace, invigorating, except when southwesterly winds blow, and then everyone feels sick and depressed. I have reason to believe that there is little if any tuberculosis in the desert: not so, however, in the cities. In Bagdad it is given as second in frequency among the causes of death; and if one could believe the vital statistics of Bagdad, it is the healthiest city the world has ever seen or ever will see; for the fiscal year ended Feb. 28, 1892 only 385 deaths were reported, and the population being in my opinion rather above than under 200,000, this would give a death rate of less than 2 per mille!!! The following year 2,042 deaths were reported which would increase the death rate to a little over 10 per mille, probably less than one fourth the actual number. There were 705 deaths recorded as caused by cholera; but the health officer himself admitted that this did not represent one half the actual number. Had he said they represented one-fourth the actual number, he would at least have been that much nearer the truth. The child mortality is very high, but few deaths in childhood are recorded, not being considered of sufficient importance to take any cognizance of.

The military statistics, which we may assume to be fairly correct, furnish, perhaps data upon which to roughly estimate the death rate. The army of Mesopotamia numbered in 1892 about 6,000 men, presumably between the ages of 20 and 35, when the mortality in a healthy country should not exceed 7 or at most 8 per mille and be less than half, perhaps nearer one third the death rate of the whole population. But there were 2,855 admissions into hospitals, with 191 deaths, a mortality of 32 per mille of the total force. I do not think the medical examination of recruits is at all thorough, so they are hardly to be regarded as selected risks from a life insurance point of view, nor are they better fed, housed or cared for than civilians: yet I think it fair to assume that the general mortality is at least twice that of the army. This would then in healthy years, when there are no epidemics, fix it at 64 per mille.

Of the causes of death in the army during said year, dysentery headed the list with 81; typhoid fever came next with 36, enteritis 20, tuberculosis 18, pneumonia 7, cerebral disease 6, heart disease 3, other causes one or two each, among these abscess of the liver 1, while two admitted into the hospital from this cause were discharged cured. It is worthy of note that there was not a single case of alcoholism and but 573 (95.5 per mille) venereal cases admitted.

In my next I shall tell some of my experiences in "The Home of Cholera" (Bengal) during 1877-79.

JOHN C. SUNDBERG.

A Case of Acute Coryza.

CHICAGO, Nov. 10, 1897.

To the Editor:—Recently I had the opportunity to examine, two days after the onset of an attack of acute coryza, the secretion from the nasal mucous membrane and found a fission fungus present in large numbers.

The patient, some 30 years of age, had had an attack annually, usually in the fall, ever since a boy. Sometimes he would escape an attack for a year, or instead of its occurring in the fall it would come on in the early summer, and in one instance it occurred in the spring. The first intimation of an approaching illness would be a feeling of lassitude, a disinclination to exertion; in twenty-four hours the symptoms would be fully developed and the patient would know he was going to be laid up with a fever for a week. At this time there would be great fulness of the head, throbbing temples and high fever, 102, 103, 104 degrees F., with dizziness and marked prostra-

on. The pituitary membrane, at first hot and dry, would soon be covered by a thin mucous secretion which later on would gradually change to a copious mucopurulent discharge, very annoying and very persistent. These symptoms would continue from three to seven days, when the fever would gradually subside, the dizziness and the feeling of fulness in the head would disappear and convalescence be fully established. In one or two weeks from time of onset recovery would be complete, except that the discharge from the nose would persist very much the same as during the acute attack, being of about the same consistency but less in quantity.

At first this condition would continue for a few months and then the discharge would disappear, but with repeated attacks. The interval of freedom from this annoying symptom grew shorter and finally the discharge persisted from one attack to another throughout the year.

Rarely was there freedom from the recurring annual attacks until seven years ago, when the hypertrophied mucous membrane was partially removed by means of the electro-cautery, and since then until the present he has enjoyed entire freedom from attack.

At the time I placed the first specimen under the microscope, Oct. 28, 1897, the secretion was not very abundant, and was the only symptom complained of except that during some part of the day, usually late in the afternoon, there was a strange feeling of numbness at the root of the nose, which seemed to the patient to portend an approaching illness.

After this one, a number of other specimens were examined, but no bacilli were found except a very few; close search could show perhaps two or four in the entire field, and no new symptoms developed.

On the evening of November 2, however, he complained of feeling quite ill. There was considerable fever, headache, slight dizziness, and the whole chain of symptoms that had so often ushered in an attack of catarrhal fever, so that he was convinced his old trouble had come back again. I resolved on heroic treatment and irrigated the pituitary membrane with a solution of 1 to 4,000 bichlorid solution. By following immediately with Casselberry's spray for catarrh, the irritation resulting from the douche was reduced to a minimum, and the treatment followed by the happiest results.

The next morning the patient was surprised to find his fever gone and he was feeling comparatively well. By the continued use of milder antiseptics the attack was completely aborted and after recovery the amount of discharge was almost *null*.

The douching with the bichlorid solution brought away a large amount of a whitish, albuminous semi-fluid mass, that floated on the surface of the water, and the formed elements were found to consist largely of desquamated epithelium interspersed with bacilli and their spores. The latter were large and luminous, not having taken the stain, and the bacilli containing them were very active, moving rapidly across the field. The spores developed in the end of a bacillus and formed by far the larger part of it. The bacilli containing no spores possessed a slight motion. This last specimen did not contain nearly so many bacilli as the first, but there were a goodly number present.

I feel no hesitancy in ascribing the cause of the attack to the presence of this bacillus, and attribute the abortion of the attack to the suppression of the same micro-organism.

The bacillus closely resembles the bacillus subtilis and may be identical with it, but I could not say positively without further research.

I do not regard it too much to assume that this bacillus, which is some form of fission-fungus, was the exciting cause of the attack of acute coryza, nor do I consider it chimeric to assume that these repeated attacks were probably caused by the same micro-organism and that it was this frequent repetition that finally resulted in a typical case of chronic hypertrophic rhinitis.

H. G. GRAHAM, M.D.

The Late Leprosy Congress.

NEW YORK, NOV. 15, 1897.

To the Editor:—I took great pleasure in reading your editorial in the *JOURNAL* of November 13, "The Late Leprosy Congress," but allow me to say that there are points on which I believe you are not quite accurate, which, in the absence so far of complete report, is natural enough. You must allow me to call your attention to the following points:

You say: "The general tone of the convention, judging from the utterances as given in the press, was opposed to the excitement of any general alarm on the part of the public as to the possible dangers from this disease, at least as far as the principal civilized countries are concerned."

I read in the extract given by Dr. Max Joseph, in the *Berliner Wochenschrift*, the following: "The Minister of Worship, Dr. Bosse declared the statement that the Prussian administration takes the greatest interest in the conference, as the frontiers of Prussia have already been crossed by leprosy, and as leprosy no longer can be considered as a dead disease. On the contrary, the district of Memel is to be considered as infected. Besides the surveillance of the frontier traffic, he said the most important measure taken is the sequestration of the diseased in special hospitals to be built shortly. In the district of Memel a leprosy for the shelter and nursing of eighteen patients is being built (there have been thirty-four cases in Memel). The plans are ready, etc."

Says the *British Medical Journal*, "Professor Neumann of Vienna called attention to the fact (in the Berlin conference) that the Austro-Hungarian Government is awaiting the result of the deliberations before instituting administrative measures against leprosy of which 133 cases have occurred within seven years in Bosnia and Herzegovina. . . . The object of the congress is exclusively to formulate conclusions which may be made the basis for administrative measures to be taken by the various governments for combating the propagation of this disease and staying its ravages. These may ultimately be followed by an international convention against leprosy."

The *Wochenschrift* gives this detail: "Dr. Dehio of Dorpat, Russia, reported that the number of the lepers had, in forty years, increased from 300 to 600, and that there nothing was to be done but to isolate the patients."

The following conclusions of Hansen were adopted by the Congress:

1. In all countries in which leprosy exists focus-wise or in greater extension, isolation is the best means to prevent the spread of the disease.

2. A system of obligatory report of the cases, of surveillance, and of isolation, like that which is in force in Norway, is to be recommended to all nations with autonomic commissions, and a sufficient number of physicians.

3. It must be left to the legal authorities to determine, after hearing the sanitary authorities, the closer prescriptions which must be adapted to the social circumstances.

It must be borne in mind that, if this conference was called at all, it was for that precise reason, that leprosy was felt and known to be increasing in civilized communities in which isolation had not been as yet adopted.

I have no doubt, when the complete report of the transactions is published, you will find that the majority of the conference has not at all so sanguine and non-alarming opinion as you seem to imply. I can assure you that if my proposition of a permanent international committee was rejected, it was not because it did not seem warranted by the greatness of the danger. As Hansen wrote me some time ago that the intention of the conference would be to promulgate principles to be adopted by every government and that afterward, these having failed, an international treaty may still be proposed and obtained. Unna wrote me only last month, strongly favoring international delegates. Neumann of Vienna, and Max Joseph

of Berlin, have published articles strongly favoring international measures.

One thing is perfectly sure: The position taken by the members of the New York County Medical Society's Committee and the New York Board of Health, that the disease is not contagious in this climate, and that consequently isolation is a supererogatory and purely alarmed affair, is untenable. There seems to be a heroic effort made, to solve the question, *How not to do it?*

ALBERT S. ASHMEAD, M.D.

Typhoid Fever.

SHAFTSBURG, MICH., Nov. 15, 1897.

To the Editor:—My experience with the Woodbridge treatment of typhoid fever leads me to these conclusions: The treatment will abort the fever as claimed, but it does not leave the patient immune. I certainly have on different occasions, noticed that fact. Immunity is secured, it would seem, only by the full and complete saturation of the system by the toxins (or whatever else you may call it) as in the old treatment, which allowed the fever to run for weeks. But the old methods are by no means safe. The greater safety is in aborting it. While there is this one drawback, immunity not secured, Dr. Woodbridge has enabled us to speak with confidence as to our prognosis. This treatment enables us to give more latitude to the diet and makes feeding much easier. In a country practice this is very desirable.

G. W. CHROUCH, M.D.

Carbolic Acid Poisoning.

CHICAGO, Nov. 18, 1897.

To the Editor:—The frequency with which carbolic acid poisoning is met with, either accidental or intentional, leads me to call the attention of the profession to the use of atropin, as suggested by Bartholow, in this condition.

I have had four cases, one that of a boy two years and four months old drinking about one and one-half ounces of pure carbolic acid, who was brought to me in a state of coma, breathing four or five times a minute, with no pulse, the surface cold and clammy. I resorted at once to artificial respiration, and injected hypodermically one-fiftieth grain of atropin to increase the respiration and pulse rate, and introduced the stomach pump, using warm water and lime water in proportion. By this time the child's breathing became more vigorous, and he was somewhat conscious, and I then gave a dose of magnesium sulphate and ordered the continuance of small doses of the same, which I believe does more than produce catharsis in this condition.

Another case was a boy five years of age who drank about a tablespoonful. The third case was a lady thirty-three years of age who swallowed two ounces of carbolic acid. The fourth case was a young man twenty-eight years of age who mixed one ounce of the acid in beer. The two last named cases were attempts at suicide. All made a favorable recovery.

The hypodermic injections of atropin can be repeated, however, in smaller doses, if the stupor continues or the patient shows a tendency to collapse again within two hours after the first injection, as I believe that it is a better stimulant, both respiratory and circulatory, than any other in these cases. The use of the catheter is not to be omitted.

Yours truly, EDW. E. KOLAR, M.D.

Surgeons of the Merchant Marine.

HILLTOP FARM, GROVELAND, MASS., Nov. 15, 1897.

To the Editor:—I am very much interested in noticing in this week's JOURNAL an item concerning "Ships' Doctors." Our medical journals in this country, as well as in Europe, have of late given this matter considerable attention, and the betterment of the service is steadily going on. This is one of

the main objects of the International League of Surgeons of the Merchant Marine. For those of your readers who are not familiar with this organization. I will state that its objects are:

1. To increase the efficiency of the medical service on the ocean liners.
2. To encourage the surgeons to respect their positions and to prevent unworthy applicants from receiving employment.
3. To provide information on professional subjects relating to sea service with a view to lessen the difficulties of recently appointed medical officers.
4. To collect a history of the members for publication.
5. To publish a volume of records which shall be of value to those interested.
6. To furnish a list of medical officers of the merchant marine serving at sea throughout the world.

Membership.—Any past or present surgeon of the merchant marine in good professional standing, is eligible to membership. The enrollment fee shall be \$1. For further information address the Secretary for the United States Division.

W. THORNTON PARKER, M.D.

Woman's Medical Mission, Ceylon.

22 CIRCUIT ST., ROXBURY, MASS., Nov. 15, 1897.

To the Editor:—In connection with the Woman's Medical Mission in Jaffna, Ceylon, there is an opening for a lady doctor to be the associate of Dr. Isabella Curr, who went to Ceylon last year.

The five large new buildings of the Woman's Medical Mission, viz., the Mission House, the Nurses Training School, the Medical and Surgical Wards, and the Dispensary, together with the necessary outbuildings, are completed and ready for use. The wards provide accommodation for forty in-patients. The training school will accommodate eighteen nurses and a matron.

Rev. T. B. Scott, M.D., and Mrs. T. B. Scott, M.D., who are in charge of the General Medical Mission near by, will act as consulting physicians.

A population of 300,000 people in this province is accessible. The climate is healthful. The outlook for the work is promising. Ten families of American and British missionaries reside in the province. There are 3,000 native Christian members of mission churches, and 15,000 children and youths in mission schools.

As the training of educated Christian young women as nurses will be an important feature of the work, we are desirous of finding, to fill this vacancy, a medical lady who has had a nurse's training, or one who would be willing, before going out, to take some special instruction in nursing. She should be possessed of a true missionary spirit.

We would be glad to hear from any one who is fully qualified or who is about to graduate the coming spring.

Yours truly, MARY AND MARGARET W. LEITCH.

The Tonic for Alcoholics.

TRENTON, N.J., Nov. 18, 1897.

To the Editor:—Replying to the query of Dr. W. K. Curtis, (*vide* JOURNAL of November 13), I would say that the tonic used in all the cure establishments is:

- | | |
|---|-----------------|
| Fl. ext. coca | c.c. |
| Fl. ext. gentian | |
| Fl. ext. black haw | (āā 5 ij) āā 64 |
| Dilute alcohol q. s. | O j 250 |
| Sig. F. ʒ j every four hours in warm water. | |

This is the tonic. Ipecac added to this will produce nausea, and is tasteless. The more ipecac the more nausea. This will in time disgust a patient and produce a dislike for liquor. The ipecac is added after drinking, without the knowledge of the patient. A hypodermic of apomorphia, one-tenth grain, a

short time after drinking, will produce excessive vomiting. The patient must not know the cause of the vomiting. These things can be worked in the tonic without arousing the patient's suspicion; thus the trick of these institutions. The hypodermic is used when a tonic is given hypodermically, on some pretext, after drinking.

Yours fraternally, H. G. NORTON, M.D.

Medical Laws of the State of Washington.

SEATTLE, WASH., NOV. 10, 1897.

To the Editor:—I am in receipt of many inquiries concerning the medical laws of the State of Washington. I would say that all persons intending to practice medicine or surgery in the State of Washington are obliged to pass an examination before the State Board of Medical Examiners.

These examinations are held the first Tuesday in January and the first Tuesday in July. The January meeting is held on the west side of the Cascade mountains and the July meeting on the east side.

No temporary certificates are granted by this Board, and no exception is made to this rule.

F. H. COE, Sec. Med. Soc. State of Washington.

Correction.

NEW YORK, NOV. 8, 1897.

To the Editor:—Please publish the following errata: *JOURNAL* of Nov. 6, 1897, p. 972, second column, lines 21 and 22, for "medium" please read *median*; line 32, for "them" read *thon*; line 43, for "per os" read *per orem*. I am anxious to have the word *thon* come into general use, as it is needed very much. Yours truly, E. CUTTER, M.D.

BOOK NOTICES.

Text-book of Nervous Diseases. By CHARLES L. DANA, A.M., M.D., New York. Fourth revised edition. One volume, octavo, pp. 640. Profusely illustrated. Muslin, \$3.50 net. New York: William Wood and Company. 1897.

This edition of the book has been given a very complete revision, and some parts of it have been entirely rewritten. Says the author: "Those who have the pleasure of knowing him personally and his conscientious work will accept his statement as they would his bond." A chapter has been added on alcoholic meningitis, a very necessary addition, and one that should appeal especially to those connected with ambulance service everywhere. Such additions have been made to the therapeutics as the experience of the author has seemed to him to warrant.

The author says: "The number of nervous diseases has not lessened as the years have rolled by, but their grouping and relations are better understood, and the essential unity of many groups has been made more distinct. Those who read the present volume will perhaps be somewhat disturbed at first by the new nomenclature, which has so much to say about neurons, dendrites and neuraxons. These have come to stay, that is, anatomically, and the modern student must become familiar with them. I have to confess, however, that our conception of the neuron has aided us more in our anatomic work than in our pathology. A practical application of the neuron to disease has not yet furnished us very much help."

Text-book of Special Pathological Anatomy. By ERNEST ZIEGLER. Translated by Donald MacAllister, M.D., M.A., and Henry W. Cattell, M.D. Sections 9 to 15. New York and London: The Macmillan Company. 1897.

These sections containing the work as heretofore noticed in the *JOURNAL* are devoted to the pathology of the liver and pancreas, the respiratory system, the urinary organs, the genital system and the eye and ear.

The paging of the work is continuous with the preceding

one and brings it down to 1221 pages. It is expected that this volume will be followed with a volume on general pathology in due course.

No words of ours are needed in commendation of this magnificent work, without which the library of no pathologist would be complete.

The style of the translation and the arrangement of the topics resembles the volume of D. J. Hamilton, but the volumes are richer in illustration. At the end of each chapter there is a very full list of references to the literature of the subject treated.

Hare's Practical Diagnosis. The Use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, Laureate of the Medical Society of London, of the Royal Academy in Belgium, etc. New (2d) and revised edition. In one octavo volume of 598 pages with 201 engravings and 13 full-page colored plates. Cloth, \$4.75. Philadelphia: Lea Brothers and Co., Publishers.

In our review of the first edition of this book (see *JOURNAL*, Sept. 26, 1896, page 718), we made the following statement:

"We have here a work in which semeiology, the visible symptoms with which we are confronted, is made to tell the story of the patient's pathologic condition, the natural or Hippocratic method. The work is profusely illustrated and the illustrations are fine. The title of the volume is not a misnomer in this instance, for it is indeed a practical diagnosis. An excellent index concludes the volume."

There seems to be few changes from the former edition and we have little to add to what we then said.

Clinical Diagnosis. The Bacteriological, Chemical and Microscopical Evidences of Disease. By Dr. RUDOLPH V. JAKSCH. Translated from the fourth German edition and enlarged by JAMES CAGNEY, M.A., M.D. Third edition, with numerous illustrations, partly in colors. Pages, 523; price, \$6. London: Charles Griffin & Co., Limited. 1897.

This is the third English edition of Professor v. Jaksch's work, which has been largely rewritten and reconstructed. There is no work on the subject more authoritative than this and there are few, if any, more comprehensive of the essentials. Even the most minute are found here and to the practical worker no better guide to clinical diagnosis can be had. The day has gone by when much is left to chance in the matter of diagnosis, as by examination of excrementitious matters, the blood, the urine, histologically and bacteriologically, exact conditions may be understood.

This work is divided into ten chapters, of which Chapter 1 is on the blood; 2, the buccal secretion; 3, the nasal secretion; 4, the sputum; 5, gastric juice; 6, the feces; 7, examination of the urine; 8, exudations, transudations and cystic fluids; 9, secretions of the genital organs, including mammary secretion; 10, methods of bacteriologic research.

Simon's Clinical Diagnosis. New (2d) edition, revised and enlarged. A Manual of Clinical Diagnosis by Microscopical and Chemical Methods. For students, hospital physicians and practitioners. By CHARLES E. SIMON, M.D., late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. In one very handsome octavo volume of 530 pages, with 135 engravings and 14 full page colored plates. Cloth, \$3.50.

The present edition of the volume has been brought thoroughly up to date. The parasitology and bacteriology of the blood, saliva, feces, urine and vaginal discharges have been written. New methods of clinical examination, which have appeared since the publication of the first edition, have been included in the work. Numerous additions have been made and the size of the volume increased about fifty pages. The illustrations are excellent and include a number of handsome chromolithographs. The publishers have apparently spared no pains to make the work complete and valuable. The rapid exhaustion of the first edition, published in 1896, indicates the favorable reception of the progress of the work.

Cutaneous Medicine. A Systematic Treatise on the Diseases of the Skin. By LOUIS A. DUHRING, M.D. Part II., Classification of Anemias, Hyperemias and Inflammations. Illustrated. Philadelphia and London: J. B. Lippincott Company, 1898. Pages 494.

The second part of this work, the first part of which we noticed favorably in the JOURNAL, is devoted to classification and the diseases following under the head of anemias, hyperemias and inflammations. After a brief history of the classification of the diseases of the skin down to recent periods, the author gives his reasons for preferring his own classification to those in use, which he gives at some length. Dermatologists will add this work to their libraries with great pleasure, and as it contains the most recent literature, besides embodying the author's vast experience, it is a distinct and valuable contribution to American medical literature, and from this standpoint the general practitioner as well will be interested in the work. The illustrations are good and the references throughout the text with the current literature are exhaustive.

Pathological Technique. A Practical Manual for the Pathologic Laboratory. By FRANK BURR MALLORY, A.M., M.D., and JAMES HOMER WRIGHT, A.M., M.D., with 105 illustrations. Philadelphia: W. B. Saunders, 1897. Pages 397. Price \$2.50 net.

This book is destined for practical use in pathologic laboratories, both as a guide to beginners and as a reference for the advanced. It will also meet the wants of practitioners who have more or less opportunity to do general pathologic work. The book is divided into three parts, of which the first is devoted to postmortem examinations, external and internal examinations of the body. Part 2 to bacteriologic examinations, the apparatus, culture media, examinations at autopsies, methods of studying bacteria in cultures, bacteriologic diagnosis and clinical bacteriology. Part 3 is devoted to histologic methods. We regard this as one of the most complete works on the subject recently issued and one which should be in the library of every physician who hopes to keep pace with the great advances made in pathology.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In twenty volumes. Volume XII, "Mental Diseases, Childhood and Old Age." New York: William Wood & Co. Pages 948. 1897.

The contributors to Volume xii are J. Boy-Teisser, D.C.L., M.D., Marseilles; J. F. Blanford, M.D., London; Jules Comby, M.D., Paris; C. Lombroso, M.D., Turin, and Paul A. Sollier, M.D., Paris. This volume opens with a carefully prepared paper by Dr. Blanford which occupies the first 254 pages. This is followed by Sollier's article on idiocy, which has been assigned 100 pages, and a shorter article by Lombroso on criminal anthropology. J. Boy-Teisser writes on old age, and the remainder of the volume is taken up by Dr. Comby on diseases of children. No higher authorities can be found in Europe on the respective subjects treated of in this volume than the respective authors. It is a work of supererogation for the reviewer to commend what has been written by experts in the truest sense.

A Treatise on Gynecology, Medical and Surgical. By Dr. S. POZZI of Paris. Third revised edition. Translated by Dr. BROOKS H. WELLS of New York. One volume of 950 pages, royal octavo, illustrated by over 600 wood engravings. Muslin, \$5.50 net; leather, \$6.50 net. New York: William Wood & Co. 1897.

This edition is an exact translation of the third French edition, and as the work has been translated into German, English, Spanish, Italian and Russian and has received the prize of the Institute of the Academy of Medicine of Paris, it is almost beyond the province of the reviewer, and additional interest will attach to the work of Pozzi since his trip to America, where he was entertained royally by the surgical craft generally and particularly by those surgeons whose practice is

limited to gynecology. Few changes have been made in the work since the last edition, but they are such as to bring the volume down to date and within the compass of a single volume. The gynecologist who follows the instructions of Pozzi closely will make no mistake.

Lectures on the Action of Medicines, Being a Course of Lectures on Pharmacology and Therapeutics, delivered at St. Bartholomew's Hospital during the summer session of 1896. By T. LAUDER BRUNTON, M.D., D.Sc., LL.D., F.R.S. New York and London, Macmillan Co., 1897, and Chicago, A. C. McClurg & Co. Price \$4, pp. 673.

Anything written by Dr. Lauder Brunton is always received with pleasure, and these lectures are no exception to the rule. They are entertaining as well as instructive, and one will rarely commence reading one of the lectures without finishing it. The scope of the lectures is fully covered by the title, that is, on the action of ordinary medicines.

Outlines of Anatomy. A Guide to the Methodical Study of the Human Body in the dissecting room. By EDMUND W. HOLMES, A.B., M.D. Press of Avil Printing Company, 1897. Pages 183, quarto; twelve original illustrations. Price \$2 net.

This little book will be found useful to students in memorizing, an anatomic bugbear which is encountered in the shades of the dissecting room.

Essentials of Bacteriology, Being a Concise and Systematic Introduction to the Study of Micro-organisms, for the use of Students and Practitioners. By M. V. BALL, M.D. Third edition, revised, with eighty-one illustrations, some in colors, and five plates. Pages 218. Philadelphia: W. B. Saunders, 1897. Price \$1.

This is a carefully compiled little book, and as we have given a favorable opinion of its two former editions we see no reason to change it now, and it seems as if the medical profession generally have been of our opinion, for as it will be seen the work has now passed to its third edition.

A Manual of Legal Medicine. For the use of Practitioners and Students of Medicine and Law. By JUSTIN HEROLD, A.M., M.D. Philadelphia and London: J. B. Lippincott Company, 1898. Pages 677.

Notwithstanding the many excellent works on medical jurisprudence, the author has long since satisfied himself from his long experience as a coroner's physician that there was need of a work of a different character, giving condensed information on the special subjects which it treats.

The work is divided into two parts. Part 1, toxicology, with sixteen chapters; Part 2, forensic medicine, twenty-six chapters. There is an appendix of some fifty pages. The author is clear in his statements, precise, methodic, and has produced an excellent book. We commend it.

Constipation in Adults and Children; with Special Reference to Habitual Constipation in Its Most Successful Treatment by the Mechanical Methods. By H. ILLOWAY, M.D. New York, Macmillan Company, also London, 1897. Pages 495. Price \$4.00.

The text-book is evanescent, but the monograph lasts forever and is always valuable as a reference book, long enough until the period of its usefulness in certain directions has passed. We should expect a little more, therefore, of a monograph than of a text-book. We would expect it to be more conservative, more complete, and more practical. Looking to these requirements, we find that the volume under consideration fairly fulfills the indications. The type is large and clear; the paper is good; the illustrations are numerous and well executed. The remedies given are judicious, due consideration being devoted to massage and gymnastics.

Essentials of Obstetrics. By CHARLES JEWETT, A.M., M.D., Sc.D., assisted by HAROLD F. JEWETT, M.D. Illustrated by eighty wood-cuts and three colored plates. Lea Bros. and Co. New York and Philadelphia. 1897. Pages 358.

This work contains the elements of obstetrics in easy lessons for the information of students. The author truly says: "The pupil in any department of learning succeeds best by first mas-

tering its elements." Consequently the beginner will do well to leave the more elaborate encyclopedic treatises until after he has become master of the elements of the subject.

Quiz Manual of Histology, General and Dental. By CHARLES B. REED, M.D., and FREDERICK B. NOYES, B.A., D.D.S. Chicago, W. T. Keener & Co., 1897. Pages 203.

This quiz manual has been prepared for the use of students, and the subjects are arranged under questions and answers. It makes no claims to original statements, but the answers indicate a thorough acquaintance with the subject. The arrangement of the book is excellent.

NECROLOGY.

HARRISON ALLEN, M.D., emeritus professor of comparative anatomy and zoology in the University of Pennsylvania, from which he was graduated in 1861, died in Philadelphia, November 14. Soon after his graduation he entered the regular army and was stationed in Washington, D. C. He was known as a scientist and as the author of monographs, papers and books on many phases of medicine. At the Columbian Exposition in Chicago Dr. Allen was one of the judges on anthropology. He was a member of the Academy of Natural Sciences, Natural History Society of Boston, Pathological Society of Philadelphia, Biological Society of Washington, Philadelphia County Medical Society, American Laryngological Association, Neurological Society of Philadelphia, Historical Society of Texas and the Association of American Anatomists. He was also the correspondent of the Society of Natural Sciences of Chili, and was corresponding secretary of the Academy of Natural Sciences in 1868, vice-president of the Pathological Society, 1877; president of the American Laryngological Association, 1886; president of the Association of American Anatomists from 1891 to 1893. He visited Europe in 1878 and 1890 as delegate to the International Medical Congress at Berlin. In 1894 and 1895 he was president of the Contemporary Club of Philadelphia.

JAMES CAREY THOMAS, M.D., Baltimore, Md., November 9. When 19 years old he was graduated from Haverford College, near Philadelphia, receiving the degree of Bachelor of Arts. When 21 he graduated from the University of Maryland, and at once began the practice of medicine. He was at one time president of the Young Men's Christian Association, and at the time of his death a vice-president. He was a trustee and chairman of the executive committee of the Johns Hopkins University, a trustee of the Wilson Sanitarium, president of the Wilson Fuel Saving Society, a trustee of Haverford College, Pennsylvania; of Bryn Mawr, Pennsylvania; stated clerk of Baltimore Yearly Meeting of the Orthodox Friends, and a member of many other organizations and institutions.

W. H. H. KING, M.D., surgeon-in-chief of the Passavant Memorial Hospital, Jacksonville, Ill., November 15. The Doctor was a graduate of Rush Medical College, Chicago, class of 1866.—Richard E. Sutton, M.D., Rome, N. Y., November 10.

PUBLIC HEALTH.

Beri-Beri at New Bedford.—The whaling bark, *Greyhound*, arrived at New Bedford, November 4, after a five years' voyage. The crew were stricken with beri-beri about a month ago, of so grave a type that three of the number died and five others were brought into port still suffering from the disease.

Time Schedule for Frost at New Orleans.—In the "Public Health Report" for October 23 is published a table of the dates of the first killing frosts in New Orleans for the years 1873 to 1896. The earliest killing frost occurred in 1877, on November 11, and the latest in 1887, on December 29. The average date was December 7. In Memphis the earliest frost occurred in 1876,

on October 2, and the latest in 1889, on November 29, the average being October 26. In Mobile the average date of the first killing frost is November 22; in Montgomery, Ala., November 12, and in Galveston, Texas, December 18. In Vicksburg, Miss., the average date is November 10. The figures are furnished by the United States Weather Bureau, and, as will be seen, furnish a fair indication for Edwards and vicinity.

Condemnation Proceedings Against Insanitary Tenements in New York City.—In the appellate division of the supreme court of New York a decision was handed down by Justice Rumsey to the effect that the condemnation and destruction by the Board of Health of four tenement houses in the rear of 308 to 314 Mott Street, New York, on the ground that they were unfit for habitation, was unlawful in that it was not proved that they could not be made habitable. In the opinion, however, the power of the Board of Health to vacate and destroy unhealthy tenements is expressly upheld, and it only provides for a new trial at which the Health Board may offer further evidence to prove that sanitary evils caused by the condition of the buildings could only be remedied by their destruction. The Board of Health will appeal the case.—*Medical News*.

An antiseptic residence has recently been constructed at Yokohama, Japan, by Dr. W. van der Heyden, the bacteriologist, according to the *Journal d'Hygiène* of October 14. The walls are made of large blocks and slabs of glass, mounted in metal, and the whole hermetically closed. None of the windows open. A row of small openings near the ceiling of the upper story allow the egress of the air without permitting the entrance of the outer air, which is exclusively supplied through a pipe extending some distance beyond the house, into which it is forced, filtered and sterilized by passing over glycerin. The house is entered through a long hall and no germs can enter except those brought on the persons or clothes of the inmates. These microbes, however, find no further chance to develop, as is shown by the fact that butter and milk can be kept a long while without turning rancid or sour. The space left between the glass in the walls is filled with a special saline solution which absorbs the heat of the sun and moderates the temperature within even on the hottest days, while the slow radiation of the absorbed heat and chemic processes in the solution keep the house warm at night.

The Dangers of Aerial Infection of Tuberculosis.—Flügge now announces that the assumption of the transmission of tuberculosis by the inhalation of fine dust from dried sputa has never been proved, although so generally accepted. It is, in fact, refuted by all experimental research to date and no authentic cases in man are on record. The dried germs are not sufficiently virulent to inoculate animals and it is more than probable that the same is true of man. But the danger from moist germs is far greater than hitherto realized, and those germs are disseminated abroad in speaking, coughing, sneezing, etc., floating on the tiny drops of moisture expelled from the mouth as described in his previous communication (*vide* JOURNAL November 6, p. 978). He and others have succeeded in inoculating animals every time with these moist germs from the mouth, or in a fine spray blown in their faces, similar to the spray expelled by a consumptive coughing with open mouth. A convincing proof is afforded by the death of the laboratory attendant in charge of the spray experiments, who neglected the imposed precautions and contracted acute phthisis. The spray also floated in the air from one end of the laboratory to the other and infected some dogs kept there for another purpose. The danger, therefore, of infection from the moisture expelled by tuberculous individuals is imminent, but it can be reduced to an insignificant minimum if they hold a handkerchief before their mouth when coughing, and take other obvious precautions to prevent sowing the virulent germs broadcast. Another favorable feature of the case is

that as the moisture dries the danger ceases. He hastens to add, however, that disinfection of apartments, etc., is still as necessary as hitherto considered, for coarse fragments of dried sputa may be swept into the air by sweeping, dusting, etc., and the germs contained in these large pieces may retain their virulence and infect someone before they settle down to the floor or the nearest surface again.—*Deutsche Med. Woch.* October 14.

The Declaration of the Jenner Society.—Dr. Francis T. Bond, the health officer of Gloucester, England, has been active in agitating a modernized practice of vaccination among his fellow countrymen. He now writes to the London *Lancet* regarding the propaganda of the Jenner Society. The following declaration, whilst affirming the report of the late Royal Commission that "sanitation can not be relied on as a substitute for vaccination," also confirms two other conclusions contained in the report, that: First, vaccination, especially by the use of calf lymph, is free from any serious danger, and that, second, to perpetuate the protection against smallpox afforded by vaccination in infancy it is expedient to repeat the operation at a later age.

Declaration. We, the undersigned, actually or recently medical officers of health, think it right, in view of assertions which have been published with some appearance of authority as to the efficacy of "sanitation" as a substitute for vaccination in dealing with smallpox, to make the following statement:

1. As responsible sanitary officials, to whom the care of the health and lives of the community is especially entrusted, we have every inducement to give due weight to the value of "sanitation" in the widest sense of the term for the prevention of smallpox as of other forms of infectious diseases. We include in that term good drainage, the removal of refuse, the supply of pure air and water, and all other conditions which are calculated to fortify the body against disease in general.

2. We are no less alive to the importance of those special precautionary measures which experience has shown to be so valuable, when effectively used, to arrest the spread of infectious disease, such as the immediate notification of illness, the efficient isolation of the sick and of those who have been exposed to infection, and thorough disinfection of persons and things.

3. While thus fully appreciating the value of these agencies for such purposes, we unhesitatingly declare our belief that they can not alone be relied on either to prevent or to stamp out epidemics of smallpox.

4. We believe that the only trustworthy protection at present known against smallpox, alike for the individual and the community, is efficient vaccination in infancy and subsequent re-vaccination, and that the only effective way of stamping out epidemics of this disease lies in the free use of these agencies.

5. We are so thoroughly convinced that the dangers alleged against vaccination are, as the Royal Commissioners have asserted, "insignificant," even without the additional safeguards which the Commissioners have recommended, that in common with nearly the whole of the medical profession, we not only prescribe it generally, but use it for ourselves, our families, and others, in whose welfare we are personally interested.

6. We repudiate the calumny which has been freely circulated that either we or other members of the medical profession have been influenced in forming or expressing our belief in vaccination by any consideration other than that of the public health, but we think it well to add that a considerable number of us derive no emoluments of any kind from the practice of vaccination.

It has already been signed by upward of eight hundred and fifty medical officers of health in Great Britain, India and the colonies. The signatures of those having no pecuniary interest of any kind in vaccination, nearly two hundred and fifty of the above number, include those of officers to a number of English, Welsh and Scotch counties, the metropolitan and nearly all of the large cities and towns. It is still in process of signature and will, it is believed, be endorsed by medical officers of health in all parts of the world.

Preventive Measures Against Rabies.—Dr. T. M. Dolan, editor of the *Scalpel*, has prepared the following résumé of the procedures to be recommended in his dog ridden country for the "stamping out" of rabies and for the protection of the human species against its extension in the form of hydrophobia:

1. The owners of dogs and other animals should be made to

understand the responsibility that rests upon them with regard to the health of their animals, particularly when contagious diseases appear among them.

2. The number of useless dogs should be diminished as much as possible, and a tax should be levied on all dogs.

3. Every dog should wear a collar with the owner's name and address engraved thereon, as well as a particular mark impressed by the licensing or police authorities for the proper registration and identification of the animal.

4. All stray dogs without the collar or the owner's name and address thereon should be captured and, and if not claimed within a limited period, sold or destroyed; and dogs straying with the proper collar on may, where circumstances render it necessary, be seized and confined or returned to the owner, who pays expenses and is fined if need be. Bitches in rut should not be allowed to go at large at any time.

5. Unless under special circumstances, as when rabies is prevalent, or when certain animals are vicious, the muzzle should not be worn.

6. The owners of dogs should be held responsible for the damage done by them.

7. Diseased dogs or those which show the slightest signs of disease, altered habits, etc., should be carefully watched and precautions adopted. If the symptoms of rabies appear, the circumstances should be reported to the police by the owner or attendant on the dog or other persons who know of its condition. Neglect of this should be estimated as a criminal offense. The police should know the early symptoms of the disease.

8. If other animals which have been in contact with or bitten by a rabid dog and become unwell afterward the symptoms ought to be noticed, and should they lead to a suspicion of rabies the creatures must be isolated and their condition reported to the police.

9. Suspected animals should not be killed at once if they have bitten any person, but only destroyed when the disease is unmistakably present.

10. A mad or suspected dog, escaping from its owner, or appearing in the district, should be the signal for alertness, and those who know of the circumstance ought to warn the police at once. Children should be guarded and animals confined or kept from strange dogs. All wandering dogs should be confined or killed.

11. Rabid dogs should be killed, or, if suspected, kept until their condition is ascertained.

12. The police authorities should endeavor to obtain every information about any rabid or suspected dog, and to discover the name and address of its owner, learning also what damage it may have done. Regulations and restrictions should be extended over a wide space of country, and neighboring districts should be warned. All information necessary to put the inhabitants on the alert ought also to be given.

13. When the disease appears in a virulent or epizootic form, all measures ought to be rigorously enforced. Owners of dogs should give due notice of all changes occurring among their animals. Muzzling may be necessary, but the muzzle for each dog should be properly and securely constructed, and sufficient in size without being too large. It must have appliances for attaching it firmly to the head.

14. The destruction and confinement of dogs must be assiduously carried out, and heavy fines or imprisonment should be imposed upon those who attempt to evade or neglect the regulations.

15. Dogs should be slaughtered with as little cruelty as possible. They ought to be buried deeply in the ground, if possible cremated.

16. Disinfection should be carried out as with other contagious diseases.

17. The police regulations and restrictions should be continued for some months beyond the appearance of the last case of rabies. This period should be dependent on the limit of the incubatory stage of the disease in the dog.

18. With regard to other animals when wounded by a suspected or rapid dog, the circumstances should be reported and steps taken to ensure safety. Horses, oxen, and other working animals, may be employed in the immediate vicinity of their homes, but must not be sold, bartered or removed within a certain period. The immediate slaughter of wounded or suspected animals is not necessary, but as soon as rabies manifests itself notice should be given to the local authorities, and the necessary steps taken to prevent damage. The bodies should be buried intact, though, under special circumstances; skinning them may be allowed, in order to tan or dress these parts.

19. Disinfection be resorted to as in the case of rabid dogs.

20. The flesh is not dangerous as food until the symptoms of the disease have appeared. If used before this period certain precautions should be adopted.

21. The milk may also be utilized during the same period.
 22. Competent veterinarians must co-operate in the execution of these measures.

Bubonic Plague Ravages.—According to dispatches dated November 15 and deemed authentic, the bubonic plague shows no abatement in the Poona district. Within the last forty-eight hours there have been 134 new cases reported and 94 deaths. Six hundred and thirty victims of the disease are now in the hospital at Poona. Business in several of the principal streets is suspended and the town is being rapidly deserted by the inhabitants.

Epidemic of Typhoid Fever at Belfast, Ireland.—At the present time there is a wide-spread epidemic of typhoid fever in Belfast, and a large number of cases are being treated in the Union Fever Hospital and in the Royal Hospital. One of the dispensary medical officers asked his committee for further medical assistance, which was granted, owing to the large number of cases in his district. The Public Health Committee of the city at a meeting on October 7 advised that the water retailed from the Cromac springs had not improved in quality and was unfit for human consumption. They pointed out the necessity for the regular cleansing of cisterns in houses and instructed their sanitary officer to have them inspected.

Yellow Fever. Since our report of last week quarantine regulations in Florida have been so far modified as to permit passengers from all Northern points to enter the State without trouble or annoyance. Alabama has also raised her quarantine, and many other districts have either raised or modified quarantine, so that traffic and business throughout the South is being resumed and many refugees returning home. Dispatches have been as follows: November 16, New Orleans, 11 new cases and 2 deaths; Montgomery, Ala., 2 new cases; Mobile, 3 new cases; Clinton, Miss., 1 new case; Edwards, 3 new cases and 1 death; Scranton, 10 new cases and 1 death; Pensacola, Fla., 1 death. November 17, New Orleans, 7 new cases and 3 deaths; Mobile, 3 new cases. November 18, New Orleans, 6 new cases and 2 deaths. November 19, New Orleans, 6 new cases; Mobile, 2 new cases and 1 death. November 20, New Orleans, 6 new cases and 3 deaths; Fort Barrancas (near Pensacola, Fla.), 1 death. November 21, Fort Barrancas, 1 new case; New Orleans, 8 new cases and 3 deaths; Mobile, 3 new cases and 1 death.

MISCELLANY.

The Toxic Effect of Animal Parasites in Man is ascribed by Peiper to the toxic substances they produce, which are absorbed by the organism and cause the nervous phenomena, etc., which have been imputed hitherto to reflex action.—*Deutsche Med. Woch.*, October 14.

Medical Legislation. The Joint Committee on Medical Legislation appointed by Illinois State Medical Society, the Eclectic State Medical Society, and the Homeopathic State Medical Society, held a session November 23 in Chicago. A subcommittee was appointed to draft a bill for presentation at the next regular session of the Legislature. The bill is to be reported to the next meeting of the general committee.

The Hedge Doctor.—A "hedge doctor," a kind of quack in Ireland, was being examined at an inquest on his treatment of a patient who had died. "I gave him ipecaeuana," he said. "You might just as well have given him the aurora borealis," said the coroner. "Indade, yer honor, and that's just what I should have given him next, if he hadn't died."—*St. Thomas' Hospital Gazette*.

The Bertillon System in New York State.—In the New York State Reformatory the Bertillon system of identification is in full operation. In the opinion of experts the maximum of bony

growth in this country is not attained much before the twenty-fifth year. The value of this system in growing lives therefore remains to be determined, as it is founded upon the almost absolute immutability of the human frame after the twentieth year.

Officers of the New York County Society for 1898.—At the annual meeting of the New York County Medical Society, held Monday evening, October 25, the following officers were elected for the ensuing year: President, A. M. Jacobus; first vice-president, Nathan E. Brill; second vice-president, B. Farquhar Curtis; secretary, Chas. H. Avery, whose death took place just one week later; treasurer, John S. Warren.

Protektin is a new inexpensive, adhesive, aseptic, waterproof silk paper impregnated with rubber, which surgeons will find useful to apply freely around the field of operation to assure asepsis, particularly over hair-covered surfaces, garments, etc. It can also be used to fasten a permanent catheter in place or close a fistula temporarily.—*Cbl. f. Chir.*, October 30.

A Slick Trick on Physicians.—A very smooth party, representing a new Western life insurance company, dropped into Cleveland recently and called upon a number of physicians with the tale that he was about to do a large business here and wished to appoint two examiners. His company, however, had "instructed him to do business with those who would do business with him," so if the doctor would kindly take a policy for \$5,000 (no less would do), he would be appointed an examiner. It is to be regretted that, if rumor speaks truly, a few doctors were still to be found there who jumped at this threadbare bait.

New Medical Journal.—In January, 1898, the Philadelphia Medical Publishing Company, incorporated under the laws of Pennsylvania, will begin the publication of a weekly medical journal, to be called *The Philadelphia Medical Journal*. The company has a capital of \$30,000, in shares of \$10 par value, full paid and non-assessable. The management of the company is entrusted to a board of trustees, in which are representatives of leading medical schools. The editorial management has been entrusted to Dr. George M. Gould. The price of subscription is \$3 per annum.

The Third International Leprosy Conference confirmed the Hansen-Neisser bacillus as the cause of leprosy according to our present knowledge, and proclaimed again the contagious, non-hereditary character of the disease. Treatment to date, including serum treatment, has only scored palliative results. Isolation is endorsed as the only radical means of combating leprosy, and the success obtained by Norway in the forcible isolation of lepers when necessary, was recommended to other nations with sufficient local authority and medical attendance to enforce such measures.

Hysteria in the Male. Vogt reports the case of a workingman aged 42 years, suddenly attacked by paralysis of the left side of the body, which later extended to the whole of that side. There was no sign of syphilis. The condition lasted for four months without much change. There was polyuria. There was anesthesia of the left side and paresis of both upper and lower limbs. The left testicle was hyperesthetic and there were hyperesthetic spots on the left side of the back. There was diminution of hearing and sight on the left side; on the right there was nothing abnormal. Purely suggestive treatment without any drugs effected a complete cure.—*British Medical Journal*.

Disturbances in the Digestion Caused by Hernia. Kuttner describes in the *Mittl. a. d. Grenzboten der Med. u. Chir.*, No. 5, the colic, vomiting, or permanent pain with eructations, nausea, loss of appetite and vomiting which often accompany hernia, especially in the linea alba. These phenomena are familiar to the surgeon, but are scarcely referred to in the works on affections of the digestive apparatus, and are mis-

taken for gastric neuroses by some physicians. The phenomena are the same whether the trouble is caused by a subperitoneal ligament pulling on the peritoneum, or an actual hernia, consisting usually mostly of the omentum. The operation that cures the hernia abolishes the digestive disturbances.—*Cbl. f. Chir.*, October 30.

St. Louis Academy of Medical and Surgical Sciences.—The St. Louis Academy of Medical and Surgical Sciences has elected the following officers for the ensuing year: President, A. H. Ohmann-Dumesnil; senior vice-president, G. C. Eggers; junior vice president, J. B. Ross; secretary, Emory Lamphear; treasurer, George F. Hulbert; curator, G. H. Thompson; orator, Phil Schultz; librarian, James Moores Ball.

The New Orleans Isolation Hospital.—The Isolation Hospital at New Orleans up to October 25 has cared for 118 patients. Of this number, 64 have been discharged cured, 13 have died, 41 remain under treatment. The showing is not bad, as it must be considered that many of the patients have been brought there in an advanced stage of the disease, a few being actually *in extremis*. The hospital is under the management of the Charity Hospital authorities, and is visited by Drs. Bloom and Veazie, while Dr. Hamilton Jones is the resident physician in charge.—*New Orleans Medical and Surgical Journal*, November.

How to Banish All Disease and Misery.—The Vegetarian Congress has lately held its meetings in London. The "provost" of the "order" presided and explained that the body claimed members in nineteen countries, and existed for the purpose of hastening "the coming of the Golden Age, when love, peace and good-will shall reign in every human heart, and by endeavoring to promote universal benevolence and philanthropy." The "provost" alluded to the symptoms of a great wave of human feeling setting in throughout the world in recognition of the rights and claims of animals. He looked forward to an end of the era of butchery ere many decades were passed, and in a reform dietary saw the solution of the problems of drink and agricultural depression. The hospitals will be occupied by cases of senile decay.

The Congress of the Association of Surgeons in France.—The eleventh congress of the French Association of Surgery was opened on October 18, in the great amphitheater of the Faculty of Medicine at Paris, under the presidency of Professor Gross of Nancy, a large number of French, Belgian and Swiss surgeons being present. Professor Gross made an important speech in which he passed in review all the recent victories of science, and referred particularly to the services which the discovery of the Roentgen rays had rendered to medicine and surgery. This medium, as Professor Ollier remarked, allowed one to make a veritable necropsy of the skeleton in the living being. M. Poncet of Lyons, read a paper upon "Botryomycosis in Human Beings," in which he argued that certain papillary tumors in man were identical with the botryomycosis caused by a fungus which brings about complications in the castration of horses. M. Berger read a paper on "Epithelioma of the Neck Having a Bronchial Origin," and mentioned certain aberrant epitheliomata of the thyroid body. M. Lavise of Brussels, read a communication upon the "Treatment of Hernia," and M. Demous of Bordeaux, one upon "Contusions of the Abdomen."

American Association for the Study and Cure of Inebriety. The twenty-seventh annual meeting of this Association will be held Dec. 8, 1897, in the hall of the Washingtonian Home, 41 Waltham Street, Boston. The following papers are announced: "The Prognosis of Inebriety," by J. M. French, Milford, Mass.; "The Alcoholic Question in Medicine," by John P. Couch, Somerville, Mass.; "The Causation and Heredity in Inebriety," by Surgeon-Major Pool, London, England;

"Treatment of Inebriety by Baths," by C. H. Shepard, Brooklyn; "Treatment of Delirium Tremens, with a case," by V. A. Ellsworth, Boston; "The Insanity of Inebriety," by T. D. Crothers, Hartford, Conn.; "The Use of Alcohol in Practical Medicines," by I. N. Quimby, Jersey City, N. J.; "Some New Methods in the Treatment of Alcohol and Opium Addiction," by J. H. Kellogg, Battle Creek, Mich. Papers have been received from Drs. Motet and Lagrand of Paris, France; also from Drs. Clark, Ridge and Stearns. Papers are promised from Drs. Mattison, Seavsey, Hall and others. The annual address will be delivered by Ira Van Geason, Director of the New York State Pathological Institute: "On Some Recent Researches on the Action of Alcohol on Brain Cells."

The Oakbourne Colony for Epileptics in Pennsylvania.—The *Medical News* announces that the Pennsylvania Hospital for Epileptics and Colony-farm at Oakbourne has been lately completed, and is now ready for occupancy. The formal opening will take place in a few weeks. The new hospital is made up of three buildings, but it is intended to extend, from time to time, the fields of the work, as funds permit, and to establish cottage after cottage on the grounds of the institution. The idea of the managers of the hospital to colonize on a large scale in this locality as many epileptics as the State can support, is an undertaking which, from its humane basis and its eminently practical results, must meet with the sympathy of every one interested in the welfare of this unfortunate class of the community, and that such results outweigh the cost of the monetary outlay is conceded by all students of sociology. The institution has been made a possibility through the generosity of Henry C. Lea of Philadelphia, who contributed \$50,000 for the erection of the buildings, while the hospital has also received liberal endowments from other individuals and from the State. The medical staff of the hospital is as follows: Medical director, Dr. S. W. Morton; staff of visiting physicians, Drs. Harvey Shoemaker, G. E. Shoemaker, H. A. Slocum, Wm. C. Posey, A. A. Bliss, Wm. G. Spiller, A. Ferree Witmer, and S. W. Morton. The consulting physicians are Drs. S. Weir Mitchell, J. M. Da Costa, G. E. de Schweinitz, J. William White and Charles H. Burnett.

Bellevue Hospital Medical College.—The cornerstone of the new building of the Bellevue Hospital Medical College was laid November 13. The structure will be five stories high, of red brick, and trimmed with limestone. It is to have a steel frame, and it will cost about \$200,000, which has been subscribed by members of the faculty. It stands at the corner of Twenty-sixth street and First avenue, next to the Carnegie Laboratory, and will be ready for occupancy in the spring. D. O. Mills, president of the Board of Trustees, presided at the laying of the cornerstone yesterday. Dr. Austin Flint introduced Dr. Lewis A. Sayre, Emeritus Professor of Orthopedic Surgery, who said, after the cornerstone had been lowered into place, giving it a final tap with the trowel: "By virtue of the power given me by the trustees and faculty of Bellevue Hospital Medical College, I hereby dedicate this building to the cause of suffering humanity." Under the stone was placed a copper chest containing an account of the inauguration of the college in October, 1861, the alumni catalogue containing a history of the college, a history of the Bellevue Hospital, lecture cards and alumni circulars for each year since 1861; diphtheria antitoxin; a tube containing spores of *aerogenes capsulatus* (the bacilli of a form of gangrene) which were discovered in April, 1896, and are the oldest identified spores of this species in the world; yesterday morning's *Tribune* and *The Evening Sun*. Dr. Landon Carter Gray, representing the alumni, the Rev. Dr. Roderick Terry of the trustees, and Dr. John S. Billings, representing the medical profession, delivered addresses of congratulation and eulogy in the lecture room of the Carnegie Laboratory after the exercises at the stone.

After the exercises Mayor Strong, Commissioner Faure, and Gen. O'Beirne inspected the new erysipelas pavilion, boiler house, women's wards, and morgue at Bellevue. Mayor Strong said the Bellevue ambulance service was the best in the city, and complimented Superintendent Murphy and the physicians on the appearance of the hospital.—*N. Y. Sun*, November 14.

Massage in the Treatment of Sprains.—Dr. Graham refers to the advantages to be derived from the treatment of a sprain with almost immediate massage and passive or active motion. Applied intelligently, massage is allowable from the first, the presence of, or increase in the pain being the surest guide to an excessive or faulty use of this method of treatment. From study and a large and continued experience, the writer draws the following conclusions:

1. A sprain is a wrench or twist of a joint, a sudden partial displacement of two articulating surfaces, followed by immediate replacement. 2. The symptoms are pain, swelling, discoloration, and usually heat and impaired motion. 3. Its diagnosis may be obscured by the swelling which may conceal a fracture. 4. Whatever will quickly reduce the heat, pain and swelling, such as massage, snug bandaging, and elevated position of the joint, will proportionately make the diagnosis easier. 5. The means just mentioned are, therefore, not only valuable for diagnosis, but also for treatment: and their use in many cases of sprains of all degrees of severity show that they recover in one third of the time required under absolute rest and fixed dressings without massage. 6. Even the sprain of a joint previously weakened by malignant disease may be rapidly ameliorated by massage.

Other articles by Lovett and Mumford, in the same number of this journal, substantiate these claims and give details of treatment.—*Boston Medical and Surgical Journal*.

Injections of Alumol in Laryngeal Disease.—Dr. Metzertott of Washington has had favorable results from the use of this drug in the forms of gargle, spray, atomized solution and with the laryngeal syringe. He instances with special satisfaction the following case, probably syphilitic in origin, in the September issue of the *American Therapist*:

In a case of symptomatic edema of the larynx, accompanied with a perichondritis of the crico-arytenoid cartilages, in which there was stenosis of a most severe grade, I was able by means of solutions of alumol, administered in the form of injections and the steam spray, to defer the performance of tracheotomy for a period of six months. In this particular patient it was really remarkable how quickly the inflammatory edema would be reduced by one or two injections of a solution of alumol into the larynx, and maintained for a longer time by inhalations of vapor charged with the same remedy. Indeed, it was a pleasure to behold with the laryngoscope how rapidly a laryngeal image of swollen ventricular bands and injected and tumefied vocal cords would change to a picture almost normal. It is immaterial whether this particular case to which I have just alluded was due to cancer, tuberculosis or what it has the clinical appearance of being now, syphilis, the fact remains that a most powerful impression was made upon the accompanying inflammatory edema, which at the time I took charge of the patient was of such a degree that I myself and the attending physician regarded the case as hopeless without the performance of tracheotomy.

No bad after-effects were noticed, although the steam spray was daily applied for several months. In a case of subglottic laryngitis accompanied with that wave-like fluttering of the vocal cords, a condition usually very stubborn to treatment, I was able to relieve my patient, a singer, in a very short while by using nothing but alumol in the spray. In another case of chondritis nodosa (singer's nodules) I was able to dispense with instruments by employing strong solutions of alumol.

The Sixty-Ninth Annual Congress of the Physicians and Naturalists of Germany assembled last month at Brunswick. Most of what was presented has already been described in these columns, but the general session devoted to scientific photography opens a new era in scientific teaching, with the improved cinematographic projections, on a large scale, of the movements of the exposed heart in animals, exhibited by Ludwig Braun of Vienna. The entire picture of the action of the heart was clearly presented to the assembly. Professor Lassar's artistically colored "diapositive" projections of dermatologic and histologic subjects also illustrated the marvelous progress in photography, and views of two cases of lupus of the face and arm created quite a sensation, as the series showed

recovery and finally complete cure by the therapeutic application of the Roentgen ray, Max Lewy of Berlin exhibited his sensitive plates with film on both sides, which only require an exposure of thirty seconds. Kohlrausch illustrated with cinematograms the gait of tabetics, and Rosenthal of Munich announced further improvements in the technique of Roentgen photography. In the discussion of trigeminal neuralgia, Krause stated that there are 113 operations on record, with a mortality of 15 per cent. His own operations number fifteen with one fatality; the others free from recurrence: five years the longest period. He first administers aconitin nitricum, with which alone he has cured two cases. He does not operate until he has consulted a specialist to eliminate neuritis. A slight operation does not prevent more radical intervention later if necessary. Operations on the facialis he does not consider permanent and therefore rejects them. The extracranial method is more certain when the lesion can be located at the branching of the nerve, or in single branches. The nerve should be severed above the junction of the branches involved. When the nerve can be reached outside the cranium at the base, it should be operated on at this point, but if necessary to operate within the cranial cavity; if the skull is cut down deep the brain can be raised a little, and a slight compression will suffice, which will not cause disturbances in the speech. The motor root need not be touched, as it is readily distinguished by its harder consistency. Glück added that any injury to the carotid can be easily remedied by a ligature. Bruns ascribes to arteriosclerosis the severer cases, especially in elderly people with neuralgia in the second or third branch, reflex muscular contractions, *fetor ex ore*, etc. Rumpf emphasized the unmistakable benefits to be derived from electricity, which are not all due to suggestion. Franke reported a case that had recurred after an operation two years before, which he had cured since with pyramidol. Sprengel also reported a case with tic, cured by stretching the facialis.

Economy in Ourselves is Parsimony in Others.—"How I dislike the word 'economy.'"

"On what grounds?"

"It is such a queer thing—the world condemns us if we do not practice it and despises us if we do."—*Detroit Free Press*.

Medical Colleges in United States and Canada Conditionally and Unconditionally Recognized by the Illinois State Board of Health.

Students from these Institutions may be accorded advanced standing without examination, for the number of full courses taken, by colleges recognized as in "good standing" by the Illinois State Board of Health.

ALABAMA.—Medical College of Mobile.
ARKANSAS.—Medical Department Arkansas Industrial University, Little Rock.

CALIFORNIA.—Cooper Medical College, San Francisco. Medical Department University of California, San Francisco. California Medical College, San Francisco. Hahnemann Hospital College, San Francisco. College of Medicine of the University of Southern California, Los Angeles.

CANADA.—University of Toronto, Medical Faculty, Toronto, Ont., Trinity Medical College, Toronto, Ont. Royal College of Physicians and Surgeons, Kingston, Ont. Medical Department of Western University, London, Ont. Woman's Medical College, Toronto, Ont. McGill University, Faculty of Medicine, Montreal, Que. Montreal School of Medicine and Surgery, Montreal, Que. (L'École de Médecine). Laval University, Medical Department, Quebec, Que. University of Bishop's College, Faculty of Medicine, Montreal, Que. Dalhousie University, Faculty of Medicine, Halifax, N.S. Halifax Medical College, Halifax, N.S. Manitoba Medical College, Winnipeg, Man. Woman's Medical College, Kingston, Ont.

COLORADO.—College of Medicine, University of Denver, Denver. Colorado School of Medicine, Boulder (Medical Department of the University of Colorado). Gross Medical School, Denver (Medical Department of Rocky Mountain University).

CONNECTICUT.—Yale Medical College (Medical Department Yale University).

DISTRICT OF COLUMBIA.—National Medical College, Washington (Medical Department Columbian University). University of Georgetown, Medical Department, Washington. Howard University, Medical Department, Washington. Medical Department National University, Washington. United States Medical School, Washington. United States Naval School, Washington.

FLORIDA.—Medical Department of Florida University, Tallahassee (Tallahassee College of Medicine and Surgery).

GEORGIA.—Medical College of Georgia, Augusta (Medical Department University of Georgia). Medical College, Atlanta. Georgia College of Eclectic Medicine and Surgery, Atlanta. Southern Medical College, Atlanta.

ILLINOIS.—Rush Medical College, Chicago (Medical Department Lake Forest University). Northwestern University Medical School, Chicago (Chicago Medical School). Bennett College of Eclectic Medicine and Surgery, Chicago. Hahnemann Medical College and Hospital, Chicago. Northwestern University Woman's Medical School, Chicago (Woman's Medical College). Chicago Homeopathic Medical College, Chicago. College of Physicians and Surgeons, Chicago. Chicago Physio-Medical College, Chicago. National Medical College, Chicago (National Homeopathic Medical College). Hering Medical College, Chicago. Harvey Medical College, Chicago. Jenner Medical College, Chicago (Harvar Medical School). Illinois Medical College, Chicago (Chicago Summer School of Medicine). Dunham Medical College, Chicago.

INDIANA.—Physio-Medical College of Indiana, Indianapolis. Medical College of Indiana, Indianapolis. Central College of Physicians and Surgeons, Indianapolis. Fort Wayne College of Medicine, Fort Wayne. Eclectic College of Physicians and Surgeons, Indianapolis.

IOWA.—College of Physicians and Surgeons, Keokuk. Medical Department State University of Iowa, Iowa City. Homeopathic Medical Department State University of Iowa, Iowa City. Iowa College of Physicians and Surgeons, Des Moines. Keokuk Medical College, Keokuk. Sioux City College of Medicine, Sioux City.

KANSAS.—University of Kansas, Preparatory Medical School, Lawrence. Kansas Medical College, Topeka.

KENTUCKY.—University of Louisville Medical Department, Louisville. Kentucky School of Medicine, Louisville. Louisville Medical College, Louisville. Hospital College of Medicine, Louisville (Medical Department Central University of Kentucky). Southwestern Homeopathic Medical College, Louisville.

LOUISIANA.—Medical Department Tulane University of Louisiana, New Orleans. New Orleans University, Medical Department, New Orleans.

MAINE.—Medical School of Maine at Bowdoin College, Brunswick.

MARYLAND.—University of Maryland, School of Medicine, Baltimore. College of Physicians and Surgeons, Baltimore. Baltimore Medical College, Baltimore "A." Baltimore University School of Medicine, Baltimore. Woman's Medical College of Baltimore. Johns Hopkins Medical School, Baltimore. Southern Homeopathic Medical College, Baltimore.

MASSACHUSETTS.—Medical College of Harvard University, Boston. College of Physicians and Surgeons, Boston (Previous to 1894). Boston University School of Medicine, Boston. Tuft's College Medical School, Boston.

MICHIGAN.—Department of Medicine and Surgery of the University of Michigan, Ann Arbor. Homeopathic Medical Department of the University of Michigan, Ann Arbor. Michigan College of Medicine and Surgery, Detroit. Detroit College of Medicine, Detroit (formerly Detroit Medical College; consolidated with the Michigan College of Medicine in 1885 and formed the Detroit Medical College).

MINNESOTA.—College of Medicine and Surgery, Minneapolis (Department of Medicine University of Minnesota). Minneapolis College of Physicians and Surgeons, Minneapolis. College of Homeopathic Medicine and Surgery, Minneapolis.

MISSOURI.—Missouri Medical College, St. Louis. St. Louis Medical College, St. Louis (Medical Department Washington University). Medical Department University of Missouri, Columbia. Homeopathic Medical College of Missouri, St. Louis. Kansas City Medical College, Kansas City. St. Louis College of Physicians and Surgeons, St. Louis. American Medical College (Eclectic), St. Louis. Northwestern Medical College, St. Joseph. University Medical College of Kansas City. Ensworth Medical College, St. Joseph (formerly St. Joseph Medical College). Beaumont Hospital Medical College, St. Louis. Central Medical College, St. Joseph. Barnes Medical College, St. Louis. Marton-Sims College of Medicine, St. Louis. Kansas City Homeopathic Medical College, Kansas City. Woman's Medical College, Kansas City. Woman's Medical College of St. Louis.

NEBRASKA.—Omaha Medical College, Omaha. Medical Department Cotner University (Eclectic), Lincoln. John A. Creighton Medical School, Omaha.

NEW HAMPSHIRE.—Dartmouth Medical College, Hanover (New Hampshire Medical College).

NEW YORK.—College of Physicians and Surgeons of Columbia University, New York. Albany Medical College, Albany. University Medical College, New York (Medical Department University of the City of New York). Medical Department of the University of Buffalo. Long Island College Hospital, Brooklyn. New York Homeopathic Medical College and Hospital, New York. Bellevue Hospital Medical College, New York. New York Medical College and Hospital for Women, New York. Eclectic Medical College of the City of New York. Woman's Medical College of the New York Infirmary, New York. Syracuse University College of Medicine, Syracuse. Medical Department of Niagara University, Buffalo.

NORTH CAROLINA.—Leonard Medical School, Raleigh. North Carolina Medical School, Davidson (formerly Davidson School of Medicine).

OHIO.—Medical College of Ohio, Cincinnati (Medical Department University of Cincinnati). Eclectic Medical Institute, Cincinnati. Western Reserve University, Medical Department, Cleveland. Starling Medical College, Columbus. Cleveland Homeopathic Medical College, Cleveland (formerly Cleveland University of Medicine and Surgery, formerly the Homeopathic Medical College; Cleveland Homeopathic Medical College is a consolidation of the Cleveland Medical College and Cleveland University of Medicine and Surgery). Cincinnati College of Medicine and Surgery, Cincinnati. Miami Medical College, Cincinnati. Medical Department of the University of Wooster, Cleveland. Pulte Medical College (Homeopath) Cincinnati. Toledo Medical College, Toledo. Woman's Medical College of Cincinnati. Laura Memorial College, Cincinnati (Woman's Medical College of Presbyterian Hospital). National Normal University College of Medicine, Lebanon (previous to 1896). Cleveland Medical College, Cleveland (consolidated with the Cleveland University of Medicine and Surgery, now Cleveland Homeopathic Medical College). Ohio Medical University, Medical Department, Columbus. Presbyterian Hospital, Woman's Medical College, Cincinnati.

OREGON.—Medical Department of Willamette University, Portland. Oregon University Medical Department, Portland.

PENNSYLVANIA.—University of Pennsylvania Department of Medicine, Philadelphia. Jefferson Medical College, Philadelphia. Hahnemann Medical College and Hospital, Philadelphia. Woman's Medical College of Pennsylvania, Philadelphia. Medico-Chirurgical Medical College, Pittsburg.

SOUTH CAROLINA.—Medical College of the State of South Carolina, Charleston.

TENNESSEE.—Medical Department of the University of Nashville and Vanderbilt University, Nashville (separated in 1895 and formed two schools, Medical Department of University of Nashville and Medical Department of Vanderbilt University). Medical Department University

of Nashville. Medical Department Vanderbilt University, Nashville. Medical Department University of Tennessee, Nashville. Meharry Hospital Medical College, Memphis (Medical Department Southwestern Baptist University). Tennessee Medical College, Knoxville. Chattanooga Medical College, Chattanooga (Medical Department of U. S. Grant University, originally East Tennessee Wesleyan University). Hannibal Medical College of Memphis. Medical Department University of the South, Sewanee.

TEXAS.—School of Medicine of the University of Texas.

VERMONT.—Medical Department of the University of Vermont, Burlington.

VIRGINIA.—University of Virginia Medical Department, Charlottesville. Medical College of Virginia, Richmond. University College of Medicine, Richmond (formerly College of Physicians and Surgeons).

WISCONSIN.—Wisconsin College of Physicians and Surgeons, Milwaukee.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from November 6 to 12, 1897.

Capt. R. G. Ebert, Asst. Surgeon, is granted leave of absence for one month.

Lieut.-Col. J. V. D. Middleton, Deputy Surgeon-General, is granted one month's extension to present leave of absence.

Lieut. Col. William E. Waters, Deputy Surgeon-General, retirement from active service this date, Nov. 13, 1897, is announced. By direction of the President.

Capt. Richard W. Johnson, Asst. Surgeon, is relieved from duty at Ft. Logan, Colo., and ordered to Ft. D. A. Russell, Wyo., for duty.

Capt. Charles E. Woodruff, Asst. Surgeon, will upon the abandonment of Ft. Custer, Mont., proceed to Jackson Bks., La., and report for duty at that post, to relieve Major William C. Shannon, Surgeon.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending November 20, 1897.

Surgeon C. G. Herndon, detached from the Bureau of Medicine and Surgery and placed on waiting orders.

Asst. Surgeon J. C. L. Thompson, detached from the naval laboratory, Brooklyn, and ordered to the naval hospital, Mare Island, Cal.

Asst. Surgeon W. B. Grove, detached from the naval hospital, Mare Island, Cal., on reporting of relief, and ordered to the "Oregon."

P. A. Surgeon T. L. B. Bailey, detached from the "Yorktown" and ordered home with two months' leave.

No. 23.

ORIGINAL ARTICLES.

COMPARATIVE INDICATIONS FOR CLASSIC AND PORRO-CÆSAREAN SECTION.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. H. CARSTENS, M.D.

Chief of Staff and Gynecologist to Harper Hospital; Professor of Obstetrics and Clinical Gynecology in the Detroit College of Medicine; Ex-President American Association of Obstetricians and Gynecologists, etc.
DETROIT, MICH.

The terrible mortality following Cæsarean section for all these centuries induced the Italian obstetrician, Porro, to advocate, in cases requiring Cæsarean section, the removal of the uterus at the same time; and the two main objects he had in view were; 1. That by removing the uterus and appendages the danger from puerperal septicemia would be removed; 2. If the woman did recover, she would not be again subject to such a serious operation.

Many coincided with these views, but there were also many who opposed them, saying that the danger of the operation itself was greater than the danger from puerperal fever, and that the woman who had a deformed pelvis and required such an operation, had no business to become pregnant. This latter argument seems to me very shallow, indeed. It might hold good in cases of illegitimate pregnancy, as is so often the case in Europe, but that argument certainly does not hold good for married women, where it is utterly impossible for a woman to prevent a recurrence of pregnancy. Hence, the question is still undecided, whether, in cases requiring abdominal section, it is better to do a Porro or a classic Cæsarean section.

With the advent of antiseptic and aseptic surgery, a new bright light shone on abdominal sections, and those advocating the preservation of the generative organs had a very strong argument on their side, *i.e.*, that the danger was comparatively small, and statistics were brought forth by eminent operators showing the mortality to be 10 per cent. and even less, and they argued that the hope of future maternity should not be taken from a woman, especially if the child was dead, and that furthermore, the liability of the child dying was considerable.

From my own experience and from what I have read and heard about it, it seems to me that both operations are indicated, that each case must be judged by itself, and that no absolute rule can be laid down. A few years ago, I performed a Porro-Cæsarean section in the case of a woman, in her first pregnancy, who had a large tumor back of the rectum, which I found to be hard and fixed and not removable. It might be an exotosis or an osteosarcoma, it might be acquired, or it might be congenital; I could not tell. It filled the hollow of the sacrum entirely and dimin-

ished the anterior posterior diameter to six centimeters. If this woman should again become pregnant, she would again be subject to a serious operation, and as the child was living, I thought the proper operation would be a Porro-Cæsarean section, which I did by the extraperitoneal clamp method. The woman made a splendid recovery, is today, five years afterward, the picture of health, and her child is also living, which shows that the growth, whatever it was, was benign, and I think at this date, as I did at the time, that I did the proper operation.

My next case was a woman in her second pregnancy. I had delivered her the year previously, in consultation, by means of craniotomy, Tarnier's forceps and the cranioclast with great difficulty, and at the time I warned her that if she became pregnant again labor must be produced at the seventh month, or perhaps even an abortion be performed. She had a universally contracted pelvis, with an anterior posterior diameter of seven centimeters. Neither her family physician nor I heard of her until she was in labor, and she stated that she was anxious to have a child, and as a seven month's child did not generally live, she was perfectly willing to undergo a Cæsarean section. I immediately transported her to the hospital and operated upon her, also doing a Porro for the same reasons as in the first case. She made a splendid recovery, and with her child, is still living. The operation was performed over four years ago.

After that, I did not see another case until February 18 of this year, when I was called by the house physician to see Mrs. L., aged 26, second child, who had entered the Open-Door Department of the Woman's Hospital. The patient had been taken in labor about twelve hours previously, with very strong labor pains. The doctor found a tumor, partly filling the pelvis, which she thought might be moved and shoved out of the way. On examination I found a tumor filling the hollow of the sacrum. It was hard and firm, and with the patient under chloroform and placed in various positions, knee-elbow, etc., it was impossible to move it. It was firmly fixed, and hard bony structures could be felt in the tumor. I diagnosed a dermoid, but saw that it was utterly impossible to deliver her as the anterior posterior diameter was diminished to less than five centimeters. The os was well dilated, and the bag of water ruptured. I had her immediately prepared and performed a Cæsarean section, and stated that I would decide after having the child delivered whether I would do a Porro or a classic section. The operation was quickly performed, and after the child and secundines were removed, I examined the tumor and found it springing from the left ovary, and adherent in the cul-de-sac, rectum, etc. With some difficulty I broke up adhesions and removed it, and finding the pelvis large and roomy, and with no obstruction to future labor, I decided to simply sew up the incision in the uterus and

preserve the other generative organs. The incision was sewed with fine sterilized catgut, with deep and superficial sutures, in the usual manner, and the abdominal incision closed with *en masse* silkworm gut sutures. The woman rallied well from the operation and got along very well for five days, the temperature not exceeding 101 degrees, lochia normal and perfectly clean. She had carbolized douches every day, her bowels were moved on the third day, but there was one suspicious symptom; that was a rapid pulse, from 120 to 130. Still, the patient felt perfectly well until the evening of the fifth day, when she suddenly collapsed and died of heart failure. On account of the rapid pulse I was a little suspicious and examined the woman carefully on the fourth day, with a Sims' retractor, and found issuing from the uterus a sanguinary, purulent, bad-smelling discharge. There was no doubt to my mind that she was suffering from sepsis. I carefully cleaned the uterus with absorbent cotton and swabbed it out with carbolic acid, but it was of no avail. On postmortem examination the uterus was removed, the abdominal cavity was perfectly normal and the incision in the uterus was closed strongly and firmly. Inside of the uterus, in the line of the incision, there was an ulcerative process going on. Dr. Sargent kindly made a careful bacteriologic examination, but only found the staphylococcus pyogenes aureus. This clearly shows that the operation had nothing to do with the result, but the infection came from the vagina, and as she had been examined by all the house physicians and a number of students, as well as myself, there must have been a break somewhere in the aseptic care. If I had performed a Porro in this case, I have no doubt that the woman would have recovered, and still, I would repeat the operation in the next case under the same circumstances.

These operations were all performed in a hospital, which is an entirely different thing to operating in a private house with poor facilities and poor assistance. That is another factor, and it seems to me that if we could lay down the general rule, that in cases where patients have a small pelvis, so that in future they might be subject to the same danger, the question should be placed before them and they should decide which operation they will have. In other cases, where patients must be operated upon at their own homes, with poor facilities the Porro operation is far safer—put on a clamp, or a heavy ligature, if nothing else is at hand, and sew up the abdominal wall, treating the stump extraperitoneally. However, in cases where the obstruction is due to a tumor, where any morbid condition which can be remedied at the time of the operation or later on, and where a woman would not be subject to such danger in future pregnancy, it seems to me that the uterus should be preserved, and if the child is dead it should certainly be preserved; yes, even if the child is living and future pregnancy can be ended at the seventh month without danger to the mother, the uterus should not be removed. I even think that the uterus should be preserved in cases where the women live in medical centers and can be removed to a properly equipped hospital if a future pregnancy should occur. In these cases, very often, the uterus becomes adherent to the anterior abdominal wall, and in future operations direct incision of the uterus can be made without opening the peritoneal cavity, and thus the danger of an operation is very much lessened. Whether it would not be best to attach the uterus to the anterior wall while we are

performing operations, so as to be sure that it will become adherent and remain there, has occurred to me. It is simply anteriorly fixed and should cause no trouble.

I would suggest, as the result of my limited experience, the following general rules for cases requiring Cæsarean section:

1. Cases operated upon at private houses, with poor facilities and by inexperienced abdominal surgeons, should be subject to the Porro operation, using the extraperitoneal clamp method.

2. Cases of deformed pelvises, perhaps requiring a similar operation in the future, should be subject to the Porro operation, even if operated upon in a well-equipped hospital, unless the patient decides otherwise.

3. Cases requiring abdominal section on account of removable tumors, only, should be subject to classic Cæsarean section if the operation can be performed in a hospital, or in a private house where all proper facilities can be obtained.

4. Classic Cæsarean section should also be performed if the patient desires it, no matter what the future may bring forth.

DISCUSSION.

Dr. W. G. MACDONALD of Albany, N. Y.—I shall endeavor to speak of some points upon which Dr. Carstens has not dwelt, particularly in relation to the indications for the performance of either one of the operations, namely, the Porro or Cæsarean operation. It seems to me, at the present time, that nowhere in this country, with our present teaching of obstetrics, ought any woman be allowed to die undelivered, and yet we find in nearly every State of the Union that a considerable number of cases occur every year. The matter should be thoroughly discussed, and surgeons ought to have in mind some simple plan of operation which any general surgeon can do, for any man who is capable of doing a good aseptic amputation of the thigh ought to be able to perform a Porro operation. We hear very much yet about the extreme difficulties of doing this operation, and it is said that the man who undertakes a Cæsarean or Porro operation has to do the most serious operation in surgery. Now, any man who approaches the subject with the belief, firmly fixed in his mind, that he is undertaking a most serious surgical procedure when he undertakes a Porro operation, had better not do it, because he will not do it well. Within the last two years there has been published a textbook on obstetrics which, in relation to the question of craniotomy on the living child, takes the ground that among the poor, who are compelled to go into maternity hospitals, all of these cases should be treated by the improved Cæsarean or Porro operation; that in the case of people of wealth the matter should be explained to the family and those having all responsibility, and the dangers of the procedure should be told them and allow them to debate among themselves and select the procedure to be carried out. It is a peculiar system of ethics which among one class in the community demands the improved Cæsarean operation, and another class of the community which demands craniotomy. I prefer no such relations, and rather than sacrifice the living child somebody else is welcome to the case. Rather than do a craniotomy, I would give the other man all the comfort he gets out of it.

We have not used pelvimetry as frequently as we should. The operation of symphysiotomy is now in competition with these operations. But there is something to be thought of concerning the relation of a symphysiotomy and a Porro. Dr. Lusk says regarding symphysiotomy, that the most dangerous man is the one who believes the operation of symphysiotomy is an easy one; that it requires no great amount of skill to perform it, and that it has a very wide application. He takes it, that it requires some considerable skill to do the operation in the first place, and that the after-treatment requires considerable attention, and, for the most part, its uses are only in cases of pelvic deformity. The indications we might form for the performance of obstetric delivery by an abdominal section can be variously classified: such as deformities of the pelvis, exostoses, tumors springing from the pelvis, and cancer of the cervix.

In looking over the literature I find a considerable number of cases in which Porros have been done, or complete extirpation has been done, in cases of carcinoma of the lower segment

of the uterus. Fibroid tumors of the lower segment do not require very frequently an abdominal section. An incision through the lower segment of the uterus from the cervix, with enucleation of the tumor, allows the surgeon to bring about delivery without serious discomfort. In one case, by making an incision over the cervix and by enucleation I was able to separate a tumor nearly as large as a child's head, then put an obstetric forceps on the tumor, extracted it, and afterward labor went on without interruption. Simple antiseptic douches were given.

In going back to the comparative mortality between Casarean section and craniotomy, even the best statistics for Casarean section and the Porro operation in this country show a relatively high mortality. On the other hand, the statistics from a number of maternity hospitals show a low mortality in the few cases where craniotomy has been done. But there are a large number of cases of craniotomy done in smaller cities and private practice which turn out very badly. In my own neighborhood, within a period of two years some twelve, or fifteen women have died after delivery by craniotomy performed by a number of physicians. The only point I want to speak of is this, that in the management of the pedicle after a Porro, I believe the external method by the use of a Koesberle clamp is far better. In removing the pregnant uterus we have the open cellular tissue, which is very easily infected. It shortens the operation a great deal and we are much more certain to bring about a cure.

Dr. C. S. BACON of Chicago—In two of the operations described I think there is a question about the justifiability of the procedure. In one case there was a benign tumor in the pelvis and a Porro operation was done. If a classic Casarean had been made in that case the benign tumor might have been removed and the woman spared her uterus. In another case of contracted pelvis a Porro operation was done where there was a contraction of the antero-posterior diameter of seven centimeters. A contraction of seven centimeters does not prevent symphysiotomy, and the woman could have been delivered, in that case, of a living child, by symphysiotomy. In that case, the Porro operation was not indicated. I think these facts should be brought out before the paper is allowed to pass as receiving the sanction of all members of the Section.

THE DESTINY OF VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASE.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY C. LESTER HALL, M.D.
KANSAS CITY, MO.

It is not my expectation to present any strikingly new features in reference to the subject. I would offer, rather, a few conclusions gleaned from personal experience and from the current literature of today, with the hope that a liberal discussion will follow, the crystallization of which may result in good and lead to a clearer understanding of the conditions met with in malignant uterine disease, and the more rational surgical procedures indicated for the removal of the same.

So far as this occasion is concerned, it matters not whether we accept Colnheim's theory that "the only cells capable of originating neoplasms are those sequestered during embryonic life," or with Williams believe that "neoplasms are of intrinsic origin, due to a modification of the formative process by abnormal forces generated within the body, rather than extrinsic, due to inflammation or to the intrusion of microorganisms," or favor the more recent idea of the bacterial origin of all malignant growths. The question, yes, the *fact* confronts us, that of all organs none is more prone to take on malignant degenerative processes than the uterus. Exposed as it is to so much irritation and injury incident to menstruation and its mishaps in early girlhood, and those disturbing causes of mature womanhood and the marital relations and the traumatism resulting from childbirth and neg-

lected repair, with constant irritating discharges setting up perverted cell action, it is not surprising that this nesting organ of all mankind, should so often be the point of election for malignant degeneration. The achievements of pelvic surgery by the vaginal route, with its *immediate* low mortality, has stimulated surgeons to extirpate the uterus for diverse conditions, without, I fear, a just regard to ultimate results.

Certainly in non-malignant conditions the removal by the vaginal route promises much in the way of completeness and lessened shock; for "benign tumors remain local, but the malignant types penetrate into the neighboring tissues and destroy them, and the tumor germs being carried off in the blood and lymph, give rise to metastatic or secondary neoplasms in all parts of the system." "Metastases have essentially the same structure as the primary tumors, and are found either in the vicinity of the latter, that is, in the region supplied by the lymph and blood which comes directly from the tumor, or in distant organs, after the tumor germs have passed through the heart." "It is characteristic of tumor metastases, especially those from really malignant tumors, to go on growing indefinitely. Normal tissue germs do not have this peculiarity" (Tillman).

"In men cancer is liable to develop in the skin, lips, mouth, and rectum. While in women, glandular carcinoma predominates, and those of the mamma and uterus are especially frequent" (Tillman).

Those of the skin and lips are less liable to secondary infection. Whereas the glandular variety are prone to secondary lymphatic infection. Senn says: "Glandular carcinoma is followed at an *early* stage by regional infection. The lymphatic glands nearest the organ affected in the direction of the lymph current are usually involved first, when step by step, successive glands are implicated, until the entire chain of glands has become infected. Secondary tumors are subject to the same degenerative changes as the primary. The glandular tissue is completely removed in the lymphatic glands by the substitution of tumor tissue." He further speaks of "a wide zone of infiltration, and says Virchow pointed this out several years ago, and Waldeyer described this as an inflammatory zone, because he found in the connective tissue numerous small cells. Infiltration consists of leucocytes and young epithelial cells which, like the leucocytes, wander by virtue of their ameboid movements into and along the connective tissue spaces. Carcinoma of the alveolar type may develop within the cervical canal, and destroy the neck of the uterus before it is discovered, or in cancer of the body of the uterus, the cervix may become constricted, causing retention of the secretions (hydrometra), or the body of the uterus may be well-nigh destroyed before the cervix is attacked." Lymphatic infection is found in the lumbar retroperitoneal and inguinal glands. "Occasionally there may be found an isolated nodule of cancer higher up than the apparent edge of the disease. Whether this is due to lymphatic infection or is multiple cancer formation is an undecided question" (Warren).

"Examination of the retroperitoneal lymphatic glands in suspected cases of carcinoma of the uterus should never be neglected. In the great majority of cases the surgeon has to deal with carcinoma after regional infection has set in and in cases where the disease has advanced too far for a successful radical operation" (Senn).

He also says: "The greatest progress in the treatment of carcinoma will have been made, when we are placed in possession of an *infallible* means of early diagnosis." This was said in treating of carcinoma in general. Difficulties multiply when we consider carcinoma of the uterus, and there are no means of overcoming the obstacles presented. The hidden location of the organ, the secretive and natural disinclination of women to communicate even to their nearest friends any suspicion entertained that "all is not well," are barriers which will require the education of many generations to remove. The average woman is so ignorant of her own organism, that she is incapable of differentiating between the normal and the abnormal. She begins early in womanhood to expect the "change of life." Allured by the dangerous and false teachings of the mother, who wisely and with knowing look, tell her that irregular flow is not uncommon, and that *her* doctor told her "forty years ago" not to be alarmed at this, or even an offensive discharge. She has kept her secret, in blissful ignorance of the progressive degeneration which has overtaken her. When at last, forced by failing strength and pallid cheek and anxious inquiry of friends to consult her physician, the discovery is made that the diseased process has destroyed the cervix, that the lymphatic pelvic glands have become infected, that the broad ligaments and peri-uterine tissues have been invaded, and little hope remains for relief, either by palliative treatment or the radical operation.

Despite statistics (which too often are deceptive) showing many apparently permanent cures, yet on high authority we are forced to the conclusion that most cases presented are inoperable, at least by the vaginal route.

With these discouraging conditions confronting us and bearing in mind the limited field of operation, the accepted infectiousness of cancer tissue, and the possibility of the "transference of living tumor cells during an operation," coupled with the impossibility of removing in many cases *all* of the diseased structure, we are forced to admit, in candor, that the removal of the uterus *per vaginam*, for malignant disease, is at least in the majority of cases, *as we see them*, a doubtful expedient.

Tillman says that "Billroth saw an isolated form in the cicatrix in the overlying abdominal wall after extirpation of a similar growth from the pylorus, which was not adherent," and claims that the prognosis of cancer is very unfavorable. Complete cures are rare, even when the carcinomata are extirpated very early in their course. As a rule one recurrence follows another until the patient succumbs to general carcinosis or exhaustion." Again: "Possibility of the total removal of a tumor depends upon its location and the kind of organ involved. In malignant tumors, especially carcinoma, the neighboring lymph glands should also be removed, even though they are not diseased."

The late lamented Samuel W. Gross long ago gave out this sound surgical opinion, based upon experience and pathologic research in reference to amputation of the mammary glands for malignant disease. He claimed as absolutely essential, that all axillary fat and glands should be removed.

In cancer of the uterus we have in a great degree a parallel condition to deal with, but the narrow vagina and the danger of invading other important organs

and structures precludes the possibility of completely removing, by the vaginal route, all probable diseased tissue.

Eastman, in quoting Gross, says: "We must likewise go wide of the disease in hysterectomy, to give the patient every possible hope, that not only the cancer, but subjective glands in which the cancer might be lurking, be removed." This to my mind is an impossibility by the vaginal route.

Senn says: "From a prognostic standpoint, imperfect removal of the primary tumor by caustics or by use of the knife, must be regarded as a measure calculated to aggravate the local conditions and to shorten life." Therefore, when complete removal is not possible, the patient will be more comfortable and live longer if no radical operation is done. In view of the opinions of some of the leaders in medical thought, we are compelled to look further for other and better methods of procedure in dealing with malignant disease of the uterus.

It is probable that *any* plan of extirpation will be found inadequate in a large percentage of cases for the entire and permanent eradication of the disease. But *that* method which permits of the largest opportunity for inspection of the diseased uterus, adnexa and infected glands, and furnishes an opportunity for a more complete removal of all diseased structures, both primary and secondary, must ultimately become the operation of election.

The dexterity which has characterized American surgeons in abdominal section for the total removal of the uterus and appendages, leads to the *belief* and justifies the *prediction*, that in the near future vaginal hysterectomy for malignant disease will be restricted to those rare cases in which women present themselves in the inception of the disease and before secondary infection has taken place. It is the opinion of the writer, that the more radical operation known as the Clark method will supersede vaginal hysterectomy for malignant disease. By this method of abdominal total extirpation of the uterus and adnexa, with dissection of the posterior peritoneum, the ureters (which have been made prominent by the introduction of ureteral bougies), and all glands at the bifurcation of the iliac vessels are brought into view and removed whether infected or otherwise. We are thus enabled in this broader field to go beyond the inflammatory zone, and to reach diseased glands not approached by the vaginal route. The bladder, the ureters, rectum and all important structures are brought directly into the field of vision. Thus directed, the hand of the operator does its thorough work and the poor sufferer has had done for her the best that science and the art of surgery can offer.

The objection urged against this operation, that it is tedious, that too long exposure results, that prolonged anesthesia endangers the patient's life, will all be overcome by that "practice which makes perfect."

DISCUSSION.

Dr. J. E. JANVRIEN of New York—My friend, Dr. Noble, told me something about the ground that was taken by Dr. Hall, and it was principally this, that the cases in which vaginal hysterectomy will prove successful are so limited and come to the surgeon so late that it is questionable whether this operation can be properly performed in more than a few cases; in other words, it is only justifiable in a certain number of cases. I have been considerably interested in this subject for the last fifteen years and have done quite a good many vaginal hysterectomies for cancer. I am perfectly well aware that the majority of cases of cancer affecting the cervix come to us too late for a radical operation; at the same time, the people at

large are becoming educated in this matter, and I find during the last six or seven years that women are coming to our hospitals and to us in private practice at an earlier stage of their disease than formerly, the disease in these cases simply affecting the cervix or the endometrium. During the last five or six years I have operated on a good many such cases. In the majority of cases in which I have operated in the early stage of the disease, there has been no general systemic infection, and I believe the success of vaginal hysterectomy for malignant disease depends entirely on this one point, that if we get hold of cases in which there is no systemic infection, in which the disease is absolutely confined to the cervix or the endometrium, or even to a limited portion of the vaginal mucous membrane alone, I believe from my own experience and the success which has attended my operations, that all such cases can be operated upon radically with the best of success. One-third of my cases are living now, at periods of three to fifteen years after the operation. If the disease has extended beyond the cervix, and much beyond the endometrium and into the peritoneal covering, these cases are not the subjects for vaginal hysterectomy, nor for any other radical operation; for I believe that if operated on, sooner or later the disease is sure to return.

Dr. JOSEPH EASTMAN of Indianapolis—I have only a few words to say in connection with the subject of vaginal hysterectomy. I do not believe the operation is destined to obscurity for several reasons. I might name twenty-five or forty reasons, did time permit. I might name women who are living from twelve years down who have had vaginal hysterectomy performed for cancer and are perfectly well today. In the case in which I have performed vaginal hysterectomy, the prolongation of life, the relief from suffering, the relief from loathsome discharge and hemorrhage were enough to justify me in recommending the operation in each and every case. It is our duty to operate even on some of the desperate cases, in order to relieve the loathsome discharge and hemorrhage. By such means I believe we can educate the general practitioner to recognize the value of early operation, so that he will send or bring his patients at the proper operative period.

A point which the doctor did not mention in his paper is this: It has been clearly shown that when cancer involves the fundus it is much less likely to return than when it involves the cervix. I could name cases in which the cancerous mass was as large as a hen's egg, taken out of the fundus and the uterus removed, and the patients remaining well six and seven years after. So in cases of cancer of the fundus of the uterus we have reason to expect definite results where the disease involves the cervix. I simply rise to make a plea for vaginal hysterectomy for malignant disease, *early*, if you can; *later*, if you must.

Dr. JOHN M. DUFF of Pittsburg—The last speaker has voiced my sentiments to a great extent. My percentage of deaths have been high, and those who did live for any length of time, without having an operation done, so far as I know, lived for a single year. On the other hand, with operations I find patients living from three up to twelve years, on whom a vaginal hysterectomy has been done. I can not believe that a case in which vaginal hysterectomy is not indicated is one in which we are justified in doing the bolder operation, namely, of going through the abdominal cavity. The great point in this question is one which I would like to emphasize, namely, that in the vast majority of cases the women have not only been careless themselves, but they have been informed by their attending physicians that they were suffering merely from a change of life. Only last week a woman came to me and said her physician had told her it was not necessary for her to pay any attention to the discharge she was having, as it was a necessary sequence in most women during the climacteric. I do not want to be too radical in expression, but as far as my observation goes, I do not think I have ever seen a woman who was healthy who had any trouble so far as the disarrangement of her menses is concerned during the climacteric. I do not say all have cancer, but may have some disturbance. They have some uterine trouble in the vast majority of cases, and we as physicians can do considerable good by impressing on the public the necessity of examination in these cases.

Dr. G. B. MASSEY of Philadelphia—I do not think one can blame the general practitioner for being slow in sending these cases to the gynecologist, for the general practitioner knows that there is a difference of opinion among them as to the value of hysterectomy for cancer of the uterus. The difference of opinion sometimes depends upon the place and the manner in which the opinion is given. The opinion was expressed to me personally by one of the most eminent operators in this country, privately, that the cancer returned after this operation in a different situation, and was always more painful; and his further remarks were certainly different from those which

men are accustomed to making before bodies like this. There are other reasons for keeping these patients from the hands of operators, natural timidity, a widespread lack of belief in the cure of cancer, etc. Before another Section I shall report a case of incipient carcinoma of the cervix which was cured by the cataphoretic method, and I now feel disposed to recommend it as a new and most valuable cure for cancer. It consists in disseminating mercury throughout the cancer by cataphoresis, the physical transition of mercury, but more particularly of its oxychlorid in an acid condition from the electrode placed in contact with the cancer. I had a record of four out of eight cases which were cured under experimental conditions, in conditions where I first did not use enough of the current. The later cases proved the necessity of a very heavy current, as much as a thousand milliamperes for carcinoma; while less current will do in cases of sarcoma. I will briefly report one case.

Something over a year ago a woman had a slight ulceration. She was examined accidentally by Professor Parvin, who pronounced it carcinoma, advised curetting and the alternative hysterectomy. She was placed under treatment a year ago this month by this method. I used about one hundred milliamperes daily. There was immediate improvement and now it has entirely healed up. I have had other cases, one of cancer of the breast, which I shall not report at this time. Since we do not know what cancer really is, it is proven by this method that the cells of cancer, or whatever it is, may be killed *in situ* by the diffusion of the most powerful antiseptic known, the oxychlorid or chlorid of mercury in an acid condition. It has been proven that the impact or association of these atoms at a distance of from one-quarter to an inch from the electrode will cure cancer without killing connective tissue in old subjects.

Dr. HENRY O. MARCY of Boston—We usually have supposed that we were indebted to Dr. Bennett of Edinburgh, who thirty years ago made a clear demonstration that cancer was first a local and afterward a constitutional or disseminated disease. If we accept this as the basis of our interpretation, I am quite sure that we are equally certain that we have but one answer to make in the discussion of the subject before us. If the disease is local, it is within the limitation of the surgeon, and it is a bounden duty on his part to remove it from the general organism. Based upon these premises, I am quite sure vaginal hysterectomy is as scientific a procedure as is the removal of the cancerous breast, or when the disease occurs in any other part of the organism. The question arises: When and how thoroughly shall the operation be done in a given case? Hence the discussion is narrowed down to a comparatively safe and sure limit for determination. Scarcely more than a decade since we first held that such an operation was the correct one, but the question now is: What are its limitations? How far may we trespass upon such an important structure as the uterus? If we have a patient in which it is determined that the disease is local, the surgeon's duty is plain. The trouble formerly was that the local physician first tried his own application until the case had progressed too far for operation. This is, fortunately, not so common now. If the disease has become disseminated throughout the broad ligaments it is quite another matter, and the operation is not possible.

Dr. J. WESLEY BOVEE of Washington, D. C.—I wish to enter a plea in the same direction as Dr. Marcy, particularly in those late cases. There is no doubt in my mind of the necessity and efficacy of vaginal hysterectomy in the early cases, and I am sure that in my experience vaginal hysterectomy in the late cases have been very beneficial. I have operated on a number of cases that have been cauterized and curetted previously by other operators with the idea that hysterectomy was of no use, and some of those cases are living now, it being more than two years since the operation was performed, and without evidences of return of the disease. A great deal can be done surgically for those cases in which the disease has involved the broad ligaments. The advantage of a surgical operation over the method described by Dr. Massey is along these lines. Surgical interference does practically all it can do at the time of the operation; whereas the treatment with electricity does not do it in one application, but by continued applications, and after the first application there is a possibility of the disease continuing to spread, while surgical interference cuts it short. There is no doubt but what we have a number of excellent results following what we might consider hopeless cases for hysterectomy.

Dr. JAMES T. JELKS of Hot Springs, Ark.—I want to dissent from the opinion advanced by one of the gentlemen this afternoon, that we should operate on all cases of cancer of the uterus by vaginal hysterectomy. If we get the case early enough, and

the operation is a radical one, it is followed by recovery of the patient. But there is a line somewhere beyond which these operations are not followed by successful results, and inside of this line they get well permanently. I am in favor of early total hysterectomy. It is a comparatively common affair for patients to enter our offices with carcinoma of the cervix or of the body of the uterus absolutely breaking down, with involvement of the vagina and broad ligaments, and to my mind it is hopeless to operate on such cases. My experience has been that where these patients would probably have lived without operation for some time, they die within one year after operation. It may be different with some of the gentlemen here, but I am certain that we shorten the lives of the old women by resorting to vaginal hysterectomy by sowing the seed of the disease in the cut surface. Instead of there being localized disease, involving the sloughing or ulcerating cervix, we have the cancerous disease disseminated through the broad ligaments and lymphatics. I want to dissent from the opinion that we should resort to total hysterectomy in late cases; but I am in favor of early and radical interference in all recent cases.

Dr. J. HENRY CARSTENS of Detroit—It seems to me, we do not know very much about cancer. I see some of the cases very early and resort to vaginal hysterectomy and feel sure the disease will never recur. About six months thereafter the patient comes back with the disease having returned. My next case is a very bad one, reaching on the border-line, and I do not know whether an operation is justifiable or not. I operate, however, giving the patient the benefit of the doubt, knowing, beyond the question of a doubt, that in this case the disease is going to recur in a few months, but it does not and has not up to this day. So I make up my mind that we do not know after operation whether the disease is going to recur or not. I agree, with Dr. Eastman, that we ought to give these patients the benefit of an operation, if only to relieve the distressing discharges, the hemorrhage, etc. In surgery, when we do this, we must use a good deal of tact and have it thoroughly understood that we must not promise too much in any case. Let the patient understand also that the disease may recur. The family physician promises too much in some cases and we ought to be careful to guard the interests of surgery.

Dr. DUDLEY of New York—Vaginal hysterectomy for malignant disease depends simply upon the diagnosis. If a patient comes to us with the uterus free from disease, and the disease has not gone beyond the limits of the cervix, vaginal hysterectomy in my judgment is the proper operation, but if there is intrapelvic disease and the uterus is fixed, or if the vaginal wall or broad ligaments are involved, then an entirely different operation should be performed. Therefore, he who would operate successfully for malignant disease of the uterus should be able to make a diagnosis as to the limitations of it. The limitation of the disease must be first determined. If the disease is not limited to the organ, then the combined method should be resorted to in order to accurately ascertain the extent of involvement. I have operated on a number of such cases and have found it has always been good judgment on my part to invade the abdominal cavity from above and do the combined method. I therefore believe that vaginal hysterectomy will depend upon the point I have mentioned.

Dr. C. C. FREDERICK of Buffalo—I concur in all that has been said and rise simply to report a case bearing upon the point of rapidity with which certain cancers progress, and the slowness with which other cases advance. Within the past week it has been my fortune to see a well-advanced case of cancer, the woman having severe hemorrhages. Dr. Mann some seven years ago made a diagnosis of carcinoma of the cervix in this case and at that time advised extirpation. I immediately saw Dr. Mann, who had made sections from the case seven years ago and pronounced the disease cancer, and still the woman was alive. This case points out the malignancy of different cases, and consequently we are not able in any given case to determine whether the disease is going to progress rapidly or slowly. Therefore, in some cases we think vaginal hysterectomy or total extirpation is not indicated, while in others it is. In one case upon which I operated, the disease returned at the end of four months. Quite an extensive operation was done with the expectation that the disease would not return, but it recurred in a pronounced form at the end of the period named, and was rapidly progressive.

Dr. HOWARD A. KELLY of Baltimore I believe that the destiny of vaginal hysterectomy is that it will be performed by the abdominal route, by which means the large wings of the broad ligaments can be removed and all the involved tissues dissected out. Preliminary catheterization of the ureters is the one essential feature in this operation to enable us to keep these organs under the finger and thereby avoid injuring them. I believe that many physicians can not recognize cancer of the

uterus even in its late stages. The immediate mortality of the Clarke operation is slightly greater than that of vaginal hysterectomy, but the ultimate results are better. I would insist upon repeated examinations of women who have borne children, beginning within four months after labor, and repeated at suitable intervals.

Dr. A. GOELET of New York—I agree with Dr. Kelly in regard to the destiny of vaginal hysterectomy, and I will mention briefly a case of my own which illustrates this point. It came under my observation quite recently. The case was sent to me with a suspicious history. A short time ago the uterus was carefully curetted, the scrapings examined and the disease pronounced adenocarcinoma. The patient was absolutely relieved of every symptom and was in good condition in spite of the revelations of the microscopic examination. However, I decided that a hysterectomy was necessary. There was slight suspicion of involvement of one broad ligament. I found that I could not cope with the conditions by the vaginal route, and that in order to be certain of removing every vestige of the disease I would have to enter from above. To show how difficult it is to be certain of diagnosis by ordinary methods, I will state that the specimen showed the mucous membrane of the uterus to be in an absolutely healthy condition, excepting in one place, the cornu of the uterus, where perhaps the curette had skipped. But the mass in the broad ligament, which was scarcely perceptible in my examination before, was of such a character as to be difficult to remove through the abdomen. However, I succeeded in removing it, but feel satisfied that it could not have been removed by vaginal section.

Dr. JOSEPH PRICE of Philadelphia—We all know that a discussion is very much smoother than an operation. We know very well that it is exceedingly common for some operators, if they find complications, to abandon an operation and call the case inoperable or hopeless. To go back a short way in this discussion, many years ago Sims visited Boston and was asked by Oliver Wendell Holmes to make some remarks to his class. He lectured on the treatment of cancer of the cervix. He recommended the curette in removing the disease and cauterization, repeating this procedure thrice or many times, and it is stated that his patient lived a long time. In some of the cases, the more malignant ones, there was a speedy recurrence of the disease with early death. The use of the curette and cautery in seemingly hopeless cases has been followed by great improvement. This is true, notwithstanding that the curette and cautery had been used twelve or eighteen months prior to a radical operation by a second operator. Twelve months is quite a long time for recurrence in many cases of this character. We have all known or have seen so-called hopeless cases with extensive invasion of the vaginal walls whose lives have been prolonged for twelve months or three years in which the curette and cautery were freely used. I am surprised quite frequently at the statements of physicians when they return to me with a second or third case for operation. For instance, a physician brought me a patient upon whom I was to perform a hysterectomy, and I asked him what about the cancer case? He replied that she was doing well, and it was about two years since I used the curette and cautery in that case. I operate on every patient who comes to me. No one can accuse me of backing out from a vaginal hysterectomy, as I prefer the vaginal route to all others, excepting in those conditions to which Dr. Hall has alluded, the presence of complications in the tubes and ovaries. In case the tubes and ovaries are involved in the malignant disease, I would resort to the abdominal method. I have repeatedly removed half the vagina in these cases. As to recurrences of the disease, they are usually to be found in the bowel and bladder, and in these cases the suffering is intense. I do not remember of seeing a single case of cancer that did not recur in eleven years. One observer has made the statement that if it is cancer, it does return: if it does not return, it is an error in diagnosis. Some of the cases that do not recur are erosions of the cervix.

Dr. THOMPSON—I am glad to have the opportunity of saying a word relative to operating upon cases of carcinoma of the cervix, and also with reference to the importance of early diagnosis. I can not refrain from emphasizing the importance of exactness in diagnosis, not only as regards carcinoma of the uterus, but of carcinoma of the mammary gland. About three years ago a patient came to me with a small lump in the mammary gland. The woman was rapidly getting worse and was mentally depressed by the presence of this growth, and although she had been seen by eminent gynecologists both in Boston and Philadelphia, none of these gentlemen saw fit to advise operation. When she came under my care I decided to consult my friend, Dr. Kelly of Baltimore. Dr. Kelly advised operative interference and the mass was successfully removed. A section of the tumor mass was examined microscopically and

was found to be carcinoma. It is now two and a half years since the operation was performed and the woman is living and in perfect health.

Dr. HALL (closing the discussion)—I am very glad indeed that my paper has had the desired effect of bringing out a very liberal discussion, although many of the members present did not hear the paper. Many of those who differed with me in the first part of the discussion practically agreed with me that early diagnosis was absolutely necessary in order to extirpate the uterus by the vaginal method with good results. Total extirpation by the abdominal route and catheterization of the ureters were mentioned in the paper. One great difficulty we have to contend with is in getting women to come to us for early examination. If Dr. Kelly can accomplish what he proposes, then there will be no excuse for abdominal hysterectomy.

FIBROID TUMORS OF THE VAGINA, WITH REPORT OF A CASE.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. M. EMMERT, M.D.

PRESIDENT IOWA STATE BOARD OF HEALTH.
ATLANTIC, IOWA.

May 10, 1895, I was called in consultation with Dr. Weaver of Cumberland, Iowa, to see Mrs. A. G. M., who gave the following history: Born in Germany; aged 46; married three times; now living with last husband; had six children, of whom three are now living; last child delivered by forceps. About 1892, while working in a brewery, lifting and carrying heavy baskets of bottles, she felt a heavy, dragging sensation in her pelvis and upon examination a tumor was found in the vagina. She was taken to a hospital where she says she remained twenty weeks. She states that no operation was performed, but the tumor was allowed to slough away, or partly so. After leaving the hospital and coming to this country she for a time felt no inconvenience from the tumor; but the dragging sensation again returned and Dr. Weaver was sent for, who asked me to see and remove it. On examination I found a tumor protruding from the vagina. The dependant part had undergone necrosis and was bathed in foul-smelling muco-pus. It was found to be attached to the anterior wall of the vagina by a sessile base, extending from an inch posterior to the meatus and to within about an inch of the cervix. It was removed by enucleation and the patient recovered without any difficulty. The tumor, after its removal, weighed one and one-fourth pounds, was four inches in length and two and two-thirds inches in diameter, being oval in shape. It was hard, and cutting into it presented the feel and appearance of a fibroid growth. When I looked up the literature and found how rare these growths were, I concluded that my diagnosis was wrong, and a section was sent to Prof. J. C. Bay, bacteriologist to the Iowa State Board of Health, who made the following report:

March 5, 1895.

Dear Doctor:—The specimen from a tumor was duly received and examined. A number of sections through the fragment and in different directions failed to show any signs of carcinoma, but gave evidence of fatty degeneration. The growth is, however, not one of lipoma, but rather of fibro-muscular nature. The latter are quite polymorphous, and I judge that the present case is one of so-called fibromyoma.

Respectfully, J. CHRISTIAN BAY.

In connection with the report of this case, I desire to present the result of a careful review of the literature as well as an extensive correspondence, not only with the prominent surgeons and gynecologists of the country but the general practitioner as well. My experience has convinced me that the growth is

very rare, but not so much so as a review of American text-books would suggest. Several of the most popular works do not even mention it; others dismiss it with from three to ten lines. "The American System of Gynecology," by Mann, devotes a page and a half to the subject, three times as much as any of the rest. My reason for believing the cases are more numerous than supposed, is the result of my canvass of Iowa, which was quite thorough, and where I found one half of my list of unpublished cases, besides rejecting a number of cases which gave such incomplete and unsatisfactory data that it was thought best not to include them in the list. I had a number of small tumors reported, always on the posterior wall. These cases were reported as fibroid tumors, but a letter from Prof. W. R. Pryor of New York caused me to reject them. He says: "I have met with hard fibrous nodules in the posterior wall and never over one-half inch in diameter. I have always considered them due to coagulation of blood in a hemorrhoidal vaginal vein, and a few times I have found even the smallest ones containing calcareous deposits." Rejecting this class of cases, with some others where the authors were not sure that the tumor did not grow from the uterus, and a few that gave a history of malignancy from the start, I have succeeded in collecting twelve published cases and twelve unpublished cases.

My examination of the literature was confined to that found in the Newberry Library in Chicago. I am aware that this list is imperfect both as to numbers as well as scientific value, as the diagnosis in most of the cases was made by macroscopic examination, and some cases which had been seen some years ago were reported from memory alone. Yet these cases were mostly reported by men standing high in the profession and, therefore, the diagnosis more readily accepted. When there was any question as to the diagnosis in the mind of the author the case was thrown out. The following is a very brief report of each case:

Case 1.—Oct. 17, 1895, J. B. Murphy, M.D., of Chicago removed a tumor from the anterior wall of a woman, the size of an apple and weighing 57 grams. It had been operated on two years before. Microscopic examination showed it to be a myxofibroma.

Case 2.—Operator, Henry T. Byford, M.D., read before the Chicago Gynecological Society June 19, 1895. Age 35, married; site of attachment and weight of tumor not given. There was also a tumor the size of a goose egg felt on the right side of the uterus. Cause given, overwork. No microscopic examination.

Case 3.—An interesting case by John C. DaCosta, M.D., of Philadelphia, published in the *Medical News* of Oct. 26, 1895. Age of patient 40 years; a Pole; attachment, anterior wall; sessile. It measured, antero posterior, six and one-half inches, transverse, four inches. The dependant portion of tumor was ulcerated.

Case 4.—Edward B. Stevens reports a case in the *Obstetrical Gazette*, 1881. Age of patient not given; size, that of a walnut; grew from posterior wall; attachment, sessile. It was first diagnosed as an abscess, as pus had been discharged from the tumor. Upon removal it proved by the microscope to be a fibroid, with a small abscess cavity in it.

Case 5.—In the *Virginia Medical Monthly* for 1886-87, Horatio R. Storer, M. D., reports a case. Age 35, married; attachment, anterior wall, high up and sessile; weight one and a half pounds; shape and appearance that of an ox heart; measured fifteen inches in circumference. Considerable difficulty was experienced in delivering the tumor after cutting off with an *ecraseur*.

Case 6.—A. M. Cartledge, M.D., reports a case in the *American Practitioner*, 1888, under the head of "A Rare Vaginal Tumor." Age and attachment not given. On microscopic examination it proved to be a fibroid tumor with *earcomatous* degeneration.

Case 7.—In the *Boston Medical and Surgical Journal* for 1892 Charles M. Green reports the following case: Age 51,

married; history good; size, as large as a hen's egg; attachment, anterior wall. Microscopic examination showed it to be fibromyoma.

Case 8.—Archibald Donald, in the *Medical Clinical* for 1888, reports a case in a woman aged 36, married; attachment high up in the posterior wall; size, as large as a small orange. Anemic from loss of blood. Microscopic examination, fibromyoma.

Case 9.—A case reported to the New York Obstetrical Society by Dr. Hunter, and published in the "Transactions." Size not given; attachment extensive, to posterior wall. The patient was pregnant and question of operation was discussed, but he does not state whether it was removed.

Case 10.—Dr. A. C. Godfrey, in the *Colorado Medical Journal*, reports the following case: Age 35, married; attachment, anterior wall by pedicle, which dragged the bladder down, forming a cul-de-sac. Size of tumor not given, but large enough to fill the vagina. Under the microscope it proved to be a fibromyoma.

Case 11.—A case reported to the New York Obstetrical Society by W. M. Polk, M.D., and published in the "Transactions" of the society. I was unable to find this case in the "Transactions" but quote from a personal letter: "It is ten or twelve years ago since I presented it. There was nothing remarkable in the history, and the woman seems to have had her attention called to it on the score that it was a case of prolapse of the uterus. The tumor itself was about two inches long by about three-quarters of an inch in diameter. In general outline it was cylindrical, with rounded ends and was imbedded in a capsule which was very much attenuated, except at the end of the tumor where attached to the vagina."

Case 12.—A case reported by J. C. Moore, M.D., in the *St. Louis Medical and Surgical Journal* for 1895, and referred to by John C. DaCosta, M.D., in his paper reporting his case.

The following are the cases never published, but collected by correspondence. In my circular letter I asked the following questions: Did you ever treat a case of fibroid tumor of the vagina? What was the age of the patient? Was she married or unmarried? What was her social environment? To what part of the vagina was it attached? What was its size and weight? Was it examined microscopically? What treatment was adopted?

Case 13.—Reported by J. J. Maxwell, M.D., of Keokuk, Iowa. Age 62, farmer's wife; posterior wall attached by pedicle; weight eight ounces. No examination made (this means microscopic examination).

Case 14.—Reported by D. Macrae, M.D., of Council Bluffs, Iowa. Age 35, Dane, working woman, married; anterior wall by pedicle, two ounces; not examined.

Cases 15 and 16.—Reported by J. Taggart Priestley, M.D., of Des Moines, Iowa. No. 15: Age 21, unmarried, wealthy; posterior wall; as large as an English walnut; woman had double vagina and double uterus. No. 16: Age 32, married; posterior wall; as large as a goose egg. Neither were examined microscopically.

Case 17.—Reported by Dr. Williamson of Ottumwa, Iowa. Age 40, married, middle class; attachment, right and posterior wall; as large as a hen's egg; no examination.

Case 18.—Reported by Dr. Aldrich of Galesburg, Ill. Age 36, married, environment good; attachment to right side; as large as a hen's egg; was not examined.

Case 19.—Reported by E. Lampher, M.D., of St. Louis. Age 54, married; attachment to anterior wall; size, two inches in diameter; examined by microscope and found to be a fibroma without any evidence of malignant degeneration.

Case 20.—Reported by Dr. Skinner of Cedar Rapids, Iowa. Age 44, married, environment good; attachment to anterior wall; weight one ounce; no examination.

Case 21.—An interesting case reported by William Watson, M.D., of Dubuque, Iowa, and removed in 1862. I quote briefly from the Doctor's letter: "The patient was single, age 45. It was extruded as by labor pains. I at first thought it was the womb. The attachment was large and fleshy, but I am not just positive as to its attachment. I passed a strong double ligature through the neck and tied it as tight as possible both ways and cut it off. It was as large as a child's head at birth; was somewhat elongated. My recollection is, that it weighed over twelve pounds. The woman made a good recovery."

There is a question as to the propriety of including this case in the list; as it may have been a fibroid of the cervix or uterus.

Cases 22 and 23.—Reported by Herman J. Boldt of New York, who was unable to find the notes of his cases, but kindly wrote me a description from memory. I quote from his letter: "They occurred in women in the 30's, married. The tumors were in the middle third of the vaginal tube, one in posterior wall, the other in right side. Both tumors were the size of small guinea eggs."

Case 24.—An unpublished case of Henry T. Byford, M.D., of Chicago and reported from memory. Tumor as large as a large egg, but no further particulars.

The following is a brief note from T. Gaillard Thomas, M.D., of New York: "In a practice of over forty years I have seen several cases of fibrous tumors taking their origin in the vaginal wall, but I have no notes of them and am unable to aid you." He also quotes the following from Sydenham: "False facts are more dangerous than false theories," which may be appropriately applied to at least a part of this paper.

The following is quoted from a letter from E. C. Dudley, M.D., of Chicago: "I have seen three or four cases of fibroid tumors of the vagina. I have no record of these cases and, therefore, regret that I am unable to supply you with further details."

Leaving out the cases of Drs. Thomas and Dudley, I have tabulated twelve published and twelve unpublished cases. Counting two for Dr. Thomas and three for Dr. Dudley, would bring the number up to twenty-nine. In reporting the published cases I have included none outside of the United States. In 1882 Kleinwächter collected fifty cases. Bresky, up to 1887, had collected thirty-seven cases, but, in my investigation, I found a number of cases reported in Europe since that time. It would make this report too lengthy to enter into a discussion of the etiology, symptomatology and pathology of these tumors.

The following is a brief summary of the cases collected: Out of sixteen cases where the age was reported, ten were over 30 and under 40 years of age. The youngest was 21 and the oldest 62 years old. The average age was thirty-five and seven-eighths years. The attachment of the tumor was given in seventeen cases, of which ten were in the anterior wall, five in posterior and two in lateral. This agrees with Briskey, as he found 63 per cent. in the anterior, 26 per cent. in the posterior and 11 per cent. in the lateral wall.

There were fourteen reported as married and two unmarried. One 45 years of age; six reported as examined with the microscope; twelve reported as not being examined and the balance no report. Sessile attachment occurred in fifteen, pedicle in three, balance not given.

The weight was from a few grains to twelve pounds, Dr. Watson's case. If we accept this as a fibroid of the vagina, it is the largest on record, as the celebrated case of Gremler weighed ten pounds.

Where the social status was given, with one exception, the cases were from the middle or inferior class. This would indicate that they occurred at the period of greatest sexual activity. Yet that can not be given as the only cause of the disease, as Martin found a case in a newborn infant.

The Sclerogenic Method in Strumous Synovitis.—Prof. Delassus has been treating several cases of white swelling of the knee with Lannelongue's sclerogenic method and is impressed with its value in all such affections of the joints. It does not compromise more radical intervention later, in case of failure, and the functional results secured are satisfactory in most cases.

CRITICISMS ON REMARKS IN THE DISCUSSION OF DR. CLARKE'S¹ PAPER ON DISPLACEMENT OF THE UTERUS.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY FRANKLIN H. MARTIN, M.D.

Professor of Gynecology, Post-Graduate School of Chicago; Surgeon to the Women's Hospital; Attending Gynecologist, Post-Graduate and Charity Hospital of Chicago.
CHICAGO.

In imagination, two days ago, I sat in this hall as an inexperienced practitioner of medicine, seeking for some light on the subject of displacements of the uterus, which might be afforded me by the discussion of Dr. Clarke's excellent paper by the many gynecologists present. The discussion, hesitatingly begun, waxed eloquent, grew aggressive and, in the vortex of its climax, many voices of learned men were heard. To me, in my capacity of an imaginary beginner, confusion existed in my mind at the commencement of the discussion, but when the discussion grew in proportions, my mind became a whirlwind of conflicting emotions, because of the many positive, not to be appealed from, opinions, of a diametrically opposite character thundered at us from as many different distinguished specialists.

The discussion was begun, as all hot discussions on gynecologic subjects are begun in Philadelphia, by one of the big four of the Philadelphia Obstetrical Society (that society from whose pap we Westerners have for long drawn inspiration and pyrotechnic ammunition). M. Price made the subject seem easy by disclosing to us the fact that displacements were always caused by atrophy of some part of the uterus or its supports, and that operations consequently were never necessary, but that the case should be treated by local stimulants, exercise, etc.; that "Johns Hopkins'" operation should never be thought of; that the Alexander or any other method of shortening the round ligament should not for a moment be dreamed of, because he had known a pedicle, representing the cervix and lower part of a uterus, to stretch under the obsolete torturing device, the *serre neural*, to a length of eight inches. Certainly, to us inexperienced light-seekers, this profound opinion and the following argument, seemed to dispose of the whole subject. But, to our confusion, up rose our distinguished ex-President from Indianapolis and, "without desiring to go into the subject deeply," he had decided that too much sexual indulgence on the part of our patients was a fruitful cause of uterine displacements. Constant exercise of the nerves presiding over this erectile organ paralyzed them, and the muscles controlled by these nerves (uterus, supports, etc.) stop acting and things in the pelvis droop, as it were. This distinguished clinician would recommend a barbed wire pessary. As about one-third of the cases of displacements of the uterus which, in my limited experience, I had observed were in women I had supposed to be virgins, my nerves received a severe shock and I began to grow a little incredulous.

When the applause had subsided on the barbed wire pessary, a slight stir ensued, and there stood before us another member of the Price family, the veritable Ajax of the big four of the Philadelphia Obstetrical Society, with the lightning transferred

from his hands to his eyes, and while we settled back to drink wisdom from his caustic tongue, lo! what did we hear! Why, that the whole trouble was that the uterus is too large: that it is not atrophy at all, as the other member of the family would have us think, but that it is hypertrophy which induces displacements. Instead of sewing the uterus to the abdominal wall and inducing a tangle of omentum, intestine and other important internal organs, for which he would subsequently be called several hundred miles into the country to make a second life-saving operation, for, instead of this he would remove the Indianapolis barbed wire pessary, and insist that the good woman put herself in the way to conceive, even if she had to send her husband away from her to a Berlin Congress in order to accomplish the result. As a proof of the efficacy of this treatment, he cited eleven cases in the families of his immediate medical friends in Philadelphia, in which just such treatment effected a cure of retroversion in each and every case. He ended his profound observation by advising twins as a treatment for all misplacements of the uterus. The applause which followed his scientific remarks almost convinced me that he must have struck the keynote of the whole subject, and that in the future my patients with misplacements would have to seek conception or forever go uncured.

At this point a member of the Section, of an acrobatic turn of mind, suggested that we should advise our women with retrodisplacements of the uterus, to go on all fours. If this should prove to be successful, what an argument against the evolution of man it would be!

Goldspohn here shot in a short argument in favor of Alexander's operation for certain forms of retroversion.

Hall of Cincinnati condemned *in toto* Alexander's operation, because the operation, when done by *other* operators, was a frequent cause of inguinal hernia.

Our temporary Secretary then astonished us all and upset our already confused ideas, by stating that the uterus did not have any normal position; that it just existed anywhere in the pelvis that was not occupied by feces in the bowel or urine in the bladder; that it was retroverted when the bladder was full and the bowel was empty; that it was anteverted when the bowel was full and the bladder was empty; and I am still wondering what becomes of it when both bladder and rectum are full at the same time. The logical conclusion of this reasoning, I should think, would be that the uterus should be removed from the body in order that the rectum and bladder might perform their normal functions at the same time. If the speaker wished to convey that idea, however, by his argument, he did not state it in so many words. We were left to draw our own conclusions the best we might, and to treat misplacements in our own way, if we were fortunate enough to catch the uterus in its numerous excursions about the lower part of the abdomen.

Then Newman got into the discussion long enough to advocate Alexander's operation in proper cases; that it cured hernias instead of making them; and those of us who had been driven to confusion by the Secretary's remarks, discovered by Dr. Newman's drawings on the blackboard that the uterus could always be found and drawn back from its excursions about the body, by pulling out one of the round ligaments.

¹ Dr. Clarke's article having been previously published elsewhere, is not reproduced.

Pessaries, in this discussion, were praised and condemned with equal fervor by equally eminent men.

Seriously, what does all this diversity of opinion mean? It means that this subject of displacements of the uterus is as broad as our specialty. It means that displacements of the uterus may be the result of many different causes. It means that it may be caused by hypertrophy in one case; that it may be caused by hypertrophy in another case; that it may be caused by *laceration* of the vaginal outlet in one case, that it may be caused by *relaxation* of the vaginal outlet in another; that the sacro-uterine ligaments through trauma or subinvolution may be the cause; that relaxation of the round ligaments through trauma or subinvolution may be the cause; that inflammation in the uterus or its adnexa may be the cause; that tumors, peritonitis, abnormally distended bowels, abnormally distended bladder, obstructed portal circulation, weak heart, poor blood, weak muscles, improper dress, poor food, all have determining influences in causing displacements of the uterus. It also means that no one form of treatment will cure displacements. It means that some of our patients require operations; that some of them require treatment; that some of them should conceive and nurse their offspring; that some of them should cease from excessive sexual indulgence; that some of them should be relieved of the strain of motherhood. It means that some of our patients should receive pelvic massage, postural treatment with supporting and depleting tampons; that they should be fed, their clothes regulated, their habits changed. It means that occasionally we should remove offending and diseased appendages; that we should remove tumors, and in suitable cases we should reinforce the natural supports by temporary or permanent artificial ones; that we should build perinei, repair cervices, lengthen the anterior vaginal wall; we should even do the ventral fixation operation, or the much-abused Alexander operation. Pessaries should be employed with intelligence, patients should be put at rest, others should be exercised.

Once for all, no scientific gynecologist can have a routine treatment for displacements. He should have many routine treatments for them, and each of these treatments subject to variation with each new patient.

The man who condemns, *in toto*, Alexander's operation, pessaries, ventral fixation, restoration of the perineum, amputation of the cervix, lengthening of the anterior vaginal wall, pelvic massage, postural treatments, any one of them for occasional means of cure of displacements of the uterus, is not, in my opinion, an all-round gynecologist. And, if you will apply that test to every gynecologist you know, you will find the successful and eminent ones practicing them in direct proportion to his eminence and success as a *gynecologist*.

Under the long list of remedies, medical, mechanical and surgical, which influence beneficially retrodisplacements of the uterus, I wish to single out and speak briefly on two, viz., Alexander's operation and ventral fixation. The men who condemn the Alexander operation are the men who have not done the operation a sufficient number of times to learn of its advantages and to have learned by experience its contraindications. The Alexander operation is one of the most difficult and delicate procedures in surgery. There are three stages which a surgeon must successfully encounter and overcome before he

can practice it with success and proper conservatism. 1. He must learn that a great deal of unfounded prejudice exists in the minds of those who are ignorant concerning it, which, when it is duly sifted, will be found to arise from lack of actual personal experience with it. 2. He must spend a long apprenticeship in learning how to do the operation properly. 3. He must learn to discriminate carefully in the selection of his cases in the first enthusiasm of having learned to overcome the mechanical difficulties of the operation. I would not expect a man to utter a very valuable opinion on the subject of the Alexander operation who has not done, personally, at least one hundred cases. I would never expect to hear the operation condemned, in any particular, by a surgeon who has had that experience. He would invariably tell you that it is the rarest thing in the world for a hernia to result from it. He would almost invariably tell you that that erroneous opinion about the operation is usually disseminated by some busy surgeon who has not time to do refined plastic work, and whose only experience with it is the waiting for a hernia of this kind to turn up, on which he may operate.

This operation has but a small range of usefulness. That range is definite however, and most important. It is indicated in cases of retroversion without adhesions, without fixations, on account of atrophy; in uteri without diseased appendages. Inflammatory or cystic conditions in the pelvis, outside of the uterus, are a positive contraindication to the operation. The operation should not be performed in cases of prolapse of the uterus unless a concomitant operation, previously or at the same sitting, will restore the supports. The round ligaments are not constant supports; they are guys, the function of which is to exert an occasional restraining influence in preventing the uterus from being thrown, by unexpected jars or violence, into a position so that the intra-abdominal pressure will exert its influence in front of the crest of the fundus, instead of in the natural position posterior to its crest. They restrain the uterus from getting into retroversion, they have little influence after it once gets into extreme retroversion.

While there are many methods of doing the Alexander operation, the technique which will fix the round ligament successfully without burying the permanent sutures, in my experience, is the most satisfactory. I shorten and fix the ligaments by tying them together in a hard knot beneath the skin, fat and superficial fascie, on the strong structures of the conjoined tendon over the symphysis pubis. The wound is closed, including the external ring, by silk-worm gut sutures through the skin, which are removed in ten days.

Ventral fixation is not an operation which should be condemned without a hearing. Its range of usefulness, too, is limited, but definite.

I seldom do the operation, unless the condition of the patient is such that future child-bearing is out of the question. I would not favor opening the abdomen for the specific purpose of fixing the uterus to the abdominal wall. I should limit the operation to cases of strong peritoneal adhesions, in which the appendages must be sacrificed on account of disease. To women near the menopause, or whose matrimonial prospects were *nil*, in cases of retroversion complicated with ovarian tumors, or other pelvic conditions demanding a laparotomy. I fear to fix the uterus in

cases in which pregnancy is possible or probable. This is because of the peculiar technique which I adopt. I perform an operation which requires no permanent buried sutures. I perform an operation in which there is no question about the permanency of the result.

The operation I refer to is that first described by George R. Fowler of the New York Polyclinic in the *New York Record*, Oct. 5, 1895. Briefly, it consists in suspending the uterus on a strip of the peritoneal tissue taken from one side of the abdominal wound, with attachment left at the lower angle of the wound above the bladder. This strip also includes the urachus, if it is present. This is accomplished by transfixing the posterior surface of the uterus, just back of the crest, to an extent of one cm. and to the depth of two mm., with a Cleveland ligature carrier, grasping the strip of tissue and drawing it through from the front, pushing the uterus well forward on the new ligament, temporarily fixing the uterus with a catgut suture and finally burying the upper and free end of the ligament in the abdominal incision in process of closing it. This makes a permanent and firm fixation, without buried permanent sutures, and without being obliged to depend on uncertain peritoneal adhesions for the success of the operation.

ULTIMATE RESULTS OF ELECTRICITY IN FIBROID TUMORS.

Presented in the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY G. BETTON MASSEY, M.D.

PHILADELPHIA.

A physician recently asked me the question if there really was any value in the electric treatment of fibroid tumors of the uterus. Being a general practitioner unfamiliar with the subject itself, and yet not entirely unfamiliar with my well-known position on this question, I was somewhat taken aback, as the expression is, at the assumption that my private views could differ from my public statements, and was most emphatic in my endorsement of published views. Subsequent reflection convinced me, however, that his question was a natural one and intended to elicit an expression of these esoteric views of our work which we sometimes indulge in to intimate professional friends, and which so happily govern the deliberate work of many men who are commonly thought too enthusiastic and over-professional. Taking for granted that those interested in hearing this short paper are in the same confidentially inquiring mood I shall endeavor to present a truly esoteric view of this question, as it appears to me at the present time, and am the more strongly impelled to do so from recollections of many frank conversations with my surgical colleagues when sending me patients whose relationship to themselves was such as to cause them to take an esoteric view of their own work.

And the difficulties in presenting this deliberately critical view of the Apostoli treatment are by no means inconsiderable. If the tumor were on the outside of the body, as in the case of skin tumors, carcinoma, etc., the question of electric treatment would be purely one of electric engineering, for there is no form of moisture-containing growth on the outside of the body that can not be reduced, at one sitting, to its

inorganic elements of naked atoms of carbon, nitrogen, oxygen, chlorine, etc., without the loss of a drop of blood external to the tumor. But this can not for obvious reasons be done safely within the interior of the body. The electrophysics of the Apostoli treatment are not a destructive electrolysis of the growth so much as the use of sufficient current to change the biochemic processes on which the existence of the growth depends, and to stimulate the physiologic resistance of the surrounding structures to an absorption of the redundant tissues. The question of the adaptability of a given tumor to this treatment is largely a question of the vital conditions around and within the tumor therefore, and is only capable of being determined in the light of experience. But it should not be overlooked that this careful selection to ensure best results applies almost entirely to the question of the anatomic cure. Nearly all uterine fibroids, mainly except the cystic and subperitoneal varieties, are made better by electric treatment. But it is interesting to know in how many cases this improvement is permanent and sufficient to be satisfactory to the patient and her friends. To determine this point with accuracy I made, some months ago, a special inquiry into the after-history of cases treated by myself. The facts concerning seventy-one cases of the intra-mural and interstitial varieties were thus ascertained, and as these are the varieties regarded as best adapted to the Apostoli treatment the results of the inquiry were most interesting. Of these seventy-one cases I ascertained, personally, that the tumor and all symptoms had disappeared by absorption in five cases. In seven cases the patients themselves reported a disappearance of the tumors with all symptoms. That made twelve anatomic and symptomatic cures, five of which were verified. Of the remainder, twenty-nine had been greatly reduced in size and symptomatically cured; and seven had been failures to effect any change. This gives a rate of 90 per cent. of practical successes and 10 per cent. of failures.

All the cases with arrested and slightly reduced growths were comfortable and satisfied except two, who still found the remaining portion of the tumor a discomfort.

Seven cases had been operated upon, all but one of which were in the list of failures to be helped by electricity. The one case that was operated upon after satisfactory results had been attained by electricity was a very ignorant dispensary patient who accidentally fell into the hands of a surgeon who was unaware of my work and interest in her case. The result was fatal in this case and in two others out of the seven operated upon. In none of these cases was the operation that was finally performed made more dangerous or difficult by the previous electric treatment.

These were practically ultimate results of electric treatment, for the reports were obtained at periods varying from three to nine years after the cessation of treatment.

Viewed as a whole it is evident that a method that yields 90 per cent. of practical successes without the risk of an operation, and with the retention of all the organs, is one worthy of more extended application, particularly when the 10 per cent. of failures merely left this percentage of cases where they were at in the beginning and did not prejudice other forms of treatment.

Aside from the results obtained in the arrest and reduction of these growths it is a most significant fact

that symptomatic cures were almost invariably secured, for in some of the failures enumerated in the list published in the "Transactions of the American Electro-Therapeutic Association," the symptoms were either ameliorated or they were growths whose chief symptoms were their bulk alone. That most troublesome symptom, hemorrhage, was invariably relieved, and more quickly since the use of mercurialized zinc electrodes, possibly due to the same interstitial influence of the cataphoric diffusion of nascent oxychlorid of mercury which I announce in another Section of this meeting as a new specific for cancer.

As to the varieties of fibroid tumors easiest affected by carefully conducted electric treatment, it has already been said that, with some exceptions, it is practically restricted to the intramural and interstitial forms. Since all small tumors are of either of these varieties, it may be said that, in their earlier stages, all fibroids are amenable to electricity, hence the early recognition and electric treatment of small tumors will not only arrest their growth but preserve in its entirety the sexual and other pelvic functions of the patient. Of the larger intramural and interstitial tumors those are most amenable that have multiple foci of growth, the large, smooth, monocentric growths being least amenable.

As to the comparative value of the method over any other treatment in the cases adapted to it, it is hardly necessary for me to say anything, for of the risks and final results in successful cases of its chief alternative, hysterectomy, others are better judges. I may, however, say that no treatment is better that does not result in 90 per cent. of the cases being returned to their families and society as whole women, as these patients have been.

DISCUSSION.

Dr. A. G. BANKER of Columbus, Ind. In electricity for the treatment of fibroid tumors we have a valuable agent, and if the practitioner has perseverance and can maintain the confidence of his patients he will effect a cure in a large number of cases. He will have no ventral hernias; no subsequent risk of constriction of the bowels from adhesions following operations, and he will satisfy his patients. My experience with this agent in the treatment of these growths has been limited in country practice. I have treated about twenty patients who had fibroid tumors of the uterus. Some of them had previously consulted experienced abdominal surgeons, who had given an unfavorable opinion, but the patients after receiving electric treatment are perfectly well today. In one case the growth was quite rapid. The patient had been previously seen by a noted gynecologist who decided that an operation would mean certain death. She had been in bed for several months. Her feet and legs were greatly swollen. After beginning the electricity, which was kept up for some time, the tumor was materially reduced in size, and menstruation, which had been previously irregular, became normal from the commencement of the treatment. She is now practically well and no one would suspect that she had ever had a fibroid.

Of the twenty cases I have treated, in seven the fibroid tumors were quite large, and in none of them can there be found, at the present time, any evidence of the tumors.

COMPARISON BETWEEN TYPHOID FEVER OF INFANTS AND CHILDREN AND THAT OF ADULTS.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY H. A. FAIRBAIRN, M.D.

ATTENDING PHYSICIAN TO ST. JOHN'S HOSPITAL,
BROOKLYN, N. Y.

Typhoid fever occurs so rarely in very young infants and children and, as a rule, pursues such a short and

mild course, that many have denied that it is ever seen in infants under two years of age, and have maintained that it seldom occurs in those younger than five years. Systematic observations have altered these views. Pathologic investigations have shown that no time of life is exempt from the disease, although they have strengthened the opinion that it is very rare below the age of two years. The child is subject to every other form of contagion and removed from the sources of this only by reason of special care in diet. This may explain its continued absence from large institutions devoted to the care of children. It argues strongly in favor of prophylactic measures.

The study of the disease as it occurs in the child is of importance, as it appears to throw special light on some of its features and to yield indications for treatment.

The problem presented is, Why should the bacillus of typhoid produce a disturbance of shorter duration and less severity at one period of life than at a more advanced?

In considering this question let us first examine the pathology, then the symptoms and treatment. All writers on this subject agree that there is redness and swelling of Peyer's patches, the solitary follicles and the mesenteric lymph nodes, and accompanying these are the evidences of a catarrhal enteritis. They agree, moreover, in the statement that these lesions found in the intestinal tract are very much milder than in the adult, that ulceration is rare, and that when it does occur it is not extensive or deep and seldom goes on to perforation. The spleen is enlarged. The degeneration in the tissues of the heart, kidneys and liver is less frequent and less marked than in the adult. It would seem from this that there was some cause besides the typhoid fever poison operating in the adult to intensify these lesions, or some element of protection for the very young child against the dangerous processes so often prominent in the adult that they have been named as a part of the natural history of the disease. What is this?

Let us proceed a step farther and inquire into the symptoms, to see if they differ also. The statement is frequently made that typhoid fever begins abruptly in very young children, that it is not characterized by the prodromal symptoms found in the adult. My limited experience does not warrant a denial of this statement, but I am led to believe that they do exist and escape notice. It is a characteristic of small children to hide their minor discomforts from fear of the doctor or of confinement to bed. Careful inquiry will often show sickness of some days' continuance, which the parents pronounce sudden. The little ones will keep at their play until their strength gives out. How often do we see this in some of the other diseases! The prodromes of this disease are often neglected by the adult.

The earlier individual symptoms differ but little from those of the adult. There is a wider range of temperature, the marked exacerbations having given origin to the name remittent. But extended observation has shown that this is a characteristic of all fevers occurring in young children. The abdominal symptoms are usually moderate. There is the splenic enlargement, the loss of flesh and strength. There is the bronchitis also. The nervous symptoms, cerebral in character, as a rule intensified by high temperature, are present. There is indolent ulceration of the mouth as in the adult, at times. The importance of observ-

ing this has been pointed out lately. I have seen and noted it in the adult and child. Attention has been called to it as an index of the progress of the intestinal lesions. The statement has been made by good authority that its progress is in keeping with that of the latter lesions. This seemed to be so in an adult case under my care in April last.

As in the adult, we must look at the picture as a whole to arrive at a diagnosis. The eruption, bowel symptoms, visceral symptoms and fever, when combined form a group found in no other disease. To make our diagnosis logical, we must state the differentia. We will exclude remittent fever from the fact that the temperature will not show the same regularity. There will not be the same gastric irritability and there will not be the same remission of symptoms as in remittent fever. There is a constipation in remittent fever which is often difficult to remove, whereas in typhoid the mildest laxatives are often all that are required, and they frequently do more than they are intended to, or in other words, the bowel is liable to be irritable. The eruption offers another point of difference.

We will exclude meningitis by the mild intermittent delirium, the regularity of the pulse and respiration, as compared with the irregular pulse and sighing respiration found in inflammation in the meninges. Then, in the latter disease would be found signs of localized convulsions or paralysis and strabismus. From ileocolitis, at times, there is difficulty in making an exclusion. In a late work by a high authority, this question is dismissed in the following way: That the disease, typhoid, does not often arise in infancy (we want farther light on that subject), and that it is slower in invasion; but unfortunately, the same author remarks in his article on typhoid that a sudden is quite as frequent as an insidious invasion. Surely this does not throw much light on the subject. Again, he names the absence of eruption, but shows also that this symptom is often absent in typhoid. Disinfection of excrement will be in order in severe and protracted cases until the bacteriologist gives us more ready and certain means of diagnosis.

Pleurisy, pneumonia and otitis media may at times simulate this disease. Careful physical examination will solve the problem.

Elsner's preparation of cultures on a proper medium to exclude the coli communis bacillus is complicated and not always successful. Widal's test, the clumping together of the bacilli of a pure culture of the typhoid bacillus in the presence of blood serum drawn from a patient with typhoid, has been shown variable. It served well in a number of cases in which it was used in St. John's Hospital, Brooklyn.

Ehrlich's "diazo-reaction" occurs in the urine in other diseases, and in health at times. It is therefore not positive.

One turns from this question of positive diagnosis with the feeling that the means for arriving at it, at an early period of the disease, are wanting, and is inclined to believe that it eventually, as the diagnosis of diphtheria, must be solved by the bacteriologist.

The duration of the disease in the young child is from eight to fourteen or nineteen days. This is variously stated, but the average duration is shorter than in the adult and the mortality very small. We find therefore, as we proceed, that accompanying lesions are less pronounced and less severe in young

children than in the adult, systemic disturbances are milder and less apt to terminate fatally and of much shorter duration. Is it not reasonable to suppose, in the light of these facts, that the later stages of adult typhoid are due to inflammatory and ulcerative lesions in the bowel, and that the degeneration of heart and kidneys is due to nutrition thus interfered with?

The reason for this difference in the character of the intestinal lesions, the reason for their being less marked and less deep, has been stated by some to be the unirritating diet usually taken by the very young. This looks reasonable. And does not this condition of affairs in the intestinal tract offer an explanation of the shorter duration of the disease and the lower death rate? I have been led to believe, for some years, from an experience in hospital and private practice, that the range of temperature in the third and fourth weeks in adult typhoid was due not so much to the typhoid poison *per se* as to the inflamed and ulcerated condition of the intestine. Modern methods of treatment have been directed to these conditions and by some aimed at the bacillus in the intestine, or in other words, antiseptic methods have been employed, and although they may have missed the bacillus typhosus, careful observers have maintained that they have done much toward alleviating the pathologic conditions found in the form of ulcers and general catarrhal enteritis. The course of adult typhoid seems to have been rendered milder at the same time. I have failed to meet an experienced practitioner in late years who does not allow that the classic cases of this disease with their intense intestinal symptoms are rare. Better methods of administering food and more rational medication offer an explanation.

The use of intestinal antiseptics in typhoid has found its able opponents, although one of them allows that there are few symptoms to be dreaded more than diarrhea, "and that cases which are constipated or in which the bowels are regular rarely die." They have maintained, and correctly I think, that it is impossible to attack a bacillus which, like the typhosus, lies buried deeply, by a remedy applied to the surface of the membrane. They have maintained also that no measures have been devised to render the bowel aseptic, forgetting possibly what regulation of diet alone has done toward that end. I have subscribed to the use of this line of remedies on the ground that it meets the pathologic conditions in the intestine, during the progress of which the greatest danger seems to be met in the latter stage of this disease. It may not render the bowel aseptic, but a long line of testimony gives strong ground for the belief that it renders it less septic, and that is frequently as far as the surgeon goes with his treatment of wounds, and he congratulates himself that he has made an advance. He does not fold his hands and desist in the attempt because bacteriologic examination tells him his work is incomplete. As well might we say to the advocates of the Brand treatment alone that it does not remove the element of temperature entirely, and for that reason is useless.

Methods of treatment which receive the support of some of our best observers deserve trial, or at least careful recognition, especially where they are directed to a lesion which is prominent in the cause of death, and most of all when clinical experience seems to point to their efficacy. There is very general agreement as to its use in cases of ordinary enteritis and

colitis. What should be the objection to it in this disease, where the same condition of affairs is presented arising from a different origin? It would seem that the objection arose from a misconception as to the object aimed at. The necessity would appear to exist to remove or disinfect products of inflammation as in the case of any other mucous membrane, and it would be rational to expect the same amelioration of symptoms of constitutional disturbance as follows the use of these agents in inflammation of membranes generally. It has become a well-recognized fact that where the resistance of the tissues has been lowered bacteria otherwise saprophytic become virulent. Such bacteria are found in the intestine. If they are not removed or rendered innocuous it is reasonable to suppose that they will create disturbance, as they do in other membranes under similar conditions. The obstetrician's investigation with regard to the action of the streptococcus in a healthy woman gives a case in point. He exhibits it to us as saprophyte under ordinary circumstances, and as virulent as any special germ when the vitality of the tissues is lowered. This brings us to the point I wish to emphasize, and it is this: In typhoid fever we have presented to us a complex condition.

The different methods of treatment which have been presented to us from time to time appear to reflect this view. The excursions made by the therapeutic pendulum have been large. We have had treatment aimed at temperature, treatment with elimination as its main point, treatment directed to the destruction of the bacillus and the protection of the intestinal tract. They have all had their advocates, armed with temperature charts and histories which, to say the least, have appeared enticing as far as they go.

It is a well-founded principle, however, that in the treatment of disease experience of a small number of cases will not establish a criterion. Experience has taught reliance upon methods established by long and extensive use only.

Let us try to gather together points of common agreement in this department. The necessity for controlling the temperature is one. Of the means to this end, the application of water of variable temperature to the surface of the body or to the intestine by high enemata, has received most favor. The sponging of the surface, the coil, the wet pack, or the systematic cold bath known as the Brand treatment, are the various methods. Whatever objection we may have to offer to the form in which it is applied, I think we will allow that this general principle is the best. There is an additional reason for its use. It acts as a tonic to the nervous system and through the sympathetic favorably affects the general nutrition. The use of antipyretic drugs has its advocates, but it is always accompanied by the warning to watch the heart, showing that there is danger in it. We may say with safety, I think, that for steady and prolonged use water has the most advocates.

There is a general agreement as to diet, that it should be milk or food in the liquid form. That it should be moderate in quantity. That it should not be given too often, that the introduction of one portion of food into the stomach before it has had time to digest a previous may be avoided. The warning is general, that if we do not obey these directions we will produce disorder of the stomach and intestine and aggravate the lesions in the latter. In other words, while all may not advocate the use of so-called intes-

tinal antiseptics, they take all the means in their power, outside of these agents, to put the digestive organs in a position to use their own antiseptics; or, in other words, they allow that the intestine must be guarded.

Then there has been proposed a line of treatment called the eliminative. Although not generally accepted, it has had the effect of calling attention to the excretory functions, to see that they are properly performed.

Then there is the antiseptic treatment. Various drugs have been employed in this line with two avowed ends in view; one of which is the destruction of the bacillus typhosus, and the other the limitation of the ulcerative and inflammatory changes in the intestine. While there is not evidence to support the first claim, the second is rational and has received the support of too many able observers to be gainsaid. They do not render the bowel aseptic, but they appear to render it less septic and control the symptoms in the latter stages. Calomel, salophen, carbonate of guaiacol and the bismuth salts have found favor with me. Turpentine, the time-honored drug, has surely done much for me in cases marked by intestinal involvement as indicated by tympanites, tenderness, and frequent dark and offensive stools accompanied with marked constitutional symptoms.

I have found no drug equal to opium to control marked nervous disturbances, and that statement is backed by the experience of many.

There seems to be a very general consensus of opinion with regard to the use of strychnin to guard the heart's action, *i. e.*, that it holds the first place.

Alcohol in some form is esteemed by many.

The nose, mouth and pharynx should be cleansed carefully and frequently.

The fact that the specific bacillus is present in the urine as well as feces emphasizes the necessity for scrupulous care and disinfection to avoid contagion.

In adult typhoid fever it has been found that the period of greatest danger is during and toward the end of the third week, and that death rarely occurs before the fourteenth day. It has been found that the mortality among adults in this disease is not small. It has been found that, during and after the third week, the changes in the intestinal tract are prominent factors in the disease.

In the case of children, on the other hand, below five years, it has been found that the disease rarely goes beyond the fourteenth or nineteenth day. It has been found that the mortality is very small, that the changes in the intestine are as a rule mild, and the degeneration in the tissues of the heart and kidneys less, showing better nutrition. Also, in the last few years, testimony points to a milder form of the disease in adults, a shorter duration and smaller mortality, and during this period the intestine has received more careful treatment. It is fair to assume, in the light of these facts, that the treatment and result bear a relation one to the other. It seems fair to suggest that the care of the intestinal lesions should play as prominent a part in our treatment as the holding of the temperature within bounds by either the Brand treatment or a modification of it. While the latter will tend to lessen the lowering of the vitality of the tissues, the former will care for and protect the intestinal tract from new invasions and enable it the better to perform its important work.

Appendicitis, like typhoid, is said to be rare at the

two extremes of life. There is a growing belief that the former, like the latter, is due to the invasion of bacteria. The unirritating diet of early childhood has been offered as an explanation for the milder intestinal involvement in typhoid. May not the same explanation hold in the aged who have learned to be cautious in diet, and may it not hold in the case of appendicitis in both? Both extremes of life are subject to febrile and intestinal disturbances. Is it not fair to suppose that the course of the diseases, appendicitis and typhoid, may expend itself with mild manifestations only and go unrecognized, the intestinal tract, better cared for and therefore in better condition, not offering the opportunity for development of the more serious lesions found in these diseases?

The following table is a record of my personal experience in the treatment of typhoid fever:

	Private.	Hospital.	Total.	Deaths.
Under 15 years of age	13	5	18	0
Over 15 years of age	41	20	61	5
Total	54	25	79	5

Mortality 6.3 per cent.

Youngest child 14 months; next 23 months; between the ages of 2 and 3 years, 2; between the ages of 4 and 5 years, 6; between the ages of 7 and 15 years, 8; between the ages of 15 and 20 years, 17; between the ages of 20 and 30 years, 32; between the ages of 30 and 40 years, 7; between the ages of 40 and 50 years, 5.

249 McDonough Street.

MENINGITIS A COMPLICATION OF MEASLES.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY THOMAS W. HARVEY, M.D.

ORANGE, N. J.

The relative rareness of this complication is my reason for bringing it to your consideration. I find that very few practitioners have met this condition after measles. The literature of the subject presents few recorded cases and many writers do not mention it as one of the possible complications. Others relegate all forms of meningitis following measles to the tubercular class. There are at least a dozen of the most commonly used authors on general medicine who do not mention this complication of measles (Flint, Aitken, Trousseau, Ringer in Reynolds' System, Bartholow, Watson, Neimeyer, Tanner, Barlow, Wood Struempell, Wood and Fitz).

Of the writers on diseases of children, there are at least twenty who make no mention of such a complication (Conden, Dewees, Ellis, Eustace Smith, Evan-son and Maunsell, West, Day, Billard, Stewart, Stevens, Duncan, Donkin, Churchill, Cadet-de-Casse-court, Bouchut, Ashby and Wright, Tanner, Starr, F. E. Waxham in Keating's Cyclopedia).

Dr. Potts, in the *Jahrb. f. Kinderheilkunde*, 1880, reports 844 cases of measles and no complication of meningitis.

Dr. Chadburne, in *Journal of Obstetrics*, reports 300 cases, no meningitis.

Dr. Bernardy, in *Annals of Gyn. and Ped.*, 1893, reports 160 cases, no meningitis.

J. E. Atkinson, in "Wood's Reference Handbook," makes no mention of meningitis as a complication, except incidentally that convulsions may occur in measles.

Vogel, "Diseases of Children," translated by Raphael, 1870, says "meningitis occurs so rarely as to make doubtful the connection."

Brothers, *Archives of Pediatrics* (U. S.), 1893, mentions one case of fatal meningitis complicating measles.

J. Lewis Smith says, "there are other complications of measles of less frequent occurrence, among which may be mentioned congestion of the brain, with or without serious effusion."

Loomis says, "secondary meningitis not infrequently occurs as a complication of measles. When it does occur, it is developed during the period in which the eruption is disappearing. It is more likely to occur in this disease than in scarlet fever." This last statement certainly does not agree with the experience of most practitioners, and the first statement is not entirely in accord with other writers on this subject.

Meigs and Pepper mention one case of meningitis observed in a series of 314 cases of measles. The patient had fatal cerebral symptoms, just as the rash was disappearing, due either to congestion of the brain or to uremia. On the fifth day he was dull, heavy, apathetic, soon comatose, with irregular convulsions and arms contracted.

Pepper, in "Text-book of Medicine," says "true meningitis is rare; strabismus, tetanus, contractures, cataleptic states and maniacal attacks have been observed.

Thomas, in *Ziemssen's Cyclopedia of Practical Medicine*, vol. ii, p. 97, says, "Measles differs from scarlet fever in this, that affections of other organs not essentially complicated in the process of measles, especially inflammation of important internal organs, of serous membranes and joints, are tolerably rare; yet now and then affections of various kinds occur, especially inflammations during the eruptive stage. They are mostly without influence on the exanthem, but effect alterations in the course of the fever and prevent rapid defervescence of the measles. Conspicuous among the affections of the nervous system are meningitis, meningitis with tetanus and cataleptic rigidity of the limbs, spinal meningitis, hyperemia of the brain, menigo-encephalitis and encephalitis."

Hench, Sydenham's translation, 1887, says, "The least frequent complications are connected with the nervous system." He mentions a case of a child 3 years old, when, in the middle of the second week after eruption, drowsiness set in suddenly, out of which the child could hardly be aroused. There was rigid contracture of the neck, moderate fever and irregular pulse. The treatment was leeches, ice bag, calomel and mercurial inunction. The patient recovered. He thinks that some of the cases collected by Thonias in Ziemssen were coincidences for which the measles was not to blame. On the other hand, a case of diffuse myelitis published by Barlow ("Med. Chirurgical Transactions," Vol. 70, 1887), which ended fatally on the eleventh day of the measles, was certainly directly due to the disease. This case seems to have become a classic, as it is referred to by many of the French and German writers on the subject; it was characterized by the same muscular rigidity and contractures of the limbs that have been noted by so many observers, and which were present in the case I mention hereinafter.

Rilliet and Barthez mention a case complicating measles, where the symptoms of diffuse myelitis were

present, paraplegia, abolition of patellar reflex, paralysis of bladder and rectum, partial paralysis of the arms, difficulty of speech, asphyxia and death.

Baginsky mentions tetanic contractures of the lower extremities, sopor, strabismus and convulsions as symptoms complicating a case of measles.

H. B. Atkyn. *Medical Times*, 1891, reports a case of measles and catarrhal pneumonia. In the second week there was partial stupor and turning to the right side, paralysis of right eyelid, left arm and leg, anesthesia, contracted pupils, slight elevation of temperature, irregular pulse, Cheyne-Stokes respiration and contractures. There was very gradual improvement and a paralysis lasting six months.

Tobeitz, in the *Jahrb. f. Kinderheilkunde*, 1887, reports a case where a girl 2 years old, at the end of one week showed the following symptoms: Strabismus, loss of memory, paralysis, sleeplessness and delirium; after two months paralysis of the lower extremities with distinct inco-ordination, articulation difficult, tendon and other reflexes normal, pupils normal, temperature always normal, no improvement for four months, when she left the hospital.

Prof. Crozer Griffith, *Archives of Pediatrics*, 1893, reports a case of measles with abnormal symptoms of cerebral irritation. On the seventh day the patient complained of nausea, stiffness and retraction of the neck, severe headache and vomiting, tremor of hands so that he could not hold anything, grinding of teeth, difficult articulation; in a few days tremors over the whole body, including tongue. At the end of three weeks the patient gradually recovered and the temperature during the whole time was subnormal with the exception of one day when it was 38.8 degrees C.

Dr. Buttner of Orange, N. J., in a personal communication, reports the following case: "A German girl, 11 years old, passed through an entirely regular attack of measles and had apparently fully recovered when, on the tenth day after the appearance of the eruption, she had an attack of vomiting which was repeated several times during the next twenty-four hours. At the same time the temperature rose to 103 degrees F. She was very restless and complained of severe frontal headache. From this time until death she was drowsy, answering no questions except on great urging; both pupils had become by this time dilated and she had two convulsions. After the last one her left arm became paralyzed; she also passed the urine involuntary; death came on the sixth day in coma. Postmortem examination showed the dura mater much injected with the sinuses full of coagulated blood; on opening the dura, the convex surfaces of both hemispheres were covered with a yellowish layer of pus and lymph. There was no signs of tuberculosis."

My own patient was a Cuban girl of 10 years, who on the sixth day of her measles developed serious nervous symptoms; she had a low fever, was unconscious for five weeks and had muscular tremors, rigidity and contractures, all of which gradually passed away, ending in complete recovery. The history is as follows:

Miss C. S., Cuban, aged 10 years, has never menstruated; previous health good; parents living and healthy; history of tuberculosis in mother's family, none in her father's.

July 10, 1895, she commenced to have an acute attack of fever with catarrhal symptoms followed by an eruption characteristic of measles.

July 13, with the appearance of the eruption there was a diminution of the fever, so that on July 14 she was very well.

On the fifth day (July 15) the rash was beginning to fade, but she had a sharp rise of fever. On that day she still had some catarrhal symptoms and the rash was still well defined. She was very constipated and complained of a severe pain in the back of her neck. A cathartic and a mild febrifuge was ordered.

The sixth day the temperature was normal; the eruption had largely disappeared; the patient was very nervous, restless; complained of the pain in the back of her neck and preferred the room to be dark, although there was no well-marked photophobia. She had entire loss of appetite. The cathartic had not acted and there was marked diminution of the urine.

These symptoms showed little change on the next day except increasing stupor.

July 18, the eighth day, she was unconscious, although she could be aroused and made to answer questions in monosyllables. Her former restlessness and nervousness had disappeared. The axillary temperature was 99 degrees F. The urine gave no indication of kidney insufficiency or congestion. The rash had entirely disappeared, as had also the catarrhal symptoms. The pupils reacted sluggishly to the light, and she would respond to tickling. She lay with her eyes open and vacant or closed and apparently sleeping; she would not voluntarily move a muscle.

From this date, the eighth day, until August 20, *i. e.*, for thirty-three days, she lay entirely unconscious. Her temperature on the afternoon of July 18 rose to 101 degrees F., rectal: from then until August 7, nineteen days, her temperature varied between 97 and 99 degrees F., taken every two hours, in the rectum.

August 7, the afternoon temperature was 100 degrees F.

August 8, morning, 98.4; afternoon, 100.4 degrees.

August 9, morning, 100.4; afternoon, 100.8 degrees.

August 10, morning, 100; afternoon, 103 degrees.

August 11, morning, 99.4; afternoon, 101.2 degrees.

August 12, morning, 98.8; afternoon, 99.6 degrees.

August 13, morning, 98.8; afternoon, 99.6 degrees.

The temperature did not rise again until August 29, the forty-first day, when the afternoon temperature was 100.8 degrees, after which it did not again rise above 99.5 degrees and by September 7, the fiftieth day, was normal all day long. The pulse rarely reached 100 per minute until August 9, when the rise of temperature was accompanied by a rise in the pulse rate. For a few days it was very irregular, varying from 100 to 120 until September 1, when it fell below 100 and subsequently varied from 80 to 90. It was impossible to arouse her during this long period, although it often seemed as if, when she lay with eyes open, coma vigil, there must be a certain amount of intelligence.

During the first two weeks of her unconsciousness there was little emaciation and little change in her muscular system beyond this, that while in the morning she would be relaxed, as the day wore on she would gradually stiffen, so that her limbs were bent with difficulty, her back would be rigid and there would be opisthotonos. She at no time had anything approaching a convulsion, but there were frequent muscular tremors affecting sometimes a part of a muscle, sometimes an entire muscle, and occasionally a group of muscles would twitch.

There was complete anesthesia of the skin except in the soles of the feet. She was deaf, and so far as we could tell, blind, although occasionally setting her up in bed or the disturbance necessary to feeding her or changing her clothing, would stimulate her to open her eyes. Light had little effect upon the pupils, but when the hand was brought near the brow she would quickly close her eyes. She passed her urine involuntarily and it was normal in appearance and quantity. Her bowels were moved involuntarily by suppository or enema assisted occasionally by a small dose of calomel. She would not swallow or make any motion to take food and was fed every two hours with five ounces of milk by pouring it spoonful by spoon-

ful into the mouth and stimulating the act of swallowing by pressing on the back of the tongue. In the later stages of the disease, when the patient had well marked trismus for some time, the act of feeding was accomplished with great difficulty.

After August 1, the fourteenth day, she began to emaciate very rapidly and contractures took place in many groups of muscles, beginning in the left arm, which was held in a position of over-extension and extreme pronation: the elbow could be bent only with the greatest difficulty.

Trismus and opisthotonos became more marked, the legs were gradually drawn up to the body and resisted all but the strongest efforts to straighten the knees, the hip joints never quite yielded to the efforts to straighten the thighs. Such attempts to straighten the limbs caused an expression of pain to pass over the patient's face and were evidently felt. The right arm did not become so completely rigid as the left. When the temperature dropped on the thirty-third day the patient became brighter, she would follow a movement with the eyes a little and would lie with her eyes open longer at a time.

From the thirty-sixth to the forty-third day there was again a slight rise of temperature for a few days; during this time she became brighter every day. She began to talk on the thirty-seventh day, at first only in monosyllables. On the forty-second day she put a sentence together. At this time she became very much excited, singing and chattering continually. After September 1 she calmed down and gradually began to recognize her friends and to call them by name, but she did not swallow of her own accord nor did she recognize the calls to urination and defecation until September 7.

The muscular rigidity and contractures passed off in the order in which they had come on. First, she began to move the head, then the neck, the right arm, the left and later the legs. It was several weeks before the muscular symptoms entirely disappeared.

As to the treatment: At first leeches and blisters were placed behind the ears and on the back of the neck. On July 19 the iodid of potassium was administered, beginning with five grains every two hours, increasing the dose gradually until July 31, when she was taking 25 grains every two hours or 300 grains a day. As symptoms of iodism began to present themselves the dose was rapidly decreased to 120 grains per day and the tinct. digitalis 2 minims every four hours, given with the iodid. Strychnin was given for about one week, but was stopped as the tetanic symptoms seemed to increase. August 20 the sodium iodid was substituted for the potassium, and strophanthus for digitalis. The iodid was given in 20 grain doses three times a day, with the addition of 2 minims of the strophanthus.

The question of diagnosis in this case was one not easily answered by those who saw the case regularly or who saw it in consultation occasionally. As the meningeal symptoms became more marked, the low and often subnormal temperature suggested tubercular meningitis, particularly because the attack followed measles.

The complete recovery without any permanent paralytic symptoms contradicts such a theory. The muscular tremors, tetanic symptoms, the contractures, the unconsciousness and the irregular fever are similar to the symptoms noted by other observers and justified us in considering the case as one of cerebro-spinal meningitis.

HYSTERIA IN CHILDREN.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES W. BURR, M.D.

PHILADELPHIA, PA.

The time is so short and the program so full of more important matter that I shall detain you but a little and, not attempting to be at all exhaustive, will simply sketch the histories of a few cases. This is my only excuse for offering a paper purely clinical and of value only in recalling to you the fact that hysteria is not a disease of women or adults alone, but may occur at any age and in either sex.

The first patient had pseudo-Pott's disease. She was 9 years of age, with nothing significant in her previous personal or family history. For some time before I saw her she had complained of pain along the spine, worse in shifting spots, coming on in attacks, and sometimes so severe as to cause long continued spells of weeping. The spine became slightly curved laterally and she walked with a limp and complained of great weakness in the legs at times. On examination she was found to be a fairly well nourished but distinctly neurotic child. There was apparently severe pain on light pressure over the spine, the point of greatest pain varying greatly from time to time, but if the pressure was increased, and at the same time the child's attention attracted to something else, all signs of pain disappeared. There was slight apparent lateral curvature, but it was only apparent, not real, due to attitude and nothing more. There was no rigidity of the muscles of the back either at rest or during movement. She walked with a slight limp and complained that her legs were weak and painful, but she rose from the ground without difficulty. The knee-jerks were normal. There was no anesthesia, no muscular wasting, no palsy of the bladder or rectum. Temperature remained normal. Vision was good and there was neither contraction nor reversal of the fields of vision. In this case the mimicry of caries of the spine by hysteria was so superficial that diagnosis was not difficult. Separation of the child from her family, strict confinement in bed and hospital control soon cured the attack.

Another child, A. B., female, 10 years old, had never had any serious illness, but had always been nervous, supersensitive and mentally too active. In January, 1894, she had an attack of influenza, from which she recovered completely, but during convalescence a hard, barking cough began. After a few days, the cough continuing and no fever having developed, she suddenly became delirious, saw visions of ugly men whom she talked to and about, showed horror and fear, seemed not to know her parents and became very dramatic. The attack lasted for several hours and recurred several times during the next two weeks. She was then brought to me and examination revealed the following condition: She was a healthy-looking, well developed child. Every few moments there was a long deep inspiration followed by a sudden explosive expiration, which by some use of the imagination might have been said to have resembled a bark. If the attention were occupied it ceased, but only for a time. It was not willed. It ceased during sleep, but often prevented sleep for hours. There were also irregular, choreiform, half purposive shrugging movements of the shoulders, and the facial muscles of expression were in constant action. The heart

and lungs were normal and the general nutrition good. The fields of vision were normal, the reflexes present and there was no anesthesia. Under treatment she soon recovered.

A girl 11 years of age presented an interesting combination of hysteria and organic joint disease. During convalescence from typhoid fever and after the temperature had permanently fallen to the normal, she began to complain of pain in both hips. Soon she ceased to move the legs and they became rigidly flexed upon the abdomen. On examination I found a stout, well nourished, bright and too sedate child. She was bedridden. The legs were flexed upon the thighs, the thighs upon the abdomen, and the knees pressed strongly against each other. No force permissible could overcome the contractures. All attempts at passive movement caused extreme pain. The patient could not move the legs at all. Sensation was normal. There was no atrophy. The knee-jerks could not be obtained, probably not because they were absent but on account of the contractures. There was no palsy of the bladder or rectum and no change in the fields of vision. Under ether all the contractures except that of the right hip relaxed, returning, however, with returning consciousness. It had been a question whether there was distinct organic joint disease, or whether it was all hysteria, or a mixture of both. The result solved the problem. All the contractures save that of the right hip rapidly passed away, and careful surgical examination proved there the existence of organic trouble. Doubtless this organic disease acted as an unconscious suggestion and so caused the hysteric outbreak.

Another case of hysteric contracture occurred in a girl 7 years of age. She has always been neurotic, selfish and unmanageable, and is the daughter of an hysteric mother and an overworked and unsuccessful father. One day, after a scolding, she said she could not walk because she could not put the right foot to the ground, but only the toes. The scared mother thought of course of palsy and petted where she had before abused, and the trouble became still worse. I saw the child a few days later. There was marked, apparent spasmodic clubfoot. She stood upon the toes and outer side of the right foot, the heel being drawn up from the ground and the muscles of the calf in rigid spasm. There were no other physical signs. Hysteria alone explains the case. No organic disease can cause a sudden clubfoot, without palsy, increased reflexes, muscular wasting, change in the electric reactions or alterations of sensibility. Medical neglect cured the patient in a few days.

More serious than any of the above is a case now under observation in which the question, still unsolved, is whether there is hysteria alone or complicating a tumor of the brain. A girl, 10 years old, several months ago had some acute fever from which she recovered in a few weeks. A short time afterward she began to complain of severe diffuse headache, constant and preventing sleep, and attacks of vomiting immediately or almost immediately after eating. A few weeks ago she suddenly became violent, seemed to have visual hallucinations, talked about seeing people and about men trying to murder her. The attack lasted a day and has not recurred. Later she began to stagger in walking, said her legs were weak, and finally could not walk at all. The amount of weakness in the legs has varied greatly, she sometimes being able to walk. On examination I found a well nour-

ished, bright child. While in bed she could move the legs well, without palsy and without ataxia, but as soon as she attempted to stand both appeared. The knee-jerks were normal. There was neither wasting nor anesthesia. The bladder and rectum were under complete control. Examination of the thoracic and abdominal organs was negative. The urine contained neither albumin, sugar nor casts. After sending her to the hospital, headache and vomiting ceased almost immediately and in a few days she could walk some, though she still staggered very much and could not stand at all with the feet close together. The palsy and ataxia varied much from day to day. This complex of symptoms might be hysteric, but ophthalmoscopic examination showed suspicious signs of a beginning optic neuritis, and a cerebellar tumor would also explain the case. The diagnosis must await events.

These cases, all too hastily sketched and leaving much of importance undescribed, are of interest as examples of hysteria in childhood. They show well the power of acute organic nervous or non-nervous disease in precipitating an hysteric outburst and the occasional impossibility of differential diagnosis between organic brain disease and hysteria. They illustrate the power of treatment, a subject too well known to need detailed attention. I have used the word cure several times. I wish it to be understood to refer only to the specific attack and not to the inherited predisposition. We usually cure not the hysteria but the attack. Hysteria in children, even when apparently transient and trifling, is in reality very serious, for it signifies inherent and often inherited nervous instability. These children need not only treatment for the attack, but most careful education of the will and the emotions, to save them in the future from suffering from hysteria.

SOME CAUSES OF CONGENITAL DEFORMITIES.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY ELLA E. BARNES, M.D.

BIRMINGHAM, ALA.

"As pliant twig by fair and careful bending,
In perfect trunk of future tree will show,
So in this life of Fate's mysterious sending,
Our ends by our beginnings we shall know."

More attention is given each year to preventive measures against disease, and we who stand on the watch-towers guarding humanity, have a right to inquire into the origin of these little charges; we are allowed to "go behind the boards" and investigate the cause of the defects.

We find anomalies much less frequent in animals than in man, and less common in the negro race than in the white.

There is a vast amount of superstitious material concerning maternal impressions. Here are specimens of such "old folk lore." One woman, two and a half months pregnant, goes to the kitchen, and in searching for a match in the darkness, puts her hand on a fish that her husband has brought home for breakfast. When her babe comes it is afflicted with ichthyosis. Another is terrified by a man in a state of inebriety staggering into her room, with the result of an idiotic offspring. Another attends the circus and menagerie with an alleged result of a dog-faced

babe. Still another goes down cellar and steps on a toad and faints at the revolting sensation, followed by birth of an anencephalia.

All of these deviations from the normal can be accounted for from anatomic disturbances. Lebadeff ascribes this latter, the toad-like head, to an abnormally sharp cranial flexure in the embryo, else the head fold of the amnion is retarded in development, thus closing the upper part of the medullary canal. This easily explains the absence of brain, also causes cyclopia or synophthalmia.

The evolution of the human organism from the ovum, set into activity by impregnation, its segmentation both lateral and central, is acceded. The environments play only a secondary part in the special direction in which the development is to take place, but if these are abnormal or adverse, various perversions occur.

Conformation of figure and of feature is inherent and inherited properties of the primordial cell. This I do not discuss.

The gross anomalies are usually from external causes. The earlier the injury, the greater the result. This is clear to any one, for the loss of a few cells in the earlier stages of growth may ultimate in the absence of an entire limb or organ, while at a subsequent period, after the general form is rounded out, the same loss would pass unobserved or be repaired by nature or the multiplication of cells. Let the first three months of fetal life be undisturbed and the perfection of the coming entity is almost assured. Ziegler says: "Later disturbances give rise rather to changes that manifest themselves after birth as congenital disorders, and are therefore more fitly regarded as anatomic bases of fetal diseases than true malformations."

The literature on this subject is prolix. Great men have discussed, experimented and wrote upon these causes, assigning injury and diseases of the uterus, membranes and placenta, small amount of amniotic fluid, hemorrhages in the membranes, separation of the membranes and other various causes; but some of the causes of these conditions and arrested or perverted development are what I propose to investigate.

Hasty conclusions are not ideal ones. It is only by long observation and close study of a subject that any result deserves respect.

In my student life in 1892, I began my observation on this line. The first case was an illegitimate birth in the Lying-in Charities. The child was still-born, but was greatly deformed in the lower extremities. I questioned the young mother and she admitted having made every effort to bring on abortion by the use of various advertised drugs and the attempted use of a piece of corset steel, producing hemorrhages but no radical results, she continuing till her full term.

Another case, Mrs. A.'s child, at birth had one hand web-fingered, a strip of membrane binding them together. This was easily remedied by a trivial severance and proper surgical dressings, but the cause, to my mind, was revealed later, when she told me that between the second and third months of her pregnancy, she obtained a uterine sound and inserted it, twisting it around, causing a slight flow for a day. This undoubtedly entangled the amnion about the digits of one extremity, causing an adherence of the membranes.

The last case was and is more serious. Mrs. M.

sent for me to consult about something that was troubling her exceedingly. She was three and one-half months pregnant, was in bed and had a slight hemorrhage. She unfolded a bit of paper and showed me a fleshy formation which had separations at the edge, was not larger than a bean and had passed the night before. I was convinced that it was an extremity, either a hand or foot. I asked for a true history of the case and she said that about two weeks previously she had inserted a crochet-hook but produced no results till the night before, when she passed some clots and this specimen. The instrument was a hard polished wooden rod, with a crochet-hook end, such as rugs are crocheted with. I had grave misgivings but hoped nature in a mysterious way might repair the damage. She flowed no more, and completed the gestation. On the birth of the child it had a handless right arm, and she is now in our fair southern city an evidence of a crime that most women do not appreciate.

While Jenner, Lister, Hunter, Morton and Long electrify the world by its discoveries to prevent disease or ameliorate suffering, it remains for us by persistent effort to teach womanhood the full extent of this awful crime against humanity by these efforts to prevent the consummation of conception.

DISCUSSION.

Dr. BEDFORD BROWN of Alexandria, Va.—To arrive at any clear comprehension of the nature of the causes of congenital deformity, we must trace back those causes to the origin of man, to be found in the union of the male spermatozoon and the female ovule, and the processes of protoplasmic formation and cell growth evolved by the vitalizing influence of this union. Practically, it may be accepted as a fact that the healthy evolution of the fetus requires the union of a perfect ovule and an equally perfect spermatozoon. And, on the contrary, that a defective ovule and spermatozoon, though capable of fructification and to a certain extent development of a living being, that living being will be defective in some of its parts.

Hence, in tracing the causes of congenital deformities, one must go back to prime causes as well as intermediate causes. What is here understood as prime causes are certain defects seated in either the spermatozoon or ovule, one or the other, or both. What is meant by intermediate causes are such changes as may occur during gestation impairing the growth of certain parts of the fetus.

In regard to the real nature of the primary causes, no one with our present knowledge can determine with any degree of accuracy, as we are not informed of the physiologic process in operation after the union of the male and female products. All we can say is that after this union takes place, then fructification results, and this means the development of protoplasm and the beginning of cell growth, and whatever arrests or impairs protoplasmic formation and cell growth will cause fetal deformity.

This law, I think, holds good both in ovule and spermatozoa, and in the intermediate growth and development of the fetus *in utero*. Thus, whatever influence will impair the formation of protoplasm or cell growth, as alcohol, injury, infectious disease, or inability of the mother to perfect fetal development, will produce this result. Great mental or physical shock, excessive alarm or fright, or physical injury of the mother would, during the earlier months of gestation, seem to be capable of impairing the nutrition of the fetus in a degree to cause deformity. Thus the interruption of the fructification and growth of an artery in the process of fetal development will suspend the development of the organ intended to be supplied by that artery, and we have either a partial formation or absence of the organ, known as congenital deformity.

An instance occurred in my experience in which a woman in three consecutive labors had a completely adherent placenta, and in every case the child born proved to be idiotic and deformed in some of its limbs. Subsequently she gave birth to two children without the adherent placenta, and both of these children were perfect in mind and body. I regard the history of this interesting case as positive evidence of interrupted or obstructed circulation and impaired nutrition of the fetus as the intermediate cause of the congenital deformities.

We come now to the consideration of some of those influ-

ences which impair the vital organization of the spermatozoa and the ovule, and which become primary causes of congenital deformity. This is a very intricate question, but one not incapable of solution.

Alcoholism, or habitual intemperance, rank first among the deleterious influences which effect the vital endowments of the original germs. You will find congenital deformity nowhere so common or existing in such hideous forms as among the habitually intemperate and degraded of the world's population. The effects of the constant saturation of the system with alcohol must tend to impair the vital organization of the spermatozoa and ovule, as it does any other organ of the body. On the other hand, habitual intemperance on the part of the female when pregnant must tend to impair the development of the fetus *in utero* by impairing cell growth. Again, we see children born of perfectly temperate parents, with congenital deformities. In a family of five children, born of temperate parents, all were defective in a more or less degree. The maternal grandfather was an habitual drunkard. The father, an intelligent man, was an eight month child and very delicate until nearly maturity. The mother was a feeble, delicate woman who was never capable of nourishing the fetus *in utero* in a proper manner. The causes of deformity in this case were probably both primary and intermediate in character, and were due to hereditary influences descending from the grandfather and inability on the part of the mother to sustain the nutrition of the fetus.

Heredity must unquestionably be classed among the chief causes of congenital deformity. We are capable of inheriting the abnormal as well as the normal traits of mind and body of our ancestry. Hereditary tendencies of this kind must be transmitted through impressions made either on the ovule or spermatozoa and impressions made upon these by hereditary influences must be of a permanent character and affect, in a positive manner, the growth and evolution of the fetus. Hence, heredity becomes one of the most important factors known for the transmission and perpetuation of mental and physical types both normal and abnormal.

Where the starting point of these hereditary tendencies in families begins is a difficult matter to determine. The tendency may date its origin, in many generations, back to the sins of an ancestor. He may have been a drunkard and impressed upon his offspring tendencies which through generations became fixed hereditary traits to be transmitted to all posterity. In such families bearing the burden of hereditary defects we see congenital deformities of the brain cropping out in successive generations, the origin of the hereditary tendency to which extends so far back that no man knows the origin, and it may skip one generation and appear in another. In these same families there will appear physical deformities otherwise. In a family of my acquaintance there has been for generations, deformities of the internal ear and deafness. Then again, these hereditary tendencies disappear suddenly by intermarriage with healthy individuals.

Of the millions, hundreds of millions, and billions of infants born, it is a most wonderful circumstance that of these vast numbers, so few cases of congenital deformity occur. In my own professional experience, extending now over forty years, of three thousand cases of delivery, the cases of deformity have not exceeded thirty, of all grades.

Consanguineous marriages and incestuous connections must be admitted as important causes of congenital deformity. In a single case of the intermarriage of first cousins, to my knowledge there resulted ten births. Of these, three sons were idiotic and otherwise defective, and one was insane. Of the daughters, all married and all were sterile. In another family, the marriage of first cousins, there resulted six births. Of these, four were idiotic and deformed.

An interesting case of incestuous connection came under my observation many years ago. This incestuous connection between a father and daughter had been maintained for many years. The father was a robust widower and the daughter a buxom young single woman. They resided in a remote section of the country. From this connection there resulted five births. Each child was not only idiotic but also otherwise deformed. In one there was wanting a forearm, in another a foot. In two there was absence of all the fingers, and in the fifth the eyes were merely rudimentary with complete absence of vision. I had a good opportunity of observing this alllicted family while inmates of an almshouse, and they were free to confess their unnatural alliance. Here was an undoubted case of incestuous connection between father and daughter lasting for many years, the product of which was five idiotic and deformed children, while the parents presented an appearance of fairly robust health. It would seem that nature abhors such transgressions of the moral law and rebels against

them in the most hideous and revolting forms possible for her to assume.

In summing up the remote and direct causes of congenital deformity, their nature and action, I think that the immediate or direct cause of congenital deformity may be in every instance attributable to defects of nutrition of the fetus. The remote causes producing these defects of nutrition may be varied, often widely in character, and even of an entirely opposite character. Thus, as has been attempted to be shown in the course of this paper, the various causes primary and intermediate are due to such influences as alcohol, shock, infectious disease, injury, fright, consanguineous marriage, incestuous connection, all of a widely different character. The tendency of all these is to obstruct nutrition of the fetus by impairing the process of cell growth and formation of protoplasm somewhere in the process of gestation, either in the original germ or during the growth of the fetus.

A RARE CASE OF CIRCUMSCRIBED TRAUMATIC ANEURYSM OF THE RIGHT INTERNAL CAROTID ARTERY WITHIN THE CRANIUM, WITH RECOVERY AFTER OPERATION.

BY ALFRED HINDE, M.D.

Senior Surgeon Eye and Ear Department Central Free Dispensary;
Ophthalmologist to the Neurologic Clinic and Assistant to the
Chair of Ophthalmology, Rush Medical College.

CHICAGO.

A Chinaman, Chan Ling, aged 36 years, was referred to me as a private patient Feb. 12, 1897, with the following history: About eighteen months before (September, 1895) he had been felled to the sidewalk by a shoulder blow, striking on the occiput. He got up at once and walked home, a distance of one block and laid down for about ten minutes. During this time he says his head "awful hurt." There was no history of unconsciousness nor bleeding from nose, mouth or ears; no ecchymosis of eyelids or conjunctivæ. The day following the fall he felt well and went to his work as usual and continued at it for seven months, apparently unhurt, save one exception, which he failed to mention until after its discovery by myself on examination. At this period, he states, both eyes began to redden, the right one becoming worse in this respect, and in a few days' time he noticed that the right eyeball began to bulge forward. The redness and exophthalmos of the right eye steadily increased until the time he was referred to me, and hence had existed during a period of ten to eleven months.

At the time I first saw him (Feb. 12, 1897) there was an exophthalmos of the right eyeball of one-quarter of an inch, together with *great* enlargement and tortuosity of the palpebral, conjunctival, subconjunctival and anterior ciliary veins of this eye, but no pulsation in any of the vessels mentioned; no pulsations were felt on light palpation with the finger tips on this eyeball. The latter could be pressed slightly backward into the orbit. The tension was normal. The superficial arteries were of normal size and there was no visible evidence of inflammation of any of the tissues of either eye. The motility of the right eyeball was perfect, excepting in an outward direction, and in attempts at abduction it halted at a point slightly beyond the mid-direction. The right pupil was of three millimeters diameter and below normal in its reflexes. With the ophthalmoscope the media were found to be clear and the retinal veins were *considerably* enlarged and tortuous, but without pulsation. The arteries were of normal size and course. Both kinds of vessels, especially on the surface of the disk, had white lines along their walls,

perivasculitis, so-called. The disk, retina and choroid were normal in appearance. The veins of the left eye tissues were somewhat enlarged throughout, but otherwise nothing was perceptibly wrong. Sensation in the right cornea was below that of the left. The visual fields were alike and normal. The acuity of vision was slightly greater in the left than in the right eye, but the type-test developed $\frac{2}{30}$ only in each eye and he could decipher the smallest types of Snellen ($D=0.6$) with either eye, but slightly clearer with the left. With a test-object carried into the extreme right field was no present diplopia, though the right eye failed to follow its fellow in this movement. He had become accustomed to the false image of the right eye and ignored it.

On placing the cup of a stethoscope over the closed right eyelids a loud blowing bruit or murmur was heard synchronous with the heart's beat and an intermittency of the heart's pulsations of six to eight times per minute was readily discovered. Slightly less loud the same conditions were found with the stethoscope over the right temporal region. Still less so the bruit could be heard in the left temporal region. In all positions of the stethoscope the aneurysmal sound was greatly increased by the patient stooping forward. It completely disappeared on digital compression of the right common carotid artery in the neck.

Up to this point of the examination the patient had not mentioned hearing any noises in his head and when asked if he did so he said, "Yes, kiki-kiki," trying to imitate the noise he heard and pointing his finger to his head. On further questioning he inferred that the noise was a source of great annoyance and alarm to him; that it had started very gradually six or seven days after the fall on the sidewalk and that it had got steadily louder up to the present time, but that it did not interfere with his sleeping.

To epitomize the history and present condition: We had a shoulder blow followed by a fall on the sidewalk, striking the occiput, almost immediate temporary head-pain, followed in about a week by a head-bruit, and after seven months a steadily progressive vascular obstruction and protrusion of the right eyeball. The intravascular murmur also increasing in loudness synchronous with the intermittent heart's beat, heard best over the right eyeball; stopped entirely by complete compression of the right common carotid trunk. Nothing but an aneurysm of a branch continuing the right common carotid within the skull could explain or cover the symptoms. I decided that the injured artery within the cranium was the right internal carotid where it rests its "S"-shaped form on the side of the body of the sphenoid between the layers of the dura mater and in the immediate proximity of the large cavernous sinus, compressing the latter and preventing the return of the venous blood from the right orbital contents, not affecting the arterial supply of the orbit, because the blood stream to the right ophthalmic artery was not interfered with; compressing the right sixth nerve trunk where it runs just to the outer side of the artery at the position of injury indicated, thus causing a paresis of the right external rectus muscle present in our patient; also compressing but more lightly, because further to the outside of the artery, the ophthalmic division of the fifth cranial nerve, thus accounting for the slight anesthesia of the right cornea.

That it was a rare example of an aneurysm of the right internal carotid alone, I believed, because our

case was free from a pulsating exophthalmos. That it was due to an injury of slight extent to the walls of the artery near the apex of the right petrous bone, followed by an aneurysmal swelling I decided again, because had the patient received a severe fracture of the base of the skull, either in the anterior or middle fossæ of the skull, he would have had present either intra-orbital, intra-nasal, external auditory, or throat hemorrhage, respectively, according to the location of the fracture of the base.

I believed there had been a slight fracture in the right middle fossa by *contrecoup* and the only feasible location of it, to me, was around the sharp *spicula* at the apex of the petrous portion of the right temporal bone.

That the injury to the coats of the artery was not penetrating, but only partial to the outer wall—a progressive aneurysmal enlargement at its site following, and that the latter beautifully accounted for every symptom of the case.

At my clinic at Rush Medical College, Feb. 24, 1897, I presented this case to the class and gave the foregoing history and my conclusions as herein stated, and that the only hope of cure consisted in ligation of the right common carotid artery in the neck. Lest I had erred and that a syphiloma of the base was present I had placed my patient on large doses of iodid of potassium, and these he took for a period of over six weeks without any change for the better in his condition. The indication for treatment was then fully cleared.

The case was admitted to the Presbyterian Hospital, in the service of Prof. Nicholas Senn, April 12. He agreed with me fully in my diagnosis and three days later (April 15, 1897) he tied, with two ligatures half an inch apart, the right common carotid artery in the neck.

The immediate result of the operation was a complete stoppage of the bruit. The following day the patient complained of slight pain in and around the right orbit. Pulse 72; temperature 98. The exophthalmos was one-half greater ($\frac{3}{8}$ inch) than before the operation, besides some conjunctival chemosis, with great enlargement of the veins of the region.

Four days after operation the exophthalmos had further greatly increased ($\frac{5}{8}$ inch) with the lower ocular conjunctiva extending between the swollen eyelids as a thick fleshy fold. No pain, no fever, pulse low. This condition lasted some time, and gradually disappeared, so that by May 20 the exophthalmos was greatly reduced. The edematous conjunctival fold still remained, but of lessened thickness, size and of lighter color, but yet protruding through the palpebral fissure; no subjective symptoms; no bruit. As yet he had not been out of the hospital. May 30, whilst still a resident of the hospital, he called at my office and I made the following notes: Right eye, $V = \frac{2}{30}$; conjunctival edema of fold of four millimeters wide in center extending beyond margin of lower eyelid and reaching from one canthus to the other. There is now a marked internal deviation of this eye, with complete loss of motion outward, indicating a complete paralysis of the right sixth cranial nerve. Motility in other directions perfectly normal. There was still an exophthalmos of the right eye of about one-eighth of an inch, half the original amount, and only one-fifth that of the greatest amount following the operation. The external ocular as well as the retinal veins were of greatly reduced size, but yet

larger than those of the left eyeball; no *bruit*. The vision of the left eye had improved one-third since the operation and was now normal, or $\frac{2}{20}$. The fold of edematous conjunctiva was now replaced within the eyelids and the latter slightly compressed with strips of plaster to aid the removal of the exudate.

June 13. Exophthalmos of right eye still further reduced one-half—now $\frac{1}{16}$ inch. Still complete paralysis of the right externus muscle. Right retinal veins still larger than in left eye, no white lines along their walls now. No evidence of fundus disease. Conjunctival edema about gone. He was discharged from the hospital June 19, two calendar months after the operation. On removing the dressing from the right eye the patient—to avoid diplopia—turned his head toward the right shoulder, and so favored the paralyzed right externus.

June 30. Exophthalmos of right eye about gone. Fundus of each eye alike and normal. The patient had been told to cover the left eye and practice the right alone and particularly try to move the eye by looking at objects in the right field and by this time there is a slight voluntary movement of this eye toward the mid-line of the eyelid. Diplopia still his constant and only complaint.

July 25. Without noticing further increase of motion in the right eyeball outward since last noted, and the diplopia still distressing him, I decided to try the local use of electricity and applied a galvanic current, strong enough to produce occasional phosphenes, and for two or three minutes duration. This was followed by a faradic current producing muscular contractions and for a similar period of time. The sittings were repeated every two days and soon improvement became marked, so that by August 23 only occasional diplopia was complained of and the head had assumed an almost correct position with the body.

August 25. No more double vision on ordinary eye-use noticed since last note, yet the right eyeball fails to move outwardly as far as the left one on extreme effort by a distance of three millimeters. I thought that the right retina had probably become accustomed to the false image, if present, and ignored it, so I tested him at five meters distance and found no diplopia with eyes uncovered (candle light and Dr. J. F. Herbert's screens used). With a prism 6 degrees base up before the right eye diplopia was produced and showed a condition of esophoria up to 7 degrees, succeeded by a reduction to orthophoria, with an occasional lapse to up to 4 to 7 degrees of esophoria to be again followed by orthophoria—the patient's head being correctly adjusted during the test. Therefore for ordinary uses of forward vision our patient had regained binocular single vision. The vision of this right eye had sunk to $\frac{4}{20}$, whereas that of the left remained $\frac{3}{20}$. With either eye alone he spells D=0.6 of Snellen up to 7 $\frac{1}{4}$ inches, thus showing a normal amplitude of accommodation for his age (36) of 5.5 D. The distant vision of the right eye could not be improved with any glass and both eyes rejecting the weakest plus spherical lens I decided the case to be an emmetrope. The position of the two eyes is now alike, as is also the appearance of the extra- and intra-ocular details.

The only remaining evidences of a pathologic condition are a slight and possibly wholly removable paresis of the right externus muscle; together with

¹ Six weeks later orthophoria at 5 meters was the constant condition, and the right externus muscle had gained still more, so that on extreme abduction this eyeball fell short of its fellow only 1.5 millimeters.

an amblyopia of the right eyeball, probably permanent and due to pressure atrophy of some of the fibers of the optic nerve; yet, again, this eye may have been possessed of a congenital amblyopia of the amount present. The patient now has no complaints whatever.

HYPERPLASTIC SUBCONJUNCTIVITIS.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY H. McI. MORTON, M.S., M.D.

MINNEAPOLIS, MINN.

As a contribution to a rare condition, I desire to present the following cases:

Case 1.—A. V., white, age 35 years. The man, a tobacco-ist by occupation, consulted me on July 23, 1894. Until two weeks previous to this time, he had had no ocular trouble. On July 9, while riding a bicycle, he fell and was thrown into a bush by the wayside. He realized immediately that a foreign body had entered his left eye, which at once began to swell. This swelling continued so rapidly that in two days he noticed a large fleshy mass protruding from the swollen lids. He consulted his family physician, who, finding the usual antiphlogistic measures of no avail, brought him to my office, two weeks after the date of the accident. Inspection revealed great infiltration of both upper and lower palpebræ. In both lids existed an external wound, each of which communicated with a cavity formed by the breaking down of the cellular structure of the subcutaneous tissue of the lids, and from which there was a free discharge of pus. These cavities did not communicate with the conjunctival cul-de-sac. From out of the interpalpebral tissue projected a red tumor mass. It sprang from the inner surface of the lower lid and bulbar conjunctiva, involving in fact the entire lower cul-de-sac, up to within 1 mm. of the corneal limbus, and extended from the outer to the inner canthus. It resembled a large granuloma, was firm in consistency and shiny. There existed a marked infiltration of conjunctiva at the fornix of the upper lid, and associated with much chemosis of the upper bulbar conjunctiva. The cornea was transparent. The iris was of proper color and pattern, the pupil normal in size and, in both direct and consensual reaction. The patient had not suffered any pain. He was admitted to the hospital, where, after two days preparatory treatment, was chloroformed, the openings in the lids enlarged, some pieces of wood and bark removed, and the wounds thoroughly cleansed. The tumor mass was incised freely in several places from canthus to canthus. It was of very dense structure, seemingly almost cartilaginous. An antiseptic dressing with pressure bandage was applied. By this treatment I thought it possible a retrogressive process might be started, which with the relief following the removal of the foreign bodies, might make more radical measures unnecessary. The next day the bandage and dressings were dispensed with and cold compresses were ordered, alternating every fifteen minutes, day and night. Boracic solution was instilled hourly and atropin twice daily. After two weeks the phlegmonous state of the lids entirely subsided, but the tumor mass had increased. Although I feared a malignant growth, no recourse remained but the enucleation of the tumor. Under chloroform the tumor was dissected out. It was firmly adherent to the anterior, and extending beneath, was also adhered to the lower part of the globe. There was a firmly adherent projection of the mass to the upper palpebral conjunctiva, beginning 5 mm. from and extending to the inner angle. After the removal of the tumor there existed a practical denudation of the entire lower cul-de-sac. To avoid the serious results following adhesion of the raw surfaces, I transplanted from the left arm a large skin graft, completely covering the raw surfaces of the globe and lid. This took excellently and left a freely movable globe. There existed an almost complete ptosis of the upper lid due to the injury sustained by the levator at the time of accident and on October 5, I performed Pannas' operation for its relief.

Macroscopic examination of the tumor showed the upper third to be of a granular consistency which, lower assumed a dense and elastic nature and terminated in stringy nodules. It weighed about two drachms, was 2.5 cm. long and 1.5 cm. broad and 1.5 cm. thick.

Microscopic examination, which was made by my friend, Dr. J. Clark Stewart, was as follows: "From the section studied I should think, the tissue was simply hyperplastic.

There does not appear to be any tumor proper, but an infiltration of the normal tissues with round cells. Of course it may be small round-celled sarcoma, but I should say not. I should consider it non-malignant so far as the microscope can say." The photograph shows the patient at the time of operation. It has now been three years and the patient has had no trouble with his eye.

Case 2.—S. H., white, age 8 years: boy referred to me by Dr. N. M. Black, May 12, 1896, with no history of ocular trouble until three months ago. At this time his father informs me, his eyes were inflamed, but did not cause him any great amount of inconvenience. Two weeks ago his family noticed a growth projecting from between the lids. This has grown to its present proportion in this short time. It now extends from canthus to canthus of the left eye and is as large as my little finger. As its attachment was along a narrow line of lower lid it was easily removed without loss of much conjunctiva, after which the edges of the conjunctiva were approximated by silk sutures. The case made a rapid recovery. There was no history of traumatism in this case: no disease, as granulation, was found to exist. The tissue proved a simple hyperplasia of the subconjunctival elements. I regret that the photograph taken of this case proved a failure.

Case 3.—Miss K. M., aged 17 years. This case presented itself at my office, May, 1896, to consult me in regard to the disfigurement due to an immensely hypertrophied plica semilunaris in the right eye. There is no history of trauma and the eyes have never been inflamed. The conjunctivæ are normal, and the only defect in either eye is this large mass which extends to within 1 mm. of the inner corneal limbus and is very thick. She insists that two years ago the eye was the same as her left eye, which is normal. I did not see the case subsequently.

The last case was rather an atypical picture, but cases 1 and 2 present a typical picture of a very unusual disease. I can find no mention in literature of this condition, except in the work of Berry, who has, accompanying a few lines upon this subject, a most excellent colored illustration. In case 1 the origin was clearly traumatic. In the second case, no such cause can be directly assigned, but as the patient lived upon the prairies of North Dakota, it is fair to assume that the constant winds and dust may have been a factor in its causation. In none of the cases was there any granular disease of the lids, so it can not be assumed to have been a progression of granular conjunctivitis into a tumor. The tissue which was firm and smooth was, aside from the size, entirely different from the picture presented in young subjects

with the enlargement of the folds about the fornix from follicular inflammation. Then, the extreme rapidity with which the growths progress is a striking feature. The upper cul-de-sac is not involved in any of these cases, as is usual in granular disease. This fact Berry also notes and suggests, that it may disappear of itself, a statement that will hold, I fear, only in much milder form of the disease than illustrated by my cases. Berry also notes the dense cartilaginous nature of the growths. Excision seems to be the only method of relief, and where large surfaces of the conjunctiva are lost, I should advise skin grafting in preference to mucous membrane from the mouth. It is possible a more extended experience with the skin and mucous membrane grafting might modify or entirely change my views, but having such a satisfactory result with the skin grafting, and in a case of transplanting of mucous membrane not only such a perfect result I am more favorably impressed with the former method. The graft must be a great deal larger than the surface to be covered, and must be cut very thin, by the sharpest razor. All bleeding must be absolutely stopped before the graft is laid on the denuded area or failure is assured. In cases where the hyperplastic mass is not attached over a broad area of the conjunctiva, the edges of the conjunctiva may be approximated without further proceeding. I have no doubt but that many unreported cases of this disease exist, and it is with the hope that this brief report may stimulate a more careful study of this at the present time unusual ophthalmic disease, that I present these cases to your notice.

504 Dayton Building.

THE APPLICATION OF THE ROENTGEN RAYS TO MEDICAL DIAGNOSIS.

Abstract of paper read before the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES LESTER LEONARD, A.M., M.D.

PEPPER LABORATORY OF CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

The application of the Roentgen rays to medical science has already given to surgery a method of diagnosis the precision of which makes it of the greatest value: this value lies in the absolute pictures which we are able to secure by its means, and loses its pre-eminence as soon as we are compelled to substitute for the absolute picture in black and white, mental pictures which always involve the personal equation of the observer.

It is worse than useless to suppose that any new method of forming mental pictures, no matter how startling or radical, can equal in accuracy or approach in value those which the science of medical diagnosis has already taught us to form with well-nigh infallible precision. It would be supererogation on the part of anyone to think that the mental pictures which he might form by the use of the Roentgen rays could replace or even add much to the pictures which modern physical diagnosis is capable of presenting.

The property which gives this new method of diagnosis its greatest value and helps it to add to the sum of our knowledge, is its power to form real images, to make tangible shadows where only mental pictures were before possible. These tangible shadows eliminate the personal equation of the observer from the resulting diagnosis, and thus remove a source of error

common to all methods that depend on the senses of the individual for the accuracy of their results. To this advantage is added the fact that they produce permanent data which different individuals may study at various stages of the same case or compare with other cases.

The true value of the Roentgen rays and the advance made in their adaptation to medical diagnosis must be judged by the advance in our ability to replace or confirm by skiagraphs the mental images obtained by other methods. In cases where the lesion is extensive, where the symptoms and physical signs are pronounced, the skiagraph may only confirm the diagnosis, adding perhaps a few facts—as to the exact shape of an aneurysm or the extent of the diseased area. It is, however, in the early stages of disease, during its inception, that it aids, chiefly by establishing a diagnosis which our most careful means of physical examination fail to make certain. This it does by differentiating between different areas of dulness, which by other methods present identical physical signs.

The application of this method to medical diagnosis is far more difficult than its application to surgery, for here we must deal with the relative opacities of structures which vary from one another by only slight degrees. To make this possible, the varying qualities of the X-ray must be under the control of the operator, so that he may employ more or less penetration as he may desire, and use at will the X¹, X² or X³ rays. The results already attained in medical diagnosis are perhaps not as practical as those in surgery, but the possibilities which they open up are so great that this first insight gives promise of a future development of even greater value than in surgery.

After presenting skiagraphs which showed the entire trunk and upper extremities of a normal 5-year-old boy and the thorax of an adult male, the author draws a comparison between them and a series of skiagraphs of aortic aneurysm. The series of intrathoracic aneurysms illustrates the accuracy with which we may depict their extent and form, even in portions that are too deeply situated to permit of their definite determination by percussion, or in aneurysms so small that their existence would be difficult to determine by other means of diagnosis. It is in the cases where our diagnosis is most wanting that the skiagraph gives the greatest aid, and differentiates between small aneurysms of the aorta and mediastinal tumors. In a case where the symptoms and physical signs were not sufficiently distinct to warrant a diagnosis of aneurysm and might have been accounted for by a spasmodic irritation, an asthmatic attack or some disturbance of the circulation, the skiagraph decided the question and the area of dulness, which might have been due to tuberculosis of the mediastinal glands as was the case in one instance studied, was found to be due to a deep-seated small aneurysm. The relative opacity of tubercular glands in the mediastinum has been shown to be less than that of aneurysms.

Although deprecating the prominence which some would give to fluoroscopic diagnosis, the author realizes its possibilities and has confirmed by personal observation the results attained by others. He believes, however, that its greatest usefulness is in the detection and study of motion, either normal or pathologic, in organs whose motion is beyond the field of ordinary vision. In the study of aneurysms and their patho-

logic expansive motion as observed by the fluoroscope there is, therefore, a definite addition to our knowledge. The author showed in addition skiagraphs of aneurysm of the innominate artery, marked dilatation and hypertrophy of the heart, and the condition within the thorax resulting from empyema and thoracotomy. By washing out the stomach and subsequently introducing an emulsion of bismuth in a case of gastroptosis, he was enabled to show the area of the stomach through the bones of the pelvis.

In reference to X-ray "burns," the author does not believe that they are due to the X-ray *per se*, but that they are the results of induced electric currents in the tissues of the patient. The X-ray depends for its production on the physical phenomena of electric induction, and it is certain that any conductor of electricity, as the patient's tissues, if approached sufficiently near to the X-ray tube, *i. e.*, within the field of electric induction, will have a current of electricity induced in it which may be capable of destroying its vitality. A substantiation of this theory is seen in the fact recently made known, that a sheet of aluminum if grounded and placed between the tube and patient, will prevent the burn, while interfering in no way with the X-ray phenomena. The induced currents are formed in the aluminum and carried by the wire to earth without injury to the patient.

1930 Chestnut Street.

PHASES OF THE PATHOLOGY OF APPENDICITIS.

BY WILLIAM CUTHBERTSON, M.D.

PROFESSOR OF SURGERY, CHICAGO CLINICAL SCHOOL; SURGEON TO WEST SIDE AND LAKESIDE HOSPITALS; FELLOW CHICAGO ACADEMY OF MEDICINE; EX-PRES. CIVIL SERVICE EXAMINING BOARD; ETC. CHICAGO.

The varied etiology of appendicitis and the present somewhat chaotic conception of it renders any unique case interesting, and constitutes a reason for the publication of the following cases:

Case 1.—On June 9, 1897, I was called at 6 P.M. to see Mrs. W., 57 years of age, a large fleshy woman, who that morning was seized with colicky pains in the abdomen. Her temperature was 99 degrees F., pulse 96. The abdomen was generally tender, without any localization of pain. She had arteriosclerosis and complained of a cardiac irregularity which had troubled her for some years; otherwise personal and family history were good.

June 10, temperature 100 degrees F.; pulse 104; pain more localized in right iliac region; bowels loose, having been moved by citrate of magnesium.

June 11, temperature 101 degrees F.; pulse 108; localized tenderness in right iliac region. A sense of resistance over an area about the size of the palm of the hand existed over McBurney's point. A positive diagnosis of appendicitis was made and the patient removed to St. Luke's Hospital for operation.

Operation at 2 P.M. June 11. An incision about two and one-half inches in length was made midway between the anterior superior iliac spine and the umbilicus, and the abdomen opened. A mass could be felt in the abdomen which, after being walled off from the general cavity by aseptic gauze, was brought up into the wound and found to consist of the cecum and ileum glued together by layers of plastic lymph. The two portions of the gut being gently separated, the appendix was seen lying in a pouch formed by the cecum, ileum and meso-appendix. The appendix was swollen and gangrenous throughout about two thirds of its circumference at its proximal end.

A ligature was introduced close to the cecum, the appendix amputated, a strip of iodoform gauze inserted down to the stump, and the abdominal wound closed by silk-worm gut sutures. The patient made an uninterrupted recovery.

Case 2.—Mrs. S., 53 years of age, of good family and personal history, sent for me at 5 A.M. August 1. She had been suffering all night with sharp abdominal pains which prevented her from sleeping. These pains were almost constant in the region of the umbilicus. Her temperature was 99.2 degrees F.; pulse

90. From the anxious expression on her face, the sudden onset of the pain, and its persistent character, I made a tentative diagnosis of appendicitis. I was called again at 11 A.M. and found the pain more aggravated and somewhat localized in the right iliac region. Moderate doses of morphin had not abated the suffering in the least. The bowels had been freely moved in the meantime by magnesia citrate. Her temperature at this hour was 100 degrees F.; pulse 110. I told the nurse to continue the morphin and apply hot applications to the abdomen.

At 2 P.M. I saw her in consultation with Arthur R. Edwards, M.D., and found her temperature 101.5 degree F., pulse 120, with an area of tenderness over the lower and right half of the abdomen.

A positive diagnosis of appendicitis was made and immediate operation advised. She was removed to St. Luke's Hospital and operated on at 4 P.M. The usual incision was made and on opening the abdomen, a large quantity of peritoneal fluid escaped. The peritoneal gloss was absent from the intestines for a considerable area, demonstrating conclusively the existence of peritonitis of considerable intensity. The appendix, readily brought into the wound, was to all appearances perfectly healthy. On examination, however, bulbosity could be felt at its distal extremity. For this reason I decided to amputate it. After removal, it was cut open and found to contain a small quantity of fecal matter, together with a live ascaris lumbricoides. The superficial epigastric artery crossed the abdomen very high up, and gave rise to troublesome hemorrhage before it could be secured.

This patient did nicely for about thirty six hours, when her pulse began to fail. It gradually became weaker and increased in frequency in spite of free stimulation, till Tuesday afternoon, when it was 160 per minute and very small. The respirations were sighing and labored, with great restlessness. At this time eight ounces of a normal salt solution was injected hypodermically. A good result was immediate, and from that time on the patient made an uninterrupted recovery.

In Case 1 on examination of the appendix after its removal, a depression was marked at the cecal opening. Evidently a hard fecal mass had become lodged there, making a pressure on the sclerosed appendiceal blood vessels, and in this way causing gangrene. The appendix was nicely shut off from the general cavity by layers of plastic lymph, agglutinating the cecum and ileum. Perforation was inevitable with the formation of an abscess cavity. In this instance an early operation saved the patient weeks of invalidism, and the increased danger of a fatal result from abscess rupturing into the abdominal cavity.

Case 2 is the first instance I have been able to find of a lubricoid causing appendicitis. The worm was lying in the lumen of the appendix and, to all appearances, had not perforated its wall. The surrounding peritonitis was intense and leads me to advance the theory of a toxin being generated by the worm, which was transmitted to the peritoneum by osmosis, thus setting up the chain of symptoms. On the other hand the worm may have penetrated the wall of the appendix and infected the peritoneum by contact.

In both these cases very small doses of morphia sulphate were given to control pain, but not sufficient to check peristalsis, or mask the symptoms.

In the first instance the patient was made comfortable; in the second, any dose of the opiate I felt it was safe to administer did not relieve the agony from which the patient suffered.

189 41st Street.

THE PREPARATION AND TESTING OF DIPHTHERIA ANTITOXIN.

BY GEORGE W. COX, M.D.

CHICAGO.

In a recent report to the Michigan State Board of Health, Dr. Charles T. McClintock of Detroit, makes the statement that "inspection of the most important

laboratories of Germany, France, Austria and Great Britain reveals the fact that the methods in use for the production of diphtheria antitoxic serum and vaccine are much the same everywhere," etc. While this statement is entirely correct in a general way, it carries with it the impression that if the same methods are used by the various manufacturers, one could make just as good a serum as another, an impression as dangerous as it is erroneous. It is only necessary to mention the great discrepancy that exists between many of our drugs of the same name in order to illustrate this point. Essentially the same methods are used by all our manufacturers in the production of fluid extracts, for example, and yet our markets are burdened with every grade and shade of these remedies from the absolutely perfect to the absolutely worthless.

There are many reasons for this, the most conspicuous being a lack of care in the selection and assaying of the crude material; the use of a poor menstruum; too great haste in the preparation, and the employment of unskilled or inexperienced labor. If, then, we notice such a variation in the quality of the remedies just mentioned, how much more we might reasonably expect to find it in such delicate substances as antitoxic blood serums, where so much more skill, experience and patience are required in their preparation. Dr. McClintock tells us that in Germany any one may manufacture antitoxin, but before it is offered for sale it must be tested by a government official. In the United States we go Germany one better. We not only allow anybody to manufacture antitoxin, but we allow anybody to test it, certify to its strength and sell it. In the report above alluded to, mention is made of dividing a bottle of serum into four equal parts and sending them to four different bacteriologists for the purpose of testing. One reported the strength to be 100 units per c.c., one 150 units, one 175 units and the fourth 250 units per c.c. Aside from the amusing aspect of such extravagant variation, it would be interesting to know how that lot of serum was labeled when it was put upon the market. Who does the testing of our domestic serums, anyway? We know that in Germany they are tested by Prof. Ehrlich, who was appointed by the government for that purpose, and we have every reason to believe that his work is uniform and reliable. In France the manufacture of antitoxin is still more directly under government control. Two or three institutions in that Republic have been authorized by special ministerial decree to make and test antitoxin, the two principal ones being the great Pasteur Laboratories at Paris and Lille, under the direction of Prof. Roux and Dr. Calmette, respectively. Inasmuch as we must rely upon the name and reputation of the manufacturer for our guidance in the selection of a serum for use, it seems but the part of wisdom for us to lay aside all prejudice and sentimentality and choose one whose label bears a name known and honored throughout the world. Diphtheria is such a treacherous and fatal disease, and our responsibility in combating it so grave, that we can not afford to jeopardize our own reputation, to say nothing about the life of the patient, by using a serum that is not vouched for by someone whose authority is recognized everywhere. In this connection it may be stated that there are four names so intimately associated with diphtheria and its cure, that the mere mention of the disease at once suggests these names: Roux, the discoverer of the diphtheria

oxin; Behring, the discoverer of the antitoxin; Calmette, the distinguished director of the Pasteur Laboratories at Lille, and Ehrlich who created the world's standard for the testing of serums. The first mentioned of this group, whose great discovery made it possible for the others to follow with their specialties, is still in the harness at the Pasteur Laboratories in Paris, exercising personal supervision over every branch of the preparation of the serum that bears his name. He not only sees that the finished products are properly tested and sealed, but he makes sure that the tests are made with toxins of the proper degree of virulence. He also prepares his serums without antiseptics, having proved not only that such antiseptics are prejudicial to the patient, but that the serums retain their freshness and potency longer without these extraneous substances than they do with them. In these two very important respects, then, it must be said that Roux's methods are not used "almost everywhere," nor indeed *almost anywhere*, except in his own laboratory. Much has been said about the relative antitoxic strength of different serums, and some fabulous claims have been made in this direction. Roux has never been favorably inclined toward serums of extra high potency, say 400 or 500 units per c.c., for the simple reason that while it is easy enough to produce them, they do not retain their strength as well as those of lesser potency, 150 to 300 units per c.c.; and if antiseptics are added, the deterioration is all the more pronounced and rapid. Originally Roux's serums were quite weak as compared with the strengths claimed for others, and consequently large doses were required; but he has gradually increased the strength until his standard serum is now about three times as strong as it was eighteen months ago. That is to say, his "regular" serum contains 150 units per c.c., while the "extra" prepared by Calmette, is just double that strength. Roux has satisfied himself, by long-continued experimentation, that this last named strength (300 units per c.c.) is about the limit beyond which a serum can not be depended upon to retain its full potency for any length of time. Inasmuch as there is no more danger in administering these antitoxins than there would be in using pure blood serum, the dosage is practically unlimited, and the required antitoxic power may always be given without fear, regardless of the bulk. However, in response to the clamor for a serum of a higher antitoxic power, Roux has now entrusted Calmette with the preparation of one of at least 1000 units per c.c. This is known as his "Concentrated" serum, and is dispensed in vials of 5 c.c. or 2500 units.

It is to be hoped that my readers will pardon me for thus dilating upon the excellencies of any one antitoxin, especially one of foreign manufacture, as sentiments of loyalty should and do naturally incline one's reference toward a home product. But aside from the great respect that is due from the entire world to the pathfinder in bacteriologic science, I am in a position to know what is going on at the Pasteur Laboratories at all times, and I do not allow my enthusiasm to lead me into statements that can not be backed up by authority from headquarters. It seems to me more than likely that if Dr. McClintock had given the Pasteur Laboratories a thorough inspection, he would not only have met there a full half dozen of the world's greatest bacteriologic specialists, but he would also have noticed many details in the methods of preparing and testing antitoxins not to be seen elsewhere. For example, he would have noticed that they do not

prepare their serums in a hurry. Nature having a considerable part in this process, she takes her own time in its performance, as she does in all her works, and no effort is made to abbreviate it. One particular serum that requires *twelve months* for its production by its discoverer is made in this country in less than half that time. It is not necessary to make comparisons as to the quality of the two products. The doctor would also have observed that the 300 or 400 horses from which the various serums are taken are kept in the country, many miles from the unsanitary surroundings of city stables, and that a portion of the time during treatment is spent in green pastures where nature's food, pure air and voluntary exercise are enjoyed to the full. It must be confessed that these and many other details in the production of antitoxin at the Pasteur Laboratories are at great variance with those in vogue at other places, and not altogether to the credit of the "other places." Finally, the writer has always been of the opinion that the laxity of our laws upon sanitation, is a mark of shameful carelessness on the part of Congress, a disgrace to the members of the medical profession for silently submitting to legislative inactivity and a constant menace to the welfare of our people. The testing of antitoxins should be under government control. Are we not as worthy of such protection as the French or Germans? I think so; and as a starter in this direction I move that the profession as a body appeal to Congress for the establishment of a Department of Public Health.

2258 Wabash Avenue.

ALKALIN ANTISEPTIC TABLETS.

BY HENRY W. WANDLESS, M.D.

DALLAS, TEXAS.

Each tablet is composed of the following: Acid boracic, grs. 22.5; sodii bicarb., grs. 7.5; sodii biborat., grs. 7.5; camphor, grs. 1½; menthol, grs. 1½; thymol, gr. .5 combined with three minims of the following combinations of oils: Oil pinus pinolias, 2 parts; oil eucalyptus, 2 parts; oil Scotch pine, 2 parts; oil spruce, 1 part; oil cedar, 1 part; oil cubebs, 1 part; oil wintergreen, .25 part; oil bay leaves .25 part; chloroform, 2 parts.

These tablets are very useful in the treatment of catarrhal conditions of the nose, throat and ear. They are used by dissolving them in hot water and used as a douche or spray, and are sometimes useful dissolved in the mouth in cases of sore throat and troublesome cough caused by irritation of the larynx. One of these tablets dissolved in one or two ounces of boiling water will make a very agreeable wash or spray for the nose, throat or ear. I usually have made one gallon of the solution at one time, which is prepared as follows: after the water reaches the boiling point, one tablet is added for each fluid ounce and allowed to boil for five minutes, after which the solution is placed in a macerating jar and allowed to stand with occasional shaking, from three to four weeks, or until needed for use. It is then filtered or siphoned from the bottom without disturbing the top and is then ready for use. The solution, prepared as described, imparts a very rich, mellow odor; and while it is a little sharp when first sprayed into the nose this is followed by a delightfully refreshing and soothing effect.

The efficacy of the solution does not seem to be

increased by age. A freshly prepared solution differs from that macerated for sometime, only in the absence of the rich, mellow odor and taste which comes with age. Some mucous membranes are much more sensitive than others, and for these the solution should be diluted with a 4 per cent. solution of acid boracic. For simple catarrhal inflammations of the nose, throat and ear, its curative influence is very marked; for dissolving and removing impacted cerumen from the ear and for general cleansing purposes of the organs named, I have not found anything that has given me the same degree of satisfaction. In fact, my entire experience with this formula (which covers a period of three or more years) has been extremely happy.

The unusual amount of volatile oils of pine held in solution by reason of the salts of soda, undoubtedly imparts to the mucous membranes of the nose and throat its acknowledged therapeutic effect, and that it is rapidly absorbed into the system by the mucous membranes, especially the nose, is shown by the effect upon certain organs of secretion.

I have the formula put up in tablets, because it is very convenient to use them, and besides a patient may make the solution at home as he needs it. It has been observed that a portion of one of these tablets dissolved in the mouth and swallowed will relieve the sickness caused by the swinging motion of a moving train; also the sickness and vomiting caused by the disagreeable effects of cocain applied to the naso-pharynx, larynx and soft palate.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

XVII.—DISEASES OF THE HEAD AND FACE.

(Continued from page 1113.)

In affections of the *tongue* Richter made use of the following principles: Large cross cuts, if they could be gotten at, were immediately sewed; small wounds, or if situated far back, were left untouched, but the patient's mouth was tied up to prevent all motion. Serious hemorrhages were stopped by the hot iron, also by compression or ice. According to Job von Meekren, for glossitis it was necessary to make two deep incisions about two inches in length. Cancer of the tongue was extirpated with a curved scissors and a pair of hooked nippers, then the wound was cauterized, which was also done in case of a relapse. Symptoms against the operation were indicated by the swollen glands under the jaw and the impossibility to remove every particle of the cancer. In case of serious macroglossia a portion of the tongue was cut away and this was done very boldly, since Louis, who was the first one to fully describe this disease and was the first to recommend the extirpation of the tongue (1774), called attention to patients who had lost nearly the whole tongue and yet were able to speak, chew and swallow. Although the operation of ankyloglossia was very simple and often performed without any danger, the instruments invented therefor were numerous and complicated. Heister constructed a spatula provided with a notch, to raise the tongue; this instrument may be found in every physician's case today. J. L. Petit invented a curved spatula

combined with a scissors and ordered children to be rigidly watched, being apt to suck the bleeding wound for a long time; Levret and Bell also made special scissors, etc.

The nature of *ranula* was variously interpreted. As a blister or a sack-like formation (Heister), or as an enlargement of a portion of the Whartonian duct in which the saliva had accumulated and this stopping up of the passage necessitated an opening. (Louis and Girard). Richter thought likewise. He split the swelling along its entire length, cut away as much as possible of both sides of the sack and besmeared the posterior wall with antimonial salve for a few days. Other methods of treatment were, to make an incision and insert caustics (Heister; Acrel introduced muriatic acid into the opening, and Camper, nitrate of silver); lead wire and charpie were inserted (Louis, Sabatier); also a fine sound into the occluded salivary duct (Desault), or a seton put in (van der Haar).

When the *tonsils* were inflamed Richter advocated scarification with the pharyngotome, which he also used to open abscesses. To remove the tonsils he caught one of them with a simple hook, which he preferred to a Muzeux forceps, and without the aid of an instrument to keep the mouth open, he cut off half of the projecting piece from the bottom to the top with a covered knife and then cut out the other half from the top to the bottom. The scissors he employed only at the base of the swelling or if after the operation a flap had remained. The cut from the base to the top Louis introduced because otherwise the half-loosened tonsil might fall on the glottis. Also for this operation many new knives and scissors were invented, among them Desault's kiotome. Since fatal hemorrhages had resulted probably from trying to extirpate the entire tonsil and England having rejected Wiseman's method of cauterizing, the tying of the tonsils was considered the safest mode, according to Cheselden, Sharp and B. Bell. Also C. C. von Siebold favored the same, while the Italians, Bertrandi and Moscati defended the incision, as they had never witnessed a hemorrhage of any consequence and were satisfied with cutting off only the prominent part of the tonsil.

Among the diseases of the *parotid gland*, a dispersion of the usual inflammation was first tried, in order to prevent suppuration and a salivary fistula. On the other hand it was considered dangerous, on account of a metastasis to the testicle and brain being apt to result, to disperse the "malignant" form of inflammation, the so-called angina parotideae, which the laity in England termed "mumps" (Hamilton, 1790) and which was first observed as an epidemic in Lyons in 1758. The metastasis of this disease to the other organs mentioned was preventable by the immediate application of a Spanish-fly plaster over the parotid gland. If the testicles were already affected, by treating them in a similar manner as the gland, the disease could be kept from going to the brain. Suppurations of the parotid glands had to be opened; but J. L. Petit noted that the face became paralyzed after he cut through the aponeurosis. In case of scirrhus swellings, of which a transition into cancer had not yet been observed, Richter almost entirely rejected extirpation on account of the existing danger of severing of important vessels and nerves, occurrence of facial paralysis or of lock-jaw. Besides, he put the question whether the easy and successful operation really concerned the parotid gland alone, or whether

instead it was not more likely that its near neighbors, the lymphatic glands, had become indurated and also removed. Furthermore, there are many patients who have grown old with an enormous swelling of the parotid. Heister performed several successful extirpations and conjectured that no one in Paris had ventured the operation; also Kaltschmidt and C. C. von Siebold were successful, and had twice succeeded in removing an immovable swelling the size of a fist and hereby injured the carotis externa, so that within two minutes two pounds of blood were lost. Lying too deep, binding was impossible, so the bleeding was topped by compression with a sponge. Desault, who like Richter thought that a full extirpation could not be made, successfully cut away the front part of the gland and gradually destroyed the remaining portion by caustics! In connection with another case he followed Roonhuysen's example and tied off the exposed swelling at its base with a ligature; so also did Ollenroth.

In conclusion, a few operations on the ear are given. The connection between the ear and the pharynx was known centuries ago, and Valsalva had described the plugging of the auditory canal as an occasional cause of deafness. Nevertheless, science owes the discovery of the catheterization of the Eustachian tube to a layman. Guyot, the ingenious postmaster of Versailles, took a tube of zinc bent like the knee-joint and passed it through his mouth into the tuba to make injections; he is said to have thus cured his deafness. The academicians in Paris thought this idea "très ingénieux," but seemed to be a little doubtful, as shown by their further remark: "On en lave au moins l'embouchure de la trompe, ce qui peut être utile en certains cas." Then an English military surgeon, Cleland, invented a flexible silver tube to be passed through the nose (1741). He it was who, in the following ingenious manner, constructed the first ear apparatus for illuminating the ear. He took a convex hand lens three inches in diameter, and opposite the middle part of it fastened a tallow candle, the rays of which he allowed to enter the auditory canal! For catheterizing the tuba, Douglas used solid silver catheters. Now the operation was often successfully performed in cases of deafness that had suddenly been caused by catarrh (Wathen, Callisen, Himly). The lever B. Bell opposed it because he doubted the possibility of introducing a probe and thought that all of the liquid would flow into the throat. The consequence was that the process was abandoned for a long time. It was furthermore asserted that the probing drove the mucus further into the tuba so that the patient would be able to hear still less. Lentin, also convinced of the difficulties connected with injections, wished to rub off the orifice of the tube with a piece of veal. A little better than this veal-roast idea was that of Sims in London in 1787, who resurrected Valsalva's theory. A second mode of treatment was the operation of perforating the mastoid process introduced in the past century. Already Riolan had proposed this method and thought that by the perforation of the bone the pent-up air might be removed from the ear. It seems that in 1704 Valsalva first made an injection through an opening in a fistula existing behind the ear and noticed that the fluid ran into the mouth. J. L. Petit was the first one to successfully perform this operation by perforating the mastoid process for abscess and then removing the filthy pus from the osseous cavities. He thereby learned the

great importance of the indications without being aware of the preceding fact. Jasser, the Prussian regimental surgeon, performed a similar operation in 1776 and was therefore, for a long time, erroneously considered to be the discoverer of it. It was an accident that led him to this discovery, for he had no knowledge of the anatomic relations of the ear to the pharynx, and so surprised was he to see the injected liquid flow out of the nose that he afterward made experiments on cadavers to convince himself. His patient was deaf in both ears and suffered much pain, and there was a purulent discharge. As soon as he felt fluctuations on the mastoid process of the right ear, Jasser made an incision down to the bone, which he found so soft that the sound easily penetrated it into the cells. After repeated injections the pain and discharge of pus were mitigated. Then he perforated the other mastoid process, which had not softened on the outside, by means of a trocar, made similar injections and finally cured his patient. He ended his communication with the following remark: "Should a patient who has lost his hearing and who is not afraid of an incision and a perforation, which, in this spot, is not considerable nor dangerous, I would repeat this experiment without hesitation" (Schmucker's *verm. chir. Schr.* III, p. 113, 1782). Five years passed by during which nothing was heard of the operation. Then it was several times successfully performed by Fielitz and Loeffler, although they did not clearly understand the symptoms; the latter did not think much of the operation. But warning messages were soon received from the northern countries. Hagstrom, a Swede, had to abandon the operation on account of hemorrhage and additional bad symptoms, but yet he considered the operation a very good one and gave more definite symptoms; so also did Acrel and Murray. Now it happened that the Danish surgeons, Callisen and Kölpin, could not save the life of the King of Denmark's court physician, Baron von Berger, who, having been afflicted with a buzzing in the ears and partial deafness, died of purulent meningitis, the eleventh day after the operation (1791). According to the measurements taken the perforation must have injured the brain. Although Himly tried to persuade them not to be discouraged by this fatality, being due to a scientific error, the operation lost its reputation and sank into obscurity for scores of years. The third operation under the subject of antral surgery was likewise an infant of the times, the puncture of the drum. Riolan had also had an idea of this operation, which came to him one day when the drum of an ear was accidentally perforated, restoring the sense of hearing, and the question whether science could not serve a similar purpose arose in his mind. Willis and Valsalva first experimented on dogs; later on Cheselden tried too, while the wandering quack, Eli, performed the operation on those hard of hearing, in Paris for the first time in 1760. Himly scientifically introduced the same into Germany and as early as 1797 recommended it in his lectures which he demonstrated by operations on cadavers and live dogs and in 1806 made the first operation on a patient hard of hearing. Similar achievements were gained for English surgery by Astley Cooper in 1801. The first idea of an artificial drum dates back to the year 1640, when Banzer of Wittenberg proposed a tube constructed from the claw of a stag, covered at one end by the bladder of a hog. Then the discovery slumbered until 1763, when it was resurrected by Leschevin.

For the removal of the little ear polyp every form of operative surgery was employed; some tore it out, others like Richter, twisted it off; again it was cut or tied off (B. Bell); what method remained? Cauterizing (Loder).

XVIII.—DISEASES OF THE THROAT, CHEST AND ABDOMEN.

Tracheotomy; Throat wounds; Foreign bodies in the esophagus; Esophagotomy; Gastrotomy; Goiter; Chest wounds; Paracentesis of the thoracic cavity; Mechanical treatment of phthisis pulmonaris; Opening of the pericardium; Paracentesis of the Abdomen; Abdominal wounds; Abscess of the liver; Openings of the gall-bladder; Extirpation of the spleen; Hernia.

In modern surgery, *tracheotomy*, by means of which many lives had already been saved from suffocation during Cicero's times, is considered an operation comparatively free from danger; yet when performed during the last stages of life on a patient suffering with croup, promises but little success. Great stress is today laid upon this point of not waiting too long. During the first decade of our century tracheotomy made a bold fight to be an operative agent in croup. When Napoleon I., in the year 1807, offered a reward of 12,000 francs for the best work on a croup, Jurine of Genf and Albers of Bremen, who captured the prize, opposed the operation. In consequence, its practice was generally limited and Caron of Paris, who, on account of an error of form, having been excluded from the assembly, had said: "Hors la trachéotomie point de salut pour les croupalisés," received no recognition. Not until 1825 did its advocates, Bretonneau and Trousseau, open a new field for the operation, but during the 40's there was as yet no thought of its general adoption. Diefenbach considered tracheotomy a very dangerous operation, compared it to trephining, in which a wound endangering life is made in order to put an end to an endangering condition, and hence advocated its use only in extreme cases of necessity. Malgaigne thanked God when people knocked at his door desiring his assistance for something else than tracheotomy for croup. When all other methods had failed the physicians of that time performed the operation as a last resort.

What ideas did surgeons entertain in the last century? Their views were identical with modern ideas. Another clear proof that the point of view with reference to science ever fluctuates, that truths are forgotten and must be discovered anew, if we pay no attentions to the teachings of our predecessors. Frank Home of Edinburgh, who introduced the name "croup," for the first time recommended tracheotomy in 1765, after croup epidemics had been observed everywhere in Europe in the first half of the past century. Soon thereafter (1768) Louis declared it to be an easy operation, connected with but little danger and expressed his surprise that it was so seldom performed. He knew that with croup it availed nothing when employed as a last resort after all other methods had failed. On the contrary, he thought it ought to be one of the first remedial agents used, as soon as a case grows worse; also as a preventive of pneumonia. "Opérez le plus tôt possible." Also Heister, who ardently favored tracheotomy, warned "not to tarry too long with an operative interference in this affection, otherwise the patient's strength would be spent, when there would be no hope of success in most cases; it must take place when the patient is still strong." Popular prejudice existed then, as it

does now. Therefore, the same surgeon advised "to always consult other learned professionals and never to perform an operation alone, so that, in case the patient died, his reputation did not suffer and have it reported that he had thereby taken his life, for most people considered the operation very dangerous (although it is not so dangerous) and would say that the surgeon had cut the patients throat; that is the reason so many surgeons do not like to undertake the operation." That it can be performed with ease and safety was a statement emphatically asserted by B. Bell and Richter, who, like Louis, designated the time for an operation in croup. According to Michaelis (1778), bleeding, leeches, plasters for blistering and emetics were the first remedial agents to be tried, and in case of failure tracheotomy, as the only means of saving the patient, was to follow immediately. In the year 1797 Richter asserted that there was not an unsuccessful case on record, and we must here remark that the first operation in a case of croup on record was performed by John Andrée in 1782; it appeared that Thomas Chevalier was the first one to make a successful operation in 1814.

Heister, who recommended the term tracheotomy, instead of laryngotomy and bronchotomy, advised the use of tracheotomy for the following indications: Distress caused from suffocation from croup (angina), for foreign bodies in the trachea, and in order to inflate the lungs of the drowned with air. The last indication had been stated by Detharding in Rostock (1714) and the first idea of tracheotomy to produce artificial respiration was advanced. Later more indications for this mode of operative interference were added. Richter (1771) supplied the following: In connection with the ligature when the nasal polyps hung far down into the pharynx, for polyps in the esophagus to aid the ligature, when suffocating spasms occur in serious inflammations of the tongue, for wounds in the larynx and for a large tumor on the neck. He, as did Louis and Desault, opposed the operation with drowned persons, while Pouteau drained the water that had been forced into the air-passages by means of a tube inserted for the purpose; this was the first account of an eagerly desired proceeding. Further indications were, foreign substances in the upper part of the esophagus, highly inflamed swollen tonsils, the condition of the jugular glands after the application of mercury (B. Bell), the suffocated and the apparently dead (Ehrlich). In croup, Sharp wished the operation restricted to the time when the throat was considerably swollen through enlargement of the thyroid gland and parts in its immediate vicinity, but was therefor reprimanded by Bell.

During Heister's time there were various methods of performing tracheotomy. The first method was as follows: beneath the Adam's apple an incision of two to three fingers' breadth was made lengthwise with or without raising a fold of skin and the blood was stanchd by applying a sponge steeped in tepid brandy. Then the wound was kept asunder with the fingers or hooks and a knife or a lancet was thrust crosswise between two segments of the trachea (between the third and fourth rings, Garengéot, Sharp), even cutting a segment in two. Before withdrawing the knife a sound was put into the opening beside it, in order to insert the tube (which may be curved, round or smooth; of silver or lead) more easily. With a tape drawn through its rings, it was fastened around the neck. A piece of fine linen (Garengéot) or a sponge steeped in

warm wine was used to plug the opening so as to prevent the penetration of cold air or foreign particles. The second method consisted of piercing the skin, muscles and trachea at the same time with a double-edged knife. Sharp rejected this mode on account of the mobility of the trachea. Finally, also, a trocar (the so-called bronchotome) was thrust into the windpipe, the point was then withdrawn and the tube allowed to remain. After three or four days, or even a longer period, according to the time necessary for the symptoms to abate, the tube was removed. The next decades improved the technic of the operation, but a few deficiencies still remained and new follies were added. The cut through the skin by means of the cross fold, Richter allowed to extend from the first ring to near the breastbone in order to obtain an aperture sufficiently large (Garengeot), and freed the space between the third and fourth rings from cellular tissue, fat and muscles. On the other hand, Sharp disapproved of cutting through the sternohyoid and sternothyroid and steadied the trachea for the opening with the nail of his left index finger. It was of the greatest importance not to open the windpipe, until the bleeding, which was excessive at times but never dangerous, was stopped by tying, and above all to avoid the thyroid gland. Therefore, B. Bell pierced the trachea above the thyroid through the fissure between the two glandular flaps, while Richter opened the windpipe as low down as possible and pushed the gland back. In order to prevent the blood from entering the trachea various instruments for opening the air passages were constructed and Percy's method by means of the scissors was no longer thought of. The first bronchotome had been proposed by Dekkers of Leyden (1673); it became the forerunner of a number of new instruments, among which was Bauchot's bronchotome, consisting of a flat, straight tube into which a short two-edged lancet was exactly fitted. Richter used the same instrument, but curved it. He preferred the flat tubes to the round ones, because the latter did not completely fill the elongated aperture, and the blood entered the trachea; he selected the curved instead of the straight tube, as this, if too long, would touch the rear wall of the windpipe and if too short, was liable to drop out of the wound. B. Bell, on the other hand, could not be convinced of the inconveniences of a straight tube and preferred it to the curved one. A single tube, which, when filled with mucus, could be cleaned by means of a feather, sufficed Richter. The first double straight canula was invented by Martini when he noticed the tube filled with coagulated blood and pus; the Paderborn surgeon, Ficker, constructed the first double and curved canula, the outer of silver and the inner one of hard rubber. Sabatier thought he could get along without a tube, seeing so many difficulties with which its insertion was connected, and based his idea on his experience with wounds of the trachea, when the air passed unimpeded through the wound. Also, Michaelis considered a tube in croup unnecessary, for, as soon as the "polyp" had been removed the wound could be immediately healed. It had happened that the tube had been thrown out by violent coughing and the suffocating spasms had become so bad that the surgeon could not quickly enough replace the same and in consequence the trachea was ruptured along its entire length (Virgil). For the removal of foreign substances, the margins of the wound were plied open with dull hooks, and a curved pair of forceps was introduced.

A new operative method based on successful attempts made with dogs was given by Vicq d'Azyr: Splitting the cricothyroid ligament crosswise ("Hist. de la Soc. roy. de Méd.," I, 1777). This found many followers (Chopart, Desault, Erlich), and was successfully performed in croup by J. Hunter. On account of the ease and less hemorrhage with which this method could be accomplished, Desault preferred it; besides, he contended that an aperture in the trachea could be of no use in treating the larynx for caries or for foreign substances contained therein. For the passage of the air, the opening in the cricothyroid ligament, which he made with a common bistoury would suffice, and he thought it only justifiable to use the bronchotome for piercing the trachea when there was an excessive discharge of blood. On the other hand, to extract foreign substances he cut open the whole length of the thyroid cartilage upward from the aperture on a hollow probe. If the impediment was not immediately removed it was taken out with the forceps, or if it lodged in the glottis it was pushed upward into the mouth. Also the operation of splitting the ring cartilage, which was not dangerous, might be added. In spite of the successes attained, Richter wished to know nothing about this new method, because the inserted tube above would necessarily tear more easily than in the lower position in the trachea.

Wherever it was necessary to furnish an opening for the air to pass through, Desault found a substitute for tracheotomy in the timely insertion of a caoutchouc tube into the windpipe, which procedure was already known in antiquity. He thus curtailed the indications for tracheotomy, which consequently remained the last remedial agent. In angina, with foreign substances and caries of the larynx, an early operation in tracheotomy ought to be performed, while in inflammations with abscesses in the pharynx and the tonsils, with foreign bodies in the throat and esophagus, and in wounds in the throat a rubber tube ought to be used. It caused irritation and cough only when passed by the glottis, but the various parts soon accustomed themselves to it, so that it could be left for several hours without effecting any annoyance. Desault inserted the tube through the nose, and related a case where a soldier had two sounds put through the nose, one through each nostril, leading into the trachea and esophagus respectively, which he wore two weeks. As proofs that the one was really lodged in the larynx and not in the pharynx, were cited, a painful tickling, sudden fits of coughing, the vibrating of a flame held before it and the resistance of the wall between it and the windpipe. A curved stylet as a mandrin aided the insertion of the tube into the glottis.

Had tracheotomy become naturalized among the practitioners? Not in the least. The operations in tracheotomy, especially in croup, were very infrequent. The complaints made by Louis and B. Bell were reiterated by Richter in 1797. As far as the latter was concerned, the operation was performed too infrequently, and he was greatly surprised that it was so, there being no lack of opportunities and it was "so easy and free from danger." It is not said whether he himself often made use of tracheotomy; in 1771, he asserted that he had performed the operation repeatedly for eight years on cadavers and dogs, and once on a human being; for these, he used his instrument with success and ease. An essential reason

for the infrequency of the operation in croup was that the laity recoiled from the danger connected with the same and the surgeons dreaded the censure in case of failure. A hindrance to its use in removing foreign substances was the uncertain diagnosis of the impediment. As early as 1720 Heister had successfully performed tracheotomy on a young man in Helmstädt who had a piece of moril in his windpipe that had slipped in during his meal while laughing. Rau also performed the operation for a bean, and later Wendt (1774), an acorn being the obstruction.

Among the *throat wounds*, the crosscuts of the windpipe, if occupying only half of the front, were not considered very dangerous. The piercing of the whole trachea, on the other hand, was thought fatal on account of the injuries to adjoining parts. In cases of the former kind, after stopping the hemorrhage, it was enough to bring the margins of the wound in apposition by bending the head forward and retaining the head in this position by bandages (the Köhler cap); or else the margins were joined by a suture. The needle was passed in and out through the skin and not through the cartilage, and was removed only when the patient coughed violently. And yet it was known that large wounds had been treated without a suture having been made. It was, however, recommended nearly everywhere, although Paré had already seen emphysema supervene in consequence over the entire body, so that the patient resembled a sheep which had been inflated for the purpose of shearing it. Very decidedly did Sabatier oppose the suture, deeming it more dangerous than the throat affection itself. Even slight cut wounds in the esophagus, that extended half-way across, had been known to heal (Schmucker); only complete divisions of the same were considered fatal. They also were sewed up, but if the irritation was too great only the wound in the trachea was stitched and the one in the esophagus was left to take care of itself. Amongst the injuries sustained from the interior to the exterior, an observation on the part of Boerhaave became famous. The Grand Admiral of the Dutch Republic, Baron Vassenaer, who had the habit of taking an emetic after every banquet, was suddenly seized with great pains and died after eighteen hours; the esophagus had been severed, the rupture being an inch and a half in length, without a trace of ulceration. For nourishing the patients, Ravaton had proposed to insert a tube into the esophagus; also Desault, convinced of the inutility of nourishing enemata, used a thick elastic tube therefor. He introduced the same more generally in his practice where there existed great difficulty in swallowing, as in throat wounds, shot wounds in the mouth, swelling of the tonsils and tongue, abscesses along the esophagus, inflammations of the pharynx and tetanus. The tube was allowed to remain a number of days, but would, at times, cause hemorrhage or vomiting, so that its removal was necessary (Ehrlich). In case the esophagus became paralyzed, J. Hunter proposed the idea of taking the skin of an eel, which had an incision at the lower end, inserting it down into the stomach by means of a probe and through it injecting the proper nourishment. In persistent contractions of the esophagus Richter hoped that nature would do the work in its frequent expansions of the same by food and drink. For examining and dilating the same, E. Home first advised the bougie and Wathen obtained successful cures in gradually widening the esophagus by means

of wax candles inserted daily. Pelletan made experiments with cauterization. In wounds of the large vessels of the throat, which have been very deficiently described as a rule, ligatures were applied or steady pressure. B. Bell employed similar means with the larger veins, when cut through; compression he used in throat wounds.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Ophthalmological and Otological Society.

Regular meeting held Oct. 12, 1897, in the Stewart Building.

Dr. MONTGOMERY in the Chair.

There were twenty members and visitors in attendance. Minutes of the last meeting read and approved. The application of Dr. J. B. Taylor of Bloomington, Ill., was referred to the Committee on Membership.

Dr. WILDER showed a man aged 50 years, with a good family and personal history, whose mother had suddenly become blind after suffering severe pain. In August, 1896, the patient noticed that vision in the left eye became very poor, and blood was seen at that time in the anterior chamber. There was no pain then, but it developed soon afterward. There was detachment of the retina, which is now complete. He consulted a number of oculists, some of whom called it iritis, and others glaucoma. Six months ago an iridectomy was done upward, and following the operation there was considerable pain and hemorrhage. At present the tension of the eye is slightly increased and there is slight pain. There is a large amount of fluid blood in the anterior chamber, which has been there for a long period. The lens is cataractous. About a week ago well-marked pain suddenly developed, and three days later there was found on the cornea three small vesicles overlapping each other like the three links of a chain, probably a true herpes.

Dr. HOTZ thought the case was hardly one of hemorrhagic glaucoma because of the great depth of the anterior chamber and of the slight, if any, increased tension. He had always found the chamber very shallow in cases of hemorrhagic glaucoma.

Dr. MONTGOMERY had seen a case six months ago in which the tension was +3; but there was no hemorrhage. The anterior chamber was deep. A tumor was suspected, and an iridectomy was made, following which the tension dropped to normal and there was perception of light. Recently, however, the tension had again gone up and hemorrhages had appeared in the anterior chamber.

Dr. COLBURN had seen cases in which there were retinal hemorrhages, followed later by blood in the anterior chamber. In regard to the vesicles in this case he had seen several, but none where they were arranged in this way. He had noticed in some cases of choroiditis that vesicles appeared at times, usually accompanied by great pain.

Dr. MONTGOMERY had seen cases of complete detachment develop pain from glaucoma, or from uveitis.

Dr. GRADLE had found uveitis not uncommon in detachment cases, but had never seen glaucoma following.

Dr. HOTZ had never seen glaucoma follow detachment of the retina.

Dr. DODD showed a case of ulcer on the palpebral conjunctiva, which was first seen three weeks ago, at which time there was no swelling. The ulcer was small, and the discomfort had existed about a month. It slowly extended and soon involved the whole surface, including the edge, of the lid. The lid is now considerably swollen. Nitrate of silver and other antiseptics had no effect on the ulcer, and although a history of syphilis was denied, it was probably a chancre.

Drs. MONTGOMERY, HOTZ and PINCKARD had all seen cases of chancre of the conjunctiva following the removal of a foreign body by means of the tongue.

Dr. W. H. WOODRUFF showed a boy who was struck in the left eye on July 4. He was first seen a month later, at which time there was a cataract and a small cyst in the upper outer periphery of the iris, very well defined, and occupying about a third of the breadth of the iris.

He referred to another case he had recently seen in a man 55 years old with good vision, whose pupil dilates well except at the point of the cyst. As far as could be determined this was a congenital condition.

Dr. DODD had studied two cases of cyst of

Treacher Collins of London, both of which were traumatic. Such cysts are supposed to develop, by some, from the crypts in the iris; by others, from a hemorrhage in the periphery, which later develops into a cyst.

Dr. GAMBLE showed a case of locomotor ataxia in a girl of 8 years, first seen May 17, 1897. Vision in the right eye, fingers at three feet, and left eye p.l. Ophthalmoscopic examination showed primary gray atrophy of both discs with marked atrophic cupping. Pupils dilated; no reflex to accommodation or light; patellar reflexes gone; Romberg's symptoms much pronounced; no nystagmus. She never had any severe illness except diphtheria when one year old, which was not followed by sequelae. She had severe headaches from infancy at irregular intervals, varying from one month to six months. During one of these attacks her hand became so numb that she could not feel the door knob and open the door. No cerebral disturbance noticeable; no girdle symptoms. She was examined by Dr. King, who found no change in sensation.

The father was examined in the latter part of May and found to have primary gray atrophy of the discs. He had had a chancre in 1871. He was also examined by Dr. King, who made a diagnosis of locomotor ataxia.

Dr. GAMBLE showed a case of sarcoma of the ciliary body involving also about one-third of the iris. As far as could be determined, this had existed only a few months.

Dr. WILDER showed a case of dermoid tumor of the cornea. Alice P., aged 19, came to the Illinois Eye and Ear Infirmary in July of this year on account of a growth on the left eye. She was first seen by W. L. Noble, M.D., through whose kindness she was transferred to his service. The patient has always been in good health, and has no evidence of malformation or abnormal growths in any other part. Situated at the outer margin of the cornea was a bean shaped growth whose longest diameter was about 10 mm., and shortest about 7 mm. It was a thick fleshy mass, overlapping the cornea several mm. and lying in the episcleral region with the conjunctiva extending on to it. It was yellowish white in color, of a fine consistence and had several hairs growing from the surface. The mother stated that the tumor was not present at birth, but developed in early childhood as a result of a scratch of the eye, rapidly attained its growth, and has not noticeably increased in size during the last ten years. It causes discomfort on account of its size preventing perfect closure of the lids, and because of the hairs irritating the cornea. She has frequently had the hairs drawn. In excising it care was taken to preserve as much conjunctiva as possible in order to cover the wound. The site of the growth on the cornea and sclerotic was carefully curetted with a sharp spoon after the removal of the mass, and the conjunctiva stitched over it. It healed very kindly, and in a short time the patient was discharged. The sections show typical cutaneous structures.

The Doctor is inclined to think that the term dermoid cyst is inappropriate for these growths, which, so far as his observation goes, are solid tumors and not cystic. They differ in this respect from the dermoid growths that occur in the ovary, testicle, and the abdominal cavity. Such tumors, as we know, are cystic and are probably caused by an invagination of the epiblastic layer of the embryo. In these the lining wall is epithelial and the growth is *inward*, so that the cyst becomes filled with hairs, sebaceous material, disintegrated epithelium and even teeth and bones. The same may be said of the dermoid tumors that affect the orbit and sometimes push forward on to the eyeball. But with dermoid tumor of the sclerocorneal junction the case is different. In this we have a solid mass, composed, it is true, of cutaneous structures, but with the epithelial layer on the outside, and the hairs growing outward. The interior of the mass is of connective tissue with numerous elastic fibers, as shown so well in the microscopic preparation exhibited. He was inclined to think that in the *nature of their development* they are not akin to the dermoid cysts of other parts, but are in some way connected with the development of the lids.

In the embryo the eyelids are formed from the palpebral folds which, as they grow, approach each other and become united. Later a separation takes place, but some of the epiblastic tissue may remain in contact with the eyeball and take on an independent growth. Such growth might continue even after birth, or the little mass might remain quiet for several years and then begin to increase in size.

Dr. HORTZ had seen several true cysts of a dermoid character occurring on the cornea.

Dr. HORTZ read a report on "Holocain" (see JOURNAL, p. 1012, and *Ophthalmic Record*).

Dr. HALE said it is reported that holocain is in itself an antiseptic and will keep indefinitely.

Dr. PINCKARD referred to the new form of eucain called

eucain B. He had found it very satisfactory, there being little or no pain attending its application. It will keep indefinitely and will stand boiling without changing its character.

On motion, the Society adjourned.

C. P. PINCKARD, M.D., Secretary.

103 State Street.

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Continued from page 1118.)

THURSDAY—MORNING SESSION.

After the usual announcements and election of new members, the following preamble and resolutions were presented by Dr. H. S. ANDERS of Philadelphia:

WHEREAS, The common and promiscuous public use of drinking vessels under existing conditions and well-established hygienic principles is positively and essentially unclean and insanitary, and therefore a menace to public health; and

WHEREAS, During the past three years many churches of various denominations have recognized the need of prophylaxis in administering the communion wine by adopting individual communion cups or chalices, as being cleaner and safer, at the same time not less satisfactory and sacred as substitutes for the common communion cup; be it hereby

Resolved, That the American Public Health Association in endorsing the individual communion cup, approves cordially the action of the churches, and recommends earnestly the adoption, for sanitary reasons, of individual communion cups wherever communion cups are now in use.

Resolved, That this Association recommends still more emphatically and urgently to the public the general use of individual cups, particularly in schools, on railway trains, in stations, at public fountains and the like, as contributory to the better prevention of communicable diseases.

This was referred to the Executive Committee.

The report of the Committee on Health Legislation was presented by Dr. H. P. Walcott, president of the State Board of Health of Massachusetts. It contained a proposed bill to establish a Department of Public Health to be under the management of a Commissioner of Health, who shall be a regularly graduated physician, appointed by the President of the United States, and whose term of office shall be six years. This was referred to the Executive Committee.

RECENT RESEARCHES UPON THE ETIOLOGY AND SPECIFIC TREATMENT OF YELLOW FEVER.

by G. M. Sternberg, M.D., Surgeon General U. S. A.

In a former paper he gave his reasons for believing the bacillus of Sanarelli to be identical with the bacillus X obtained by him from yellow fever cadavers at Havana. If this is not established, the claim of Sanarelli, that his bacillus is the specific infectious agent, can not be admitted. It must be the same in the fever at Havana and Rio de Janeiro. All his researches in forty cases during 1888-89, etc., show that no micro-organism other than bacillus X develops in the culture-media usually employed, except the colon bacillus and a few species exceptionally found and excluded from consideration for reasons formerly stated. The bacillus of Sanarelli readily grows in the culture-media employed in my researches and if present in the blood or tissues of the cadavers at Havana I could not have failed to find it. In stating conclusions I say: "The specific infection in yellow fever has not yet been demonstrated. I suspected at the time that it had been discovered in my bacillus X." After alluding to the association of the names of Eberth with the typhoid bacillus and Klebs with that of diphtheria as being in the same way shown by one but demonstrated by another, he said if my bacillus X and the bacillus icteroides of Sanarelli are proved to be identical, Sanarelli will deserve full credit for the demonstration and I shall not be disposed to detract from the praise due him. If, as he claims, he has obtained the final proof that this is the yellow fever germ by producing the disease in man as a result of the intravenous injection of filtered cultures, I think we must accept these as demonstrative of the bacillus in question. But without this final proof the demonstration would not be satisfactory, notwithstanding the pathogenic virulence of the bacillus when injected into several species of the lower animals. If it were constantly found in the blood and tissues of yellow fever cadavers there would be little reason to doubt its specific character. But both my researches and those of Sanarelli show that notwithstanding the most painstaking investigations this bacillus has not been found in a considerable proportion of typical fatal cases of yellow fever examined. I obtained bacillus X in a certain number of cases from the contents of intestines of yellow fever cadavers; but it was present in comparatively small numbers and I was more successful in obtaining it by culture in guinea pigs than in cultures directly from

the intestine. I suggest in my report that possibly yellow fever results from the absorption of a toxin produced during the multiplication of the specific germ in the alimentary canal. This is advanced as a hypothesis which has some facts in its favor. If, as stated by Sanarelli, comparatively small quantities of a filtered culture of this bacillus will give rise to yellow fever in man, when injected beneath the skin or directly into the circulation, this fact would appear to give additional value to the hypothesis. At all events, it would be very unfortunate if upon the strength of Sanarelli's negative researches sanitarians should neglect to disinfect the excreta of yellow fever patients. After alluding to the difficulty of isolating typhoid bacillus and yet that it could always be obtained by culture, he said: "It is evident that notwithstanding the negative results usually attending culture experiments, bacteria were present in the liver and kidneys and were developed postmortem when portions of these organs, enveloped in an antiseptic wrapping, were placed in an incubating oven. This method was followed by Sanarelli, but he neglects to refer to the fact that I had employed it in an extended series of cases or to my bacillus X, which was fully described in my official report to which he apparently had access, although he makes serious mistakes in referring to my work. Thus he says: 'Dr. Sternberg of Baltimore, author of the most recent, rich and methodical contribution to this disease known, declares that the specific microbe is yet to be found, and he affirms that the whole question is to be taken up *ab initio*.' This was not exactly my position, as I say I have commenced writing a report because I feel that an account of what I have been doing during the past two years is due, and not because I have brought my investigation to a successful termination, or because I feel that there is nothing more to be done. No one can regret more than I do that the question of the etiology of this fever is not definitely solved, but I have not to reproach myself with want of diligence or failure to embrace every opportunity. The difficulties are greater than anticipated. If the task had been to find an organism in the blood or in the organs, the researches could scarcely have failed to be crowned with success. But among the micro-organisms encountered there is not one which by its constant presence and special pathogenic power can be indisputably shown as the specific agent. Note that I say among the micro-organisms encountered there is not one which, etc., can be shown indisputably to be the infectious agent. But I carefully described one and sum up: It is possible this bacillus is concerned in the etiology of the fever. I hoped investigators would consider this possibility, no one had a right to ignore it, and continued investigations by the same method can not be considered as taking up the subject *ab initio*. Again Sanarelli says: 'Sternberg thinks there is probably a localized infection having its seat in the stomach.' This is a mistake. I advanced the hypothesis that the germ of the disease may be located in the alimentary canal, as in cholera, and the symptoms result from the absorption of a very potent toxin produced by it. But this is only a suggestion, and I know of no evidence indicating a localized infection of the stomach.'" After quoting further from his experiments, he says the writer has long been of the belief that the discovery of the germ of yellow fever would be likely to be followed by important results in the prophylaxis and in the treatment of this disease. He mentions some experiments upon horses, etc., and concludes: "Comparative experiments already made at the Army Medical Museum, by Major Walter Reed, show certain cultural differences between the bacillus icteroides of Sanarelli and my bacillus X. Whether these are due simply to the fact that bacillus X has been cultivated for eight years in artificial media, or are to be considered as evidence that we are dealing with two more or less permanent varieties of a single species, or are to be taken as evidence that the bacillus of Sanarelli is specifically distinct from my bacillus X can only be determined by further experiments, and especially relating to the pathogenic power of the culture obtained by me from yellow fever cadavers in Cuba, and by Sanarelli from yellow fever cadavers in Brazil. At present bacillus X is non-motile, while Sanarelli's bacillus is actively motile. But in my original cultures, as stated in my published report, bacillus X was motile. At present Dr. Reed informs me that the presence of flagellæ may be demonstrated by proper staining methods."

He had visited Cuba on two occasions, to learn for himself as much as was possible as to the correctness of his views as to yellow fever. He believed the bacillus of Sanarelli to be identical with his bacillus X described in his paper some years ago.

Dr. HENRY J. BARNES of Boston, read a paper

THE LACK OF PROPER HUMIDITY OF INDOOR ATMOSPHERE.

He alluded to the aridity of the West and said: Death

Valley has an aridity of 23 per cent. for five months in the year. The mean relative humidity of the United States is 60 to 80 per cent. In the northern states in winter, when the houses are heated, there is no moisture provided and everything becomes kiln-dried. Air of a house should have 50 to 75 per cent. saturation. Many devices have been offered. A new plan has been proposed for large buildings by C. J. H. Woodbury. The humidifier is about twenty four inches square, the top and two sides solid, the third side a tight door, and the fourth or front part of openwork brass, the bottom open, the whole intended to stand over a register in the floor. One half of the interior is taken up with a galvanized water-tank, with broad edge at the top, on which rests a brass frame holding several rods at the top from which are suspended strips of cotton felt nearly the width of the tank and long enough to reach its bottom. The tank is filled with water and the strips become wet; the hot air coming through the register must pass these strips and are thus charged with moisture. Should the air of the room become too moist, as shown by the deposit on the windows, by a simple mechanism acting automatically, the strips are lifted from the tank, the air dries them, and passing round the room makes the amount of moisture right, and again the strips dip into the tank. He also showed a German machine which consisted of a trough, thirty inches long, from one end of which hangs a cotton sheet, and at the other end a shallower trough so adjusted that when dry the roll rests in the trough, but when the air is saturated the surplus water drips into the bottom trough and the weight draws the roll at the top out of the water to the edge of the trough where it remains till the water in the lower trough is evaporated, the weight is removed, and the cloth slips again into the trough. This becomes stained and rendered unsightly. With the humidifier first named, it was possible to obtain a mean of 73 per cent., the atmosphere comfortable. The window glass will always serve as a guide, and the machine will be sure to work automatically. He gave the results of a series of experiments at the Boston City Hospital: The average temperature was 69 degrees, the mean relative humidity 29 per cent.; out door temperature being 30 degrees, humidity 71 per cent. In his office, for eight days, the temperature was 71 degrees, humidity 27 per cent.; outside being 31 degrees, humidity 73 per cent. A draught given by a fan produces no refreshment during the saturated atmosphere of dog days, because of the incapacity of the atmosphere to extract heat by taking up moisture. High temperatures are enervating. The dry sirocco produces suffering, extreme lassitude, parches the skin and creates a raging thirst. Much time spent in heated rooms in winter is the cause of much of the catarrhal troubles so common during this period. Breathing an atmosphere that thus robs the mucous membrane of the lungs, etc., of the moisture needed to preserve its secretion, impairs the integrity of the tissue and gives a favorable soil for the development of infectious organisms. The frequent failure of the vocal organs of public singers and speakers may be the result of excessively dry air.

Dr. P. A. BRYCE, of Canada, read a paper on

THE PLACE OF THE STATE IN DEALING WITH TUBERCULOSIS.

Should any one inquire into the legislation of any State or Province on this continent, prior to the last twenty-five years, he will be surprised at the paucity of laws dealing with any systematic plans upon social matters, or providing for systematic supervision of public health. In European countries, especially England, workhouses and dispensaries existed but they were established as a disagreeable necessity rather than because of the claims of the poor and sick upon the State. In Ontario the deaths from tuberculosis were, 1871, 11.2 of all deaths; 1881, 10.8; 1891, 11.4. In Toronto a similar condition is seen. In the United States we may divide the deaths as follows: North Atlantic division 2.2 per thousand of population; South Atlantic, 1.7; North Central, 1.3; South Central, 1.4; Western, 1.5. The quality of legislation must be judged by its effects. Compare the causes of insanity in the asylums of Ontario: In 1895 they were double the deaths by tuberculosis. But if we examine we find the deaths from consumption and those in the asylums are one-tenth the number annually. Roughly, ten times as many persons become affected with tuberculosis every year as with insanity and ten times as many die. Therefore, some 2,500 persons, mostly above fifteen years of age, are enrolled in the ranks of tubercularized, not to mention an undetermined number. The legislature of Ontario, in 1839, providing for a lunatic asylum levied a tax of one penny in the pound on the districts of the Province. In 1826 taxes had been levied to support Houses of Industry and for a district hospital. Year by year this was increased, but the systematic extension of any class of these institutions was

spasmodic till 1874 when Provincial aid was granted, upon government inspection, to the several classes of benevolent institutions. The extent to which they have grown is seen in Ontario: In 1874, 10 hospitals with grant of 30 cents *per diem*: 1887, 18 with the same; 1896, 39 with the same; 1874, 4 refugees with a grant of .07 cent *per diem*: 1887, 21 with the same; 1896, 32 with the same; 1874, 13 orphanages with a grant of .02 cent *per diem*: 1887, 29 with the same; 1896, 31 with the same. The increase of the population of asylums was 1,366 in 1871 to 4,709 in 1896. The total hospital population in 1878 was 4,372; in 1896 17,517. The inmates of refugees in 1878 was 1,300: in 1896, 4,355; orphanages, 1,300 to 3,995. The Annual increase in cost of maintenance was remarkable: Asylum in 1871, \$173,611.11 to 1895, \$595,843.13. The hospital, refuge and orphanage maintenance was equally remarkable. The population of the province increases slowly; 1871, 1,620,851; 1881, 1,926,922; 1891, 2,114,321. It is quite apparent, therefore, that aid is extended to a certain percentage of consumptives in Ontario, but from the number of deaths it is apparent that they go to the hospitals to die rather than with any idea of recovery.

The greatest distinction must be made between governmental intervention for the sake of the people and State interference for the sake of the government. Is this expedient with tuberculosis? Is it practicable? Institutions partaking somewhat of the characteristics of each of the asylums, hospitals, refuges, etc. will be required. Medical relief to be complete must deal with this properly. The average number of days in hospitals of consumptives was about 50 in 1896, or about 20 days longer than for all patients. Manifestly, general hospitals are not the places for consumptives. Naturally we turn to the single illustration on this continent, an ideal home for them, the Saranac Lake Sanitarium, which under the fostering care of Trudeau has grown up, a type upon which all future efforts must be based. Ninety millions of people represented in this Association are interested in this matter. This is the fifteenth year of Koch's discovery. During this time 2,000,000 have died here from this disease and only one model home equal to the care of 177 people. Unfortunately the beginning has been due not to the State but to private philanthropy. In Ontario we are working. The cost has been for an average of thirty-four days residence, 64 cents per capita or \$4.50 a week. At Saranac Lake it has been \$6.00 a week. According to the same rate, in Ontario, it would be comparatively easy to have several homes for consumptives to which every tuberculous case could be sent in the initial stage and in a large percentage cured. What we may then advocate is for the government to loan money, as on drainage debentures, at low interest to cities and counties, pay a percentage of the maintenance, and then private charity added to municipal grants would accomplish the rest. The choice of location is important. To France we may look for the first systematic attempts to deal with a class of the tubercularized where a number of marine or seaside hospitals have been established for children. The statistics of 1894 show 70 to 75 per cent. of cures. In Germany, private sanatoria have taught how much can be done.

Dr. SAMUEL W. ABBOTT, Secretary of the State Board of Health of Massachusetts, read a paper on "Consumption an Indoor Disease." He gave the characteristics of the disease, showed it to be an indoor infection, the conditions which influence infections outdoors and indoors; relations to industrial hygiene; proofs of the proposition that it is an indoors disease, viz., observations on occupation mortality, and observations on mortality by sex and age periods; difference in the death rate from tuberculosis in the sexes and at different ages; comparative mortality from phthisis and lung diseases of men (45 to 65 years of age) working in pure and vitiated air, etc.

A paper, the "Necessity of Adopting an International Classification of the Profession," was read by Dr. J. MONJARRAS of the Board of Health of the State of San Luis Potosi, Mexico.

Dr. S. A. KNOPP of New York City read a paper on the "Urgent Need of Sanatoria for the Consumptive Poor of Large Cities."

Dr. D. H. BERGEY of Philadelphia presented a paper on

BOVINE TUBERCULOSIS IN ITS RELATION TO PUBLIC HEALTH.

Tuberculosis in cattle is similar to human tuberculosis. This is evident from the fact that: *a*. The nature of the disease process is the same in cattle as in man, and *b*, we have evidence of the transmission of the disease from cattle to man through the use of meat and milk of tuberculous animals as food; and *c*, there is a possibility of the transmission of the disease from man to the lower animals by feeding them on tubercular sputa; and *d*, of the transmission of the disease from one class of animals to another by feeding on tuberculous meat and milk.

Each of these propositions is substantiated by numerous observations which have been reported during the last quarter of a century. The first proposition is so self-evident that it will be unnecessary to quote any authorities. Recent literature contains no dissensions from this proposition. The second proposition is supported by the clinical observations of Leonhardt, Sonntag, Hermsdorf, Demme, Bollinger, Stang, Holt and many others. The third and fourth propositions are supported by the clinical observations and experiments of Woodhead and Martin, Klebs, Demme, Bollinger, Nocard, John, Jacobs, Sonntag, McFadyean and a great many others.

The danger to public health through the use of meat and milk of tubercular animals is greater than is generally supposed, because: *a*, the disease is very insidious in its onset and for this reason it is long overlooked, and *b*, even when the disease is localized there is danger in using the meat, because: 1, the blood may contain bacilli in portions of the carcass other than those containing the tubercular nodules, and 2, because the milk may contain bacilli without there being any disease localized in the udder itself. We find numerous observations reported which substantiate these different propositions, notably those of Fütterer, Rütmeier, Sticker, Ulacocis, Meisele, Lustig, Heller, Weigert, Nosse, Herzheimer, Hanau, Bangs and others in support of the first proposition, and those of Ernst of Harvard in support of the second proposition.

The facilities for the discovery of the disease in an infected herd are excellent since the introduction of tuberculin as a diagnostic agent. From the fact that the blood of an animal may contain bacilli and thus any portion of its body may become the carrier of the disease, that the milk of the animal may contain bacilli even without there being any disease observable in the udder by ordinary methods, it is highly essential that all cattle whose milk and meat are to be used for human consumption be tested from time to time with tuberculin, to be certain that they are free from tuberculosis. Several cities now have strict inspection of all milk cows furnishing milk for the people of the city (this is the case in Minneapolis, Minn., which has a very efficient law), and it will be of great interest to watch the beneficent results of such precautions upon the general health of such cities in the future. The benefit of strict inspection of cattle slaughtered for food is shown by the lower mortality from tuberculosis among the Jews in our American cities, as shown by the results of our last census. This fact is all the more striking when we consider that as a rule these people do not live under the best of hygienic conditions. Much good must also result from the efforts made to stamp out the disease in different States, notably Pennsylvania, by testing suspected herds and slaughtering all those showing the characteristic reaction under the tuberculin tests.

P. RAVENEL, M.D., presented a paper on

TUBERCULOSIS AND MILK SUPPLY.

Tuberculosis is the most widespread disease, both in man and in animals, with which we have to deal, causing in man one-seventh of all deaths. Among animals, the bovine species appears to be the most susceptible. Geographically considered, there is a close connection between the presence and absence of tuberculosis in man, and the presence and absence of diseased cattle. The disease is very prevalent among the dairy herds of America, and has increased during recent years. We may well ask if the disease is being transmitted through the milk of tuberculous cattle. The danger was pointed out by Professor Klencke in 1846, and confirmed by Gerlach in 1869. Since then numerous observers. All cases so far reported have been in children and young persons, and postmortem examination of children dying of tuberculosis points to the intestinal tract as the most frequent channel of infection. In 127 cases examined by Dr. Woodhead, 100 showed tubercular infection of the mesenteric glands, and 43 ulceration of the intestine. Milk is so largely used by children, that one would naturally look to it as the conveyer of the infection in such cases. The suspicion is greatly strengthened by the fact that the tubercle bacillus has frequently been found in milk. It was formerly believed that this only occurred when the cow showed local lesions in the udder, but Baug, Ernst, Theobald Smith and others have shown that the tubercle bacillus may be found in the milk of cows having general tuberculosis, but the udder being healthy, so far as a careful examination could show. Beyond this, numerous feeding and inoculation experiments on pigs, guinea pigs and rabbits have shown that even when the udder is healthy the milk of tuberculous cows may be highly infectious. Galtier showed that milk is most dangerous where lesions of the udder exist, and next in general tuberculosis.

The disease as found in man and the bovine species is practically identical. Cases of accidental infection during post-mortems of tuberculous cows have been reported by Tscherr-

ming of Copenhagen, Pfeiffer, Law and the author. In the case of Pfeiffer the disease became generalized in the course of about a year, and death resulted two and a half years after the wound. Inoculation of lower animals from man confirms these results.

The author gave reports of experiments carried out by himself at the laboratory of the State Live Stock Sanitary Board at the University of Pennsylvania. Of 88 animals treated by inoculation with milk from cows known to be tuberculous, 15.4 per cent. died of tuberculosis. All of the cows from which milk was taken had perfectly healthy udders, so far as the most careful examination could reveal. In the case of one cow a postmortem examination was also made. From these and other like experiments it seems that the number of tubercle bacilli in the milk of tubercular cows may vary from day to day. In conclusion the author said: "I have given in these pages only a part of the evidence that is at hand on the question, but enough has been said, I think, to show the soundness of the conclusions arrived at by the Royal Commission on Tuberculosis, that . . . 'as to the proportion of tuberculosis acquired by man through his food, or through other means, we can form no definite opinion, but we think it probable that an appreciable part of the tuberculosis that affects man is obtained through his food.'

"And 'No doubt the largest part of the tuberculosis which man obtains through his food is by means of milk containing tuberculous matter.'

"The remedy lies in the careful inspection of milch cows and the immediate removal of any diseased animals found. Milk from suspected cattle should be carefully sterilized before being used, and especially should not be given to infants or invalids. The inspections of the animals should be at intervals frequent enough to keep the disease from gaining headway before being discovered."

(To be continued.)

PRACTICAL NOTES.

Glass Tooth Filling.—Glass, prepared by a new patented process, which renders it soft and malleable, is now used by dentists to fill the cavities in teeth. It is said that it answers the purpose admirably and is less conspicuous than gold.

Treatment of Glaucoma with Resection of the Cervical Sympathetic.—Jonnesco has applied to glaucoma with excellent results, three cases, the operation devised for exophthalmic goiter. Sight was regained and the ocular tension reduced below normal.—*Bulletin de l'Académie de Méd.*, October 19.

Rupture of the Callus in Fractures of the Patella Treated with Massage.—An article in the *Gaz. Méd. de Paris* of October 23, reviews the ultimate results of massage treatment, as reported by Scandinavian, Dutch and German surgeons, this treatment not being popular in France, and finds eight ruptures in thirty-five fractures, a proportion of 23 per cent. Koenig rejects the method. The rupture always indicates a grave functional prognosis.

Mechanical Mobilization of Ankylosis.—Phocas attached the arm of a lad of 12 years 6 months to a slowly moving machine propelled by a hydraulic motor, and in this way broke up a fibrous ankylosis of the elbow consecutive to fracture. The patient can now bend his elbow almost at a right angle, fifteen days after commencing the treatment—thirty hours in all. Previous manual attempts at mobilization had always produced intense inflammatory reaction.—*Gaz. Méd. de Paris*, Oct. 23.

Postural Treatment of Seasickness.—Rawlins, an English physician, says that the elevation of the extremities will quickly relieve the symptoms of seasickness by increasing the arterial pressure, and thus diminish the anemia of the nervous centers due to the enfeebled action of the heart. The application of warm flannel bandages to the legs and arms will increase the effect produced by the simple elevation. In this way he was able to make two ladies comfortable during a journey to India, who had previously suffered seriously from severe seasickness. This is a corroboration of a remark made to the editor of the *JOURNAL* by the surgeon of the Nord Deutscher Lloyd Str.

Spree in 1890. That officer stated that in his judgment the postural treatment was the most suitable for most cases, cerebral anemia being generally present.

The Rhythmic Contractions of the Heart originate in the cells of the myocardium in the form of automatic rhythmic impulses, corresponding to the rhythmic disintegration and integration of the contractile substance. It is communicated from one cell to the other and, by means of the sarcoplasm, to the entire heart. This statement is made by Botazzi as the result of much research. He adds that everything tends to prove the myogenic nature of the cardiac rhythmus and its independence of the nerve ganglia. His investigations are described in the *Gazz. d. Osp. e d. Clin.* of October 10.

Pills for the Treatment of Peri-uterine and Pelviperitoneal Effusions.—(N. Maldaresco.) Iodol, 6 grams; powder and extract of licorice, q. s. to make 60 pills. Commence with two pills morning and night and increase to five, equivalent to one gram of iodol a day. The pain will subside by the third or fifth day and the local process be resolved without keeping the patient in bed. After the effusion is absorbed the iodol should be continued for some time at the dose of 60 centigrams a day. Menstruation and pregnancy do not counterindicate its use. Iodism is never produced by it, even at the dose of 2 to 3 grams several days in succession.—*Sem. Méd.*, October 6.

To Prevent Recurrence of Erysipelas.—The germs lingering in the crevices after an attack of erysipelas only await a chance to germinate anew in all their virulence, and the frequency of erosions in the nose, ear or internal angle of the eye, due to the delicacy of the skin where it joins the mucous membrane, affords the germs their opportunity. Maldaresco has prevented recurrences completely by supplementing the cure with a thorough disinfection of the entire region, into its remotest crevices, preceded by several baths with general lotions of van Swieten's solution and repeated injections into the ears, nose and corners of the eyelids of van Swieten's solution, to every liter of which he adds 5 grams of tartaric acid. The intranasal injections can also be made with equal parts of water and 1 per cent. of sublimate.—Moscow Congress.

Empyema of the Maxillary Antrum in a Child of Eight Weeks.—Power (*British Medical Journal*, No. 1,917, p. 808) reports the case of a wasting boy, eight weeks old, who came under observation on account of an abscess which had pointed and was discharging at the lower part of the right lower eyelid. The right side of the face was somewhat fuller than the left and the skin of the lower eyelid and cheek was red and hot. A considerable quantity of pus could be squeezed out by pressure upon the cheek, and on looking into the mouth a small quantity of pus could be seen exuding from the alveolar border of the upper jaw. A probe passed along the sinus in the cheek showed that the upper part of the superior maxilla was bare. This sinus was enlarged, some granulation tissue scraped away and an opening made through to the floor of the antrum, so that a drainage-tube could be passed from the eyelid into the mouth. About a dram of thick pus came away at the time of the operation, but the child died ten days later. It was learned that forceps had been used at birth and that after delivery both sides of the face were badly bruised, the right more than the left. When the infant was a month old he seemed to have some difficulty in closing his mouth and he refused the bottle. About the same time the redness and swelling appeared below the right eye and eventually an abscess was opened. There had not been any case of infectious disease in the house.

Thymol as a Vermifuge.—Dr. F. M. Sandwith reports that for many years he has been using thymol as the most perfect destroyer of the ankylostomum duodenale and any accompanying parasites in the intestines of his Egyptian patients. Sometimes it takes many doses of the drug to rid a man of his last

remaining nematode, but the following case ought to encourage any doubters to persevere with the thymol treatment. A man, aged 33 years, was admitted from the out-patients April 29, 1897. He was a peasant from Assiout, but for the last two years had worked in Cairo. He was found to have anemia from ankylostomiasis of twelve years' duration, and for the last year he had had pellagra. On May 2 he was given 60 grains of thymol in two doses on an empty stomach, followed by a purge. In the feces that afternoon were found 523 specimens of ankylostomum duodenale besides fifty-five oxyurides. On May 7 the thymol treatment was repeated. No ankylostomum duodenale was found, but there were three oxyurides. On May 17 the thymol treatment was employed for the third time, but no worms were passed and no eggs were found microscopically. The three examinations in the case of this patient were made by Professor Looss of Leipzig, thus precluding all error, and it is fair to say that the cause of this chronic disease was removed by 60 grains of thymol. The patient was extremely anemic on admission, but three weeks later was much less so, owing to the administration of iron, rest and better food. His weight remained at 133 pounds before and after treatment. The symptoms of pellagra were a slight roughness of skin on the extensor surface of the hands, forearms, elbows, feet, legs and knees; the tongue pale and denuded of epithelium, and increased knee-jerks. He was sad and melancholy-looking and unable to smile, and there was tenderness on pressure over the spinal nerve on both sides of the fifth dorsal vertebra. Thymol has, of course, no direct effect on the poison of pellagra.—London *Lancet*.

Orthoform. Einhorn, in the *Münchener Med. Woch.*, August 24, has described a new synthetic local anesthetic to which the name orthoform has been given. This body is a light white powder, without smell or taste. It is only partially soluble in water: enough is brought into solution to make the fluid anesthetic. It combines with hydrochloric acid, forming a very soluble compound, which can not, however, always be used, as it irritates some mucous membranes such as the conjunctiva. Anesthesia is only induced in the places with which the orthoform comes in contact. Orthoform acts as an anesthetic wherever it comes in contact with nerves, and thus it has no effect when applied to the unbroken skin. If it be applied to a burn of the third degree the anesthetic effect is remarkable. It also allays the pain of ulcers, whether cancerous or other. In one case as much as 50 grams was sprinkled on a wound within a week, showing that it is quite harmless. It is strongly disinfectant, hindering decomposition and fermentation. Orthoform was also useful in ulceration of the larynx, after some of the powder was blown in the pain was relieved for twenty four hours. In gastric ulcer and carcinoma it was also of service, but much less so in chronic gastric catarrh. For external use free orthoform is the best, but for internal use the soluble acid salt. Further observation is needed in regard to its action on the mucous membranes of the mouth, nose and nasopharynx. As it is non-poisonous, it can be applied to large ulcerating surfaces. Internally $\frac{1}{2}$ to 19 of the hydrochlorate has been given several times in the day. Orthoform is stable, non-hygroscopic and can be added to other remedies.

Yeast Nucleinic Acid in the Treatment of Septicemia.—Several observations have been published on the treatment of pyemic affections by means of yeast and its preparations. In the *Medical News* is a paper by Dr. Walter Courtney on this subject. For the purposes of this article, Dr. Courtney defines septicemia as a general systemic invasion by one or more varieties of the pyogenic or putrefactive bacteria, their products, or both. Dr. Courtney had observed Dr. Vaughan's experiments with yeast nucleinic acid on rabbits and guinea-pigs which had been inoculated with the bacillus tuberculosis, the bacillus of tetanus and the bacillus anthracis, and in different

animals. The inhibitory and frequently curative effect of the nuclein treatment of these various infections was most marked, and Dr. Courtney subsequently tried it in the treatment of patients suffering from septicemia. The results, as shown by ten cases published in full, were very satisfactory, only one case proving fatal; but, as Dr. Courtney candidly admits, the auxiliary treatment may have had something to do with the results: these aids were those "which effect free elimination by all of the emunctories that may be pressed into service, so as to rid the system of all the toxins possible," especially free purging. Dr. Courtney sums up his experience thus: 1. The yeast nucleinic acid should be given at the earliest possible moment that septic infection is suspected. The physician should not wait for the typical and classic symptoms as given by text-books. Dr. Courtney's observations have led him to believe that if delay is made until rigors, icterus, diarrhea, delirium or apathy, profuse perspiration and a foul-smelling and discharging wound are added to an abnormal increase in temperature and pulse rate, and a restless alertness on the part of the patient, to convince the observer that it is septicemia that must be dealt with, instead of surgical fever or something else, a serious waste of most valuable time must occur. 2. The nuclein should always, in septicemia at least, be given hypodermically if possible, in order to secure prompt action of the given dose. If the 1 per cent. solution is used, at least from 30 to 40 minutes, undiluted, may be given every three or four hours.

Purpura Hemorrhagica with Multiple Infection.—Purpura, like many other terms, should no longer be regarded as a disease, but as a symptom. It may be found in a number of diseases. Of these the infectious form an important group. The following case, published in the *Montreal Medical Journal*, by Drs. Hamilton and Yates, is not only of great clinical interest, but a contribution to an ill-understood subject, the etiology of purpura hemorrhagica. A student, aged 22 years, healthy and well developed, noticed an eruption of bright red spots of the size of a pin's head, which began over the left ankle and then became numerous over both lower limbs. Three days afterward a few spots appeared on the arms and then on the chest. The abdomen remained free until the sixth day. A slight knock on any part induced the appearance of extensive and severe bruising. On the night of the fourth day, not having felt ill yet, he was awakened with coughing and spitting of blood. On the following day he lost large quantities of blood from the nose, mouth and throat, and felt for the first time weakness, rawness of the throat, and slight pains in the knees. On examination, the spots, which were also present on the face, were found to be hemorrhages. Here and there were larger purpuric areas varying in size and color. The conjunctivæ presented a few hemorrhages. The nose was slowly but constantly bleeding. The lips were of good color. The gums were not spongy. On the soft palate and left tonsil hemorrhagic areas were seen. The temperature was 102.8 degrees F., the pulse 100 and the respirations 24. The fundi were normal. Cultures of the blood were negative. The red corpuscles were 4,810,000, the white corpuscles 6,000, and the hemoglobin 87 per cent. The patient steadily became worse; the hemorrhages were persistent and intractable: hemoptysis, hematemesis, hematuria and melena occurred. The palate became sloughy and the eyelids became edematous. The temperature ranged from 99 to 104 degrees. Finally he became delirious and died on the twelfth day. A necropsy was made ten hours after death. There were many visceral hemorrhages. The cardiac vessels contained air and the right auricle was distended with gas. The great vessels contained mixed frothy clots. The liver was emphysematous and floated in water. The bacillus aerogenes capsulatus, the staphylococcus pyogenes aureus, and a small bacillus (which on inoculation proved fatal to a rabbit) were cultivated from the blood and viscera. The clinical picture was thus similar to that of an acute infection: between good health and death there was an interval of only eight days. From the history of the case it is hardly possible that the bacillus aerogenes capsulatus was the primary infection; possibly it was the staphylococcus.

No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, DECEMBER 4, 1897.

SYPHILIS AND CIVILIZATION.

One of the most notable communications presented at the late International Congress at Moscow was that by the distinguished Austrian alienist, KRAFFT-EBING, on the etiology of progressive paresis. It created the more sensation from the fact that it coolly reported a pathologic experiment of a character that would of all others be likely to call out comment and reprobation from those who are always ready to criticise such attempts to increase our knowledge at the apparent expense of patients under medical care. A much less obviously equivocal one by a Baltimore professor has led to some severe comments from the other side of the water, and it is rather remarkable that thus far we Americans against whom Europe seems at present to have a general grudge on political and economic grounds, should have been so forbearing under a still more aggravating occasion.

While KRAFFT-EBING's experiment of inoculating paretics with chancre virus to demonstrate their non-inoculability by syphilis and hence their prior syphilisation, was certainly a bold experiment to report and certainly open to sentimental if not to other more weighty objections, it is a very interesting fact, and in the main, is strongly confirmatory of the opinion that is now all but general that paresis is a sequence if not a direct result of syphilitic infection in a vast majority of cases—indeed it may probably be said that it is such in all but very exceptional instances. His deduction from this with the other data we have on the subject that its two great etiologic factors are as he puts it, syphilisation and civilization, the stress of modern life acting on a system prepared by the results of earlier infection, is likely to be accepted as

the correct one by alienists generally, though there are yet, and possibly may be for a long time in the future, some few who will reject it against all the weight of evidence in its favor.

In the *Gazzetta degli Ospedali* of November 7, MORSELLI reviews the general facts as to the etiology and extension of paresis in rather a striking manner. He quotes statistics to show that it is very markedly increasing in its prevalence; in Italy the number of known cases for example has nearly doubled in a little over one decennium, and in Bavaria it increased from 9.3 per cent. of all the insanity in 1869 to 23.2 per cent. in 1874; it is undoubtedly in his opinion the special "disease of the nineteenth century." He holds, moreover, with NAECKE, and in opposition to the French school, that it is a disease to which there is a special predisposition, not by a congestive heredity, but by general degenerative peculiarities which, it would appear, are becoming more common in our modern civilized populations, where the fierce struggle for existence is fought out under constantly and ever increasingly severer conditions than heretofore. Its immediate exciting cause is therefore the stress of modern life acting on a predisposed and weakened nervous organization, which is itself probably more or less the result of the same general conditions.

This alone, however, is not an efficient cause; there must be generally superadded still another, the toxin of syphilis, which renders the catastrophe more inevitable, and MORSELLI follows KRAFFT-EBING in his etiologic duet but reverses the order, making it civilization and syphilis, inasmuch as the greater diffusion of the latter is, with that of alcoholism, the direct result of the former. As is often said, the modern man of the present day undergoes a very much heavier strain on his nervous system than did his predecessors of a century, or of even less than that, before him, and with each advancing decade this stress seems to be steadily on the increase. With this increase of mental and nervous strain there is also an increase of luxury which with its attendant urban concentration and sexual excess has made syphilis more common in the population of the civilized world than was heretofore the case. We have therefore the requisite conditions which combined tend to the increase of paresis, and such is their inevitable result.

As MORSELLI points out, we can see no immediately effective remedy for the great predisposing and exciting cause of paresis, the special character and peculiarities of modern civilization which aggravate the struggle for existence and at the same time increase the tendencies to degeneracy which predispose to paresis. We must, it would appear, wait for the social evolution and human development that ought in time to bring about a better equilibrium and re-establish what, borrowing an engineering term, we may call the normal regimen of humanity. But as regards the

specific predisposition, it would seem that more is possible: certainly more public effort can be exerted to check the spread of syphilis than is being done at present. We have not long since realized that all venereal diseases are disastrous and hence have more than ever reason for desiring their suppression. If it is generally admitted, and this seems to be probable, that syphilis once acquired, no matter how thoroughly and successfully treated, leaves behind it a possible liability to the most formidable of brain affections, paresis, we have another strong inducement for additional measures to check its extension. The social evil in the light of modern pathologic research is ever becoming more and more an important social question, if not the most important one of the time. How it is to be settled is a problem in the solution of which our profession can aid by showing the ever increasing need of its abatement or suppression.

THE HUMAN NEUROGLIA—GLIOMA AND NEUROGLIOMA.

The neuroglia has been a peculiarly elusive tissue; it has been beyond satisfactory reach and study by means of the ordinary histologic methods, and the numerous silver precipitations that go under the name of the Golgi method have given pictures that have been rather confusing as regards the correct interpretation of the structural details. The appearance of CARL WEIGERT'S¹ recent monograph embodying the results of his long-promised special neuroglia stain, and the independent technical publications of similar bearing by FRANK B. MALLORY² of Boston, have thrown much new light upon the neuroglia. These two investigators have, through the use of special methods, reached the same general conclusion, namely, that the neuroglia cells and neuroglia fibers in the adult human central nervous system are separate and distinct. This conclusion has been opposed, it is true, by H. STROEBE³, but whatever the ultimate outcome of the controversy may be, it will remain evident that the significance of these new methods is extremely great, because they appear to furnish what has been long needed, namely, a definite and reliable special method of studying the normal structure as well as the pathologic changes of the neuroglia, and there seems to be some hope that the problems connected with proliferation of neuroglia, for instance, may now be intelligently taken up with the promise of decisive results.

In the *Journal of Experimental Medicine*, Vol. 11, No. 6, occur two contributions with illustrative figures based upon the study of tumors of the brain, in which some of these questions in regard to the structure of the neuroglia, neuroglial proliferation, and the rela-

tion of neuroglia tumors to other tumors are discussed in the light of recent developments.

Drs. H. M. THOMAS and ALICE HAMILTON describe the clinical course and the pathologic histology of a tumor involving the ascending frontal, ascending parietal and the third frontal convolutions in a man aged 38. At the present time attention is directed solely to certain facts in connection with the histology of the growth.

The tumor was very cellular and presented a great variety of differently shaped cells, of which there could be recognized two quite distinct classes; one characterized by very faint outlines and a faintly staining protoplasm, exceedingly delicate processes, if any were present at all, and often slightly stained nuclei; the other class was distinguished by granular protoplasm, distinct outline, thicker processes, and usually a deeply stained nucleus. In addition there were normal neuroglia cells and spindle cells, some of which had single, or bunches of, long processes. There were also cells with many nuclei.

The blood vessels were not very numerous in any part of the tumor and usually the walls were thickened by the presence of spindle cells. Medullated nerve fibers were found in all parts of the tumor, as well as naked axis cylinders. The tumor occupied essentially the subcortical white matter.

In considering the value of this growth and the class of neoplasms to which it should be assigned, the question resolves itself into that of neuroglioma or gliosarcoma. In the older literature the majority of the richly cellular tumors in the central nervous system were looked upon as either partly or purely sarcomatous, or at least closely related to sarcoma, because the neuroglia was at that time looked upon as one of the forms of connective tissue and as mesoblastic in origin; a glioma therefore belonged to the mesoblastic tumors, differing from sarcoma only in having its origin in the modified stroma of the nervous system, resembling neuroglia in its structure but capable of passing gradually into pure sarcoma. Thus, for instance, FLEISCHL⁴ proposed to abandon the term glioma, because it simply meant a sarcoma which had its origin in the neuroglia. With the establishment of the epiblastic origin of the neuroglia, however, the distinction between the different forms of new growths in the nervous system can be more closely and logically carried out. It follows that all connective-tissue growths in the brain must originate either in the cerebral membranes or in the vessel walls. While the belief is gradually gaining ground that the majority of all tumors in the central nervous system are gliomata or neurogliomata, yet the possibility of a mixed growth, in which the cells of the vessel walls participate, is admitted. It would therefore be logical to restrict the term gli-

⁴ Wiener med. Jahrbüch., 1872.

sarcoma, hitherto so freely employed to tumors of undoubtedly mixed origin. The difficulty of applying this rule is undoubtedly great, but in the future the term gliosarcoma can certainly not be so loosely applied as has been done heretofore, as witness the statements in our text-books. It is, indeed, doubtful that a typical case of gliosarcoma has yet been reported, and the new growths in the brain composed of glia cells, normal or atypical, must be designated as gliomata and assigned to their proper place in our onkologic classifications, namely, as a variety of the epiblastic tumors.

The so-called neuroglioma has the same essential origin as other gliomata; the pre-existing ganglion cells can not be regarded as able to proliferate, but the cells of such tumors may be looked upon as representing earlier or later stages of the development of the originally indifferent embryonic cells in which the process started. Atypical ganglion cells, as well as atypical neuroglia cells may therefore occur. In the present case the tumor described can not, in the light of these considerations, be classified otherwise than as a neuroglioma; the great variety of cells, the presence of giant cells, the irregular ganglion cells, bear out this conclusion.

It is interesting to note the observation made in this case that nerve fibers may pass through such tumors apparently unchanged, some perhaps losing their medullary sheaths. This fact explains the absence of degeneration of neuron tracts occupied by such growths.

In the same number of the *Journal of Experimental Medicine*, Dr. EDWARD WYLLYS TAYLOR contributes a study of the human neuroglia, based upon the histologic examination of two gliomata with MALLORY'S and WEIGERT'S neuroglia stains. TAYLOR also reaches the general conclusion that the term gliosarcoma should be dropped, because it is unscientific and misleading in its significance.

In the first case examined by him he was able to demonstrate that there is a definite chemical difference between neuroglia fibers and the protoplasm of the neuroglia cells. The disputed points referred to in his study are the following: First, what is the relation of the fibers to the cells; and, secondly, if the fibers are completely differentiated, how and at what stage of their development do they become so? Are there cells which may be regarded as transitory forms? In the first tumor there was an enormous development of fibers as compared with cells; the fibers were of such density, arrangement and caliber, that it would be difficult to understand how they could all be connected with cells. The impression is gained that WEIGERT'S view that the fibers are distinct from the cells is the correct one, at least as regards what may be designated as mature and differentiated glia tissue.

TAYLOR made a painstaking study with the end in view of discovering cells still in continuity with fibers and, in the parts of the tumor where the fibrous network was least dense, he discovered occasional elongated cells, from one pole of which came off tapering processes that stained in a way similar to the protoplasm of the cell body, and the conclusion seemed justified that such fibers were direct outgrowths of the cells.

In the second tumor the structure was composed largely of cells of a transitional type; differentiated fibers in WEIGERT'S sense, *i. e.*, separate from the cells, were not discoverable by means of the special stains. The tumor is therefore looked upon as a young growth, consisting of cells with undifferentiated fibers. As the growth would become older there would be expected the manifestation of a tendency to the formation, according to the argument followed, of differentiated fibers that subsequently might come to be the predominating structural element. Hence TAYLOR'S general conclusion is that the development of neuroglia, in all probability, is from cells with protoplasmic processes, to cells with differentiated and independent fibers, and herein lies the possible reconciliation of the conflicting views of STROEBE and WEIGERT concerning the ultimate structure of human neuroglia.

Finally, it is well to emphasize once more that the recognition, through the studies of W. HIS, CAJAL⁵ and others, of the epiblastic origin of neuroglia, has led to a fundamental change in our conception of this tissue, both in its normal and its pathologic conditions. Thus, for instance, in speaking of those morbid processes that are so peculiar to the nervous system, namely, the so-called scleroses, the term connective tissue in its every-day significance must be dropped, because it is unnecessary and misleading in that it suggests a tissue of mesoblastic origin. The small part which mesoblastic connective tissue plays in proliferative processes in the central nervous system is gradually being recognized. Neuroglia, from a histogenetic standpoint, has no affinity whatever with ordinary connective tissue, but it is very interesting to note the fact that WEIGERT places so much stress on, namely, that its function in the nervous system is precisely that which belongs to connective tissue in the case of other organs. Further, with these two points in mind, the theoretic and practical confusion regarding gliomata and sarcomata ought to be easily avoided.

The term gliosarcoma, which still maintains its place in most of the text-books, as a definite form of new growth, should be dropped, and the placing of glioma among the mesoblastic tumors as is currently done in the onkologic classification of our text-books, is manifestly incorrect, because glioma is an epiblastic tumor.

⁵ Taylor, loc. cit.

AN INFANT INCUBATOR.

Whether the real interests of a race or people are better subserved by the preservation of its feeblest members is as much a matter of question, as whether it is the part of true humanity to prolong the days of a hopeless sufferer from an incurable, revolting, agonizing disease. A young and gentle mother develops cancer of the spinal cord after the very thorough removal of an affected mamma two or three years before, lies paralyzed in her lower extremities for many months, later has one thigh rigidly flexed upon the chest, suffers excruciating pain requiring heroic doses of morphia, is absolutely helpless, and repulsively unclean to herself and her family, and is only kept alive by the hypodermatic administration of brandy, while the disease progressively, but with appalling slowness involves the neighboring bones and flesh. Her doom is beyond human interference. Is it more merciful to cease to interfere and let nature end her frightful suffering, or to go on keeping the heart mechanically pumping and the sensorium acutely sensitive—a refinement of torture akin to that by which the victim of the rack or thumbscrew is kept alive to endure awhile longer? So shall the little pound or two of cold blue-black humanity prematurely ushered into the world, be cuddled and nursed into animate being, or shall the tiny spark be allowed to die out without effort to enliven it? Many intelligent men and women have lived, who would not had this been done. A prominent medical officer of the United States Navy used to attribute all his physical ailments to the fact that he had been cheated out of more than two months' intra-uterine preparation for battling with the outside world, and who, when born, was literally "put into a pint pot," yet he lived past middle-age, was well-deserving, respected and honored, but died insane. Whether these are only isolated instances which are counterbalanced by an excess of weakly survivors can not now be confirmed by statistical evidence, and until it is established that it is better to let the prematurely born die from inanition, the effort will continue to be made to keep alive these little waifs which have come before their time, and there is now in operation in the city of New York an establishment where this is being done under conditions that can hardly be improved.

At No. 2 West 18th St., in a building that could hardly be better adapted for its purpose had it been so designed, instead of as a summer-garden and dining-hall of the Hotel Logerot, there has been instituted within a few weeks a branch of the *Maternité Lion* at No. 26 Boulevard Poissonnière, Paris, itself an outcome of the *Œuvre Maternelle des Couveuses d'Enfants* established at Nice in 1891 by M. ALEXANDER LION, a philanthropist of that city, by whom the apparatus and its application were devised. The low birth-rate of France has stimulated efforts to save

every child born. From fifteen to thirty per centum of the annual birth-rate, according to place and local conditions, amounting to nearly 150,000, are born prematurely, and besides these 50,000 more which have reached full term are so feeble that they do not survive the earliest days of babyhood. To check this serious mortality French scientists have sought effective artificial means for the incubation of prematurely and weakly born infants. In 1857 Professor DENUCE of Bordeaux, produced the first incubator, and in 1880 Professor TERNIER, whose apparatus was improved by Dr. AUVARD and introduced at the Maternity Hospital in Paris, established the feasibility of saving infant lives by artificial incubation. The *couveuse* of M. LION, however, is the most satisfactory apparatus yet proposed, and since its installation at Nice in 1891 it has been awarded a silver medal in the Section of Medicine and Surgery at Lyons, 1894, the *grand prix* at numerous European expositions, and has received a first prize and gold medal at the Nashville Centennial.

The New York incubatory is a model of cleanness, neatness and elegance. The accessories of furniture and ornamentation are in admirable harmony with the beautiful little cages on three sides of the room in which nine mites of mortality were quietly sleeping, one of whom a week before was as cold, blue-black, and altogether unpromising a subject as could be imagined, requiring artificial respiration, but now with as assured a tenure of life as the other eight who were all seven months' children.

The incubator, which is supported on a metal stand, is essentially a metal box, with a glass front and side and within it, suspended by springs, a finely woven wire hammock containing a down mattress on which the baby lies in an atmosphere previously filtered, admitted through a three-inch metal pipe and discharged through a chimney of the same diameter surmounted by a fan indicating by its rotation the strength of the air current, which is warmed by means of a syphon through which water heated by a small cylindrical boiler at the right hand of the incubator, constantly circulates, the temperature being automatically regulated by a thermostat. A thermometer at the level of the infant's head is in sight through the glass door, through which the child is always visible.

It is important that the infant should be placed in the incubator immediately after birth. Every minute that it is exposed to the variations of external temperature diminishes its chance of life. The babies are fed by carefully selected wet nurses in an adjoining "nursing room" (*salle d'allaitement*), where every two hours they are taken from their cages, being first covered with a blanket, washed, cleansed and fed, and are then carried back to their little hammocks to sleep tranquilly another two hours in an atmosphere of unvarying temperature. A careful record is kept of the daily morning weight before feeding.

The official report of the physician inspector for the protection of children at Nice of the parent establishment at that city, which is conducted under the joint patronage of the municipality, the council general of the Departement des Alpes Maritimes and the ministry of the Interior of France, shows that "from October 29, 1861, to December 15, 1894, this institution has received 185 infants prematurely born, weighing from 1 $\frac{3}{4}$ pounds to 6 pounds 6 ounces: of these 133 left the institution healthy and in good condition (a proportion of 72 per centum), forty-eight died and four were still under treatment and were progressing favorably. The following tabular statement exhibits the relation of weight at birth to viability:

Weight at Birth.	No.	Survived.	Died.	Percentage Saved.
1 $\frac{3}{4}$ to 2 $\frac{1}{4}$ lbs	6		6*	
2 lbs. 3 $\frac{1}{4}$ oz. to 3 lbs. 5 oz.	36	18	18	50
3 lbs. 5 $\frac{1}{4}$ oz. to 4 lbs. 7 oz.	72	52	20	72
4 lbs. 7 $\frac{1}{4}$ oz. to 5 $\frac{1}{2}$ lbs.	54	49	5	90
5 $\frac{1}{2}$ lbs. to 6 lbs. 6 oz.	14	14	0	100

*All died on day of birth.

Of sixty-two prematurely born infants received at the Paris maternity, fifty-one (eighty-two per centum) were successfully nurtured. Six of the eleven who died weighed less than two pounds, and their cases were almost hopeless. The others were brought in too late, having been thoroughly chilled.

Results so encouraging commend the system to a fair trial in our own country for the little unfortunates whose fault it was not that they have come too soon, but having been engendered have doubtless the same inherent right to live as their more robust brothers and sisters.

VACANCIES IN THE NAVY MEDICAL DEPARTMENT.

A subcommittee of the Parliamentary Bills Committee of the British Medical Association has made a report on the condition of the Army Medical Staff, the causes of its present inefficiency and insufficiency, and the reforms needful to improve it. Military as well as medical journals discuss the subject as one of the utmost importance to the army and to the country. Numerically the Army Medical Staff is at present eighty short of its authorized total of 891 officers; and the men who come up for examination to fill the vacancies are by no means of a high standard, professionally. In August last only twenty-two men presented themselves to "compete" for thirty-six vacancies; nineteen of them were accepted. Of the last batch who passed through the Army Medical School at Netley the man who stood highest on the list of Army Medical Staff graduates had lower marks than the last man of the list for the Indian Medical Service. It is well recognized by military men that the Army wants "the best stamp of medical men that the schools turn out"; but it is not obtaining them nor is it likely that it will obtain them until the status of medical

officers as to rank and title is so defined as to place them on an equality with other officers of the Army. At the present time they have cumbrous titles, such as BRIGADE SURGEON, LIEUTENANT-COLONEL SO AND SO; but they have no rank, neither real nor relative. They are satisfied with their pay and pension, but are discontented with their practically civilian status, which in camps and garrisons is no status whatever. There are other causes of discontent, such as the difficulty of obtaining leave of absence, always great but now impossible, on account of the depleted condition of the department and the frontier and plague service in India, which require the presence of every medical officer at his post of duty.

Our own Naval Medical Department has for a long time been suffering from a grievance somewhat similar in character, but not so aggravated, which is necessarily beginning to tell on the *sufficiency* of its membership. The department is at present 17 short of its authorized total of 170 officers; but the pressure of want is not yet so great as to suggest the lowering of the standard for entrance. The *efficiency* of the membership has not therefore been impaired. Naval medical officers are satisfied with their pay, but dissatisfied with their position. The young medical man ranks as an ensign for the first three years of his service, a lower grade than is offered to the passed candidate in the Army; and although the law provides for his promotion to a passed-assistant surgency with the rank of junior lieutenant, a certain clause of it deprives him of this rank until all line officers who antedated his entry into the service have attained it; and again when he is a surgeon in his own corps his relative rank continues to be that of lieutenant until all the line officers aforesaid have become lieutenant commanders. There are some other grievances, but those affecting rank and status are the chief. The engineers of the Navy suffer from a similar injustice, but a board of officers has recently been appointed by the Secretary of the Navy to formulate a plan which will be satisfactory alike to the engineers and the officers of the Line. Should this, as now seems likely, be effected it will only be a question of time before the injustice affecting the Medical Department will be met and recognized and remedied. Our Navy is now at the beginning of a new era in its existence. The construction of new and powerful ships is progressing rapidly and the personnel must in time be increased to meet the necessities of modern service. The members of the Medical Department will no doubt have many opportunities to distinguish themselves and their service in the future history of our new battle ships. On this account and notwithstanding the discontent among naval medical officers, it seems that now is a favorable time for young graduates of medicine possessing the necessary qualifications to enter the service. The next candi-

date who satisfies the Examining Board now in session in Brooklyn, N. Y., will immediately be sixteen files from the bottom of the list; and as to the question of rank we in this country have not that conservatism which in England continues an injustice indefinitely, because a change is needed to remedy it.

CORRESPONDENCE.

Department of Public Health.

PENSACOLA, ALA., Nov. 24, 1897.

HON. FRANK S. GARDNER, Secretary New York Board of Trade and Transportation, New York City.

Dear Sir:—In response to your inquiry concerning the efficiency of the Marine-Hospital Service in the conduct of Federal health affairs, I forwarded you some days ago copies of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, the *Florida Times Union* and *Citizen* and *New Orleans Times Democrat*, as I was not able to reply immediately on account of certain professional engagements. I desire now to answer your queries briefly, but by the presentation of such facts only as may not be successfully controverted, and which are detailed without malice toward any one, or animus of a personal character whatever.

The first objection to be urged against such control of our health affairs by this service or branch of the Federal Government, is one relating to its organic construction. You are doubtless familiar with the fact that only applicants between the ages of 21 and 28 years are examined for admission to this service, and you may easily infer that 98 per cent. of them have never had experience with epidemic diseases such as are likely to prevail at any time in our country. That they may be skilled in bacteriologic lore, I will readily admit; that they are without practical knowledge of any epidemic diseases, they are, I am sure, also honest enough to confess. Thus, a young graduate from a Maryland, Michigan or Massachusetts medical college, standing an excellent but purely theoretical examination before the Board of Examining Surgeons, is dispatched by his Chief to preside over the health destiny of New Orleans, Galveston or Mobile, with no more knowledge of the character of the prevailing diseases or the commercial necessities of the people, than an Ashantee Chief possesses of the military strength of Gibraltar.

The second objection is largely an emphasis of the first, relating however more nearly to the fact that these officials are taken indiscriminately from every part of the United States, less than 5 per cent. of them belonging south of latitude 37, or that area of the country likely to be invaded by yellow fever—our most common and most dreaded foe. Less than 10 per cent. of the regular force of the service have had any experience with these diseases, and less than 3 per cent. are regarded by sanitarians or the general public as possessing any knowledge of this disease whatever. Possibly 2 or 3 per cent. may have acquired immunity from the diseases incident to the South, either by residence or a previous attack of such disease. What a commentary upon the much advertised and magnificent equipment of this service for the health preservation of our country!

The third objection is one relating largely to the autocratic management of this service. Its officials are responsible to no one save the head of the Bureau at Washington—a Cæsarian system of government. See the utter disregard manifested for the health of the people in Georgia in 1893, when the medical officer of the service at the quarantine station sickened with yellow fever (the first victim), was removed to the principal hotel of Brunswick, where he died, and an epidemic

of the dread disease followed. Witness the humiliating spectacle of Mississippi's delegation in the Federal Congress pleading in vain for the removal of a near and constant menace to the health of their beloved State—the Ship Island Quarantine Station; then ask yourself if the Czar of all the Russias could lend so deaf an ear to the plaintive wails of his humble subjects!

The fourth objection is one based entirely upon the past inefficiency of this service as compared with the alleged weak control by the State. Twice in four years, at quarantine stations operated only by the authority of this service, yellow fever has gained entrance to our country, put to flight its people and ruined its commerce; whereas, under the management by the much-despised State Boards of Health of quarantine stations, exclusively in their possession, no such invasion has occurred for nearly twenty years, save in Florida, and there not since the creation of the State Board of Health some nine years ago. These are cold, stubborn facts, the proof of which, if desired, can be obtained from contemporaneous authorities, or the archives of the Marine-Hospital Service at Washington.

That this service is equipped in any manner save in the possession of a magnificent bacteriologic laboratory for the protection of the people of the United States against the invasion of epidemic diseases, it were sheer folly to contend. That it is thoroughly equipped in this one particular, I am willing to believe, but I still maintain that the use of a few grains of common sense in the management of Federal quarantine matters, is worth barrels of gelatin culture, uniquely prepared and labeled, for the inspection of the distinguished microscopist, while helpless communities are being ravaged by pestilence and panic.

It is not my object or purpose to hold the head of this Bureau, Dr. Wyman, responsible for its many defects, as I consider most of them organic in their character, and far beyond the reach of any reform measure he might desire to institute. It is as impossible to unite a sailors' hospital service and the health affairs of this great country, as to mix oil and water. The attempts of the future in this direction will show as dismal and disastrous failures as those of the recent past, and I believe the history of the world does not present a parallel to so gruesome and absurd a system. Let us try, however, to obtain a system wherein are combined the wisdom and judgment of the State in the matter of the appointment of its own citizens to these responsible positions, and the enormous power of the general government to control and direct the operations against the common enemy. Let us have a Marine-Hospital Service and its capable ministrations to sick seamen, but let us also have a separate department of public health, composed of men only of known ability and experience in such matters, whose sole object and aim shall be the promotion of the health interests of the entire country.

If this can not be done, for one I shall prefer a continuance of the control over maritime quarantine by the State, to the exercise of these powers by a service so incongruous and so unsuccessful as this autocratic Bureau of the Treasury Department has demonstrated itself to be.

The idea of a Department of Public Health has taken a firm hold upon our people; from North, South East and West come endorsements of such a general system; marked by many differences of opinion, it is true, as to minor details, etc. The press of the country almost without exception commend such a course; commercial organizations approve of it enthusiastically; and the two great bodies of advanced scientific thought on this Continent—the AMERICAN MEDICAL ASSOCIATION and the American Public Health Association—have given it an unqualified endorsement. So far as my information extends, the sentiment in favor of the supervision or control of the public health, both maritime and domestic, by the Federal Government, is overwhelmingly in favor of such a system as is diame-

trically opposed to the management of the Marine-Hospital Service; and I believe such opinions will assume a concrete form not differing materially from the ideas embodied in Senate Bill No. 2343.

I desire to publish this communication, as I believe it more fully emphasizes my position than any other communication which I have written. Very truly yours,

WARREN E. ANDERSON.

The Editor and the Contributor.

NEW YORK, Nov. 27, 1897.

To the Editor:—At the top of an editorial page, one occasionally meets with such a declaration as: "Original communications are received only when exclusively contributed to this journal." Yet the editor himself, who rejects what is not exclusively given to him, will contribute a paper to a European Medical Congress, to be published in the transactions of that Congress, and will, ten days before the Congress meets, fore-stall its publication in Berlin by publication in his own paper. Another editor of a medical publisher's paper, rather than take sides against an authoritative body, which might hurt the publisher's interests, will smother the *right* side of a controversy by refusing to publish a paper, on a plea that there are in it no facts not generally known. This editor adds that these same facts are not accepted with unanimity. Does he mean that he will not publish any facts which are not accepted with unanimity? A medical paper is for medical discussion, and both sides should be heard.

To whom does a contribution, not paid for, belong? To the medical publisher, to the editor, or to the contributor? Whose interest is to govern the publication of a paper, the publisher's, the editor's, or the public's?

Why should not a contributor be at liberty to present his side of a question to as many audiences as he can find and thinks fit? If a subject is only of municipal interest, let it be published in the city alone. If the author believes it to be of National interest, why should he not publish it in as many States, in as many journals as he can? If the subject is of international interest, who shall blame him if he desires to make himself heard, or read, in French, German, Italian, and every language spoken? The subject which the contributor is to confine exclusively in a local paper, may be too big for it and be stifled in its paltry circulation.

Of course, the contributor thinks only of his subject; the scientific interest is his criterion. The editor thinks only of the advantage of his paper, or of that of the medical publisher who owns it.

If an editor insists on having papers exclusively given to him, let him pay for them as other scientific or literary papers do. That creates a right which nobody could contest.

Are not the following things strange, and even funny?

1. A medical editor seems to be sincerely convinced that an author who makes him a present of an article, acts dishonorably if he publishes the same article in another paper, and even in another country. Yet he has not paid a cent for that article, conceiving it to be honorable enough to receive gratis the result of another's labor and enrich himself by it.

2. The owner of the medical paper is not content with thus appropriating, without remuneration, the work of another; he stamps it emphatically as his own, in every manner and for all time; in other words, he copyrights it. After this remarkable operation, the work of the author's brain (not sold, not paid for) is forever divorced from him; and if he was foolhardy enough to republish it, he would be considered as a kind of a thief, having robbed a stranger of his (the author's) own property.

Let any impartial person, lay or professional, say whether this is not odd?

ALBERT S. ASHMEAD, M.D.

The Dixon Case.

ROCK ISLAND, ILL., Nov. 22, 1897.

To the Editor:—About a year ago I received a letter from a Springfield, Ill., physician asking me to contribute to the expense of carrying the Dixon case through the courts until a decision by the supreme court was obtained. I declined to do so except with the understanding that if the verdict should be against us that an effort would be made to organize the physicians of the State of Illinois pledged to fight everything that was against us, for I was quite sure that the decision in that case would be against us, when we would be worse off than we were before if we let it go at that. I received no reply to my letter. The reason for my belief that the decision would be against us was this: Probably twenty-five years ago Dr. Patrick Gregg of this city refused to testify in a case similar to that of Dr. Dixon. Judge Pleasants was on the bench and the matter was submitted to him. He took his time, considered it thoroughly and gave an opinion practically the same as that of Judge Creighton. Judge Pleasants was at that time considered one of the best jurists in the State. Dr. S. C. Plummer of this city is still living and probably remembers the case. At the time the Dixon case was pending, Judge Pleasants was one of the Springfield appellate court. Considering the circumstances it looked like running into a loaded gun. The medical profession, however, ought to organize. They educate themselves, pay for it themselves, do more for the public gratuitously, and do it cheerfully, than any other profession. Still there is no body of men of their numbers in existence that receive the kicks and cuffs that they do. It is not right and we should not stand it. We can organize in this State a body of five thousand men as solid as a rock, ask for nothing but what is fair, but plump our solid little army fair and square against anything that attempts to hit us. Then, and then only, will we be considered a factor that had better be respected.

Yours truly, G. G. CRAIG, M.D.

Edema Universalis?

DETROIT, MICH., Nov. 23, 1897.

To the Editor:—Joseph Zeisler, M.D., comments on my short note by correcting my Latin orthography or grammar, and suggests that the case of general edema spoken about is in all probability due to "sclerema neonatorum."

Now, I am glad indeed Joseph Zeisler, M.D., has given me a lesson in Latin and discussed the subject. I admit my error and apologize for the occurrence, it being an oversight rather than anything else, for again and again I have used *edema acutum*, etc. While writing down my note, I must have had in mind edema arsenicalis. While *edema universale* is correct in science, by the way, grammar, as far as a describing adjective is concerned, is not always adhered to, this being illustrated in botanic terminology.

The Doctor furthermore criticises the meagerness of the description. That the description of the case was meager I admit, but inasmuch as I have not examined the blood, secretions and excretions save the urine, which proved normal, I have nothing further to offer.

The case, however, was not one of sclerema neonatorum. If it were, I know as well as does Joseph Zeisler, M.D., that there would be no need inventing a term or name for it, science having already provided one for it, viz., edema algidum.

I suggested the name of "universal edema," but if I were to write again, I would add the word "idiopathic," because no cause for it could be ascertained.

Dr. GUSTAVUS BLECH.

Alcohol in Health and Old Age.

PITTSBURG, PA., Nov. 23, 1897.

To the Editor:—The article in the JOURNAL Nov. 20, 1897,

"The Needs and Rights of Old Age," by Dr. I. N. Love, I read with much interest. One of the questions which he raises in the article, "Is moderate drinking of alcohols conducive to health and old age?" is of sufficient interest to the readers of the *JOURNAL* to call for an expression of opinion on this subject. I know how difficult it is to prove a negative. I think many of the medical profession as they tread along in life's journey assume to believe in the different periods of life's duties, first in youth, that alcohols do no harm and make the heart glad, and second, they in middle age believe they (alcohols) increase the *advoirdupois*, while third they in old age believe total abstinence is conducive to a prolongation of life.

My own opinion is that every drink of alcohol is but adding one nail to the coffin of the individual that takes it. I also believe that health and old age are on the side of total abstainers. To prove this I can only cite two individual instances (but there are many others); one is the much respected and venerable Dr. N. S. Davis, the other my mother, who died at the age of 86 years.

I believe that statistics will bear me out in stating that women, who as a rule are total abstainers, after they have passed the climacteric period are longer lived than men. This is a strong argument in favor of total abstinence.

The only way we could prove the question satisfactorily would be to have statistics of undoubted authority bearing on this subject.

Yours truly,

JOHN M. BATTEN, M.D.

License in Germany.

DETROIT, MICH., Nov. 24, 1897.

To the Editor:—A reader wants to know the laws regulating the practice of medicine in Germany. Here they are:

Every one desiring to practice medicine in any part of the Empire, must produce proof of having attended four full years (eight seasons or semesters) of lectures, laboratories (the last must be in a German university), be of good moral character, a citizen of Germany (or holder of a permit from the police to residence), and pass a very rigid so called *Staats-examen* before a body of examiners appointed by the minister of education and *not* connected with the faculty. A candidate need not necessarily be a *doctor medicince*.

An American physician would have to attend, at least a year, lectures and laboratories, get his residence permit from the police, and then come up for the *Staats-examen*.

Very respectfully, Dr. GUSTAVUS M. BLECH.

Colleges Recognized by the Illinois State Board of Health.

SPRINGFIELD, Nov. 27, 1897.

To the Editor:—The list of medical colleges recognized by the Illinois State Board of Health, published in the *JOURNAL* of the 27th inst., was made out in this office last September, and received my sanction after a hurried examination just prior to my leaving the office for several days. On returning I found that many errors had been made, so the lists distributed were at once recalled, and on October 1 a corrected list was sent out with the statement that it took the place of that issued in September, a copy of which you published.

This Board does not permit colleges which are recognized as in "good standing" to accord advanced standing to students from non-recognized or partially recognized colleges, without full examination.

J. A. EGAN, M.D.,

Secretary Illinois State Board of Health.

Notice to Physicians.

CONCORD, N. H., Nov. 20, 1897.

To the Editor:—The second examination for licenses to prac-

tice medicine in the State of New Hampshire will be held at the State House, Concord, Tuesday and Wednesday, Dec. 21 and 22, 1897, beginning at 8 o'clock A.M.

All unlicensed physicians who were not in practice in this State on and before March 16, 1897, must pass the examinations in order to receive a license to legally practice their profession.

Application blanks should be procured at once, as these papers must be filled out and in the hands of the Regent by December 15.

All information regarding the coming examinations will be cheerfully given from the Department of Public Instruction, State Library, Concord.

FRED GOWING, *Regent*.

The Late William Warren Greene.

ST. PAUL, MINN., Nov. 26, 1897.

To the Editor:—I am making an effort to obtain a complete list of the articles published by my father, the late William Warren Greene of Portland. The references are scattered and difficult to obtain, and I would ask that any of his old students or professional friends who have reprints or references to articles, will kindly advise me concerning them, thereby conferring a favor which will be greatly appreciated.

CHARLES LYMAN GREENE, M.D.

PUBLIC HEALTH.

The Typhoid Fever Epidemic in Mt. Vernon, N. Y.—The mayor of Mt. Vernon says that there have been only a few deaths in a year from typhoid fever, and that there is no epidemic, no closing of schools and no investigation by the health board as has been currently reported. The other boards of education and trade will join the health board in the issue of public statements of denial.

Measures to Disseminate Knowledge of Hygiene.—Burgerstein of Vienna urges the establishment of special chairs of hygiene in the medical colleges to train young physician-hygienists for the purpose of instructing the public in the principles of hygiene. The State should appropriate funds to support this propaganda, and send qualified persons into the rural districts to lecture and demonstrate the subject with special efforts during fairs and similar gatherings. Pamphlets describing the proper measures to be taken should be given to parents when births are reported, children inscribed in the schools and on other occasions of the kind. The influence of the clergy should be utilized and the theologic seminaries should have facilities for the instruction of the students in the principles of hygiene, which should also be taught the children in the schools.—*Journal d'Hygiène*, October 14.

Action on the Public Health Bill—According to the *Scimitar* of Memphis, Tenn., November 20, the physicians of that city in conference assembled took action on the public health bill, unanimously favoring the same as prepared by the AMERICAN MEDICAL ASSOCIATION. Their action is as follows:

Resolved, That we respectfully invite the attention of the Senators and Representatives of the State of Tennessee to this very important subject, with the request that they will as soon as Congress convenes, use their best directed efforts to obtain relief for us through the means of some such legislation as we have here suggested, which may commend itself to their wisdom and experience. Furthermore we earnestly ask the co-operation of the business exchanges of this city and of the great railroad corporations which are near to us, to obtain this much needed legislation.

The resolution is signed by the President of the Board of Health and sixty-five other physicians.

The Maryland Public Health Association concluded its first

semi-annual session November 19 at Baltimore. William K. Brooks, M.D., spoke on "The Influence of Crude Sewage on Animal Life in the Bay," treating particularly of the effect on oysters. In a consideration of the sanitary condition of the public schools and the children's eyesight, appeals were made for a better condition of affairs. Hiram Woods, M.D., presented "School Life and Children's Eyesight" and William Dulany Thomas a paper on the "Sanitary Condition of the City Public Schools." Observations on the "Hygiene of the Public Schools of Howard County" were reported by S. J. Fort, M.D. The State Board of Health will publish a pamphlet giving the symptoms of contagious diseases, proper methods of ventilation and lighting, to be distributed among teachers in schools.

The Ship Island Quarantine Station.—The following communications are taken from the *New Orleans Picayune* of November 7.

THE PICAYUNE BUREAU, 218 CAPITOL STREET, (JACKSON, MISS., Nov. 6, 1897.)

As the belief prevails in many quarters that the yellow fever due to Ocean Springs, from whence it spread to other points, was due to the proximity of the Ship Island quarantine station to the main land, a statement compiled from official sources will be of interest, especially when read in connection with Ex-Superintending Surgeon Hamilton's discussion of the matter recently contained in the *Picayune*. The following propositions seem to be established:

1. That nearly ten years ago, congress, without division in either house, on the representations of members of the Mississippi delegation in both branches, that the health and safety of the people were endangered by the proximity of the quarantine station at Ship Island to the main land, passed an act for its removal and appropriated \$45,000 to establish a station at a more remote point.

2. That, in 1893, after the removal was made, and the expense of establishing a new station at a safer distance incurred, Chandeleur Island, the new station, was visited by hurricane, and the "hospital ward" destroyed. Then "the quarantine was immediately transferred to Ship Island," while the act providing for the transfer from Ship Island was in full force, and has remained there ever since.

3. That from October, 1893, until Aug. 18, 1894, the Ship Island quarantine was maintained in open violation of law, and is so yet unless the removal has been indirectly legalized by an item of three lines, which found its way into an appropriation bill, and was doubtless intended to operate in that way.

4. That the wishes and warnings of the people of the locality, and of their representatives in both houses of congress (the action of congress itself), the reports of then Surgeon General Hamilton pointing out the danger, were all ignored when the quarantine station was removed back to Ship Island, after the hurricane.

There is a great deal of responsibility somewhere, and the following statement has been compiled, to aid the public in fixing it where it belongs.

STATEMENTS.

The Congressional Record shows the following:

At the second session of the forty-ninth congress, Jan. 17, 1887, in the senate:

"Mr. Walthall introduced a bill (S. 3157) to authorize the removal of the quarantine station from Ship Island, Miss., which was read twice by its title.

"Mr. Walthall—I ask that the bill, with the accompanying papers, be referred to the committee on commerce. These papers are a memorial from the board of supervisors of Harrison county, Miss., praying for the removal of this quarantine station, and a special report from the surgeon general, dated the 8th inst. I desire to call the attention of the committee to the fact that the surgeon general has repeatedly reported that the quarantine station is too near the shore, and dangerous to the people on the main land.

"Mr. Harris—I am inclined to think that the bill ought to go to the committee on epidemic diseases, which has had control heretofore of all quarantine matters.

"The President pro tem.—The senator from Tennessee moves that the bill be referred to the committee on epidemic diseases.

"Mr. Harris—However, if the senator from Mississippi desires to have it referred to the committee on commerce, I shall not test the sense of the senate on the question.

"Mr. Walthall—I am entirely willing to have it go to the committee on epidemic diseases, but I thought the other was the appropriate committee.

"The President pro tem.—The bill will be referred to the committee on epidemic diseases."

Jan. 26, 1887:

"Mr. Eustis—I am instructed by the committee on epidemic diseases to report favorably the bill (S. 3157) to authorize the removal of the quarantine station from Ship Island, Miss., and I ask unanimous consent to have the bill considered at this time."

Objection being made, the bill went to the calendar.

Feb. 2, 1887: "Mr. Walthall—The senator from New York having the floor, I ask him to yield to me. I ask unanimous consent to proceed to the consideration of order of business No. 2,045, being the bill (S. 3157) to authorize the removal of the quarantine station from Ship Island, Miss. I will state that this bill relates to a very urgent matter that involves the health and safety of the people of the gulf coast of Mississippi and Louisiana. It can be disposed of without discussion, I am sure. There being no objection the bill (S. 3157) to authorize the removal of the quarantine station from Ship Island, Miss., was considered as in committee of the whole. It authorizes the secretary of the treasury to cause the removal of the national quarantine station, now located on Ship Island, in the Gulf of Mexico, to some other island in the gulf, or in such pass in the Mississippi delta as may be recommended by a board to be designated by him, and the necessary quarantine buildings and appliances are to be established there, for which \$45,000, or so much thereof as may be necessary, is appropriated.

"The bill was reported to the senate, ordered to be engrossed for a third reading and passed."

Feb. 4, 1887—In the house:

The speaker laid the bill before the house and it was referred to the committee on commerce, and February 8 it was reported back and, with the accompanying report, ordered to be printed.

March 3, 1887:

Mr. Barksdale asked unanimous consent to take the bill up and put it on its passage and said: "It is designed to protect the entire gulf and south Atlantic coast and people from epidemic and contagious disease. I appeal to the house to suspend the rules and pass this important measure," but the regular order was demanded and the forty-ninth congress adjourned without its becoming a law.

At the first session of the fiftieth congress it was reintroduced and the following proceedings were had:

Dec. 13, 1887. In the senate.

Mr. Walthall introduced a bill (section 642) to authorize the removal of the quarantine station from Ship Island, Miss., which was read twice by its title.

The President—The bill will be referred to the committee on commerce if there be no objection.

Mr. Walthall—The bill just read in relation to Ship Island, was before the senate at the last session and referred to the committee on epidemic diseases, after some little discussion, and I would prefer that reference now.

The bill was referred to that committee.

Dec. 22, 1887:

Mr. Eustis reported it without amendment.

Feb. 23, 1888, the bill passed the senate.

Feb. 24, 1888, it passed the house on motion of Mr. Stockdale, who said: "It is a matter of great importance to the whole continent that that quarantine station should be removed. I ask unanimous consent that the senate bill be put upon its passage."

March 5, 1888, the bill was approved by the president, and in virtue of its provisions the quarantine station was removed to Chandeleur Island.

Dr. Hamilton was then the supervising surgeon general of marine hospital service of the United States. It was his "special report" which Senator Walthall submitted with the memorial of the board of supervisors of Harrison County, praying for the removal of the quarantine station, when he introduced the bill Jan. 7, 1887, Dr. Hamilton had more than once recommended the removal, and warmly favored it.

Dr. Wyman, who succeeded Dr. Hamilton, in his annual report for 1893, says, on page 12, volume 1:

"On October 1 a violent hurricane visited the Gulf Quarantine Station, located on Chandeleur Island, in the Gulf of Mexico, and on the following day the hospital ward was completely destroyed and swept out to sea. Five persons connected with the station lost their lives, namely: Stewart L. A. Duckart, a nurse, a boatsman and two patients. A full account of the storm will be found in the portion of this report relating to the

quarantine stations. The quarantine was immediately transferred to Ship Island, and some congressional action is required to legalize the establishment of a permanent station on that island, its removal from Ship Island to Chandeleur Island having been directed by special act of congress."

No action was had by congress, or asked for in any direct form, so far as can be found, to "legalize" the removal back to Ship Island in confessed violation of a special act referred to, but in the voluminous sundry civil bill passed August 18, 1894, covering fifty pages in the "Laws of the Fifty-third Congress," was found this brief and apparently harmless appropriation, intended doubtless by whoever had an interest in having it inserted, as a ratification of the unauthorized removal:

"For ballast scows, small hospital, repairs to buildings and boat landings for the Gulf Quarantine Station, Ship Island, Miss., (transferred from Chandeleur Island), \$5,000."

The point in the case seems to be inclosed in the brackets, in view of the surgeon general's statement that "some congressional action is required to legalize the establishment of a permanent station in that island"—he considering apparently that to the extent of his ability he had made it "permanent" in advance of any legalizing action by the congress whose special act he had disregarded.

[NOTE, by the editor of the JOURNAL: The foregoing compilation, which seems an accurate copy of the records, should set at rest the statement that my views on this subject were recent. They were published, as is seen, while I was still Supervising Surgeon General, four years before the acts of the present incumbent had entailed any criticism.—EDITOR.]

SHIP ISLAND QUARANTINE STATION,
BILONI, MISS., Nov. 6, 1897.

Editor Picayune:—Although a matter of record, it is not generally known that the Mississippi State Board of Health has more than once protested against the location of the gulf quarantine station at Ship Island.

One year ago last April our executive committee by order of the board, went to Ship Island to study the situation there. After an investigation, the committee was so thoroughly impressed with the great danger that threatened not only our own State, but the entire South, that it decided to place a man here to further study the situation, note maladministration of the station, and watch developments.

I was placed in charge of this work. I had been here but a short time when I made a report to the chairman of the executive committee, which was forwarded to the secretary of the treasury by the governor of our State. The secretary referred the report to the supervising surgeon-general of the marine-hospital service. The supervising surgeon-general made a caustic reply, the arguments of which were based on false premises. This was sent by the secretary of the treasury to the governor and by the governor to me.

By permission of the governor, I replied by making a report to the State Board of Health the following October. Surgeon-General Wyman, upon my request, was invited by the governor to be present in person or by representative at this meeting of our board and participate in the discussion of this report, the quarantine station at Ship Island and the methods practiced there. He was not present, nor did he send a representative. The report made on that occasion has been published and is a matter of history. The South today is paying the penalty of the unheeded warning then sounded; the prediction then made has been verified, and crippled commerce and hundreds of desolate and saddened homes remain as a grim-visaged reminder of the stupidity and arrogance of one high in National authority.

But the Mississippi State Board of Health did not stop here. At its meeting last April it appointed a committee to go to Washington and wait on the secretary of the treasury in person. This committee, consisting of Drs. H. A. Gant, Water Valley; S. R. Dunn, Greenville, and Walton S. Greene, Aberdeen; was prepared to lay all the facts before the secretary. After conferring with Mississippi's representatives in the lower house and Senator Walthall, and after being assured by the latter gentleman that the station was removed to Ship Island without authority of law, they called on Supervising Surgeon-General Wyman, who discussed the matter with them, but showed plainly that he was absolutely fixed in his determination to retain the station at Ship Island. His main argument, and, in fact, his only argument, was that a cyclone visited Chandeleur in 1893, and was liable to visit the island again at any time. He was assured by the committee that a little town down in Mississippi, Beauregard, was visited by one of these monsters of the elements about fifteen years ago; that it wrought more destruction than the 1893 cyclone did at Chandeleur Island; that it had not been visited by one since, and possibly never

would be visited by one again. The surgeon-general is very considerate of the welfare of the men engaged in his service, and we commend him for it, but we reserve the right to protest against this consideration when done at the peril of the lives of our people and of the commerce of our country.

After leaving the surgeon-general, being convinced that "none is so blind as he who will not see," the committee repaired to the office of the secretary of the treasury. They were very anxious to get the ear of the secretary, but he, being a very overworked man, and a consideration of a question involving the health and lives of the people being of such minor importance, and since these gentlemen had taken so little trouble on themselves, having traveled only about 1,800 miles to see him in person officially, they were very courteously referred to his first assistant. It is, indeed, interesting to hear this committee relate its experience with this self-opionated first assistant. It has its amusing side and its interesting side. The twin elements, arrogance and stupidity, in one small cranium are always amusing, but when we see these elements in a cranium at the head of the affairs of the Nation, it then becomes interesting—interesting because it is an unerring finger-board of what centralization of power means in these United States. This distinguished first assistant refused absolutely to discuss the matter or open up the question. These gentlemen, representing a great State, had gone hundreds of miles, had taken a trip attended with no small expenditure of time and money, on a mission involving the health and happiness of their people and their rights to a voice in questions of quarantine, only to be met with a discourteous and rude "we do not want you." They insisted on reading their memorials, and he positively, discourteously and rudely declined a hearing, reiterating that the matter was a "closed book and that he would not open it." It now remains to see if Congress will heed the warning and open the book. If it does not, I make the prediction that it will not be half a decade until the South will be visited by another epidemic, and it will again be followed, as this one will be, by an expenditure of time and money by the marine-hospital service to saddle the responsibility of its admittance upon some efficient State board of health.

H. H. HARALSON, M.D.,
Member Mississippi State Board of Health.

NECROLOGY.

JULIUS A. SKILTON, M.D., Albany Medical College 1855, who died at his home in Brooklyn, N. Y., November 20, was a private practitioner in Albany, N. Y., until his entrance into the service of the United States during the Civil War. He was promoted from assistant surgeon of the Thirtieth New York Infantry to full surgeon of the Eighty-seventh New York Infantry, and was also honored with a staff appointment under Gen. N. P. Banks. He participated in twenty-seven different engagements and acquired a brilliant record. In 1865 he went to Vera Cruz as a newspaper correspondent to watch the operations of the French troops. On one occasion he was suspected of being a spy and narrowly escaped death. After the conflict he was made a medical officer in the escort which accompanied General Juarez and his family to Mexico and restored the General to power. Dr. Skilton continued to act as correspondent until General Grant's election, when he was made consul-general in the City of Mexico, acting also in special matters for England, France and Austria. It was Dr. Skilton who exhumed the body of Emperor Maximilian and sent it to Austria, at the request of Emperor Francis Joseph. Dr. Skilton also obtained the release of Maximilian's prime minister, and as a token of gratitude was asked to take the custody of the dead Emperor's personal effects. While in Mexico he gave much of his time to archeologic research. His collection of relics is now in the Yale Museum. When President Grant's second term expired Dr. Skilton remained in Mexico and became prominent in railroad mining enterprises. About twelve years ago he came to New York to look after his interests in electric and other contract work in Mexico, the West Indies and South America. While consul general in Mexico he had much to do with the establishment of the missions of the Methodist Episcopal Church in and near the City of Mexico.

E. E. FULLER, M.D., Keokuk, Iowa, November 18, aged 65 years. During the Civil War he went to the front, serving at the battle of Athens, Mo., one of the first engagements of the war. Soon after he was given a commission as assistant surgeon of the Third Iowa Cavalry and was with that regiment for two years, when his health failed from the arduous work which he had done in the line of duty and he was compelled to return home. Soon after his return he went on duty in the hospitals.

WILLIAM D. FLYNN, M.D., Redwood Falls, Minn., November 23, aged 56 years, last year president of the State Medical Society.—George H. Horn, M.D., Philadelphia, for many years secretary of the American Philosophical Society, November 25, aged 53 years.—G. A. Jule, M.D., Eau Claire, Wis., died at Drammen, Norway, November 22, aged 37 years. The Doctor was a graduate of the University of Christiania, Norway, class of 1887.—R. B. Parks, M.D., Jamestown, N. Y., November 17.—Isaiah B. Sexton, M.D., Sparta, Mich., November 19, aged 93 years.—Michael C. O'Toole, M.D., University of Michigan 1862, a native of Wexford, Ireland, aged 65 years, died at his home in San Francisco, Cal., November 22.

NEW INSTRUMENTS.

WOODLING'S ETHER CONE.

Gauze lined; ready for use; clean, convenient. Use once and throw away. It consists of a strong paper cone and separate gauze lining, with impervious tissue paper between. The cone is folded in, around its mouth, so as to more securely hold the lining and also obtain a smooth surface to come in

contact with the patient's face. The trough formed by this fold catches any surplus ether and it is reabsorbed by the lining instead of running out over the patient's face. These cones are cheaper than cleaning and replacing the lining in any permanent inhaler, besides saving the cost of the latter. A clean, new cone for each patient.

DR. M. E. WOODLING.

SOCIETY NEWS.

The North Central Illinois Medical Association will hold its twenty-fourth annual meeting at Pontiac, Ill., December 7 and 8.

The Western Surgical and Gynecological Association will hold its seventh annual meeting at Denver, December 28 and 29. Herman E. Pearse, M.D., 1018 East Fifteenth Street, Kansas City, Mo., is the secretary.

The Des Moines Pathological Society.—On November 22 a number of physicians organized a society to be known as The Des Moines Pathological Society. Officers elected were as follows: M. N. Voldeng, president; C. E. Currie, vice-president; M. F. Patterson, secretary; Dr. Seiger, treasurer; A. R. Ames, curator. Meetings will be held every Monday evening.

The Medical Society of Westchester County held its monthly meeting at Yonkers, N. Y., November 17. E. M. Hermance presided. Evarts M. Morrill of New York City, Robert Abbe and J. Lindsay Porteous read papers. After the discussion of the papers dinner was enjoyed, and speeches of an informal nature were made by Z. N. Lewis, the Rev. James E. Freeman, Joseph F. Daly and S. B. Carlisle.

The New York State Association of Railway Surgeons, held their seventh annual meeting November 16, at the Academy of Medicine. Dr. J. Frank Valentine of Brooklyn presided, and Dr. C. B. Herrick of Troy was the secretary. The morning program included papers by Dr. Thomas H. Manley of New York; Dr. W. B. Outten of St. Louis; Dr. W. J. Herdman of Ann Arbor, and Dr. L. L. Gilbert, of Pittsburg. Dr. R. H. Eccleston of Providence; William J. Kelly, counsel to the Long Island Railroad, and Drs. Charles L. Dana, Reginald H. Sayre, and Landon Carter Gray and Clark Bell of New York, took part in the discussion which followed. Papers were read in the afternoon by Clark Bell of New York; Dr. C. B. Herrick of Troy; Dr. C. S. Parkhill of Hornellsville; Dr. John F. Burns of Brooklyn; Dr. W. C. Wood of Gloversville; Dr. A. F. Palmer of Mechanicsville; Dr. Harvey P. Jack of Canisteo, and Dr. Charles R. Phillips of Hornellsville. W. H. Baldwin, Jr., president of the Long Island Railway Company, made an address. The following officers were elected: President, Dr. Clinton B. Herrick of Troy; vice-presidents, Dr. Thomas D. Mills of Middletown, and Dr. William D. Morrow of Walton; secretary, Dr. George Chaffee of Brooklyn; treasurer, Dr. Harvey P. Jack of Canisteo.

BOOK NOTICES.

A *Text-book of Practical Therapeutics*, with especial reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia, etc. With special chapters by Drs. George E. De Schweinitz, Edward Martin and Barton C. Hirst. Sixth edition, thoroughly revised and largely rewritten. In one octavo volume of 756 pages. Cloth, \$3.75; leather, \$4.75. Philadelphia and New York: Lea Brothers & Co. 1897.

Although, says the author, the number of copies printed of the fifth edition of this work was almost three times as great as was the case with the earlier editions, they have been rapidly exhausted and the author has been called upon within two years to prepare the manuscript for the sixth edition.

He further says: "Many books after appearing in several editions lose a large part of their original value, because the statements that have been added are so confused with the original text that its conciseness is extinguished; because of that the author has rewritten a very considerable portion of the present edition in order to render the statements in the text clear and concise. He has also endeavored to arrange work that can be used in conjunction with the text-book on practical diagnosis."

We have no reason to change our favorable opinion of this work, and congratulate the author on the generally favorable reception by the profession, and the appreciations we hope may long continue.

A *Handbook of Therapeutics*. By SIDNEY RINGER, M.D., Fr.S. and HARRINGTON SAINSBURY, M.D., F.R.C.P. Thirteenth edition. New York: Wm. Wood & Co. 1897. Pp. 746.

A long interval has elapsed since the last edition, and the list of new drugs and of new methods has been proportionately great. A special chapter has been introduced on serum therapeutics and, in connection with the invalid dietary, a short section upon the use of the digestive fermenta.

In the early part of the work brief reference is made to the Nauheim (Schott) treatment.

Ringer's Handbook of Therapeutics has been so long before the public, and so established a favorite, that little need be said in regard to it, except that the present edition has been brought down to date, and refers to the recent addition to armamentarium, and it has retained those features which made it so long a favorite in England and in this country.

A Text-Book of the Diseases of Women. By HENRY J. GARRIGUES, A.M., M.D., containing 335 engravings and colored plates. Second edition, thoroughly revised. Philadelphia: W. B. Saunders. 1897. Pp. 728. Price, cloth \$4.00; half morocco, \$5.00.

In this edition some defective illustrations have been re-drawn and many new figures have been added; the work has been thoroughly revised and made to correspond with the changes that have taken place in pathology and treatment since the appearance of the first edition of the work. The description of the chief methods employed in abdominal surgery have been added in the appendix. The work is thorough and complete, is thoroughly up to date, with the exception that the old system of weights and measures, instead of the decimal system, is still carried out throughout the work.

Twenty-eighth Annual Report of the State Board of Health of Massachusetts. Boards, pp. 920. Boston. 1897.

This twenty-eighth annual report of the pioneer Board of Health is up to usual standard of excellence. It contains reports on water supply; sewerage and sewage disposal; pollution of ponds and streams; Lawrence Experimental Station experiments in sewage and water purification; food and drug inspection; diagnosis of malaria; examinations for tuberculosis and "A Comparative Study of the Toxin Production of Diphtheria Bacilli." In addition vital statistics of the State (1856-1895) are considered. Many concise tables and charts present their contents in convenient form. The paper and typography are excellent and the Board deserves credit for the volume.

Fiftieth Anniversary of the Hartford Medical Society, September 15, 1846. Proceedings of the celebration October 26, 1896, at Hartford, Conn.

This volume includes the introductory remarks by the president, M. Stone, M.D. Historic addresses by Gurdon W. Russell, M.D., on the deceased members and those connected with the later years of the Society, by Horace S. Fuller, M.D. "Esprit de Corps," by Henry P. Stearns; The present and future of the Historical Medical Society as suggested by a study of the fundamental enactments, by Elantham Stone, M.D.

The smooth and pleasant course of the Hartford Medical Society from its foundation in 1846 to the present time made it a pleasant task for its members to meet and celebrate the occasion. No one can peruse the work without feeling that they missed a very important event by not being present. This commemorative volume is of interest to every member of the medical profession, and the biographies contained in Dr. Fuller's address add something to American medical biographies.

Some of the speeches on the occasion of the anniversary dinner were of a high order of literary merit, and all were amusing and entertaining.

The Hartford Medical Society, judging from this volume, is composed of very pleasant people.

The Principles of Bacteriology. A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D. Fourth Edition, enlarged and thoroughly revised with 106 illustrations, of which 19 are colored. Pp. 543. Philadelphia and New York: Lea Brothers & Co. 1897.

As the various editions of this standard text-book have made their appearance we have taken occasion to give our favorable opinion of the work and to welcome it to the editor's table. It has now become so well established that we have no doubt of its firm place in medical literature.

In this edition will be found descriptions of the bacillus of

bubonic plague and bacillus of influenza, as well as a number of new illustrations.

Those who favored the former edition will find every reason to continue their favorable opinion of the work.

Transactions of the New Hampshire Medical Society at the 106th Anniversary held at Concord, May 24 and 25, 1897. Cloth. Pages 318. Concord. 1897.

The volume contains, besides the Society proceedings, the following papers, many with discussion: "Medical Expert Testimony;" "Causes and Recent Treatment of Neurasthenia;" "When to Call a Surgeon in Acute Abdominal Affections;" "The History of X-Rays and their Application in Medical and Surgical Diagnosis;" "Degeneration of Eyes;" "Glaucoma;" "Mucous Colitis;" "Foreign Bodies in the Alimentary Canal in Children;" "Acute Cerebral Meningitis;" "Some Obstinate Forms of Eczema;" "Phlebotomy;" "Causes and Conditions of Pulmonary Tuberculosis, and How to Avoid Them."

Medical Education and Registration; United States and Canada. By WILLIAM T. SLAYTON, M.D. Pp. 105. Hyde Park, Vt.: Lamoille Publishing Co. 1897.

This timely volume contains, in small compass, much data of value to the practitioner. Part I, "Requirements for License to Practice Medicine in the United States," contains just what one wishes to know on that subject: The population of the various States for 1870, 1880 and 1890; proportion of physicians to population; medical schools in each and authorities having licensing power, etc. Part II treats of "Requirements for Admission to the Medical Colleges of the United States." Part III presents "Statistics of the Medical Schools of the United States." Part IV covers requirements for license to practice in Canada and treats of Canadian medical schools.

Transactions of the Colorado State Medical Society. Cloth, pp. 470. Published by the Society. Denver. 1897.

The book contains lists of officers, committees, members, presidents of the Society, by-laws and complete proceedings of the twenty-seventh annual convention. The list of contributors of papers contains names of many prominent men in the profession, and the papers are printed with their discussions. The general make-up, paper and typography make the book a credit to the Society.

Twenty-third Annual Report of the Secretary of the State Board of Health of the State of Michigan, for the fiscal year ending Jan. 30, 1895. Cloth, pp. 568. Lansing. 1896.

Part I contains reports of the Board's work, sanitary conventions, board meetings, etc., and officers' reports.

Part II treats of communicable diseases, time of greatest prevalence of each, injuries and loss of life, nuisances, etc., the whole containing many tables and charts of interest. The work is well indexed and on good paper.

Proceedings and Addresses at a Sanitary Convention held at Hanover, Mich., June 3 and 4, 1897. Paper. Lansing. 1897.

This is a supplement to the Michigan State Board Report for 1897, and contains twelve papers on various sanitary questions. Many of the papers are accompanied with the discussion thereon.

International Clinics. Edited by JUDSON DALAND, M.D. Vol. III, Seventh Series, 1897. Pp. 360. Illustrated, cloth. Philadelphia: J. B. Lippincott Company. 1897.

The contents of this volume comprises papers as follows: "Opium, Its Use and Abuse;" "The Treatment of Pulmonary Tuberculosis;" "The Treatment of Injuries of the Eye-ball . . .;" "Clinical Observations upon Senile Heart . . .;" "Treatment of Carcinoma of the Stomach;" "Hemoptysis. . .;" ". . . Hypertrophic Nasal Catarrh;" "Antisepsis in the Treatment of Skin Diseases of Children;" "Treatment of Infantile Uric Acid Infarction . . .;" with ten papers in the department of medicine, seven in surgery, five in gynecology and obstetrics and several on neurologic, ophthalmologic, laryngologic and dermatologic topics.

Centrifugal Analysis. A Manual for the Use of the Centrifuge in every-day Work. Bausch & Lomb Optical Co., Rochester, N. Y. 1897.

This little book is designed to popularize the use of the centrifugal machine in the examination of blood, urine, sputum, etc., and contains full directions concerning the use of the centrifuge. It is mailed free on application.

Report of the Commissioner of Health of Milwaukee, Wis. Paper, pp. 139. Milwaukee: 1897.

This is the twentieth annual report, and contains such tables and reports as are necessary to make clear the working of the Department in Milwaukee. The reports are concise, the tables well arranged and the typography and presswork excellent.

Special Articles on Yellow Fever.—The Etiology and Pathology, by R. Matas, M.D., New Orleans, La.; The Symptomatology and Diagnosis, by F. W. Parham, M.D., New Orleans, La.; The Treatment, by F. S. Dabney, M.D., New Orleans, La. These articles were read before the Orleans Parish Medical Society September 11 and 18, and after unanimous endorsement ordered printed for complimentary distribution for each member and its corresponding scientific bodies.

MISCELLANY.

A Physician Honored.—G. H. Bridgman, M.D., of Elizabeth, N. J., has received the appointment of Ambassador and Minister Plenipotentiary to Bolivia.

Correction.—In "The Serum Therapy of Diphtheria, 'The Antitoxin Question,'" in the JOURNAL of November 27, page 1099, line 18, the word "serum" was omitted. The sentence should read: "If diphtheria serum contained, etc."

A Parity of Rights.—If the government, says *Food and Sanitation*, undertakes the stamping of money there is no reason why it should not stamp foods. There should be the stamp of some authority able to enforce penalties for counterfeiting, as in the case of money.

Municipal Aid to the Needy.—London spends \$6,000,000 a year for the relief of the needy, Paris \$4,500,000, Vienna \$3,000,000 and Berlin \$2,000,000. Greater New York will spend, approximately, \$2,500,000. The statistics of Chicago in this particular have not yet been made available.

Can not Evade Rule upon Cross-Examination of Expert.—The only circumstances under which medical books can be read in evidence, the supreme court of Michigan declares, in the case of Hall against Murdock, is where the witness has based his opinions upon them, and has referred to them as authority. The established rule, it maintains, is that it is incompetent to read from these books. This rule, it adds, can not be evaded upon cross-examination.

A Case of Subdural Hematoma with Uncrossed Motor Nerve-Tracts is described in the *Wien. klin. Rundsch.*, September 31. After a fall, dangerous symptoms developed, all indicating a subdural hematoma on the left side, but trephining the left motor cortical centers was without results: no blood issued from the puncture. As a fatal termination was imminent, trephining was performed on the opposite side and the hematoma found. Recovery was prompt and complete, demonstrating the existence of uncrossed nerve tracts.

City Aid to Charities in New York.—The corporation counsel of New York City has rendered an opinion to the effect that under an act passed by the legislature in 1895, all mandatory legislation requiring the city to pay certain sums of money annually to charitable institutions has been made permissible. The controller, in accordance with the decision, is sending out letters to all charitable organizations that have received public aid through mandatory legislation that their claims for support will hereafter be considered on their merits only.

The *Journal of the Boston Society of the Medical Sciences* has been enlarged to octavo size. By general consent of the heads of Departments it will contain abstracts of experimental work carried on in the Medical School of Harvard University, the Experimental Laboratories of the Massachusetts General and the Boston City Hospitals, the Physiological and Biological Departments of the Massachusetts Institute of Technology and Clark University. It is proposed to issue the numbers of the *Journal* promptly after each meeting of the Society, and to give a rapid means of communication of the results of investigation. The intention is to publish at least ten numbers a year, running from October to June.

Electricity and Acetone.—Dr. Regnier describes, in the *Jour. de Méd. de Paris* of October 31, the remarkable benefit derived by a diabetic patient, with double sciatic neuritis, atrophy of the triceps, angina pectoris and paresis of the lower limbs, from electric treatment with the continuous current and inductive electricity with massage. The sugar did not seem to be affected by this treatment, but the acetone entirely vanished. If confirmed by other experiences, this complete elimination of the acetone, which is the probable cause of the spinal complications, etc., will be an invaluable aid in the treatment of diabetes and acetonuria. He completed the cure of his patient with "almond biscuits," and the general improvement resulted in a marked decrease in the amount of sugar, which fell from 42 to 15 grams per liter, after having resisted two seasons at Vichy and the electricity.

Health Commissioner can not fix Hours of Labor.—Where a city charter gives to the board of health alone the power of appointing its employes, and "to prescribe the powers and duties and determine the annual salary and compensation" of each of same, the supreme court of Michigan holds, in the case of Goodson against Board of Health of City of Detroit, that the health commissioner can not fix the hours of labor, to determine how many hours should constitute a day's work, for an employe of the board, and bind the city to pay therefor. If, for example, a clerk of the board is dissatisfied with his employment and hours of labor, he should apply to the board to fix them, and not to the commissioner, the action of the board thereon being conclusive.

A Panic Averted.—The electric plant of the Manhattan State Asylum for the Insane, on Ward's Island, together with the other institutions there, was totally destroyed by fire on the night of October 19 soon after 7 o'clock. The damage will exceed \$25,000. The electric plant is in the basement of the female branch of the asylum, and immediately over the flames 100 of the most violent maniacs were confined. In the other end of the building 250 others were in danger. All were removed to a place of safety, and the loss is altogether to property, human life being spared. One hundred of the worst maniacs marched through a blazing corridor to safety, believing, according to a reporter of perhaps exuberant imagination, that "such nice fireworks were for their amusement." Dr. A. E. MacDonald, the superintendent, highly praises the conduct of his nurses, male and female. The police and fire departments also did efficient service, while the known hallucinations of the more violent patients were adroitly managed.

Physician Presumed to be Respectable.—The evidence and certificate of at least two "respectable" physicians is required, by a Maine statute, to establish the fact of insanity. But the supreme judicial court of that State holds, in the recent case of the City of Bangor against the Inhabitants of Orneville, that a record of the proceedings attending the examination and commitment of an insane pauper that omits to state, according to the statute, that the two practicing physicians who made the medical examination were also "respectable," will be held sufficient when it appears to contain a statement of all facts requisite to establish the regularity of the proceedings and a legal

commitment; no evidence being adduced that the two physicians, who signed the certificate, were not in fact respectable. In such cases, it says, the court is aided by the presumption in regard to public officers, expressed by the maxim, "all things are presumed to be done in due form."

The Polhemus Clinic of Brooklyn.—A magnificent addition to the medical resources of Brooklyn was opened November 18, under the unassuming title given above. It has been erected under the direction and bounteous contributions of Mrs. Caroline Polhemus as a memorial to her husband, the late Henry D. Polhemus; it was opened for a private view on Thursday afternoon. Mr. Polhemus had for many years been a regent of the leading medical institution of his city, and on this account largely, Mrs. Polhemus decided to erect this useful memorial, which will nobly further the work of the Long Island College Hospital. The building with its equipment, will cost \$450,000. It is of the most substantial structure and as nearly fireproof as possible. The top floor has been devoted to large operating and dissecting rooms, which when fitted up will be the most perfectly appointed in the city. Lecture rooms, class rooms, and chemical laboratories occupy the floors beneath. These will be turned over to the use of the medical students of the hospital, who are further provided with a complete set of lockers. The lower floors are to be devoted to the dispensary work. A large and splendid library will be a feature of the first floor of the building. The Clinic has been transferred to a corporation, created under the laws of the State of New York, with the consent of the State Board of Charities, to hold in perpetuity. It will be managed by the Long Island College Hospital. Mrs. Polhemus has provided a fund for the support of the Clinic.

Examination of Patient under Influence of Chloroform.—In a personal injury case, a physician was called by the plaintiff, and testified that chloroform was administered to the plaintiff, and that she was examined while under that influence, and as to what he found in reference to the condition of his patient at the time. The defendant contended that an examination of the plaintiff's injuries had been made by the doctor only a day or two before this without administering chloroform, and that this testimony about giving it had a tendency to make the plaintiff's case appear more serious than it really was, and that this was prejudicial to the defendant. But the supreme court of Michigan says, *Holman against Union Street Railway Company*, that the chloroform was administered as a part of the treatment, and while the patient was under its influence the muscles of the shoulder and hip were given motion with the purpose of breaking up the adhesions; and it expresses the opinion that the testimony was not objectionable, and was introduced for the purpose of showing the then condition of the plaintiff. This decision it further seeks to justify by the statement that there was nothing in the testimony to show that this treatment was unnecessary, or that it was had for the purpose of the trial of the case. That the doctor was asked, while upon the stand, whether or not, in his judgment, the plaintiff still continued to suffer pain, and whether she would be able to do her household duties, it does not consider error.

Expert Evidence Superior to Mere Conjecture.—In the personal injury case of *Mahar against Railroad Company*, medical experts were permitted to testify what effect certain conditions which had been ascertained would produce upon the plaintiff's system, what causes would naturally induce such conditions, and the probable duration of the same. This evidence, the fourth appellate division of the supreme court of New York pronounces something superior to and beyond mere conjecture, for it expressed the deliberate judgment of men of science, based upon actual observation and experience, as to results and conditions which might naturally and ordinarily be anticipated, and not as to those which were only within the

range of possibility. It was therefore, the court thinks, of some value to the jury, and competent for the purpose for which it was received. In this, the court distinguished between the evidence in question and that rejected in another and leading case where the testimony was that the plaintiff's injury was "very likely to prove permanent," as furnishing the jury too good an opportunity for speculation as to consequences.

Rheumatism, Gout and Rheumatoid Arthritis.—Dr. Edmund L. Geos, of the Faculty of Paris, has just completed a monograph on "Rheumatism, Gout and Rheumatoid Arthritis and allied affections." He first gives a brief historical exposé of the subject and claims that acute articular rheumatism is always due to a specific germ or micro-organism which, like the germs of measles, scarlatina and syphilis, though still undiscovered are believed to exist and play the most important rôle in the causation of these diseases. The more recent bacteriologic discoveries are alluded to and the different definitions and explanations of arthritis given in detail. Much emphasis is laid upon the importance of carefully examining the amount of uric acid present and the extent of uricemia or lithemia present. After briefly but carefully considering the various treatments that have been followed by both the most eminent English and French authorities, Dr. Geos presents the results obtained by the use of the salicylates and colchicin, which have been very efficacious in his hands. He uses a combination of colchicin and methyl salicylate dispensed in gelatin capsules, each containing one-fourth milligram (1-260 grain) of colchicin and 20 centigrams of the natural methyl salicylate distilled from the *betula lenta* (*N. O. amentacea*). It is essential, when exhibiting these remedies, to properly divide the doses, and small capsules which can be administered every hour or every alternate hour seem best to fill all requirements. In addition to using this combination internally it has also been used by the author externally in the form of *betul-ol*: this is almost immediately absorbed, which is evidenced by its presence in the urine within ten minutes after its application: this is to supplement the internal administration.

Oxytuberculin Treatment of Tuberculosis.—Report of a Committee of the Faculty of Cooper Medical College upon the oxytuberculin treatment of tuberculosis of Dr. J. O. Hirschfelder, adopted by the Faculty, Nov. 5, 1897.

In February, 1896, Prof. J. O. Hirschfelder, of San Francisco, called the attention of some of his professional friends to a new method of treatment of tuberculosis with a bacteriologic product of his devising which he called oxytuberculin. He presented a number of patients for examination and apparently demonstrated its value. Nevertheless he was advised to withhold the results from publication until further experience and time should verify them.

Subsequently, that is in April, 1897, he read before the State Medical Society a paper recording seventy cases treated with oxytuberculin.¹ Thirty of these were in advanced stages of the disease, many having vomica, and forty were in earlier stages. Each of these exhibited the physical signs of tuberculosis in one or other of its stages; bacilli were found in the sputa of all. Other physicians had examined a large number of the patients at the beginning of and at different periods of the treatment, and had verified the diagnosis. Dr. Hirschfelder reported that sixteen of these patients were cured; that is, no evidence of the disease can now be discovered objectively or subjectively. Thirty-six were much improved: that is, they are subjectively well, little evidence of present disease can be discovered: there are few or no sputa and no bacilli. In some of these latter large vomica exist, but seem healed. Six cases were slightly improved: six remained unchanged: one became worse and five died. All the latter were in the worst stages of the disease when treatment was begun: four died in from a month and a half to two months, and one in three and a half months.

During the progress of these investigations Dr. Hirschfelder made forty-one series of culture experiments in the laboratory. These uniformly proved the inhibitory power of the oxytuberculin upon the growth of tubercle bacilli in veal bouillon. It appeared a just inference that similar results might follow the injection of oxytuberculin into the body.

¹ Transactions Medical Society State of California. 1897.

With these facts and statements before them, the members of the faculty of Cooper Medical College determined to investigate the new treatment, and for that purpose the undersigned committee was appointed. Its several members have repeatedly witnessed the laboratory culture experiments and have had before them for examination fifteen patients who have been under treatment from two to several months during the past two years, together with their histories, bacteriologic specimens and the corroborative evidence of other physicians as to the diagnosis. Two of these patients at the beginning of treatment presented a mild form of the disease; in five the disease was pronounced; in four the lung was very seriously involved, and the remaining four seemed hopeless. There is no reason to doubt that all were cases of tuberculosis. Fever, cough, expectoration, hemorrhages, night sweats, etc., had been present in nearly all; the physical signs and bacilli had been found in all; in many the diagnosis had been confirmed by other physicians. Physical examination of many of these cases was made by the members of the committee. No evidence of present tuberculosis could be discovered, although in some, old cavities were found. The concurrent testimony of all, except two or three recent cases, was of complete return to health so far as appetite, weight and vigor are concerned. There were no cough, expectoration, hemorrhages or other symptom of disease. Several had been discharged from treatment months ago.

The conclusions reached by the committee are:

1. Oxytuberculin prevents the growth of tubercle bacilli in veal bouillon.
2. A positive therapeutic value has been demonstrated for it, in the fifteen cases examined; the more clearly as no other treatment was used.
3. No dangerous or untoward effects have resulted from its use.
4. It has been legitimately brought before the profession, since a full description of its mode of preparation has been published, thereby putting it within the reach of all.²

Finally, the Committee feels justified in certifying these facts to the profession to the end that oxytuberculin may be thoroughly tested, the limits of its successful application determined and its place in therapeutics established at the earliest possible time.

While some remarkable results have been obtained in advanced cases, no claims are made for the later stages of the disease.

Societies.

The following meetings are noted:

- Connecticut*.—Waterbury Medical Society, November 15.
District of Columbia.—Medical Association, Washington, November 23.
Illinois.—Chicago Medical Society, November 24.
Minnesota.—Olmstead County Medical Society, Rochester, November 23.
Missouri.—St. Louis Medical Society of Missouri, November 27.
New York.—Academy of Medicine, Syracuse, November 23. Albany County Medical Society, Albany, November 17. Che-mung County Medical Society, Elmira, November 16. Medical Society of the County of New York, New York City, November 22.

Cincinnati.

THE GERMAN DEACONESS HOME has opened a branch known as the Ohio Maternity Hospital located at No. 222 West Liberty Street. The staff consists of Drs. Gustav Zinke, M. A. Tate and J. M. Rowe. Dr. Bookwalter has been appointed house physician.

THE MIAMI VALLEY MEDICAL SOCIETY held its regular annual meeting at Torland, Ohio, October 13. The following papers were presented: "New Method of Skin Grafting after Bone Operations," by E. W. Walker, Cincinnati; "Abnormal Adhesions of the Placenta," by C. A. Tribbett, Westboro; "Can Typhoid Fever be Aborted?" by J. H. Andrews, Goshen;

"Headache in Nasal Disease," by Max Thorner, Cincinnati; "Bright's Disease," by P. M. Ashburn, Cincinnati. The following resolution was passed and its hearty support pledged by the individual members of the Society present:

Resolved, That the members of the Miami Valley Medical Society are earnestly urged to correspond with all candidates for members of the Legislature in their respective counties to learn whether or not said candidates favor any injurious amendment to the Kimmel law and when so informed the members are urged to actively work for the election of the candidates who favor the amendment of the present law by its friends and not by its enemies.

President-elect Dr. Chas. A. Hough of Lebanon presented an interesting review of the first year's work of the Ohio State Board of Medical Examiners.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY.—At the regular meeting of this Society, held Nov. 18, 1897, Dr. Samuel Bell, medical superintendent of the Upper Peninsula Hospital for Insane, and honorary member of the Society, read a paper on the subject of "Physical Conditions Producing Mental Aberrations." After introducing the subject by referring to the conflict between authorities in regard to the relation of insanity to certain conditions of the procreative organs, the author took up insanity following operations. He said that a few years ago Dr. Rohe of Baltimore sent letters to the medical officers of all the insane institutions of the United States and Canada requesting information on this subject. Replies were received from all, giving altogether only twenty-five cases in the last ten years of insanity following operations on the female generative organs. In persons of nervous instability, the shock of a grave operation may produce transitory delirium and even more prolonged mental derangement, but derangement does not appear to follow operations on the female organs of generation more than operations on organs in any other part of the human organism. The Doctor then gave an analysis of six cases at present under treatment at the Upper Peninsula Hospital for the Insane, who had operations. In four of the cases cited, mental aberration either developed or became aggravated after the operation, while in two, decided mental improvement followed the operation. "If a patient becomes insane after an operation," the author went on to state, "it is not reasonable to conclude that the mental trouble is the result of it, though it is possible that where hereditary taint predisposes to insanity, the operation might act as an exciting cause. Dr. R. M. Buck, medical superintendent of the London, Ontario, Insane Asylum, reports that out of sixty-two cases of insanity operated on, twenty-three completely recovered their mental balance and fifteen others were very much improved. There is sufficient evidence to show conclusively that child-bearing and lactation bear an important relation to mental disorders; also, at the climacteric period, mental disorders are liable to occur in some women, it being found that 4 per cent. of insanity in women is due to the menopause. Puerperal insanity is responsible for from 10 to 12 per cent. of all cases of insanity in women. A typical case is now under treatment at the Upper Peninsula Hospital and is an illustration of what effect neglect will have on a woman during the child-bearing period. She lived sixteen miles from a physician and when children were born, which occurred often, she had neither medical care nor proper attention. Her health gave way, delusions of persecution appeared and she is now hopelessly insane." The Doctor then went into a consideration of the subject, "Is menstruation influenced by insanity, or is insanity influenced by menstruation?" and said: "Observations by Skene show that the menstrual function is markedly disarranged in insane women. In the Upper Peninsula Hospital the same was found to be true. The greatly impaired physical condition which usually obtains in the insane may wholly or partly account for this derangement. My experience does not bear out the opinion of Dr. Skene that where menstruation is regular the insanity is of a mild form. In regard to syphilis as a cause of insanity, parietic dements supply 12 per cent. of the insane in our institutions, and about 75 per cent. of them are of syphilitic origin. Dr. Mott, pathologist to the London County hospitals for the insane, as a result of extensive experiments during the past year, states that the

virus which is responsible for locomotor ataxia will also produce dementia, but there need not necessarily be specific lesions."

HEALTH REPORT for the week ending November 27: Deaths 71, of which 23 were children under 5 years of age; births, male 45, female 44: 20 cases of diphtheria, 58 of scarlet fever; deaths from diphtheria 2, from scarlet fever 1.

Washington.

REPORT OF THE HEALTH OFFICER.—The report of Health Officer Woodward for the week ended November 20, shows the total number of deaths to have been 142, of which 76 were white and 66 colored. The number of births, white 31, colored 20.

WOMAN'S CLINIC.—At the annual meeting of the Woman's Clinic recently held Drs. D. S. Lamb and Robert Reyburn were elected vice-presidents. Members of the attending staff, Drs. Ida J. Heiberger, Julia E. Smith, Nancy D. Richards, Phebe R. Norris, Sophie A. Jung, Jessie Keppalar, Ada R. Thomas, Adeline E. Portman, Susan J. Squires and May D. Baker. Consulting staff, Drs. J. H. Bryan, S. M. Burnett, H. L. E. Johnson, Mary Parsons, H. C. Yarrow, D. W. Prentiss, and Robert Reyburn. Superintendent of hospital, Dr. Ida J. Heiberger.

AT THE RECENT MEETING of the attending staff of the Central Dispensary and Emergency Hospital the following report for the month of October was made: Number of new cases 11,000, visits 3,364, operations 200, deaths 3, postmortems 1, ambulance calls 47, ward cases 30, prescriptions 3,464. The Executive Committee of the Board of Directors adopted the recent recommendations of the Medical Association of the District of Columbia with respect to poor and emergency patients.

MEDICAL SOCIETY.—At the recent meetings of the medical society, Dr. Bishop read a paper on "Neurasthenia." Dr. Richardson reported cases of intubation with remarks on antitoxin. Dr. Eliot reported a case of hysteric dysphagia with the specimen, and Dr. Lamb, cerebral hemorrhage and cancer of the ovary; filaria in heart of dog, specimens with history.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—At the 270th meeting of the Society, held at the residence of Dr. S. S. Adams, Dr. T. J. Winter read a very valuable paper on "Criminal Abortion." The subject was discussed by every member present and proved to be one of the most interesting meetings the Society has held for a long time.

THE DAISY-CHAIN HOSPITAL GUILD, which has for its object the erection of a hospital for contagious diseases, has donated to the general fund \$11,300.

A Bill to Regulate Expert Testimony in the Courts of the District of Columbia.

Be It enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

SECTION 1.—That in courts of the United States in the District of Columbia no opinion or expert evidence shall be admissible except as hereinafter provided.

SEC. 2.—That in any cases it shall be the duty of the trial judge, subject to review by the appellate court, to decide whether the skill of any person, in the matter in which evidence of his opinion is offered, is sufficient to entitle him to be considered as an expert.

SEC. 3.—That in any civil action, upon a showing by either party, that the testimony of an expert is necessary for an intelligent understanding of a question in issue, or for the understanding of any evidence relevant to the issue, the court shall name some person or persons, not to exceed three in number, of special skill as to the matter in question, who shall be examined by the court, subject to cross-examination by counsel, upon the matters of special skill or knowledge relating to or growing out of matters in controversy. The cost of such expert testimony to be taxed against the party requesting the same. Provided, that nothing herein contained shall be construed to deprive any party of the right of exception to the ruling of the court on the sufficiency of the showing calling for expert testimony, or as to the person of the expert designated.

SEC. 4.—That in criminal proceedings, except in cases involving the sanity of any defendant, whenever in the opinion of the court the ends of justice demand, the court may on its own motion, or upon a proper showing of either party, appoint or designate such person or persons as by reason of their special skill may be qualified, to give testimony upon such matters as may be involved in the case on trial. The cost of such testimony to be borne by the government. Provided, that nothing herein contained shall be construed to deprive any defendant of the right of exception to the ruling of the court on the sufficiency of the showing calling for expert testimony, or as to the person of the expert designated.

SEC. 5.—That in all criminal cases involving the sanity of any defendant, the court shall appoint a commission, consisting of three physicians skilled in the treatment of mental disorders, one of whom shall be chosen from persons nominated by the government, one from persons nominated by the defendant, and the third to be selected at large by the court; in event of either the government or the defendant, or both, failing to make such nominations, the court may appoint without such nomination the expert or experts to which either or both may be entitled; said commission shall make such investigation as the court

may direct and shall submit to the court a finding, to be signed by the majority, which said finding shall be final and not subject to exception or appeal; said finding to be submitted to the jury to receive the same weight as other evidence. Provided, that nothing herein contained shall be construed to deprive any defendant of the right of exception to the ruling of the court on the sufficiency of the showing calling for expert testimony, or as to the person of the expert designated.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from November 20 to 26, 1897.

Capt. Isaac P. Ware, Asst. Surgeon, is relieved from duty at Ft. Grant, Ariz., to take effect upon the expiration of his present leave of absence, and ordered to Benicia Bks., Cal., for duty.
Capt. Merritt W. Ireland, Asst. Surgeon, is relieved from duty at Benicia Bks., Cal., to take effect upon the arrival at that post of Capt. Ware, and ordered to the Presidio of San Francisco, Cal., for duty.

PROMOTIONS.

Major Peter J. A. Cleary, Surgeon, to be Deputy Surgeon General with rank of Lieut. Colonel, Nov. 15, 1897, vice Waters, retired.
Capt. Charles Richard, Asst. Surgeon, to be Surgeon with the rank of Major, Nov. 15, 1897.
First Lieut. Paul F. Straub, Asst. Surgeon, to be Asst. Surgeon with the rank of Captain, Nov. 4, 1897, after five years' service.

RETIREMENT.

Lieut.-Col. William E. Waters, Deputy Surgeon-General, Nov. 15, 1897.

CHICAGO, ILL., DECEMBER 11, 1897.

No. 24.

ADDRESS.

PRESIDENTIAL ADDRESS.

Address delivered before the Middle Tennessee Medical Society at
Murfreesboro, Tenn., Nov. 18, 1897.

BY A. B. RAMSEY, M.D.
M'MINNVILLE, TENN.

The mission of the doctor of medicine should not be merely to relieve the physical ills of humanity. His association with the inner side of human life is the closest, his knowledge of human nature and the human mind is the most exact, therefore his ideas of their needs should be the most reliable.

These facts being true he should open his eyes to many questions that concern the moral health of humanity and its offspring.

He should study the cause and effect of moral disease, he should endeavor to become so expert as to be enabled to recognize the prodromus of vice, and above all he should seek earnestly and diligently for remedies, both preventive and curative, for moral perversion and disease.

The subject of my address is not, strictly speaking, a scientific question, yet it is so pre-eminently a question whose ultimate solution can be found only through us as physical and moral educators of the people, and through the people of the law-makers of our commonwealth, a question fraught with such grave import now, and one promising infinitely graver importance a few generations in the future that I deem no apology necessary for its presentation to you.

Dr. Holmes said, "the time to begin the training of a child is one hundred years before its birth." I say the time to begin moral character building, physical development and the teaching of obedience to natural and civil law is many generations before the birth of the child.

After God had created the world, the heavens with an effulgent sun, pale beautiful moon and myriads of bright twinkling stars, and the earth and sea with their countless forms of animate life and inanimate matter, He reached the climax of His creative power and made in His own image the being called man. He endowed him with physical strength and beauty and mental power. He made him a perfect creature, limiting the likeness to Himself only in so far as He withheld His own attribute of divinity. By reason of this limitation man was prone to human thought, emotion, impulse and desire; hence God in His omniscience foreseeing the loneliness and uselessness of his future, in a very ecstasy of creative desire conceived fair, beautiful woman. This peerless creature pleased the man, she realized to him his ideal of a companion and helpmeet, he loved her and wooed her, and so for the first time in history of the universe was a wedding celebrated.

With these two beings God's creative office ceased; the necessity for further creative acts was ended, for

the world was replete with animal life, and all His creatures were given the power to reproduce their kind; a power little less wonderful when viewed from a physiologic standpoint than the divine creation itself; a power of heredity capable of marring the earth with crime and sin, or blessing it with peace and love.

God, judging from the beautiful richness, the chaste beauty and the peaceful congruity of Eden, intended His creatures to be forever happy and innocent. To this end He formulated an incomparable code of natural laws to govern them. He bestowed upon all creatures other than man a brain faculty called instinct that enables them to live in obedience to these laws; thus they do with resultant health and contentment. Man, the highest form of animate nature, He endowed with faculties of intellection and judgment to enable him to differentiate between right and wrong, to enable him to make his gross and sensual self subservient to the spiritual and moral, but at the same time with volition to choose between them.

We, as physicians, know these natural or physiologic laws; we know that their observance will insure health and happiness to mankind and to his offspring, and that disobedience will destroy the peace and purity of his conscience, will pervert the strong qualities of his mind, will corrupt his body and will entail a heritage of mental depravity, physical imperfection and predisposition to crime upon unborn generations. Shall we then view with sightless eyes and hear with deaf ears the manifold depravities of the people who support us, and their grave errors of training to children perhaps already vitiated with an unhealthy heredity?

The first man and woman must have been ideal creatures. It requires small effort of imagination to picture the elegant contour of the man's form, the brawn of his muscles, the grace of his actions and the perfect poise of his mind, because we are told he was created in the image of his creator.

Even less effort is needed to picture the first woman. Her form must have been the perfection of symmetry and grace, and her face must have looked the sunshine of beauty and intelligence. Clothed in raiment of chastity, no wonder she became the mother and type of creatures whom men will love forever.

These two creatures, perfect at their creation, embodying the height and breadth of physical, moral and mental development, full grown, well-rounded manhood and womanhood with the first breath were intended to reproduce men and women equally as perfect. And but for transgressions of nature's law from the beginning of time men and women would be today without flaw or blemish.

Flaws and blemishes of physical organism, mental faculties and moral character are transmissible by heredity just as are form and feature. Our progenitors, by reason of their transgressions of physiologic

laws and error of development, the result of their forefathers' sins, have given to us as a heritage many mental, moral and physical defects coupled with manifold good qualities of character and conscience. What we are at birth and during childhood we are not responsible for, but we are responsible for what we become after judgment and discretion have developed, unless perchance our environments were previously so depraved as to perpetually deform our moral natures, and the atmosphere of vice so dense as to forever exclude the sunshine of virtue.

Parents are responsible for those perversions that find root and flourish in and control the natures of their children before the development of discretionary power.

We as physicians are responsible for our failure to do missionary work of reform and education among the ignorant and indifferent on this subject; and our fair State is disgraced beyond power of expression by her manufacture of confirmed criminals out of children before and at the threshold of maturity through her infamous practice of imprisoning them into the company and tutorship of criminals, who long since ceased to sigh for their lost purity and are dead to reformation.

A vitiated heredity is beyond doubt responsible for an impulse in childhood to commit crime that is well nigh resistless, possibly wholly so, if there have been no counteracting influences at work in the life of the little criminal. Because this is a fact, should in cases of legal trial of the youthful call for the most intelligent jury of investigation, whereas, probably in most cases densest ignorance sits in judgment. It should provoke the most painstaking inquiry into heredity and environment in courts of law, whereas legal inquiry into this question is comparatively unknown. If found to exist it should call forth acquittal so far as imprisonment with hardened criminals is concerned and provoke the consideration of reformatory action, whereas under present conditions, knowledge of tainted heredity and vicious training creates in the minds of judge, jury and populace, prejudice that is the initial step to conviction.

Many boys have been sentenced to our State prison and confined with common criminals. Our governor has informed me that immediately upon the advent of one of these children there is a fierce fight among the men for his possession. The victor uses him for sexual gratification, thus transforming him into a sexual pervert, and in many instances a hopeless invalid. And yet our governor is criticised for the free exercise of his pardoning power.

The sexual perversions and criminal desires that will be surely and irremediably engrafted upon the tainted inheritance of these imprisoned children will forever preclude a normal, healthy sexual and moral post-prison life, so that whereas confinement in a suitable reformatory institution, under wise, capable and Christian supervision might have so far overcome hereditary predisposition as to have at least made law-abiding citizens of them, they are now forever shut out of opportunities of useful citizenship. They perhaps become the heads of families of libertines and prostitutes, and worse, they become eager and indefatigable teachers of perversion and crime to the innocent.

Picture if you can the pitiable and hopeless condition of individuals born with an inheritance of moral depravity, they can not unaided shake off, forced by

inheritance and environment to become criminals and reprobates, then show the pity, charity and compassion that are claimed as the bed-rocks of our profession by united and untiring efforts toward an ultimate and radical change in the management of our youthful criminals.

Mr. Dugdale, former member of the prison association of New York, has made an interesting study of this question and gives us the following information: "When visiting the various jails of the State he found in one six persons incarcerated for crimes, between all of whom there was a family relationship. On further inquiry he found that of the same family there were twenty-nine relatives in the vicinity, seventeen of whom were criminals. Still further inquiry developed the following facts: Within seventy-five years a family of 1,200 persons have sprung from five sisters, several of whom were illegitimate, and three of whom were known to be unchaste, and who married men whose father was an idle, shiftless hunter, a hard drinker and licentious. Of this family the history of 709 was traced. Here is what is claimed as a true summary of said history: Paupers, 280; years of pauperism, 798; criminals, 140; years of infamy, 750; thieves, 60; murderers, 7; prostitutes and adulteresses, 165; illegitimate children, 91; number of syphilitics, 480; cost to State in various ways, \$1,308,000" (Kellogg). This is a statement of what could be discovered. A complete discovery of the history of the whole 1,200 would doubtless have revealed a more horrible showing. This is certainly a history of the grossest hereditary depravity, and proves the law of heredity in crime beyond denial. No doubt an extended study of the question would reveal an almost unlimited number of similar histories.

We hear almost daily histories of the most aggravated crimes committed by children of tender years, and are not shocked to the point of serious thought on the question of proper management of an army of children in our State, who are daily adding to inherited vice education of the most infamous character.

Gentlemen, allow me to put myself on record as saying, I believe the law of heredity is universal, and further, that in nearly all cases the degree of hereditary criminal vice is decided by the degree of maternal or paternal taint. To split the question finer, how many parents have transmitted an inheritance of absolute purity to their children? Where is the father who has not in his youth, even if outwardly pure, committed mental sins without number and nursed desires that set him aflame with ungratified lust? They are few. And I firmly believe that each uncommitted crime will give a man's delicate nervous system a shock whose influence will never be lost, will produce an impression on his moral nature, the effect of which will be transmitted to his offspring in the form of vicious predisposition differing in degree only from the most aggravated examples. If this be true the responsibility of all youthful criminals should ever be a matter of grave inquiry, and the medical profession would do an act of the most exalted humanity should it set in motion a wave of reformation that sooner or later would wash out the horrible blot on the pages of our criminal law.

Tennessee has institutions complete in all their details and appointments, that she holds open to unfortunate children deprived of certain senses, where, through wise teachers, natures' defects are supplied in especial education, and life made worth living to

them. For this she deserves the love of every patriotic man. How different with regard to little ones born blind to the beauties of a virtuous life, and deaf to the whisperings of conscience. In most of these cases early education and environment serves but to develop and intensify hereditary predisposition until crime as an inevitable sequence is irresistible. Is it now too late to take the back track in these little characters for the purpose of reformation? Are the possibilities of honest manhood and womanhood past beyond recall? I answer most emphatically, no! Even now in proper institutions under wise management, some at least of these characters could be reclaimed and trained into useful citizenship. But so long as our State prison opens her doors to children and youths who are only more or less responsible for their crimes, just so long will she close the door of honest living on them, and just so long will theft, prostitution and murder increase in the land.

There is not a remedy in our materia medica that will cure every case of any disease, no matter how potent it may be for good in the especial disease. Heredity, idiosyncrasy and environment will ever preclude the discovery of an infallible specific. Yet, notwithstanding this fact, men of science will forever study and work toward this end. So it is in moral disease. Legal statutes, reformatory measures, nor the teachings of priests, scientists and laymen will or can wholly cure moral sin. It was put into the hearts of men to stay, and the millennium will witness its extinction. Still, every man of virtuous desire and human compassion should strive to make his fellow-man better.

I believe this truth applies especially to physicians, because they know, or ought to know, the three natures of man, the mental, moral and physical, more perfectly than men in any other calling, and because they are brought in such close touch with all classes, that opportunity for salutary teaching is unlimited. I venture the assertion that if every physician in Tennessee would bend his efforts in this direction for ten years, the State prison would close its doors on child criminals. Adequate reformatory schools would spring into existence, the moral tone of the people would be infinitely improved and the number of criminals of all classes would be even in that short time noticeably reduced.

We have city, county and State boards of health that are yearly becoming more painstaking in their supervision of individual and public health. We have commodious institutions in each division of the State where those bereft of reason are nursed and cared for. We have large schools where the deaf and dumb and blind are taught and supported, but if I am correctly informed we have no adequate organized State boards for the prevention of crime, nor adequate institutions for the care and reformation of child criminals. Is this safe? Is it just? Can we as guardians of the public health shut our eyes on the fact that neglect of the adequate handling of the child-criminal question actually creates a greater necessity for the institutions above named? We know that drunkenness, prostitution, etc., predispose not only the individual but also his offspring, to the development of some of the diseases at least for the treatment of which these institutions were built. Reform the children instead of condemning them to prison cells or allowing them to drift deep into the slums of vice, and you will start an upward development toward mental, moral and phys-

ical perfection that may some day obviate the necessity for such commodious institutions, or if such good result as this is never realized perhaps we may remain in as good condition as now, a no mean result.

The *Quarterly Journal of Inebriety* states, "The fact is startling that insanity has increased in proportion to the population over 100 per cent. from 1870 to 1890. Inebriety as a disease has come into more prominence during the last quarter of a century. It is certain that many cases of inebriety become insane, and an equal number are classed with the insane in statistics. The intimacy of these two so-called diseases suggests that the increase of insanity is due largely to inebriety, the latter being unrecognized as a distinct disease. Heredity is not recognized, and the evils of both insanity and inebriety are permitted to go on unrestrained to succeeding generations."

This is appalling. At this ratio, picture, if you can, the horrible figures a few decades in the future will produce. I quote the above facts not through a desire to discuss these diseases, but simply to bring before your minds some idea of the irresponsibility being daily transmitted to innocent babes by a vast army of mentally tainted men and women. This vast army is being daily recruited, and no efforts commensurate with its rapid growth are being made to counteract the fearful results. On the contrary, the same law that fills our jails and asylums with inebriate criminals and lunatics is favoring, yea, inviting a more rapid growth of inebriety and lunacy by licensing the manufacture and sale of alcoholic beverages. Our government is daily sowing the seed of hereditary crime that will surely bear the fruit of individual damnation and civil anarchy. A vast number of innocent babes by reason of inheritance and education will grow to childhood and youth with the stigmata of mental taint and moral infamy they sought not. They will stand before the bar of so-called justice for crimes for which they are not responsible. They will be condemned to prison cells that should never know their presence. Yea, at this same bar they will receive their doom for time and eternity.

This question is not now pressing itself upon you, but the day will come when it will force itself upon you in all its enormity, and demand a solution in the interest of social, civil and national welfare.

The day is coming when the medical profession will gladly and eagerly join hands with the State and populace in efforts of reformation of the tainted children of our commonwealth, and of the criminal laws that are not just.

Would that we were not content to calmly await the advent of this day. Would that each member of our noble profession might feel it a duty he could not shirk to at least drop wholesome truths of correct living and correct training into the minds of his patrons.

Would that my profession might begin some concerted and importunate action in its official bodies looking away out to ultimate revision of our criminal laws and the reclamation as far as possible of children morally tainted by heredity and education.

Extirpation of the Thymus Gland.—Carbone has been studying the effect of the extirpation of the thymus gland, and recently announced at a meeting of the Academy of Medicine at Turin, that he finds that the thymus is not an organ indispensable to the organism; its extirpation does not affect the growth of the animal. It probably has no hematopoietic function, and the slight azoturia that follows ablation is possibly to be attributed to irritation of the vagus.—*Gaz. d. Osp. e d. Clin.*, Aug. 15.

LUMBAR NEPHROPEXY WITHOUT SUTURING.

BY N. SENN, M.D., PH.D., LL.D.

Professor Practice of Surgery and Clinical Surgery in Rush Medical College; Attending Surgeon, Presbyterian Hospital; Surgeon-in-Chief, St. Joseph's Hospital.
CHICAGO.

Nephrorrhaphy for the fixation of movable kidney has had an extensive trial at the hands of the surgical profession ever since the operation was suggested and first practiced by E. Hahn of Berlin. There can be but little doubt that the operation has been performed many times unnecessarily in cases in which the symp-

ing the capsule of the kidney and more or less of the parenchyma of the organ. All operators expose the posterior surface of the kidney by incising the adipose capsule and by displacing or excising a portion of this structure. It has been claimed that the fibrous structure of the kidney is incapable of producing new tissue, out of which adhesions are formed to anchor the organ permanently in its new location, which induced Tuffier to advise that the capsule should be freely incised and extensively stripped from the underlying parenchyma before suturing the organ in place. This practice, which fortunately was never extensively adopted, has undoubtedly resulted in serious and permanent damage to the organ operated upon. Experiments on the lower animals, as well as inspection of

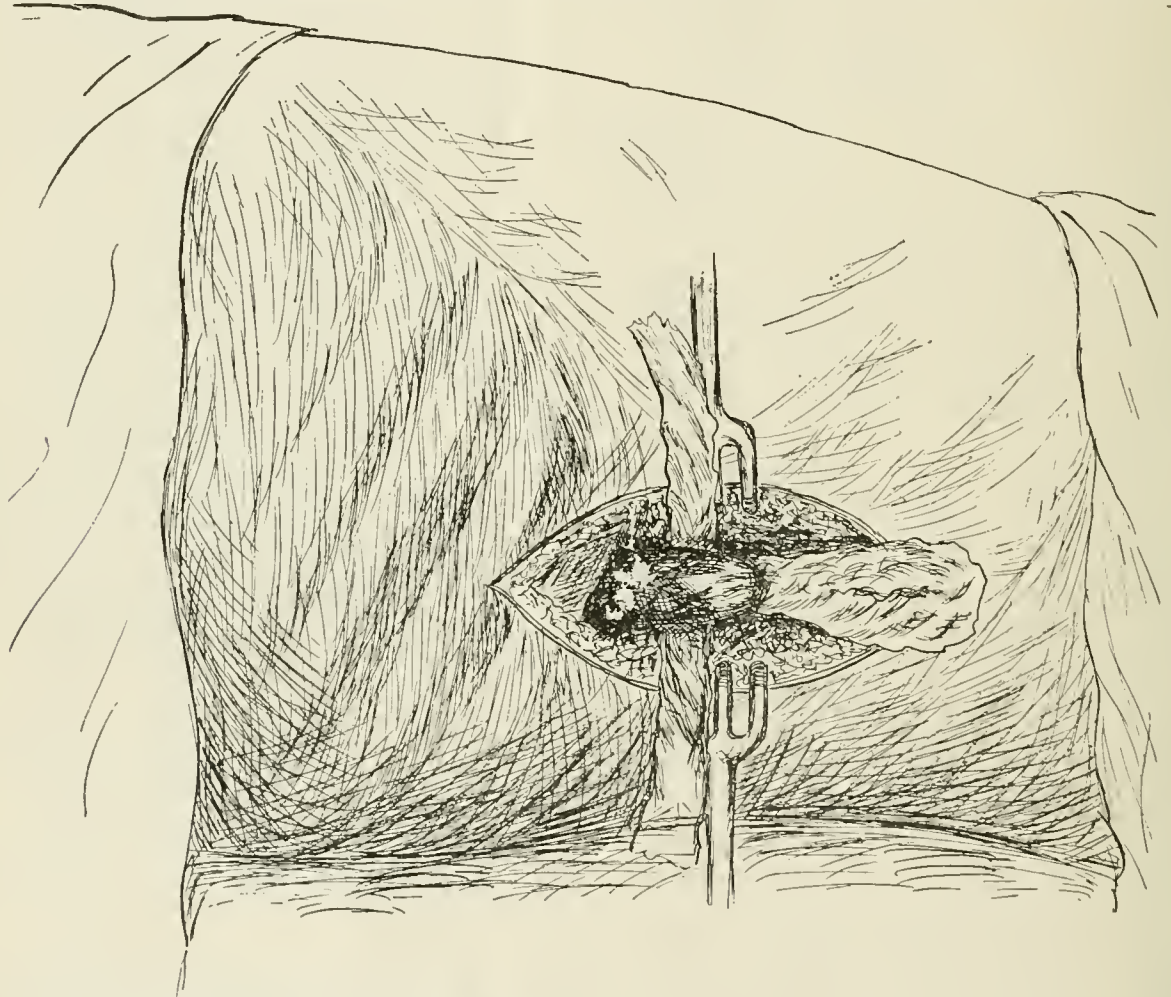

FIG. 1.—Kidney exposed by Simon's incision, adipose capsule excised and lower pole of organ brought into lower angle of incision with strip of gauze underneath it. Lower angle of wound packed with gauze.

toms were not produced by the displaced organ, and consequently failed to procure the expected relief. Nephropexy is a legitimate and established surgical procedure in all cases in which it can be established that the kidney is not only displaced, but is at the same time the direct cause of the manifold symptoms which such a condition may and often will produce. The many modifications which the operation has undergone is perhaps the best proof that the results heretofore obtained by the different methods devised have not proved satisfactory. In nearly all of the operations the kidney is sutured to the muscular structures of the lumbar incision and the lower border of the last rib, the sutures, usually four in number, includ-

the capsule of the kidney operated upon at different intervals after the operation on the human subject, have demonstrated the fact that the capsule of the kidney, like fibrous tissue in any other part of the body, possesses a maximum intrinsic power of tissue proliferation when subjected to mechanical irritation under aseptic conditions. No modern surgeon would entertain for a moment the propriety of depriving the kidney of its normal fibrous investment as a preliminary step in performing nephrorrhaphy.

Nicoladoni has recently modified Tuffier's procedure by incising the fibrous capsule only to the extent to enable him to suture the kidney without including in the sutures any of the parenchyma. He makes an

incision through the capsule along the outer border of the kidney, detaches the capsule sufficiently on side and sutures the detached portions to the margins of the muscular part of the vertical lumbar incision. In some cases he joins the vertical incision at each end with a short transverse cut to facilitate the separation of the capsule to the requisite extent. Nicoladoni devised this operation and Rutkowski was the first one to apply it in practice, and the result is said to have been a most excellent one. The many failures which have followed suturing of the kidney in the lumbar region with limited exposure of its fibrous capsule is a strong argument against this method of performing nephrorrhaphy. The kidney substance is extremely friable and even if the sutures include a quarter of an inch of the cortex of the organ they

Jonnesco aims to obviate this source of danger by employing silver wire sutures, which he removes at the expiration of ten days. I have no doubt that the silver wire sutures cut their way through the soft kidney substance long before their removal even at this early period, and that the same amount of damage results from their use as from silk or catgut sutures which are allowed to remain. For years I have relied more on the extensive excision of the adipose capsule of the kidney than the use of sutures in the fixation of movable kidney. The permanency of the result depends largely on the extent of the excision of the adipose capsule. In the last four cases I have dispensed altogether with the use of sutures and have relied exclusively on the extensive excision of the pararenal fat, scarification of the fibrous capsule,

FIG. 2.—Gauze packing around the kidney complete.

are liable to cut their way through the tissues long before the kidney has become fixed in its new location by firm adhesions. All sutures, regardless of size and material they are composed of, fail to maintain the kidney in the desired location a sufficient length of time for the para-renal adhesions to become sufficiently firm to effect permanent fixation. Serious objections have recently been made and for good reasons against sutures which are made to include, as is usually done, a considerable portion of the kidney substance. Delagénière, Zatti and Albarran have shown that in the vicinity of the sutures sclerotic connective tissue forms with corresponding destruction of the parenchyma condition which can not fail in bringing about serious functional impairment of the organ.

direct temporary support of the kidney with a strip of iodoform gauze, iodoform gauze tamponade, prolonged dorsal recumbent position and localized compression of the abdomen over the kidney. Every surgeon knows that a movable kidney, unless fixed by adhesions in its abnormal location, will return to its normal position as soon as the patient lies flat upon the back and that it is not easy to bring it within reach unless the patient resumes the sitting or standing posture. If the adipose capsule is excised over the entire posterior surface of the kidney a gutter is created in which the kidney is safely lodged and from which it is difficult to dislodge it as long as the patient remains in the dorsal recumbent position. Brian and Jabouly rely largely on the iodoform gauze tampon brought in direct contact with the fibrous

capsule of the kidney in forming permanent anchorage by pararenal adhesions. For years I have placed more reliance on the tampon than sutures in the fixation of a movable kidney. My present method of nephropexy consists in exposing the kidney by Simon's vertical lumbar incision. As soon as the adipose capsule is reached the kidney is placed in proper position and is pushed forward into the wound by an assistant. About half of the kidney should project below the lower margin of the last rib. With dissecting forceps and curved scissors the adipose capsule is excised over the whole posterior surface of the kidney. The kidney is now brought well forward into the wound, the cut margins of the adipose capsule are pushed away from the kidney until the borders are freely exposed, when the fibrous capsule is thoroughly scarified with a long needle.

At this stage of the operation the lower pole of the kidney is grasped by its capsule with a French vulsellum forceps and brought well forward into the wound. With dissecting forceps, finger and blunt dissector the lower third of the kidney is laid bare and a strip of iodoform gauze about an inch in width and composed of four layers of gauze, is placed underneath the lower end of the kidney and each end brought out over the respective wound margin. By making traction on the forceps and gauze strip the lower end of the kidney is brought sufficiently forward to rest in the lower angle of the external incision. During the operation the margins of the external incision must be well retracted. With a long strip of iodoform gauze the floor of the wound is then carefully packed in such a way as to force the pararenal fat away from the borders of the kidney, leaving the posterior scarified surface of the kidney well exposed, when, with the same strip of gauze, this is covered and the whole wound well tamponed with another piece of gauze. The strip of gauze holding the kidney is then tied over the iodoform gauze tampon, which forms a wedge, and will effectually prevent displacement of the organ until firm adhesion has rendered any direct mechanical support superfluous. The two pieces of gauze are tied together and the wound dressed in the usual manner. No part of the lumbar incision is sutured. The patient is then placed upon the back and a firm compress the size of an adult's fist is placed over the kidney below the costal arch and held in place by a wide strip of adhesive plaster encircling the entire body. The patient is placed in bed with the pelvis slightly elevated, and is directed to remain in the dorsal recumbent position or side operated upon for at least four weeks, the time required for the formation of pararenal adhesions sufficiently firm to hold the organ permanently and securely in its new location. At the end of five or six days the tampon is removed. At this time the whole wound, including the capsule of the kidney will be found paved with vigorous granulations. The granulating surfaces are now brought together and held in contact with strips of adhesive plaster over a small absorbent aseptic dressing. Over this an additional dressing is applied, which with the abdominal compress is held in place with an additional strip of adhesive plaster and gauze roller. At the end of three or four weeks the whole wound will be found healed by primary intention and the kidney firmly fixed in its new location. The retention of the kidney in its normal location by this method affords not only a firm support by permanently fixing the lower end in the lower angle of the external

incision and by securing broad surface adhesions, but the oblique angle in which it is anchored adds another mechanical condition calculated to maintain the organ in position, while this position will also tend to correct flexion of the ureter if such exists at the time the operation is performed. The immediate and remote results obtained by this method of operating in the last four cases have proved so satisfactory that I am not disposed to return to suturing again and strongly recommend this method of performing nephropexy for further trial by the profession.

THE TECHNIQUE OF ABDOMINAL HYSTERECTOMY.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. F. BALDWIN, A.M., M.D.,

PROFESSOR OF OPERATIVE GYNECOLOGY, OHIO MEDICAL UNIVERSITY;
GYNECOLOGIST TO PROTESTANT HOSPITAL, ETC.
COLUMBUS, OHIO.

The abdomen is to be opened in the usual way and by as free an incision as necessary. Free the uterine mass from adhesions as thoroughly as possible, and draw it up into the incision; draw up the most accessible broad ligament and clamp it just outside of the ovary with a long clamp, the point of which is directed obliquely downward toward the cervix; with a short forceps grasp the upper border of the broad ligament near the uterus, so as to prevent recurrent hemorrhage through the ovarian artery; then sever the broad ligament with scissors, along the clamp first applied. The other broad ligament is then, if possible, to be treated in the same way. A peritoneal flap is now made in front, between the tips of the two clamps; this is best done with scissors; as this flap is dissected up, the bladder is carried with it and is thus separated from the uterus; a shorter peritoneal flap is then made on the posterior surface between the tips of the clamps.

Up to this point the uterus itself has not been interfered with, and the uterine arteries have not yet been reached. The layers of the broad ligament are now separated on each side, by the fingers, between the tip of the clamp on each side and the uterus, and the uterine arteries found and seized with forceps. With scissors curved on the flat (or, better still, with a Kelly's spud), the body of the uterus is next detached at or just below the level of the internal os, being so detached as to give an anterior and posterior flap of uterine tissue. In case there is any great difficulty in reaching the uterine artery before detaching the uterus itself, its seizure may be omitted until it spurts, as the uterus is being severed, when it is easily seized by an assistant. It is sometimes difficult, or even impossible, to secure both arteries before getting the tumor out of the way. In that case, I cut across from the side on which I have seized the artery and, after separating the mass, seize the base of the opposite broad ligament en masse below the point of separation, and then enucleate the tumor from below upward. This is the method recommended by Kelly, and one which, in suitable cases, possesses points of advantage.

The tumor has now been removed, the pelvis is empty, and hemorrhage has been entirely controlled, except perhaps a little oozing from the cervical flaps. If the patient has not already been placed in the

Trendelenburg position, this should now be done. The uterine arteries are next separated from any surrounding tissue and ligated as far back as possible, with fine silk, catgut or kangaroo tendon, and the projecting ends snipped off. The round ligament is then caught with forceps next to the long clamp, so as to enable it to be quickly found later on, and the clamp removed from the broad ligament. The ovarian artery is then easily found and drawn out from between the folds of the ligament, ligated and the projecting end cut off. The same is then done on the opposite side. Four ligatures have controlled all hemorrhage, though occasionally an aberrant branch will require ligation.

brought into apposition by a running suture. This suture is first inserted through the anterior cervical flap at one side, is then passed through the end of the round ligament of that side, and then through the posterior flap. As this suture is now made taut and tied, the round ligament becomes implanted between the flaps. By a similar maneuver the opposite round ligament, at the proper time, is implanted between the flaps upon that side. If the round ligaments are too long they can be shortened before being transfixed, so as to give the desired degree of support to the stump.

Commencing next at the upper edge of one broad

Diagram of operation, front view.—C., C., C., C., clamps; O., A., ovarian artery; Ov., ovary; U. A., uterine artery. Broken line represents peritoneal flap.

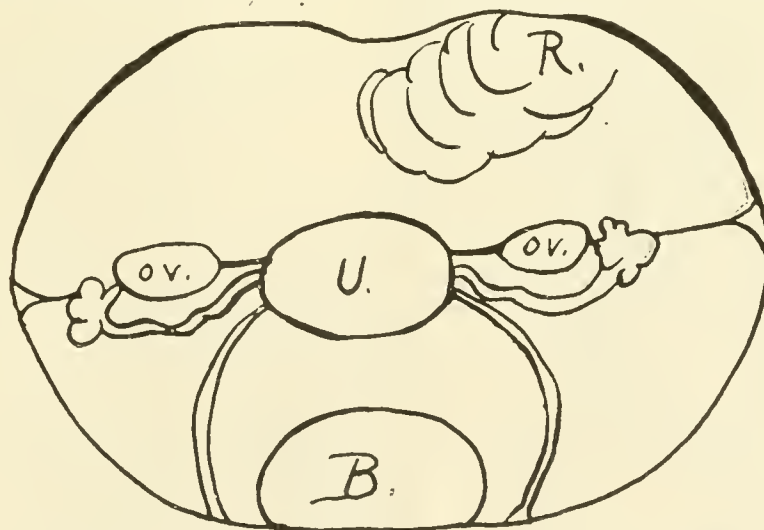

Diagram of pelvis seen from above.—B., bladder; Ov., ovary; R., rectum; U., uterus.

A long probe is now threaded with a strip of iodoform gauze, about one inch wide, passed through the cervical canal into the vagina, and seized by an assistant. The gauze is drawn through the cervix, except an inch or two which I hold in my fingers, and the probe detached as it appears at the vulva. The end of the gauze which projects above is now cut off just flush with the bottom of the wound. The passage of this gauze mechanically cleans the cervical canal, and also secures drainage in case of any oozing.

With kangaroo tendon the uterine flaps are now

ligament stump, the peritoneal layers are inverted and with kangaroo tendon, or catgut, are united by an "over-and-over" suture which runs down the broad ligament, then across over the cervical stump, turning in the peritoneal flaps as it proceeds, and up on the opposite side. This suture should be so inserted as to draw the tissues of the broad ligament snugly together. These being thus snugly apposed, unite so as to make excellent supports for the stump in addition to the round ligaments already attached. The operation when thus completed leaves a perfectly

smooth pelvic floor, with, at no point, the exposure of any raw surface for adhesions.

In case, for any reason, drainage of the pelvis is desired, this is accomplished by opening Douglas's *cul-de-sac* and introducing a strip of gauze into the vagina. The abdomen is then closed in the usual way. My own method is to unite the fascia, muscle and peritoneum with silver wire, the twisted ends being

emerge about an inch beyond the ends of the incision. Before tightening the wire, the silk-worm gut sutures are drawn up snugly and held by an assistant, but not tied; the wire is then seized at each end, drawn taut, and pulled back and forth until all bends are removed and it is practically straight; the ends are then fastened by perforated shot, several layers of iodoform gauze being interposed between the shot and the skin. The silk-worm gut sutures are then tied. The wire can be slipped out without any trouble at the end of ten days or two weeks. I am especially careful to get the fascia well into apposition. The skin is then closed with silkworm gut, or the subcuticular kangaroo tendon suture. If the abdominal walls have a thick layer of fat, this is held in apposition by two or three stay-sutures, as needed.

In case it is desirable to remove the entire uterus, the cervix instead of being cut across is enucleated in the usual way. It is sometimes better to remove the tumor first and then to enucleate the cervix. In such cases a pledget of gauze should be introduced into the vagina from above, so as to drain the point of separation of the cervix, but the peritoneum should be completely closed, as above described, including the bringing in of the round ligaments.

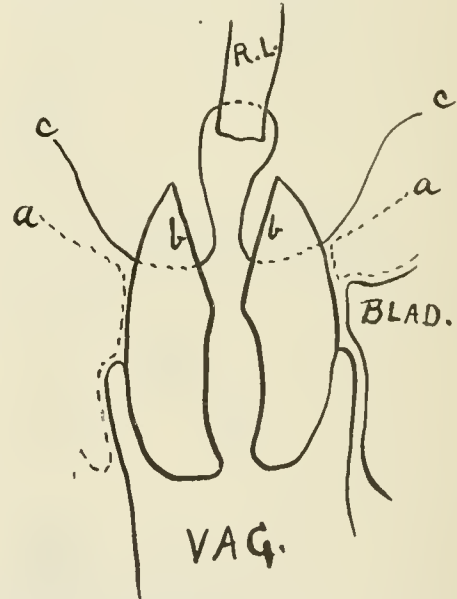

Diagram showing method of bringing down and fastening round ligaments in closing cervical flaps. a, a, peritoneal flaps; b, b, cervical flaps; c, c, suture; R. L., round ligament.

During the last two and a half years in which I have been using this method, I have made ninety-five operations with five deaths, a mortality of 5.26 per cent. Three of these were in cases of cancer of the fundus with wide dissection and unfavorable conditions. In a recent paper by E. W. Cushing, M.D., of Boston, on the "Evolution of Abdominal Hysterectomy," he tabulates 1,670 operations from the reports of thirty-six of the leading operators of the United States. The average mortality of these operations was 13.8 per cent. During the last year I had the opportunity of watching abdominal hysterectomy as performed in many of the leading gynecologic clinics abroad. Almost without exception, I found their methods quite crude and unsystematic, while their mortality I found to vary from about 15 to 25 per cent.

In my own cases, in only one instance was death

a, a, points of making peritoneal flaps; b, b, lines of amputation of cervix. Dotted line represents peritoneum.

cut short and turned down. As it has been found that in about one case in twenty some of these wires become infected and give rise to sinuses which remain until the wires are removed, I have for several months used another method of closing the incision; silk-worm gut sutures are first introduced, these passing through the entire thickness and including plenty of fascia and muscle, but only a little of the skin and peritoneum. The fascia is then approximated by a continuous suture of silver wire, the ends of which

due to post-operative infection. Post-operative morbidity has been almost *nil*. Very few patients have remained in the hospital over twenty-one days after the operation. One case was removed to her own home on the tenth day. No cases of ventral hernia or of vaginal prolapse have occurred. There is sometimes some complaint of pain, but this is usually much less than after the performance of vaginal hysterectomy. Indeed, convalescence is very similar to that in normal child-bed, and patients usually sit up on the fourteenth day. The operation is a short one, usually requiring about forty minutes for its completion, and there is practically almost no hemorrhage. These two statements explain the fact that there is usually almost no shock.

The advantages of this method of operating are:

1. Such a shutting off of the vagina as to reduce to a minimum any danger of infection from that source.
2. The ligature placed around the uterine artery is entirely outside of the uterine wound, and being of fine material and buried in the tissues is much less likely to give any trouble.
3. The snug closing of the cervical tissue prevents oozing.
4. The smooth peritoneum in the floor of the pelvis, having no projecting stumps or raw surfaces, reduces to an absolute minimum the danger of intestinal adhesions.
5. The implantation of the round ligaments and puckering in of the stumps of the broad ligaments prevents prolapse of cervical stump and vagina.
6. The use of the clamps on the broad ligaments obviates hemorrhage, leaves the parts in better shape for the subsequent steps of the operation, and saves considerable time.

HOW SHALL WE FEED THE BABY?

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY A. C. COTTON, A.M., M.D.
CHICAGO.

If at the breast and doing well, leave it alone. If not doing well, let us ascertain the cause. Does it present evidences of innutrition, malnutrition, acute indigestion or chronic indigestion? Is there starvation from insufficient or improper food, or starvation from repletion? In some cases the fault is apparent at a glance; in many it is quite difficult to determine at first wherein the trouble lies. The apparent error as to time, frequency of feeding and quantity having been corrected, the physician may finally have to face this question, "can this mother's milk be made to fill all the requirements of this babe?" and the sooner we ascertain just what and how much this mother is secreting, the sooner we are on the way to a solution of this problem. We must examine the breast milk as to its total amount and as to the relative quantity and quality of its constituents. The old haphazard procedures must be relegated to the past; the time has come when the same exactitude is demanded in this as in other means of diagnosis. We must know *what* the babe is *getting* before we can intelligently consider any changes in food. Analysis, then, of the mother's milk must be the prime desideratum if we would give advice as to the feeding of babies.

There are a number of methods in vogue for determining, with greater or less accuracy, the relative pro-

portion of some of the leading ingredients. For clinical purposes a determination of the total solids may be had from the known specific gravity, temperature and percentage of butter fat by means of Richmond's equation: $T = (G \div 4) + (6 \div 5) F + 0.14$, in which $T =$ total solids, $G =$ specific gravity (the last two figures), and $F =$ fat. Care should be taken to correct specific gravity for temperature if the ordinary hydrometer adjusted at 60 degrees F. be employed. Holland subtracts one from the hydrometer reading for each ten degrees below 60 degrees F., and adds one to the reading for each ten degrees above 60 degrees F., proportionate fractions expressing variations of less than ten degrees.

For determining the percentage of fat we have employed Fesser's lactoscope, also the methods of Holt, Marchand, Leffmann and Beam, and Babcock, with preference for the last-named on account of its simplicity and accuracy. The first mentioned has the disadvantage of inaccuracy from the varying visual power of different observers, also from the fact that the opacity of milk is not due alone to the fat globules but also to the phosphate of calcium present. Holt's method, so easy of employment, requires time, twenty-four hours, and the ratio 5 to 3 does not always express the relation of cream to fat. Marchand's test has never given the results obtained by us from more accurate analysis.

The centrifugal machines adapted to the Babcock test bottles have heretofore been too clumsy, but recently the Chicago Dairy Supply Company, No. 5 West Washington Street, has brought out a small cheap machine. My attention has been called to a bottle manufactured by Wood & Comer, 130 Juvenal Street, Philadelphia, of shape and size to fit the ordinary office centrifuge and adapted by graduation to the Leffmann and Beam method. The capacity of this tube is certainly not more than 20 c.c., so that the quantity of milk required by the Leffmann and Beam test would not exceed 8 or 10 c.c., an item greatly in its favor. If experience proves the utility of this tube its advantages place it far in advance of any previous device for determining the fat in breast milk. The microscope is a necessary adjunct to the examination for the presence in the milk of blood, pus or colostrum corpuscles.

If the child's nutrition does not improve soon, I would remove it from the breast temporarily, keeping up lactation by pumping regularly and testing the milk meanwhile for the improvement sought. Not infrequently the child may be returned to the breast after an interval of from a few days to a few weeks. In my opinion there is no question as to the desirability of maternal nursing in preference to any method of artificial feeding. If, after all, the mother's milk can not be brought to suitable proportions for complete nutrition, or for any reason weaning is necessary, then substitute feeding must be adopted, and the choice of a substitute becomes at once a question of the highest importance. The multitude of infant foods and substitutes for mother's milk suggests the conclusion that none are completely successful, and the startling mortality statistics would be conclusive evidence did any doubt exist. So long as the medical profession relegates its thinking to commercial men, the market will continue to be flooded with "baby foods" and the figures of infant mortality repeat themselves with sickening regularity. What, then, of a substitute for mother's milk? We have no substitute, as the death rate shows, but we have well-

established principles of substitution, by the thoughtful application of which to the especial requirements of each individual case, we may claim to have made some headway in the management of disordered infant nutrition. In the selection of the food we must consider all the requirements of the infant at each stage of its development, and a few cardinal principles kept well in mind may serve as a foundation for specialization. Professor Cheadle, in his post-graduate course of lectures at St. Mary's Hospital, London, emphasizes six essential conditions to be observed in the diet of infants:

1. "The food must contain the different elements in the proportion which obtain in human milk," viz., according to Harrington: Proteid, 1 to 2 per cent.; fat, 3 to 4 per cent.; sugar, 6 to 7 per cent.; ash 1 to 2 per cent.; water, 87 to 88 per cent.; or, according to Luff, proteid, 2.35 per cent.; fat, 2.41 per cent.; carbohydrate, 6.39 per cent.; salts, .34 per cent.; water, 88.51 per cent.

2. "The total quantity in twenty-four hours must be such as to represent the nutritive value of from one to three pints of human milk, according to age," viz. proteids, 225 to 675 grains; fat, 231 to 693 grains; sugar, 613 to 1,839 grains.

3. "It must be in a form suited to the physiologic condition of the digestive function of the infant."

4. "It must not be purely vegetable, but must contain a large proportion of animal matter."

5. "It must possess the antiscorbutic element," raw.

6. "It must be fresh and free from all taint of decomposition."

These six statements as to essential conditions seem to be almost axiomatic and if faithfully observed will keep the practitioner quite close to the line of safety.

Since the sources from which the essential ingredients of infant food may be obtained are so numerous, and the facilities of different physicians so varied, it is not strange that a variety of methods of assembling the necessary constituents for a perfect substitute food should be advocated. Eminent observers and experimentors along this line have seemed to array themselves by their practices into three general classes, viz.:

1. Those, who by their use of cereals, treat the human infant as if belonging to the *herbivora*.

2. Those who would place him with the *carnivora* and find nothing to meet his physiologic requirements outside of milk, meat juice, animal extracts, etc.

3. Those who by a judicious selection of the essential elements of food from both animal and vegetable sources consider the babe *omnivorous*. Certainly, analogy, and I believe, also experience shows that the young infant finds its most assimilable and nutritious elements in *animal* foods, and no teacher of infant feeding has recently laid the world under greater tribute for his positive stand in this direction than Dr. Rotch, the father of the milk laboratory in this country. Believing that the babe should have exclusively animal diet, and that cow's milk contains all the essentials of mother's milk, but in different proportions, he founded the laboratory for the modification by separating cow's milk into its grosser constituents and reassembling them in exact and definite proportions to meet the requirements of the individual case. I have never heard it claimed that there was anything *new* in the modification of milk. In fact, many practitioners claim to have done this long before Rotch, and wonder why the process should be

deemed worthy of a patent. The putting of the idea into practical form through the laboratory, securing uniformity of manipulation by trained experts, the supervision of the milk supply (perhaps the most important feature) and last but not least, the stimulation of keeping exact records, all mark the advent of the laboratory as the longest stride in the advancement of substitute feeding.

The province of the milk laboratory, however, is broader than many would at first suppose from its name. With all due respect to Dr. Rotch I should prefer to call it a "food laboratory," where prescriptions may be compounded to meet the requirements of prescribers who do not believe that all the ingredients should be derived from cow's milk. Some infants can not digest cow's casein in any form, be the quantity reduced to the minimum limits of laboratory modification, or if only so small an amount can be endured as must of necessity appear in the cream, his nutrition will show faults from lack of proteids. In such cases many of our best men order raw meat juice.

The need of albuminoids when cow casein can not be tolerated (and this condition, I believe, is one of great frequency) must be met by substitution of some soluble, readily absorbed, concentrated albuminoid. No source of albumin in a condition to meet all the requirements of infant digestion, is, in my experience, to be compared with the hen's egg, the white. For many years I have employed it in suitable cases with the most satisfactory results. From the opening of the first laboratory in Chicago, October 1895, I have ordered egg albumin to maintain the necessary percentage of proteids in cases where cow casein was not tolerated. To illustrate by a prescription with ingredients proportioned as follow: Fat, 4.50 per cent.; sugar, 6.50 per cent.; proteids 2 per cent.; which not being well borne, the casein appearing in the stools as curds, is reduced in its percentage of proteids experimentally until the low figure of $\frac{1}{2}$ or $\frac{1}{4}$ of 1 per cent., represents the highest toleration of this constituent of milk.

Since complete nutrition can not long be maintained on such low proteids we must enrich our prescription with albuminoids from some source other than cow's milk. The egg albumin has proved very efficient in my hands for this purpose. To illustrate by prescription: Fat, 4.50 per cent.; milk sugar, 6.50 per cent.; proteids from milk, .50 per cent.; albumin, whites of two eggs; water, q.s. ad 100 per cent.; number of feedings, 6; amount of each feed, 6 oz.; alkalinity (lime water), 6 per cent. Pasteurization is not necessary if due care be exercised in the selection of the ingredients for this emulsion.

SOME PRACTICAL POINTS ON INFANT FEEDING AND INFANT FECES.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS FISCHER, M.D.

Professor of Diseases of Children, New York School of Clinical Medicine; Attending Physician to the Children's Department of the German Poliklinik, to the Children's Department of the West Side German Dispensary, to the Messiah Home for Children; Consulting Physician to the Children's Department of the United Hebrew Charities of New York, etc.
NEW YORK, N. Y.

To properly determine the value of an infant's food

be it breast fed or hand fed, we must note the following factors:

1. Does the child appear satisfied and go to sleep after its feeding. 2. How are the stools? *a*, their color; *b*, frequency; *c*, consistency. 3. Is there any flatulence or colic? 4. Does the child increase in weight, to be determined by the scales once a week, and is the food properly assimilated?

A growing child needs far more food than its weight alone would indicate, for its income must exceed its expenditure so that it may grow. An infant for the first seven months or first one-half year of life should have nothing but milk. Up to this age vegetable food is unsuited to it; it is purely a carnivorous animal.

Human milk contains about 4 per cent. of proteids (casein), 2.6 per cent. fat, 4.3 per cent. carbohydrates (milk sugar). Of the solids, the proteids make up 36 per cent., the fats 24 per cent., and the carbohydrates 39 per cent.

In a typical adult diet, the proteids amount to 20 per cent. of the solids, fats 15 per cent., carbohydrates to more than 60 per cent. The diet of the infant is, therefore, nearly twice as rich in proteids, half as rich again in fats, and a little more than half as rich in carbohydrates as that of the adult. It is, therefore, in a physiologic sense a luxurious diet.

The strain of growth falls heavier upon the more precious proteids than upon the more cheap and common carbohydrates.¹

Rotch, speaking of proteids (p. 174) says the proteids as a whole are a valuable source of information as to whether the milk is normal or abnormal. The following formulæ indicate the proper percentage required for hand-feeding at birth of the infant—and at several other periods thereafter with the same formulæ translated for home preparation, where the luxury of a laboratory can not be afforded. Proper sterilization of bottle-nipples and food is self-understood and it is not the purpose of this paper to elaborate on the same.

Child at birth. Formula 1.—New-born infant's food. Fat, 1.0; sugar, 5.0; proteids, 0.75; reaction alkaline. Ten feedings (30 c.c. each) heated thirty minutes to 167 F. The formula for home use is the following: Cream, 2 ounces; milk, 2 ounces; lime water, 1 ounce; water, 15 ounces; milk sugar, 6 $\frac{3}{4}$ drams; cream must contain at least 10 per cent. of fat.

Child one month. Formula 2.—Fat, 2.0; sugar, 5.0; proteids, 0.75; lime water, 5.0. Formula for home use: Cream, 4 ounces; milk, none; lime water, 1 ounce; water, 15 ounces; milk sugar, 6 $\frac{3}{4}$ ounces.

At four months. Formula 3.—Fat, 3.5; sugar, 6.5; proteids, 1.5; lime water, 5.0. Formula for home use: Cream, 7 ounces; milk, 1 ounce; lime water, 1 ounce; water, 11 ounces; milk sugar, 6 $\frac{1}{4}$ ounces.

From nine to twelve months. Formula 4.—Fat, 4.0; sugar, 7.0; proteids, 3.0; lime water, 5.0. Formula for home use: Cream, 8 ounces; milk, 7 $\frac{1}{2}$ ounces; lime water, 1 ounce; water, 3 $\frac{1}{2}$ ounces; milk sugar, 6 $\frac{3}{4}$ ounces.

Stool of a nursling.—The stool of a nursling or a baby on an exclusive milk diet should be yellowish in color, smeary or pasty-like in consistency and have an acid reaction. The smell should be faintly acid but not disagreeable. The color is due to bilirubin and the reaction depends on the presence of lactic acid, the source of which is the milk-sugar. The only gases present are H and CO₂. According to Escherich, H₂S and CH₄, to which the odor of adult stools is due, are not present. There are no peculiar albuminoids. Those existing in mother's milk seem to be entirely absorbed. Peptone exists in trifling amount. Sugar

is not present. Pancreatic ferment is absent and sometimes traces of pepsin have been found. Mucus is always present in considerable quantity, also columnar intestinal epithelium.

In the stools of nurslings, large quantities of lactate of lime can be found, so also we frequently find oxalate of lime depending on the quantity of oxalate of lime ingested. Uffelmann has noted the presence of bilirubin crystals in the stools of nurslings, in perfectly healthy children.

Miller, who carefully studied the various micro-organisms in the mouth, found that most of them could again be found in the intestinal canal. He further found that certain germs possessed diastatic properties and were capable of producing lactic acid fermentation. In the milk feces of nurslings Escherich found two germs, the one he called bacterium lactis aerogenes (or bacterium aceticum, Baginsky) and the other the bacterium coli commune. In the meconium he found proteus vulgaris, streptococcus coli gracilis and bacillus subtilis. The number of stools during the first two weeks is from three to six daily. After the first month the average is two stools daily; many infants have one, others three stools daily. This latter is due largely to the excessive quantities of water given to infants.

As soon as the exclusive milk diet is changed to the mixed diet we then lose the characteristic infantile stool and they resemble more those of an adult, though remaining softer and thinner throughout infancy. They become darker in color, assume the adult odor and have more varieties of bacteria than those previously mentioned as found in the stool of a milk diet.

Reaction of stools.—Reaction of stools in diarrheal disease and in health is chiefly acid or, next in frequency, neutral. Alkaline stools are rare. Green-grass stools, usually acid, are seen in the early stage of dyspeptic diarrhea, the color from a pale greenish yellow to grass-green, owing to improper food.

Wegscheider has shown that the green color is the result of preformed biliverdin. The condition in the intestine, upon which the transformation of bilirubin into biliverdin depends has been generally regarded as one of acid fermentation.

Experiments.—Pfeiffer's experiments ("Verdaugung im Säuglings-alter bei Krankhaften Zuständen" Jahrbuch für Kinderheil., Bd. xxviii, p. 164) show this former opinion to be wrong. He found that none of the acids formed in such fermentation, lactic, acetic, butyric, propionic, etc., added to yellow stools outside the body, turned them green, but that they made them deeper yellow. But dilute alkaline solutions added to fresh yellow stools turned them green after an exposure of thirty to sixty minutes and strong solutions turned them, first brown, later, after exposure to air, intense green.

Typical green stools.—Typical green stools can be produced by giving an infant two or three grains of bicarbonate of soda. This I have tried dozens of times: the soda must be given for a few days. This explains Pfeiffer's alkaline theory. Typical green stools can also be produced by giving small or even large doses of calomel. If, after having given bicarbonate of soda and produced green stools, we give diluted hydrochloric acid in 5 to 10 drop doses, the yellow color will in a few days again reappear. This is also true in giving rhubarb.

Stools.—Stools which are pale yellow when discharged, and which afterward become green, are often

¹ "Stewart's Physiology," p. 412, 1897.

seen in disease. They may be themselves neutral or alkaline in reaction; this latter may however depend on the admixture of urine. An excess of bile may often cause very green stools.

Brown stools.—Brown stools may be due to changed biliary pigment and to drugs, *i. e.*, bismuth causes the well-known dark stool; so also tannic acid and all iron salts give the dark stool which varies from a deep brown to a black color.

Blood in stools.—Blood from the stomach or small intestine frequently gives the stool a black color resembling tar. Thus a practical point in Boas' "Diagnostik der Magen- und Darmkrankheiten" is, that the brighter the color of the blood the lower down near the rectum and anus must the pathologic lesion be looked for; the darker the blood the higher up must the cause be found, *e. g.*, the diseased conditions exist in the stomach, duodenum, jejunum, etc., if the stool contain black blood. If the corpuscular elements of the blood are wanting, then the presence of blood can only be positively diagnosed by either a micro-chemic examination or by means of the spectroscope. The presence of red blood corpuscles must always be regarded as a pathologic factor.

Brown stools, muddy stools.—A brown stool in an infant is frequently caused by a diet of animal food or by a diet principally of broth. These stools have no distinct consistency nor reaction. In dyspeptic diarrhea or in some forms of enterocolitis we have very offensive stools and they resemble muddy water; with the latter there is considerable flatus during each movement.

White or light gray stools.—White or light gray stools usually are of a putty-like consistency, sometimes like dry balls on a diaper; sometimes they appear like ashes. Usually they are very offensive, consisting principally of fat. In the latter there is scarcely a trace of bile, or the latter may be absent altogether.

Mucus.—Mucus is always present in all healthy stools and is so well mixed with the stool that it does not appear as mucus to the naked eye. Any appearance therefore of mucus easily visible should be regarded as abnormal. Mucus is present in every form of intestinal disease. Very abundant in inflammatory conditions affecting the large intestine, more so than in those affections of the small intestine, and especially so in inflammatory conditions of the colon, both acute and chronic.

Jelly-like masses.—Jelly-like masses of shreds of mucus, and where the stool consists chiefly of mucus, show that the affection is confined to the lower portion of the colon or that it is located in the rectum.

Long shreds of mucus.—Long shreds of mucus, frequently resembling false membrane, are often found in catarrh of the large intestine. If the shreds of mucus are intimately mixed with the stool, then we must look for the lesion quite high up, and if it comes from the small intestine it is usually stained from bile. If the lesion is low down the mucus is not intimately mingled with the stool.

Dyspeptic stool.—The first change noticed in the dyspeptic stool is the increase of fat. Often the stool is quite green and contains small pieces, of yellowish-white color, which vary in size from that of a pin-head to the size of an ordinary pea. Hitherto, from their color, they were supposed to be casein lumps. Wegscheider has taught us that they consist principally of fat. Baginsky has shown that large colonies of bacteria are contained in these lumps of fat. Frequently

they are so numerous that it looks as though the stool were composed only of these cheesy lumps. They can be easily differentiated from real casein lumps by their solubility in alcohol and ether.

Fat diarrhea.—Biedert and Demme have devoted considerable attention to this subject. (See Biedert "Fett-Diarrhea" in "Jahrbuch für Kinderheilkunde," 1878). In some children the feces showed 50 to 60 per cent. of fat, whereas the normal percentage in ordinary feces varied from 13.9 per cent. (which is the normal quantity) according to Uffelmann.

Casein is not nearly as common an ingredient of feces as is commonly supposed, as I have previously stated. Casein lumps can be seen in abundance in the course of a diarrhea during an exclusive diet of milk.

Quantity of feces.—The quantity of feces varies, but it has been found that 100 grams of milk food will produce about 3 grams of feces, according to Baginsky. This is a vital point, but I have found it very difficult to determine, for in most cases the napkins of the infants are soiled with urine plus the feces, thus adding to the gross weight.

Proteids.—The proteids of milk are so thoroughly absorbed that only small traces of them can be found in the feces. Normal milk feces contain large quantities of bacteria, but chiefly two kinds, previously mentioned, *viz.*, bacterium lactis aerogenes (Escherich) and bacterium coli commune. Other germs, especially those of the protolytic type (*i. e.*, those that render gelatin fluid) are not found under normal conditions.

Albuminous decomposition and its products, tyrosin, indol, phenol and skatol, are not found in milk feces. But lactic acid, acetic acid, formic acid and other fatty acids are present, causing the acid reaction.

Saccharine ferment.—V. Jaksch found a saccharine ferment in the feces of children.

Peptonizing ferment.—Baginsky found a peptonizing ferment also in infantile feces.

Escherich in "Jahrbuch für Kinderheilkunde," "Beiträge zur Antiseptischen Behandlungsmethode der Magen-Darmkrankheiten des Säuglingsalters" says: If albuminous decomposition with very foul offensive stools exists, these articles should be withheld from the diet and carbohydrates given, dextrin foods, sugars and milk. If acid fermentation is present, with sour but not offensive stools, carbohydrates are to be withheld and albuminous foods given, such as animal broths, bouillon, peptones, etc. In the decomposition of milk, the sugar of milk and not the casein is usually broken up.

Holt ("Artificial Feeding," p. 179) says: Regarding the exact indications according to which fat, sugar and proteids of milk are to be varied, much remains to be learned.

Sugar is too low.—If the sugar is too low the gain in weight is apt to be slower than when furnished in proper amount.

Sugar in excess.—Symptoms indicating an excess of sugar: Colic or thin green very acid stools, sometimes causing irritation of the buttocks; sometimes there is regurgitation of food and eructations of gas.

Excess of fat.—Excess of fat is indicated by the frequent regurgitation of food in small quantities, usually one or two hours after feeding. Sometimes an excess of fat causes very frequent passages very nearly normal in appearance. In some cases the stools contain small round lumps somewhat resembling

casein, but really masses of fat. This has already been mentioned in speaking of the differentiation of true casein curds and small fat lumps by the solubility of the latter in alcohol or ether.

Dry pasty stools.—When too little fat is given, it is indicated by hard dry pasty stools, and usually constipation. This can be easily remedied by the addition of cream three-fifths of which is fat. Holt speaks against increasing the fat above 4.5 per cent. in infants under six months old, and believes we should not go above 4 per cent. The following case is presented to illustrate the difficulties encountered in the ordinary feeding of a healthy child.

N. R., a healthy female, was put, soon after birth, on modified milk.

October 14.—Fat, 2.0; milk sugar, 5.0; albuminoids, 0.75; lime water, 1.16. Eight feedings; 2 ounces in each.

October 17.—Constipation.—Fat, 2.5; milk sugar, 6.0; albumin, 1.0; lime water, 1.16. Nine feedings; 2½ ounces in each.

October 27.—Fat, 3.0; milk sugar, 6.0; albuminoids, 1.0; lime water, 1.16; barley jelly, 1.15. Ten feedings; 3 ounces in each.

November 5.—Fat, 3.5; milk sugar, 6.0; albuminoids, 1.0; lime water, 1.16; barley jelly, 1.15. Ten feedings; 3 ounces in each.

November 17.—Fat, 4.0; milk sugar, 6.0; albuminoids, 1.5; lime water, 1.20; no barley. Ten feedings; 3 ounces in each.

November 19. Curded stools, dyspeptic diarrhea.—Fat, 4.0; milk sugar, 6.5; albuminoids, 1.0; lime water, 1.20. Ten feedings; 3 ounces in each.

The child did not increase in weight, had a rectal temperature of 100 degrees, slightly furred tongue, vomited curds, had greenish stools containing undigested particles of fat and true casein, and large masses of mucus. The diagnosis of dyspepsia infantum was made. Hand feeding was stopped. The child's alimentary tract was cleaned by giving cascara sagrada, and a proper wet nurse was secured. The infant was now about 6 weeks old. The child nursed well and improved in weight and the character of stools was changed. The child improved until it was 7 months old, when it did not increase in weight. As the child was bright and otherwise cheerful, it was decided to have the milk of the wet nurse examined by a competent chemist. Through the courtesy of John S. Adriance, the chemist of the Nursery and Child's Hospital, I found the following: Fat, 2.000 per cent.; sugar, 7.431 per cent.; proteids, .882 per cent.; ash, .162 per cent.; total solids, 10.475 per cent.; water, 89.525 per cent.; specific gravity at 70 degrees F., 1.0316; reaction alkaline.

In the result above given it is very evident that a deficiency in proteids exists, hence it accounted for the late dentition and also for the stationary weight. The child did not gain an ounce in one month. We discharged the wet nurse.

I ordered: Milk, 3 ounces; cream, 2 teaspoonfuls; oatmeal jelly, 3 ounces; lime water, 1 dram; milk-sugar, 1 teaspoonful; one pinch of salt; sterilize and feed every three hours.

The child has taken this food for six days and I was pleased to learn at the time of writing that the child is cheerful, takes the bottle very well, has had one and two yellow stools daily, and has gained six ounces in six days. Thus we must adapt our food to suit each individual body; for, this infant did so poorly on modified milk and did very well on a wet nurse for a given time. It shows that the chemic examination should be made at least once a month, and at once if we find the baby not increasing in weight, or the character of the stools abnormal.

Proteids in excess.—Proteids in excess are indi-

cated by the presence of curds in the stools. This is the most frequent cause of colic in infants. Sometimes there is diarrhea, more often constipation when the proteids are in excess. This excess of proteids frequently causes vomiting and so does an excess of both fat or sugar. If, therefore, after reducing the percentage of proteids, fat and sugar, vomiting still persists, then we must feed the baby with smaller quantities. Thus we may have to give a four ounce bottle where a six ounce or a five ounce feeding causes vomiting. Certain rules can be laid down; if an infant does not thrive, *i. e.*, does not gain in weight without showing any signs of indigestion, then the proportions, *i. e.*, percentages of all ingredients, should be gradually increased, chiefly the proteids, however, for the latter is the most important element in an infant's food.

Adriance after an examination of breast milk, both clinically and chemically, arrived at the following conclusions:

1. The fat shows no constant changes during lactation. Its most marked characteristic is its variability.

2. The carbohydrate on the second day of lactation is low, but it rises rapidly during the first few days; this increase continues, but less rapidly up to the end of lactation.

3. The proteids pursue a course the reverse of the carbohydrates.

4. The salts diminish similarly to the proteids.

5. The total solids are represented by 12.20 per cent. till the later months of lactation when they decrease steadily.

6. The colostrum period has low carbohydrates with a tendency to decrease rapidly.

7. The milk of the later months of lactation shows a deficiency in proteids and total solids.

The moment, then, that we find the baby not increasing in weight, or apparently hungry, the milk should be carefully examined for its proteids, and if the milk is deficient in this latter element then weaning must be insisted upon, for the proteids are the prime factors in infancy needed for growth, and deficiency therein will result in rickets and lay a foundation for all those conditions commonly called tuberculous.

The amylolytic function usually develops after the eighth or ninth month, at times toward the end of the first year; then starchy foods are called for, for the child's function can now transform this starch into sugar. The cereals should be given and Jacobi's plan, oatmeal where constipation or a tendency thereto exists, and barley or rice where a tendency toward diarrhea or loose bowels exists, is the most successful. To permit the indiscriminate use of cereals or to allow all patent foods to be given according as they are labeled is wrong, and many a case of rickets could have been avoided by a careful study of the infant's diet.

Condensed cream.—Hundreds of children in apparent good health appear at the children's department of the various institutions with which I am connected. I have examined them and find some in excellent health with no sign of rickets, then again hundreds appear with the same form of food and show the worst kind of rickets. Thus, while some thrive on a given food others do not. So condensed cream will be lauded by the mother whose baby is well, and again the same food will be condemned by the mother of an infant whose rickety head, bones and muscles are founded on an impoverished diet of condensed

milk. We can account for the rickety child, but we can not account for the healthy one on the same food.

Modified milk—While modified milk as it exists in the Walker-Gordon Laboratory has its advantages, much remains to be accomplished. For people who can not be relied on to properly sterilize or Pasteurize their milk, the laboratory will be beneficial. I have given the milk a careful trial in some of my best families and can not give it an indiscriminate recommendation. Constipation of the worst form was encountered in the child of a physician for whom I prescribed Walker-Gordon milk, and this proved so obstinate, although I modified the prescription by increasing the fat and lowering the proteids, that we finally abandoned it. This baby, fed on oatmeal and milk combined with a sterile albumin water, made a complete recovery without medication. Another child, also the child of a physician, for whom I prescribed modified milk, encountered this obstinate constipation and I finally abandoned this form of feeding and tried Mellin's Food, which agreed quite well with it. It is evident that in giving any form of feeding we must study the result. As each child is different in appearance so also are the requirements totally different. We must not overlook individual idiosyncrasies, for what will agree with one baby must not necessarily agree with another.

The microscopic examination of human milk.—Rotch says (page 169): Microscopic examination of milk is of value for the determination of the presence of pus, blood, epithelial cells, colostrum corpuscles and foreign matter. But the chemic analysis is the only one which can be depended on, for although the microscope may show yellow coloring matter and apparently be rich in fat, it may be misleading and not always prove so by a chemic examination. Thus, human milk of a green color (evidently produced by micro-organisms) may not even show under the microscope.

Specimen of breast milk for the chemist.—To obtain a specimen of breast milk for analysis, wash the hands so that they are sterile, and the breast and nipple with sterilized water, from 20 to 30 c.c. (5 to 8 drams) of milk drawn by the breast-pump, which being made of glass can be thoroughly washed, is poured into a sterilized bottle and tightly corked. The milk should be put on ice until the chemist is ready for the examination.

Both quality and quantity requisite.—Chemic analysis is not all; although the analysis may show the milk to be of an excellent quality an infant may not thrive owing to an insufficient quantity. The symptoms showing a deficient supply of milk being that the breasts at the time of nursing are soft and that only a small quantity can be extracted from them at the nursing time. A period of nursing longer than usual (which is fifteen or rarely twenty minutes) should lead us to suspect the milk to be lacking in quantity. We can also determine the actual quantity a child has swallowed by weighing it immediately before and after the nursing.

If we have habitual colic reduce the percentage of proteids; if frequent vomiting soon after feeding, reduce the quantity of each feeding. For regurgitation of sour masses of food, reduce the fat and sometimes also the proteids. For obstinate constipation increase the fat, also the proteids.

Rachitis.—Rickets is caused by an improper quantity and quality of food. It is evidenced by constipation

or by hard pasty stools in early infancy. Unless the food elements are altered to modify this condition it is manifested by late dentition or by the appearance of carious teeth; the bony structures are not firm; the muscles are flabby; in some instances the children are fat. Examinations of a large number of children have shown that it is not the fatty elements but the lack of proteids upon which this rachitic condition is based. When children placed on starchy foods show constipation it is to be considered a danger signal that the food is improper. It is only too plainly evident that we must individualize and can not lay down general rules and each case should be considered separately.

187 Second Avenue.

DISCUSSION ON PAPERS OF DRS. COTTON AND FISCHER.

Dr. J. P. CROZER GRIFFITH of Philadelphia—One of the things I have maintained strongly is the necessity of feeding the child at the mother's breast when it is at all possible to do so. At first thought this might seem altogether unnecessary, but still we know of physicians who make it a practice to wean the child very quickly when there is no necessity for it, maintaining it can be fed just as well on the bottle. It is true the child may be fed well on the bottle, but nobody can tell whether a child will do well on a bottle. Leaving the mother out of the question, there is no good reason for weaning the child unless it has to be weaned, and so I think it is well for us to consider whether or not we can not modify the mother's milk before we consider weaning the child. Next is the idea of having the prepared milk of the same percentage as in the mother's milk. The two substances are not alike. Although they may have the percentage the same, of different proteids, still we have different substances in the cow's milk and human milk. So it does not follow that 1 per cent. of albuminoids in the cow's milk will be digested as well as 1 per cent. of albuminoids in the mother's milk. We must try to determine what percentage of the different constituents the child will take and that often can be told only by trial. So to be on the safe side we should begin with percentages distinctly lower than we will expect the child to take. We as physicians must not forget that we are dealing with a living organism and not a machine, and we must not force our children too much to be fed. That is one danger of our modification of milk which we must uphold. Therefore we must be ready to make any changes necessary to sustain the individual case.

Dr. W. S. CHRISTOPHER of Chicago—The subject is altogether too large to discuss more than one phase of it in detail. I would especially direct attention to a point brought out, that is that condensed milk has a use. I have found there are conditions under which condensed milk is absolutely essential if life is to be saved. The dangers of condensed milk we will all admit. That it is a milk deficient in fat and proteids and that it leads to the production of scurvy and rickets we all know, but it need not lead to those things in the hands of those who know how to prevent them. Backing up the use of it with cod-liver oil and beef juice and some fruit juice for the antiscorbutic use, we have a food that is almost perfect. We find children who require condensed milk to avoid the poisonous effects from cow's milk, poisonous not in the sense that the milk is infected, but even pure milk will produce in the system of some children a substance apparently toxic which they can not bear. So I have had to take children from the breast and put them on condensed milk, when their trouble would immediately cease. The indications for the use of condensed milk appear to be these: I use it in children who have a predisposition to vomiting, so called "spitting babies." It is given not for the purpose of keeping the food down, but these children seem to have less of their disturbance when fed on condensed milk. It has been my experience to take children from modified milk, for instance, in which the albuminoids had been cut down almost to starvation and the fats greatly reduced to stop vomiting, and the form of albuminoid that could be borne was found in condensed milk. When condensed milk is not borne I have sometimes found that dried milk is. First I would give a sterilized milk and second a milk that has been boiled and the coagulum removed.

CHAIRMAN—Doctor will you tell us what you mean by sterilized milk?

Dr. CHRISTOPHER—I refer to one in which a temperature as near 212 degrees as possible is used. When we boil it we can remove the coagulum, and I think in the coagulum there is removed from the milk a substance which tends to produce these irregular features in children. If this is not sufficient, condensed milk will be frequently found satisfactory. If not, then resort to dried food, Nestle's food or what not, and in this shape the albuminoids are rendered indigestible and can not be absorbed by the child and consequently escape it. In not only the "spitting child," but also in the child that has a tendency to the formation of gas on the stomach, eruptions on the skin or catarrhal affectious, this type of food will do better than raw milk.

Dr. T. M. ROTCH of Boston—The more advances made in infant feeding the less I feel I know about it. The greatest advancement in infant feeding, I think, is that we are getting rid of the old effete ideas about it, the fears that came up about the use of cow's milk, and we have in their place an instrument that we can use, an instrument which is exact, an instrument which in the future will save the lives of a great many children. I think the fault of infant feeding lies in the physicians themselves. We do not know how to use, for instance, the different percentages. We are just in the very infancy of our knowledge. The exact modification of milk is in embryo; it is not old. In former days they modified milk by mixing cream and milk, and they do now, but that in no way compares with the exact percentages we will deal with in the future. Now we can get those exact percentages and we are just beginning to use them. After we have used them five or six years we shall be more exact in our knowledge. But to say the children can not digest the lower percentages I think is not exact and is incorrect. I was much interested in Dr. Cotton's remarks. It is important to know the quantity of fat. It seems to me that in the future the busy physician will not make the analyses himself; I think it will be left for experts to say what are the percentages, and the physician will learn to think and speak in percentages. We will know, after experimenting with exact percentages given by exact analyses, which very few of us can make, for the physician in general can not make them, and then we will simply give the percentage we desire, for instance, the three of fat, six of sugar, perhaps, and one of proteids. These will be sent to people we know will put them up exactly, just as we now do our prescriptions of drugs. If you follow the history of the giving of drugs it corresponds with the history of prescribing milk. My great grandfather in Pennsylvania, for instance, used a mortar, which I have, to compound his drugs, that we now have put up by the apothecary, and in the future I think we will send to the laboratory our prescriptions for infant food, which are much more difficult to write than are the prescriptions for drugs in disease. But it is important, as the Doctor has said, for us to get them until we have confidence in the laboratory as we have in the apothecary shop.

Then as to mother's milk. There is nothing definite known about the analysis of mother's milk. Good human breast milk differs in percentage. So a child may do well when nursed by its mother but may have indigestion when given to a wet-nurse, not that the milk is not good, but because it is not adapted to the use of the special infant. It is in the variety of the milk in which lies its virtue and not in its exact percentage, and so we must vary our foods over and over again for the special child. It is not in any one component part but in the general composition of the food. For instance, in the formula Dr. Cotton has given us the 4.50 is entirely out of proportion with the .50. I can not tell the exact proportion, but with the proper combination of the different constituents we can make use of the albuminoids which exist in cow's milk.

Dr. JAS. J. CONCANNON of New York—I have had to look over something like three or four thousand children every year and I have been accustomed to the fact that nearly every kind of artificial food will fail in many cases. The mother's milk is not only different in different women, as Dr. Rotch has said, but it varies in the same woman according to her condition and according to her diet. The various things referred to have all been tried in my practice, the use of fruit juice to prevent scurvy and the use of barley water when the child will not retain the milk. In many cases when the cow's milk will fail they supply a want and the child thrives. I do not know how it is throughout the country, but in New York we can easily obtain goats, for there we have a large Irish population. The subject of working up artificial infant foods is largely overdone. We ought to try more to compel mothers to nurse their children. I think about one-fifth of the children artificially fed are fed so because mothers will not nurse them, but give up

nursing at the end of the second month for various reasons. Some believe they do not give the child sufficient and the breasts dry up. There is one thing you can never put in an artificial food and that is the antitoxic property in the mother's milk. We all know, who have anything to do with diphtheria, that the nursing child at the mother's breast is immune. I always, when immunizing for diphtheria, let the child go without an immunizing dose when it is nursing under nine months. After the tenth month the milk loses this quality. This you can not get in the artificial foods.

Dr. KELLEY, of Ohio—I would like to inquire of Dr. Cotton how he determines clinically when to add more fat and when to reduce the fat; when to add albuminoids and when to reduce the albuminoids, and so on with the sugar? How does he determine the quantities and whether they are right or wrong?

Dr. COLEMAN of Alabama—I believe the day will come when thousands of infants will be saved to humanity by the food advised by the able authorities today. But now I wish to speak more especially to the gentlemen situated in the country districts and in towns with 10,000 or less inhabitants. These proportions are the things we want. If we can get our modified cow's milk with cream or bicarbonate of soda or a pancreatic extract, that is what we want. But there is another thing that stress has not been laid on here and that is the manner of feeding the infant. More harm arises from the contamination of the milk after the family gets it in their hands before the child gets it into its stomach than we can imagine. If we can impress the importance of exercising extreme care in handling the milk, then we have done much for our patients. I do not think it is right to feed the child with a spoon and cup altogether, but when the infant is three months of age we can greatly eliminate the dangers of the nursing-bottle, and especially the use of the long nursing-tubes.

Dr. EDWIN ROSENTHAL of Philadelphia—I would like Dr. Rotch to answer a few questions. How about children who are partly fed by the breast? How should we proceed with them? And another thing, is the method pursued by our grandmothers, the method of burning the milk and using flour which has been changed by fire? I begin with a child only one day old by giving it half milk and half water. I rarely use sugar in any shape or form; I have not used it in either of my own two children. I use for the taste a little cinnamon. Albumin I use in any kind of dose; this I give raw, as much as an egg every hour or two, in water, to an infant of three or four months, and I mix with this albumin, salt. In regard to the formula by Dr. Cotton, I have always made my proportions in table-spoonful doses. It would be well to know how to prescribe the metric system in that way. I would like to know how much he considers the two eggs to represent. Among a certain class of people they use a preparation they call *zueiback*. Oatmeal water I have seen given to children, but a good many of them become scorbutic. One case, which I fed on sterilized milk, became rickety.

Dr. T. M. ROTCH of Boston—In the present state of our knowledge in regard to the feeding of infants during the first year of life it is not necessary to discuss the various artificial foods which have been given in the past. It is accepted by the medical profession that human breast milk, when of proper quality and adapted to the especial infant, is the best food that can be given to infants, and that when this food can not be given, cow's milk, modified so as to approach as nearly as possible human breast milk, should be used.

In regard to what Dr. Cotton has said concerning certain infants not being able to digest the proteids of cow's milk, and his advice as to the substitution of egg albumin, I would say that in past years, before the opportunity was given to modify the proteids in cow's milk for the especial case, I also had much difficulty in making certain infants digest the proteids of cow's milk. I have also given egg albumin in the manner in which Dr. Cotton has suggested. At the present time, however, I meet with fewer and fewer cases where the proteids can not be given, and this is due to the fact that through the newer methods for the proper modification of milk in all its constituents we can in the vast majority of cases adapt such milk to the infant's digestion, even when its digestion has been weakened by improper foods. I do not believe that there is any especial virtue in the albumin of eggs, and I am not aware that a sufficient essential chemie difference has been shown to exist between such albumin and that of cow's milk to warrant our substituting it for the proteids of cow's milk. We know that the coagulable part of the proteids of cow's milk is proportionately greater to the non coagulable than is the case with human milk, and that, therefore, it is wiser to give a proportionately smaller amount of proteids to an infant who has difficulty in digesting the proteids of cow's milk, in comparison with the

percentage of proteids which the infant would receive in human milk. I should also draw your attention to the fact that it often is not the proteids which are disturbing the infant's digestion, but the improper combination of the fat, sugar, and proteids, which by adjusting more carefully will often agree with the infant, while the same percentage of proteids without proper adjustment would apparently cause disturbance of digestion.

Dr. Cotton has shown us a very valuable addition to the means which can be employed by the physician for preparing a substitute food for the infant in that he has shown us an apparatus by which the percentage of fat in the milk can be determined very easily. This is a step in the right direction, as it is the fat which varies so greatly in milk and wherever we can find the exact percentages of the different elements of milk, and can combine them in such a way that their exact percentages in the combination shall be known, is always valuable. I would suggest, however, that history repeats itself, and that the modification of milk by the physician himself, and in the family, will in the future probably fall into disuse, just as the combining of drugs in the physician's office has been mostly done away with. The milk laboratory will take the same place in the community as does the apothecary shop, and in the future the physician will find it both an instrument of precision and a means of saving time and labor for himself.

In regard to what Dr. Christopher has said concerning condensed milk being of vital importance for certain infants, I think that the experience of most of us has shown, and future investigations will show, that such a position as he takes is incorrect. In the first place he is not dealing with exact percentages when he gives condensed milk to infants, since the different brands of condensed milk vary very considerably; for instance, the percentage of fat varying from 2 to 28 per cent. There may be other reasons, as he has stated, for using condensed milk, but the very fact that the proper adjustment of the percentages is well known to be so important in the management of difficult digestion will in the future relegate condensed milk for the feeding of infants to the position of a food which has not proved satisfactory to the physician at large.

In regard to what Dr. Cotton asks as to the indications for increasing the fats, proteids, etc., I would say that it is well to begin with a low percentage of both fat, sugar, and proteids, and when the infant is digesting this combination well, to increase the percentages gradually until the infant shows that it is not only digesting the food but that it is getting a sufficient quantity of the elements for its nutrition by increasing in weight. Through means of the laboratory we are able to give any percentage of any of the three constituents of the milk, the fat, the sugar, or the proteids, which we wish and also to give them in any combination which we wish. Having this instrument of precision to work with we must, by noting our successes and our failures, elaborate a more complete system of treating the various phases of infantile indigestion than any we now possess, for we have none of us used the laboratory long enough to be able to say definitely in each case whether any one of these constituents should be increased or diminished.

Dr. BYERS of Alabama—I should like to ask Dr. Rotch what he regards as the normal standard of mother's milk?

Dr. ROTCH—That is obtained by averages, but you can not deal with averages when you are feeding an infant. You have to take the individual. You may take fifteen infants and change them to the breasts of other women, and you will find they will not do well.

QUESTION—Do you use the average as the standard and get the constituents from that average?

ANSWER—That is the trouble; we do not know the percentage in the individual case.

Dr. EDWIN E. GRAHAM of Philadelphia—I have discussed this subject with a number of physicians in Philadelphia and they all seem to be verging the conclusion arrived at by Dr. Rotch, that the more they use of milk from the laboratories the more persistently they stick to certain percentages for certain ages and vary those within certain limits, the better are the results they obtain. This conclusion I think has been forced upon them, because the feeding of the child by the laboratory method is certainly neither the most convenient nor the most economic. It involves an amount of study that is out of proportion to what physicians as a rule are in the habit of giving the subject, and it involves an amount of time that could very well be devoted to other subjects. Still the fact that physicians all over the country are adopting the method, and the sale of this modified milk is rapidly increasing, tends to show that the trend of modern opinion is toward the use of modified milk, modified according to definite methods.

Dr. J. A. LARRABEE of Louisville—I have listened with a great deal of interest to the subject of infant feeding, but I

will not take up your time unnecessarily with the points already gone over. The whole thing seems to show too much science. I doubt if we shall ever formulate rules that will apply to all cases. What is one's meat is another's poison, is a better rule than any other we know. What agrees admirably with one child will not agree with another; it is a matter of speculation and individuality in each case. If we hit it right we do well, but we will shoot no worse if we aim at a mark. So it is well to have formulated plans. But I think we can never prepare a food of which we can say, "Go and give this to your baby and it will be all right." As to goat's milk, I do not know why that should be a panacea. It is true the goats may feed on newspapers and the infant may acquire an immense amount of literature in that way. The higher the goats climb, perhaps the more casein the infant may get. We all know the climbing nature of the goat; and nobody would be foolish enough to rent a level pasture for his cows if he wants to make cheese. I should say that goat's milk, instead of being a panacea at all for infants, will be better suited to those who raise goats; because it is said a penitentiary diet is good for penitentiary people. As to the immunizing property, I think the Doctor has the wrong idea. The immunity in these cases comes from the infant not getting the germs. If the baby is nursed at the breast and the breasts are kept clean, the child probably will not get the infectious disease that may be prevailing in the neighborhood, showing that the entrance of these micro-organisms is largely through the alimentary canal.

The reason I asked Dr. Christopher the question I did is that a temperature above 212 degrees appears to me to devitalize and take out of the protoplasm in the milk what we want, and we can certainly render it sterile at a much lower temperature. Even in the face of fat and adipose tissue, the child may develop scorbatus for the want of an element that is lacking. When the baby is nursing from the mother's milk, it is drawing other things than milk, and other than microbes; but as life gives life, and iron sharpeneth iron, so the mother's milk, being a living substance, tends to prevent scorbatus, and the lack of it predisposes to scorbatus.

Dr. T. M. ROTCH of Boston—All I can say in answer to the gentleman is that we have some who will digest 3, but will take 1 and 2 badly. Let the fat be anywhere up to 4 and the sugar up to 7, and you can make hundreds of thousands of combinations with these figures. But it is only once in many cases that you will need to change to get the proper combination for an individual case. In the vast majority of cases you will find everything will go well. It is in the difficult cases that I find the greatest success in making these different combinations. I used condensed milk for years and made as good food as I could. All these things I have been over and so I can speak with reference to them. Some one has asked if there is not a difference in the analyses of mother's milk. In reply I would say that there is a trivial difference.

Dr. A. C. COTTON of Chicago.—In regard to the indication clinically for the increase or diminution of the various ingredients, I tried to slip that over to Dr. Rotch, but he dodged me. Now what am I to do? He said, never mind the egg but go on and trust to God and Rotch and you will get along all right. I acknowledge him as the father of this business, you will understand; but I am somewhat like the man whose lawyers told him to go ahead. "But," he said, "they will put me in jail." The lawyers told him they couldn't put him in jail. "But," he said, "I am in jail." Now we have gone ahead, by his advice, as long as we could, but we have had to do something else. The dairymen tell us to go ahead and they will feed their cows so well that their milk will melt in the babies' mouth, but it *don't* melt. Dr. Rotch reminds us of the artist when he was asked what he mixed his colors with. He said he mixed them with brains. Dr. Rotch has not answered your question and I will not try to answer it. The babies have indigestible casein when I give them cow's milk, no difference what the laboratory men may say about giving milk that will melt in the mouth. When I add egg albumin they do very well. Then, under these circumstances, what shall I do? Hold to Rotch and lose my patient? In reply to the question as to how much and when, let me illustrate. I used to be a good sailor. Somebody asks, how hard to lean against the tiller and how hard to pull the sheet, and how hard to put the helm up? Why, how many things does that depend upon? You can not get the analysis of the mother's milk from the chemist and go and have something made exactly like it. You must feel your way along, just as the laparotomist must do when he examines the adhesions. But there are certain physiologic conditions that are well known. You know when a baby is rickety and scorbutic, and when he has tympany and indigestion he is not doing well, and you must feel your way along to get results.

INFANTILE CONSTIPATION.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. WELLINGTON BYERS, M.D.

CHARLOTTE, N. C.

The purpose of this paper is to present some observations bearing upon that form of habitual constipation in infants which is, as I conceive it, associated with if not ascribable to defective conditions connected with the digestion and assimilation of certain elements in the food.

There are some reasons of an anatomic and physiologic character, why we would naturally expect to find constipation in infants of frequent occurrence. The muscular structure of the infant bowel is feeble and thin, and possesses but little capacity to propel the feces onward when they have once assumed consistency and bulk. The descending colon of the child is also longer than other parts of this bowel and readily permits of dilatation and sagging when there are accumulations within. From these physical and anatomic causes, together with the fact that the intestinal juices in general are very much lessened in children, we can easily perceive how constipation may be common in this class of subjects. I do not, however, desire to emphasize any of these agencies in the causation of the disease, but to point out others which to my mind constitute the chief factors in the production of constipation in infants.

So far as my own experience leads me, I have found infantile constipation to be almost exclusively associated with a purely milk diet and that nurslings were the most common of all. I have also noticed that the constipated baby of these nursing mothers received an overplus of milk as far as the abundance was concerned. In other words, that a baby getting too much milk was destined to suffer sooner or later from constipation. In the second class, in point of occurrence, came the infants fed upon sterilized or boiled milk, and the least of all were babies who were nourished on raw cow's milk or a mixed diet of starch and milk.

From this experience the conclusion came to me that there must be a real connection between the milk diet and constipation; that in some way the one caused the other. At first view, influenced by prevalent teachings on the subject, I was prepossessed with the idea that the casein in the milk was the disturbing factor. As long as I remained subject to this view I made but little progress in understanding the cases and had no results in their cure. You are doubtless familiar with characteristic stools passed in this condition when the baby is upon an exclusive diet of milk. They are the basis upon which has been erected the previous treatment of the disorder. A superficial examination of the stool shows it to be composed of large masses of whitish-gray ashy-colored substance which has been designated casein. Most authors transcribing from one another have so denominated these masses, and the statements have remained on record more from a failure to corroborate than their accuracy. It was considered perfectly natural that the baby living upon milk would ingest more casein than it could digest and that these masses which came away in the stools were this surplus casein. The masses, moreover, were usually yellowish in their centers when crushed open and frequently manifested a cheesy odor. A failure to carry the

examination farther has given rise to a number of false premises and bad methods. When these lumps are taken and placed in an open-mouth vessel, such as an ordinary pickle bottle, and sufficient sulphuric ether poured in to properly cover them and the vessel then shaken for a little while, these masses so long regarded as undigested casein will have disappeared and there is formed an emulsified product, proving their nature to be fatty and not proteid. Having in this way finally settled the nature of these stools beyond dispute, it became necessary to carry the thought and investigation still farther in order to ascertain the cause of this excessive passage of the fat and the failure of the organism to appropriate it. Clinical experiences in other conditions of the digestive tract will aid us here. It has been shown repeatedly that the very first step in the decline of the digestive functions of the child was an increase in the amount of the fat in the stools; that the primary stage in dyspeptic infants is failure to use fat.

It was Wegscheider who pointed out several years ago, and Holt has incorporated the statement in his work, that the little yellowish masses passed in the stools of dyspeptic infants were not casein, as commonly thought, but fat. In the constipation with which I am now dealing there is an impairment of the agencies concerned either in the digestion or assimilation of fat, or both. The fat appears as the chief constituent of the stool because of its rejection or failure to be appropriated. It produces constipation by its mechanical effects and the muscular impairment dependent on the contingencies of general malnutrition due to fat deprivation.

A large part of the so-called infant foods, or food attenuants, have been brought before the profession because of the supposed capacities to antagonize and modify what has been considered as casein. We should ever keep in mind the great fact that the real test of any food is not its digestibility, however important this may be, but the ability of the patient to assimilate and use it.

You are familiar with the fact that too little fat in the food will eventually be followed by the rickety condition. In attempting to form an adequate explanation of the condition I am now discussing, I believe we must turn to rickets to get a proper solution of these cases. You have all doubtless observed that the constipated baby is also subject to head and neck perspirations during sleep, that it has late opened fontanelles, cuts its teeth later than usual, and suffers also from bronchial disease and coryzas, has stridulous and resists disease of an acute character very poorly, although they are usually quite healthy in appearance or even fat. All of these symptoms point to rickets.

Another important, yet totally distinct cause which convinces me that the relations between the disorders is more than a mere analogy, and that constipation of this kind is really a phase of rickets, is that manifested in connection with the successful therapeutics of the cases. The treatment of both is essentially identical in character. What will aid constipation will also aid rickets. The formula devised by Dr. Lewis Smith, composed of cod-liver oil and lactophosphate of lime, when given to these children has invariably, in my hands, cured them and stopped the accumulations in the bowels. The ingredients of the prescription are not directed to conditions existing in the bowel or for their laxative effects, though I am not sure that the distinguished author saw the same

relations which I now am attempting to point out. I believe the effect of cod-liver oil is to raise the nutritory changes of the child's tissues to a state where they will resume the assimilation of the fat taken in the milk. I do not consider the oil as chiefly beneficial because of its direct action as a laxative upon the bowels, for which purpose it is frequently given, though it does have some influence in this way. It to my mind promotes nutrition in a way which enables the child to use the food which is so essential to its health, which it before treated as a foreign substance to be rejected.

Summary.—I have attempted to show that the constipated stool of the infant is fat, and not casein as commonly taught; that the fat accumulates in the stools because of its non-assimilation by the organism; that this failure to appropriate the fat was evidence of the presence of rickets as shown by the corroborating symptoms; that the disorder was amenable to a therapeusis identical with rickets and the process of cure was one of restoring the powers of fat assimilation.

SOME CASES OF TUBERCULAR MENINGITIS.

Presented to the Section on the Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY ANNIE S. DANIEL, M.D.
NEW YORK, N. Y.

Since the first description of tubercular meningitis by Whyt, in 1768, the disease has been studied and described by a legion of authors, and yet today the most experienced diagnostician finds difficulty in arriving at a correct, early diagnosis. The invariable fatality of the disease is recognized both by parents and physicians and increases the obligation of not regarding the early symptoms of no importance, or ascribing them to a gastric catarrh or nervousness. Fortunately, the life of the patient does not depend on an early recognition of the disease, for as yet no remedy has been discovered which if given either early or late in the disease can in any way affect its course. We can not depend on one symptom, but rather on a group, of at times irregular symptoms, to base a diagnosis. The younger the child the greater difficulty. A known exposure to tubercular infection or tuberculosis of bones or other parts of the body, may attract the attention, and thus lessen the difficulty. Lumbar puncture and withdrawal of fluid has not as yet yielded brilliant results. In the three undoubted cases in which I have employed it, the result was negative. It is an easy and harmless procedure.

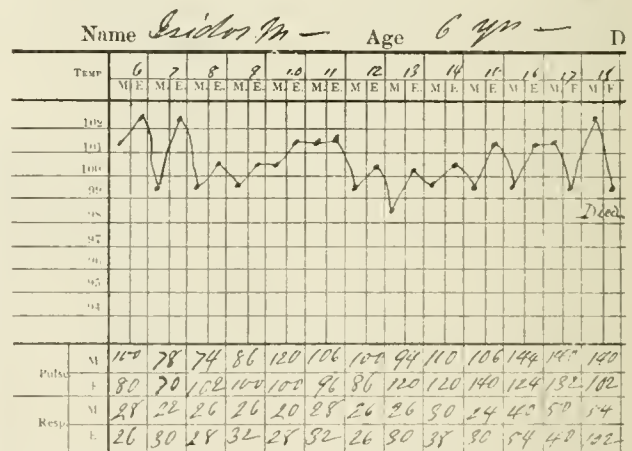

I have forty-nine cases of tubercular meningitis, studied within the past six years, to present to you. Of this number twenty-nine were under two years of age, twenty over. Nine cases were confirmed by autopsy; six of these under two years, three over. Of those under two years of age, seven had been directly exposed to tubercular infection; four of those over two years. All of the forty-nine cases were fatal. No case is presented in which there was a reasonable doubt that the diagnosis was not correct. In children under two years, the diagnosis was based on the following symptoms: A sudden spasm or spasmodic movements followed by automatic motions of arms or legs or of both, paralysis, anesthesia, irregular pupils, retracted and rigid head, a doughy sensation upon palpation of abdomen, with outline of intestines marked through

the abdominal wall, marked lengthening in the height of the child, coma and death after a brief illness. In none of the cases under two years was there found a prodromal period of ill health preceding the acute onset. In those over two years old the prodromal period was the rule, the length of time after the acute symptoms longer and the subacute rather than acute course of the disease marked points of difference. The prodromal symptoms were the usual malaise, or marked change in the disposition of the child, causeless vomiting and obstinate constipation.

The ages under two years were: Four months, one case; 6 months, two cases; 8 months, two cases; 9 months, three cases; 10 months, two cases; 1 year, three cases; 13 months, six cases; 16 months, three cases; 17 months, one case; 19 months, two cases; 20 months, one case; 22 months, three cases. Ages over two years: 2½ years, three cases; 3½ years, ten cases; 4 years, three cases; 5 years, one case; 6 years, two cases; 9 years, one case.

The sexes under two years were: Boys, seventeen cases, girls twelve cases over two years: Boys fifteen cases, girls five cases.

All the children lived in the overcrowded "East Side" of New York, none with even moderately good sanitary surroundings, and some in very bad tenements.

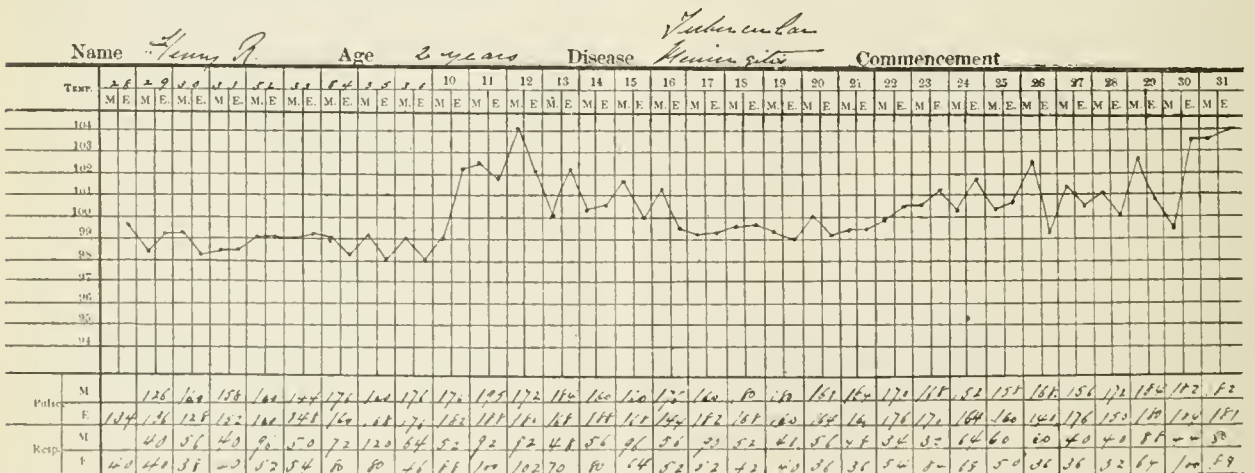

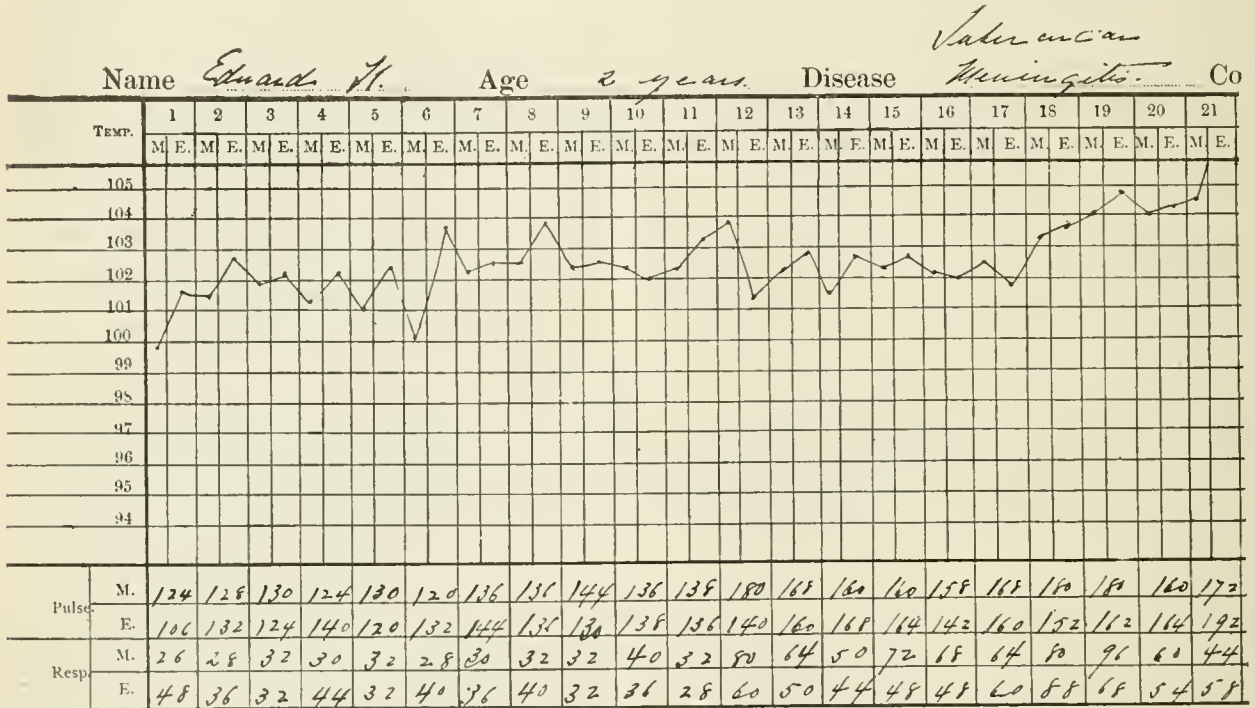

ments. Usually, only the immediate family history could be obtained. Of those under two years old, fourteen were children of healthy parentage; one was unknown, a foundling child; two had mothers with pulmonary tuberculosis; the fathers of four were tubercular; the father of one was insane; the fathers of three were chronic alcoholics. Of four both parents were alcoholic; in five cases other members of the family had had hip-joint or other tubercular bone lesions. In those cases where the parents had pulmonary tuberculosis the presence of the tubercle bacilli was confirmed in most of the cases. Of those over two years of age, the mother of one only had tuberculosis; both parents of one were tubercular; the fathers of five were chronic inebriates; both parents of one, inebriates; twelve had healthy parents; there was tubercular disease in the other members of the families of eight children. I think that the only significance of the alcoholism was the fact that the children had less care, less food, and lived in more unhealthy surroundings.

The previous medical history of the patients is of some importance. Of those under two years, five had had menses at intervals varying from six months to six weeks, but had apparently entirely recovered at

one case. On examination at the first visit, nine were found to have a bronchial catarrh, thirteen gastro-intestinal catarrh. The other seven presented the more marked symptoms of stiffness and retro-action of the head, on which the diagnosis was at once suspected. For those over two years, medical aid was summoned for vomiting and constipation in nine cases; headache, three; child growing stupid, four; spasm, in three cases only; one case developed while child was under observation in the infirmary for ankle-joint disease.

this occurring in the middle of the attack in a child nine months old; a mustard bath apparently reduced the temperature to 103. The lowest average temperature was 96.2. As all but one of the children were seen in tenement houses the temperature was taken only two or three times in the twenty-four hours. One of the children ten months old was admitted to the hospital on the sixth day of the disease; the temperature taken every two hours showed fever for ten days, after that normal or subnormal. The highest temperature recorded for this child was 103.4. At no

The premonitory symptoms were present in nineteen of twenty children over two years of age. Constipation and vomiting present as a marked symptom in the premonitory stage in nine cases. In those under two years, vomiting was present in nineteen cases, absent in ten, constipation present in seven, diarrhea in three, normal stools in nineteen. In those over two years, vomiting was present at some period in all the children and constipation in seventeen cases, the bowels normal in only two cases.

In those under two years, the highest average temperature recorded was 103.2, the highest 109 degrees,

time was there a sudden rise or sudden fall. Among the children over two years, six were observed in the hospital, and the temperature taken either every hour or every two hours. The highest average temperature in those over two years was 102, the highest 107, this toward the end. The lowest average temperature was 99, the lowest recorded 93, near death. A boy aged 4 years and 7 months, who entered the infirmary with symptoms of malaise and had had three spasms, seemed very well on entrance except that the abdomen was flat, not retracted. The temperature was normal for three days, then an evening rise of tem-

perature to 101, but with no cerebral symptoms until four days later when there was stiffness and retraction of the head, four days later convulsions and continued high fever for four days more, and death with a temperature of 106.4. A boy 6 years old who entered the infirmary on the sixth day after the initial symptom of headache and died thirteen days later, had at no time a temperature higher than 102. A boy 2 years and 10 months old, admitted with an empyema, on the seventeenth day after admittance became drowsy as the first cerebral symptom, with a temperature of 102, and during the eighteen days that he lived after the cerebral symptoms appeared the temperature rose only ten times higher than 99, varying between 93 and 99. Another boy, 2 years old, entered the infirmary for ankle-joint disease, seemed well in every other respect for four months, then cross, and evening rise of temperature without apparent reason. After the first evening rise the temperature continued elevated without either sudden rise or sudden falls until death twenty days later. A child 2 years old, who entered in the fifth week after the initial symptom of changed disposition, upon admittance presented well-marked symptoms of the disease, and did not have a temperature higher than 99, until sixth day after admission, then an evening rise to 102; two days later there was a sudden rise of 4 degrees and an equally sudden fall, the temperature being at 4 A.M., 100.9; at 5 A.M., 101.2; at 6 A.M., 100. At no other time did the temperature rise higher than 102 until twenty-four hours before death, twenty-one days after the sudden rise. There seems to be, from a study of the forty-nine cases, nothing characteristic about the temperature, except that higher temperatures are more uniformly met with in children under two years of age than over. There are rarely sudden rises or sudden falls of internal temperature. Toward the end of the disease in children over two years there was found sudden rises of surface temperature, this occurring after the child became semicomatose. That an early rise of temperature is not an early symptom of the disease in children over two years old, is demonstrated by the fact that medical aid is rarely called because a child has had fever; under two years fever as an early manifestation is more common.

Much importance is attached to the pulse rate in both early and late stages of the disease. In those under two years old, the pulse was found to be 160 in nine cases, as the highest; in one case only was it lower than 100. The highest lowest pulse was 140, the lowest 80. As the normal pulse under two years varies with the age and at two years should be about 110, very little reliance as a symptom can be attached to the pulse rate unless it is continually very rapid or continually very slow. A child ten months and six days old, after the first symptom of ill health, was admitted to the infirmary with a temperature of 103.4, pulse 132 and respiration 46. In this case, at this observation, the pulse rate was too low for the temperature and the respiration; the pulse was taken day and night every two hours for twenty-seven days, during which time the highest was 160; it was less than 100 but four times. Irregularity of the pulse in those under two years old, is not as frequent as in children over two years. Twenty-nine cases which could not be observed more frequently than these were, can not be relied on as infallible guides, or even aid in the diagnosis, but the twenty cases in the other children equally well observed, presented at some time an

irregular pulse, while under two years the pulse rate is more uniformly higher and regular. In those over two years the reverse was found, the highest pulse rate being found in the later stages of the disease and at all stages more or less irregular. The highest pulse rate noted was in a child over two years old, 180. The lowest of the highest recorded was 80; the highest of the lowest was 120, the lowest 60. In a child 2 years old, the first of the observations of the pulse taken in the fifth week after the initial premonitory symptoms, and who was semicomatose and lived thirty days after his entrance, the pulse was rarely regular, lowest at 80, and there were very frequent rapid rising and falling of the pulse rate, without reference to the time of day, to the temperature or to the respiration. An instance of this: Temperature 99.4, pulse 180, respiration 52; temperature 101.2, pulse 188, respiration 100. In the case of the child 2 years old, entering with ankle-joint disease, the temperature, pulse and respiration were in normal proportions, and was under close observation for four months preceding the tubercular meningitis. During the month preceding the first symptoms of changed disposition, the pulse was never higher than 128 or lower than 100, except on two occasions. The temperature which had not risen higher than 100, at the beginning of the changed disposition was 101; the pulse was 108 and respiration 40. After that, during the twenty days the child lived, the pulse fell to or below 100 five times and usually out of proportion to the temperature and respiration; at one time 103.6, pulse 100, respiration 40; two hours later, 103.6, pulse 132, respiration 36. This observation was made six days after the first symptom of changed disposition. On the last day of life the temperature at one time was again 103.6, the pulse 168, respiration 32. The twenty cases over two years old, while presenting the irregularity usually observed, did not present the slow pulse which is considered one of the pathognomonic signs of early tubercular meningitis. In children five years or over the slow pulse is much more apt to be found. A child 6 years old, seen the sixth day after the first symptom of ill health, had for four days, a pulse rate which on observation every two or three hours, only twice reached as high as 100; the lowest during these four days was 68, after the convulsions which occurred first on the sixth day of the disease and later on the twelfth day. The pulse at no time rose above 116. After the second spasm, which occurred when the pulse was 94, the pulse, with the exception of five observations on the day of the second spasm, never fell below 110. The pulse from the first observation was irregular. This symptom of an irregular pulse I believe to be of more importance than a simply slow pulse which may be found in other diseases.

In diagnostic value the respiration presents a more certain aid to the diagnosis than either the pulse or temperature. In those under two years it was in every case irregular early and the irregularity persisted to the end. The respirations were highest at the beginning of the disease, and slowest toward the end. There seems to be little or no ratio between pulse, temperature and respiration among the twenty-nine children under two years old. The highest number of respirations recorded were 90, the lowest 10. A marked typical Cheyne-Stokes' respiration was found in five of the twenty-nine cases. The irregularity consisted, usually, in at first a short pause

between the respirations, this pause becoming longer and more frequent as the disease advanced, the irregularity at times very regular; the number of respirations might be six, then a pause, then six more with another pause. This regularity in the irregular respiration becoming less and less marked as the disease advanced. At times there seemed to be a rapid increase or decrease in the number of respirations from hour to hour. The greatest increase and decrease was more often noticed from minute to minute, as in one instance it was 16 in one minute, 48 in the next. This usually occurs late in the disease, but it may occur at any time. The above observation was made on the eighteenth day after the first symptom of ill health and nineteen days before death. In those over two years old the highest respirations noted were 108; the lowest of the highest respirations were 27. The lowest respiration recorded was 7. All were irregular early and twelve presented a nearly characteristic Cheyne-Stokes' respiration. The fluctuations in the number of respirations to the minute are much less marked in those over two years, and the fluctuation from hour to hour less marked than in the younger child. The respirations become as a rule more rapid at the end of the disease. There is no ratio between the pulse temperature and respiration that can be relied on as occurring sufficiently often to be diagnostic, as at one time with a temperature of 104, pulse 180, respiration 96. Later in the same child on the same day, temperature 104, pulse 160, respiration 64. While the respiration leaves much to be desired as a pathognomonic symptom, the irregularity so almost constantly present early in the disease in the younger as well as in the older child makes the careful observation most important.

Many authorities place much stress on the symptom of an intermission in the acute symptoms, an apparent beginning recovery. In those under two years old this occurred three times in the twenty-nine cases. One at nine months was very marked, the child quite suddenly sitting up in the crib, playing. These symptoms lasted three days, during which time the only abnormal symptom was the irregular respirations. Two other cases had an intermission of twenty-four hours, during which time the child seemed to have regained the appetite, but appeared abnormally hungry. In those over two years, two only had an intermission of twenty-four hours, but during the premonitory stage there is marked variations; one day the child seems pretty well, then again drowsy or more cross, but the intermissions in the above cases occurred after the stiffness and retraction of the head had occurred and the diagnosis seemed very certain.

Among the twenty-nine children under two years, a positive diagnosis could be made early in only fifteen cases; these were the cases in which the stiffness and rigidity of the muscles of the neck were an early symptom. As tubercular meningitis in those over two years old more commonly begins at the base, the diagnosis was made early in twelve of the twenty cases, the early positive diagnosis being based on the stiff holding slightly backward of the head. The duration of the disease in the children under two years was an average length of fifteen and a fraction days, this from the first symptoms of ill health. The longest was twenty-six days, the shortest seven days. In those over two years, but not including the premonitory symptoms, which varied from two to three

weeks, the average duration after the symptoms directly pointing to the meninges was twenty-one and a fraction days, the longest period, fifty-four days, the shortest ten days. Under two years, the differential diagnosis lay between simple meningitis, cerebrospinal meningitis epidemic, and gastro-intestinal diseases.

Tubercular meningitis is a preventable disease, incurable when once contracted. It is not a local tuberculosis as tuberculosis of the lungs. On autopsy tubercles are more frequently found in other parts of the body. In all my cases in which there was a known source of contagion, the person from whom the disease had been contracted had pulmonary tuberculosis. The mode of infection was difficult to ascertain. It may have been through the respiratory or the gastro-intestinal tract. Most of the families where a tubercular patient was present were filthy, expectorating on the floor, rarely washing their hands, handling food and giving it to the children. It has been difficult to ascertain whether the children contracted the disease by drinking milk. A large quantity of milk is sold in the city where no examination is made to ascertain whether the cows are tubercular.

The older the child, the less danger there is among New York tenement house children of contracting the disease through milk, as children over two years drink very little, practically no milk. The treatment employed has been mustard paste applied as counter-irritant at the base of the brain, ice continually over the head, iodid of potassium given hourly, and indications for other treatment met as they arose.

THE CLINICAL IMPORTANCE OF THE EYE SYMPTOMS IN ARRIVING AT A DIAGNOSIS OF MENINGITIS IN CHILDREN.

Presented in the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY A. E. DAVIS, A.M., M.D.

Assistant Surgeon Manhattan Eye and Ear Hospital; Instructor in Diseases of the Eye, Post-graduate Medical School; Attending Ophthalmic Surgeon, Bellevue Hospital, O.D.P.
NEW YORK, N. Y.

In bringing the subject of diagnosis of meningitis in children before this Section of this learned society for consideration, it is for the purpose of specifically directing your attention to the eye symptoms in this disease and of their importance in arriving at a correct diagnosis.

In 1888, Swanzy,¹ in an instructive paper on the "Value of Eye Symptoms in the Localization of Brain Disease," was led to remark that "these eye symptoms are not as much valued as they should be, perhaps because their often subtle and sometimes subjective nature renders them less readily studied than are other focal brain symptoms." Also, that "eye symptoms are too often not looked for at first but utilized rather as a dernier ressort."

While no doubt the eyes and their symptoms in relation to all diseases have received much closer attention than formerly, it only too often happens that the general practitioner does not, until he has exhausted all other means, turn to the oculist for aid.

When it is remembered that many eye symptoms which are of great importance in meningitis are

¹ British Medical Journal, Nov. 17, 1888, pp. 1089-1095.

largely *motor* in character, that is, paralyzes of the different eye muscles, the pupillary changes, ptosis, etc., all of which may be observed without the aid of the ophthalmoscope, ignorance of the use of which most practitioners give as an excuse for not making proper examinations of the eyes, it is only the more to be regretted that the eyes do not receive earlier and more careful attention. Even in lesions affecting the *visual* apparatus of the eyes, visual centers, optic tracts, optic nerves and retina, by means of the perimeter to take the fields of vision, a moderate degree of efficiency in the use of the ophthalmoscope, and with a careful study of the motor symptoms, a correct diagnosis can be made out in most cases. However, I am not unmindful of the difficulty and many times of the impossibility of making careful examinations of the eyes in children. For this very reason I wish to emphasize the necessity of making full use of the eye symptoms that are present, and not to pass them over as of little importance, as is often done.

In the first place, I want to give a brief résumé of thirty-eight cases of meningitis that were treated in the Post-graduate Hospital of New York City. Thirteen were simple or leptomeningitis, twelve were cerebrospinal meningitis, and thirteen were tubercular in character. Some of these cases never had their eyes examined with the ophthalmoscope and only cursory examination of the eyes at all, while some of them had their eyes examined one or more times with the ophthalmoscope, and others were examined systematically with the ophthalmoscope and otherwise for eye symptoms throughout their illness. Some of these cases were examined by myself.

On the whole, I would say that the examination of the eyes in these cases may be taken as a sample of the attention that the eyes usually get in cases of meningitis.

Of the thirteen cases of leptomeningitis, including under this heading one case of purulent meningitis, there were no eye symptoms in eight cases, or they were of such a trivial character as not to be noted. Strabismus was noted in two cases and the pupils were dilated in another. One case, a girl 4 years of age, who had been treated in the hospital a year previously for purpura hemorrhagica, and was cured in two weeks' time, is of enough interest to be reported briefly by itself. The patient was sick one week before entering the hospital, being greatly depressed, complaining of severe headache, vomiting and having no appetite whatever. She was feverish and voided but little urine. On the third day after entering the hospital I examined her eyes. The pupils were dilated, but responded quickly to light or irritation of the body. There was a neuroretinitis plainly marked in the left eye. The eyes were examined every third day until death, which occurred on the thirteenth day after the child entered the hospital and the twentieth day after the beginning of the illness. Just six hours before death there was a marked neuroretinitis in the left eye and a beginning one in the right eye; the pupils were widely dilated and irresponsive to light or peripheral irritation; and there was a small ulcer on the left cornea. The right hand was drawn across the chest and there was twitching of the fingers of that hand for six or eight hours before death. No postmortem was allowed.

In the case of purulent meningitis, in which there were no eye symptoms, postmortem examination showed the meninges covered with pus, and extensive adhesions between the pia and dura mater.

In the twelve cases of cerebrospinal meningitis, eye symptoms were absent in seven cases, or not noted. There was loss of iris reflex in one; in one, dilated and fixed pupils; in one, strabismus, and in one the pupils dilated but reacted to light.

Of the thirteen cases of tubercular meningitis no eye symptoms were noted in eight cases: while in one case the pupils were dilated, in one the left pupil only was dilated, in one there was ulcerative keratitis and conjunctivitis, and in one dilated pupils and lagophthalmos. No tubercular lesion of the eye was seen in any of the cases. Postmortem examination in most of the cases was obtained and confirmed the diagnosis.

Such is the brief history of these thirty-eight cases.

In order to make the eye symptoms of value in diagnosis in the different forms of meningitis, we should, where it is possible, first decide whether such symptoms are "primary" or "secondary;" that is, if the symptom, for example paralysis of the sixth nerve, is due to direct lesion in the nucleus or in the course of the nerve itself it would be "primary" in character; or if due to a lesion far removed, which affects the nerve indirectly through pressure or in disturbance of circulation, it would be "secondary" in nature. Secondly, we should distinguish clearly between the motor and visual disturbances in the organ of sight. It is unnecessary to tell you that the primary symptoms are much more important than secondary symptoms. Unfortunately, however, it many times takes days, or even weeks, to make a distinction between the two. It must be borne in mind also that diffuse symptoms, as general headaches, etc., are not of great importance when compared to focal symptoms.

CEREBROSPINAL MENINGITIS.

Before pointing out the significance of the eye symptoms separately I shall first enumerate them as a whole.

Motor symptoms.—Paralysis of the sixth nerve, third nerve (complete or partial), fourth nerve, ophthalmic division of the fifth nerve, seventh nerve (giving rise to lagophthalmos), conjugate deviation, nystagmus and ptosis, from cortical lesions.

Visual symptoms.—Choked disc, optic neuritis, perineuritis, plastic and suppurative choroiditis, iritis, conjunctivitis, edema of the lids, hemianopsia as a cortex or tract lesion, blindness. It is a peculiarity of cerebrospinal meningitis that the eye symptoms vary in different epidemics. For instance, one epidemic may be marked simply by a conjunctivitis of a more or less severe character;² in another the chief eye symptom may be characterized by plastic or suppurative choroiditis;³ in another the cornea may be the seat of affection;⁴ while in another the optic nerve and retina may be the chief points of trouble.⁵ Nystagmus is a frequent symptom in some epidemics.⁶ At times there are no eye symptoms whatever, but these are comparatively rare cases. Randolph,⁵ in the report of forty cases, found but four cases without eye complications of some kind.

Paralysis of the sixth nerve.—Sixth nerve paralysis is one of the most common of the motor symptoms affecting the eye in cerebrospinal meningitis.

² Ziemssen and Hess: *Klin. Monatsblat. für Augenheilkunde*, 1865, p. 275, seq.

³ Knapp: *Centralb. f. med. Wissenschaften*, No. 33, 1865.

⁴ Wilson: *Dublin Quarterly Journal of Medicine*, Vol. xliii, 1867, pp. 302-6.

⁵ Randolph: *The Johns Hopkins Hospital Bulletin*, No. 32, June and July, 1898.

⁶ Leichtenstern: *Deutsch. Med. Wochen.*, No. 31, 1885.

In an epidemic of twenty-nine cases observed by Leichtenstern⁷, the external rectus was affected oftener than the other eye muscles. Randolph, on the other hand, in an epidemic reported by him, observed third nerve paralysis most frequently, eight cases out of forty having divergent strabismus, and the pupil being affected in nineteen out of the forty, while ptosis was noted but once and that unilateral.

Seventh nerve paralysis.—From pressure on the seventh nerve we may have the eyes remain half open, the child apparently not being able to close them.⁸ From the exposure of the cornea from this cause ulcers may be formed on it, and for this reason such cases should have the eyes bathed frequently to keep the corneae moist and, if necessary, a protective bandage should be applied.

Paralysis of the ophthalmic division of the fifth nerve.—From pressure on the fifth nerve we may have anesthesia of the cornea and a neuroparalytic keratitis may develop. On the other hand, from irritation of the fifth nerve, we may have paresthesia, or at times we may have hyperesthesia of the eyeball and lids, and a headache confined to the temple on the side affected. The fourth nerve is at times paralyzed, but this is infrequent.

Conjugate deviations.—Conjugate deviation of the eyes is sometimes seen, but usually it is a secondary symptom and is of short duration. Jaccoud⁹ reports a case of conjugate deviation to the right in purulent meningitis of the left hemisphere and congestion of the right hemisphere. Conjugate deviation may be due either to lesion in the cortex or in the pons. In the former the deviation is toward the side with the lesion in paralysis and from it in spasm; just the reverse of this happens when the deviation is due to a lesion in the pons.

Ptosis.—Ptosis, unilateral or bilateral, has been observed in these cases. Randolph¹⁰ found unilateral ptosis with divergent strabismus and dilated pupils in one case out of forty observed by him. In this instance, I would judge the lesion was in or near the corpora quadrigemina. Unilateral ptosis, as the only focal symptom, occurs in cortical lesions alone. Not infrequently, however, ptosis, single or double, occurs temporarily as a secondary symptom.

Nystagmus.—Nystagmus in some epidemics is frequent, as in the one observed by Leichtenstern,¹¹ while in others it is of rare occurrence. Randolph observed it in but one case in forty, and that was of an unusual kind, that is, the eye oscillated in the vertical meridian on the horizontal axis.

Visual symptoms. Optic neuritis.—Inflammation of the optic nerve occurs comparatively frequently in some epidemics and very rarely in others. Randolph¹² found it in six cases out of forty, and "great venous engorgement and tortuosity, with more or less congestion of the optic disc," in nineteen others, besides one case of hemorrhagic retinitis and thrombus of the central vein of the retina. Schirmer, quoted by Randolph, did not find it but once in an epidemic observed by him in Greifswald. Optic neuritis generally comes on late in the disease, but has been observed as early as the sixth day. When it does occur, and early, it is of vast importance in establishing a diagnosis, espe-

cially in sporadic cases where we are in doubt at times as to the correct diagnosis.

Neuroretinitis and perineuritis are other conditions similar in nature to optic neuritis, and at times are observed in these cases. So remarkable a condition as *choked disc* is comparatively rarely seen in this disease, more commonly in tubercular meningitis, and most commonly in brain abscesses and tumors of the brain.

Optic neuritis in meningitis may be caused indirectly by pressure from exudation and cell infiltration on the outside of the nerve. However, the nerve and its sheaths are frequently directly implicated by continuity of tissue. The optic disc has a more or less characteristic appearance in these cases, which is a certain "smoky" or cloudy appearance. Besides this smoky condition, the edges of the disc are indistinct or obscured altogether, there is more or less redness and at times, but rarely, hemorrhagic spots on it. Many times there is only congestion of the disc, while the veins are very tortuous and full of dark blood (Randolph, Mathewson, Andrews). The condition known as perineuritis (Galezowski) has been observed in this affection. It is characterized by a slight swelling at the periphery of the optic disc and a sinking in at its center and a moderate amount of redness, the retina presenting a grayish, striated appearance, or at times an edematous look. I have seen two such cases myself and take it to be simply a neuroretinitis.

Plastic and suppurative choroiditis.—Suppurative choroiditis with iritis and occlusion of the pupil, accompanied in some cases with hypopion, are the chief eye conditions in some epidemics.¹³ Plastic choroiditis usually appears in the second or third week and, as a rule, causes destruction of sight. The fundus of the eye, from the plastic exudation in the vitreous, gives a grayish or yellowish reflex and simulates the appearance of glioma retinae, or the so-called pseudo-glioma.

Panophthalmitis and a suppurative choroiditis may follow as a result of meningitis.

Hemianopsia.—This valuable focal symptom at times in cases of pachymeningitis, is here of no value. In the first place, because children are rarely affected with pachymeningitis, and, again, on account of the age of the patient, it usually could not be made use of.

Conjunctivitis.—Conjunctivitis and in several cases edema of the conjunctiva and the lids, are early symptoms and are important diagnostic conditions. The edema of the conjunctiva is due to the extension of the inflammation into the orbit along the veins and impeding the return flow of blood from the eyeball.

Photophobia is sometimes an early and marked symptom of this disease.

A few or many of the above eye symptoms may be present in cerebrospinal meningitis; at times, however, no eye symptoms at all are to be observed. The general symptoms in cerebrospinal meningitis, temperature, vomiting, headache, retracted head, spinal irritation, herpetic or petechial eruptions, taken together with the fact that it usually occurs in epidemics and in the winter or spring of the year, as a rule, make it easy of diagnosis without the aid of eye symptoms: but in sporadic cases where the general symptoms are not well marked and some of them absent altogether, the eye symptoms may be the chief factor establishing a correct diagnosis.

SIMPLE OR LEPTO-MENINGITIS.

The eye symptoms are of even more importance in determining the diagnosis in simple meningitis than in cerebrospinal. 1, Because it does not occur in epidemics. 2, because it is always secondary and its symptoms may be masked by the primary affection.

All of the eye symptoms that have been discussed in connection with the cerebrospinal meningitis may occur also in simple meningitis. The motor symptoms are of about equal frequency in each. But the most important eye symptom in these cases perhaps is optic neuritis. Not that it has a localizing value, or is of great value even of telling what the trouble is; but when present it points to brain complication and puts the physician on the right track. And as meningitis is one of the common causes of optic neuritis we should give it due heed, and by means of other symptoms in connection with it decide if meningitis is or is not present. I especially desire to call your attention in this connection to cases following middle ear and acute febrile affections.

Chronic suppuration of the middle ear was once and, I am afraid, is yet looked on as of little consequence when occurring in children, the child being expected to outgrow it. Fortunately extension of the inflammation to the brain in such cases is but of infrequent occurrence, but when meningitis does follow such a cause optic neuritis is almost invariably present, if not a choked disc "sometimes between edema and actual inflammation of the nerve."¹⁴ And I may say here abscess of the brain and meningitis following suppurative inflammation of the middle ear have been treated for intestinal disorders, and that even where eye examinations have been made. Mathewson¹⁵ has reported abscess of the brain with local meningitis in a little girl who had been treated by him, for chronic suppurative otitis and fistulous opening over the mastoid, for about three months and was apparently cured. Four months later, however, she was taken ill after she had "attended a children's party and was shortly after attacked with vomiting and headache and other symptoms which seemed to be due to gastric and hepatic disorder resulting from indigestion in eating and excitement." Mathewson saw the patient in consultation and was of the same opinion as the family physician, that it was gastric and hepatic disorder, and the child was treated accordingly. He saw the child again on the following day and he and the family physician remained of the same opinion as on the preceding day and the same treatment continued. The child died in convulsions on the second day. Dr. Mathewson made an examination with the ophthalmoscope, but it "showed no swelling of the optic nerve disc and the retinal vessels were not tortuous, though there was a peculiar dark color with some dilatation of the retinal veins which I shall always hereafter regard with suspicion." Autopsy showed "veins and sinuses filled with fluid blood, meninges injected, adhesions at points over the petrous portion of the temporal bone and an abscess containing an ounce or so of fetid pus in the left lobe of the cerebellum." As Mathewson says, the chief point of interest in this case was that the ear should give rise to abscess of the brain four months after it was apparently well.

Dr. Pooley¹⁶ reports an interesting case of a boy 12 years of age who had brain abscess, sinus thrombosis and meningitis with marked eye symptoms as the

result of chronic suppurative otitis in the left ear. The child had had a Wilde's incision performed six years previously, but a subacute condition remained and, when seen by Pooley, mastoiditis was present complicating the chronic otitis and the patient had high temperature. Dr. Pooley did a mastoid operation. The eyes were not examined till the fifth day, when a marked choked disc was present in the left eye with a contracted pupil. On the thirty-first day after his entrance into the hospital the patient was found to be blind in the right eye, apparently over the entire field. The ophthalmoscopic examination showed nothing in the right eye. However, on the following day the ophthalmoscope showed slight venous hyperemia on the right side and violent choked disc on the left side. The patient died on the forty-first day after entering the hospital. Pooley in one of the deductions from his paper says, "The intra-ocular end of the nerve is never inflamed when the disease remains limited to the middle ear and mastoid, but is a certain evidence of brain disease. If, therefore, optic neuritis is found, the diagnosis of extension to the brain is certain, no matter whether other evidence exists or not." And what I myself wish to emphasize is, that children do not outgrow chronic suppuration of the middle ear: and when a child is so troubled is taken with fever, severe headache, vomiting, etc., we should not be content with a diagnosis of intestinal disturbance but make a thorough examination, not omitting the eyes.

Another frequent cause of meningitis in children is by *metastasis* following acute infectious diseases, croupous pneumonia, etc., also from pyemia, septicemia, etc., and from the exanthematous diseases. Often, in these cases, some eye symptoms, as paralysis of one of its muscles or an optic neuritis, are the only symptoms pointing to a brain complication. Hence the great importance of having the eyes examined in such cases.

Optic neuritis occurring in these acute febrile diseases is nearly always consecutive to a complicating meningitis. However, it may occur without meningitis, as Stephenson¹⁷ has reported a case of double optic neuritis following measles without meningitis.

In purulent meningitis, edema of the conjunctiva is at times an early symptom. This is brought about usually by an extension of the inflammation along the veins into the orbit, but it may extend along the sheaths of the optic nerve and may be the only eye symptom. At times, however, abscesses form in the orbit with exophthalmus and paralysis of one or more of the eye muscles. Also there may be edema of the lids, which is characteristic by it being confined almost wholly within the orbital rim.

Suppurative choroiditis with ciliary injection, iritis, exudation into the vitreous, infiltration in the cornea, and even panophthalmitis may be the result of purulent meningitis. And it must not be forgotten, on the part of the general practitioner, that a purulent affection of the eye (purulent choroiditis, panophthalmitis, etc.,) may be the focal point for a purulent meningitis.

TUBERCULAR MENINGITIS.

Tubercular meningitis is perhaps the most insidious disease of infancy and childhood, creeping on from day to day as it does in its prodromal stage and, even after the prodromal, often manifesting itself in irreg-

¹⁴ Trans. Amer. Otol. Soc., 1888, Vol. 3, p. 155. ¹⁵ Loc. Cit.

¹⁶ Transactions Amer. Laryng., Rhi. and Otol. Soc., 1896.

¹⁷ Trans. Oph. Soc., Vol. 3, p. 250.

ular forms with, at times, many of the leading symptoms absent. It is almost impossible to make a correct diagnosis.

The eye symptoms in tubercular meningitis are the same as in the simple meningitis, but in rare cases in addition tubercle deposits may be seen in the choroid or iris, or both; and where tubercular masses form in the brain we may have symptoms of brain tumor present. Such a case was under my observation at the Post-Graduate Hospital and has already been reported by Professor Chapin in the February number of the *Archives of Pediatrics*, 1897. The eye symptoms in this case were nystagmus, dilated and fixed pupils and neuroretinitis in the right eye. The patient died, and the autopsy by Dr. Collins showed miliary tubercles scattered throughout the left lung and solidity of the left apex. There were three distinct tumors in the brain, the size of walnuts: 1, on the basilar surface of the left cerebellar lobe; 2, at the head of the caudate nucleus on the right side; 3, in the substance of the anterior and posterior quadrigeminal bodies. The nature of the growths were tubercular. The tumor on the under surface of the cerebellum seemed to be attached only to the pia.

Tubercle may affect the eyes primarily or secondarily, and in two ways: manifesting itself either in the form of small circular miliary deposits, grayish or yellowish-grey in color; or in masses varying in size from a split pea to half the size of the eyeball itself. When these tubercular deposits are present in the eye, especially when the other organs of the body, lungs, joints or glands, etc., are affected, they are of paramount value in determining the character of the meningitis. Tubercles are so seldom seen in the eye, however, that observers differ in their estimation of their value for diagnostic purposes. Especially rare are cases with tubercular deposits in the choroid in this country, but from the reports of Cohn and other European writers, tubercular deposits in the choroid are not very uncommon there. Tubercular iritis is a more common affection.

Bach¹⁸ thinks tubercular infection of the eye to be quite common, and says that the optic nerve may have tubercular nodules on it as a result of tubercular meningitis and that the choroid may be acutely or chronically affected by the tubercle. The uveal tract is the most common seat of infection, but tubercles may appear on the lids, conjunctiva, cornea and lacrymal canals, and may be primary and the only symptom of the disease.

Valude,¹⁹ from experiments on the rabbit, is of the opinion that the eye from its peculiar anatomic structure confines, on the one hand, tubercular lesions to itself in primary affections; and on the other hand, is slow to be infected by tubercle from other organs of the body. He thinks, as a consequence, that tubercular lesions of the uveal tract, iris, choroid, etc., are contracted not from within the body, but by external infection. He was led to this view by his experiments, which tended to show that tubercle germs are not carried by the blood vessels but by the lymph channels; and in the eye these channels are not so intimately connected with the general lymph channels as are the other organs of the body.

Minot lays but little stress on the choroidal appearances in tubercular meningitis and says: "Choroidal tubercles are so rarely seen as to be of little value in

diagnosis. In fact, they are less frequent in this disease than in general tuberculosis without meningitis. In twenty-six cases of tubercular meningitis examined by Garlic at the London Hospital for Sick Children they were found only once."

Prof. Reynold W. Wilcox of New York City, tells me that in over two hundred ophthalmoscopic examinations for tubercles in the eyes of consumptives he did not find tubercle in a single case, and Prof. W. Oliver Moore of New York writes me as follows: "I have examined ophthalmoscopically the eyes of forty-one patients with different forms of tuberculosis, in the New York Hospital and also in the Charity Hospital. In twenty-eight patients the diagnosis was made and verified at postmortem, of acute miliary tuberculosis. In thirteen cases the diagnosis was tubercular meningitis and verified by postmortem. In only one eye out of the eighty-two eyes examined was there any approach to the appearance usually described as tubercle of the choroid. In this case what appeared to be a tubercle of the choroid was found postmortem to be a 'vacuole.' One case of general acute tuberculosis was observed among the forty-two cases. Unfortunately, in none of these cases were cultures made from the eyes. But in all, the postmortem examinations showed the usual tubercular deposits in the various other tissues. Tubercle of the iris I have seen frequently, having the records of twelve cases. Tubercle of the choroid is extremely rare in this country."

But undoubted cases of tubercular affection of the choroid both primary and secondary in character have been observed, as proved on microscopic examination and by reinoculation on rabbits and guinea-pigs, and by cultivation.

Three cases of primary tubercular affections of the uveal tract are reported by Denti and Rambolitti (*Annali di Ophthalmologia*, June, 1895), one of which was cured, but the eye in the other two had to be enucleated. In the latter two cases some of the material from the enucleated eye was injected into the anterior chambers of the eyes of rabbits and guinea-pigs with development of characteristic tubercular iritis. Incidentally, at this point, I may say that the failure to obtain tubercle bacilli in the fluid after spinal puncture does not preclude tubercular meningitis, for if the eyes of rabbits be inoculated with the fluid it sometimes sets up a genuine tubercular iritis in which the tubercle bacilli are found, having developed from spores. Again, if this can not be practiced, cultures of the germs may be made from the fluid obtained from spinal puncture, though no tubercle bacilli could be detected in the spinal fluid.

On the value of the eye symptoms in the differential diagnosis of the different forms of meningitis, I do not lay great stress. I do not agree with Leichtenstern, that in tubercular meningitis we are apt to have the pupils dilated and sluggish oftener than in the epidemic forms of cerebrospinal meningitis. Neither do I agree with Nettleship, in the opinion that when the optic nerve is affected on the one side only it is on the same side as the meningeal affection if it is a true meningitis, but on the opposite side if of a tubercular character. In fact, I am inclined to side with Whittaker, "that the various forms of meningitis are to be separated and recognized more by the etiologic relations of the disease than by any difference in symptomatology."²⁰

¹⁸ Arch. f. Augenhellkun., Wiesbaden, December 1893.

¹⁹ Arch. d'Ophthal., Paris, May and June, 1892.

²⁰ Ref. Handbook, p. 721.

In conclusion, I would urge the systematic examination of the eyes of children, both for motor and visual symptoms, in all conditions simulating meningitis, especially in those cases where there has been a long standing middle ear suppuration, in cases of pneumonia, pyemia, empyema, septicemia, etc., and cases giving tubercular history and with glandular complications. At times in these cases the eye conditions are the only symptoms pointing conclusively to brain complication.

IMPAIRED VENTILATION AND DRAINAGE OF THE NOSE THE MOST COMMON CAUSES OF NASAL CATARRH.

Read before the Chicago Medical Society, Nov. 21, 1897.

BY EDWIN PYNCHON, M.D.

Professor of Rhinology and Otolaryngology and Otolaryngology, Chicago Eye, Ear, Nose and Throat College; Senior Assistant Aural Surgeon, Illinois Charitable Eye and Ear Infirmary.
CHICAGO, ILL.

The physiology of the nose was, until recent years, but imperfectly understood. Text-books on physiology, of but little more than a quarter of a century ago, taught that the nose was the organ of smell and the passage through which respiration was conducted and nothing more. No hint was given that any effect upon the air was derived from its passage through the nose. No mention was made of the sound-board influence of a patent nose upon the voice. In those days the pathology of nasal catarrh was quite in keeping with the meager knowledge extant as to the physiologic uses of the nose. The good old family physician then regarded nasal catarrh as being practically incurable and largely dependent on mal-condition of the stomach, or else a result of general poor health, and believed that the only treatment which would give promise of improvement or cure was vigorous internal medication of a powerful alterative and tonic character. Hence, as might be readily inferred, with such a faulty pathology, associated with such an imperfect idea as to the physiology of the nose, the treatment of nasal catarrh was so unsatisfactory that it became the opprobrium of the practice of medicine.

At last a change came in medicine as regards the nose, and its anatomy was more carefully studied. Advances were also made in the study of nasal physiology, and it was learned that the nasal fossæ were something more than simply two "blow holes" for convenience in respiration. Different investigators have independently made a careful study of the nose and, as their several results have in the main agreed, we now know approximately the form and character of a perfect nose, which, if even seldom met with, we should always keep in our mind's eye as an ideal standard. Our ideas of nasal physiology are also crystallized into a rational form.

In an ideal nose the two fossæ are identical in size. The septum is vertical and its walls nearly plane. It is not deformed by bony, cartilaginous or soft growths of exuberant tissue, rhinologically known as exostoses, enchondromata, etc. The turbinated bodies are of symmetrical shape, and in no case at any point should they touch the septum. Through the tortuous convolutions of these bodies the area of the nasal mucous membrane is materially increased. The inferior meatus should be clear and the inferior turbinal should never touch the floor of the nasal passage. The middle meatus should also be clear, meaning that

at no point should the inferior and middle turbinals touch each other. The superior meatus should likewise be free and there should be enough free space for the so-called superior turbinal, and even for a fourth turbinal if such anomaly be present. This upper portion of the nose may be called the nasal attic and its proper shape and condition is of more importance in the consideration of nasal catarrh than has been generally appreciated.

Finally, as a result of the combination of the requirements noted, we find that in an ideal nose no two adjacent or opposing surfaces should ever touch each other at any point or at any time. The amount of free space required about the turbinal varies with its location. The turbinals may be regarded as erectile structures, the inferior possessing the power of distention to a marked degree, and hence requires more free space about it than does the middle turbinal, the most erectile portions of which are the inferior surface and posterior end. By anterior rhinoscopy a normal inferior turbinal is found to have about it, when most shrunken, a space of not less than one-eighth to three-sixteenths of an inch, while the space between the septum and the middle turbinal is about one-sixteenth of an inch. Such free space about the turbinals is required in order that they may have sufficient room in which to swell. When owing to growths upon the septum or to a deflection thereof, or any other cause or causes, such space is not given, contact, even if not continuous, occurs periodically or whenever swelling of the turbinals takes place. In this way is explained the great susceptibility of many patients to frequent attacks of coryza and also why stoppage of the nose is so often complained of when the patient is in the recumbent posture, which position tends to increase turbinal congestion. Contact in one nostril generally means contact at some point in the other nostril, hence alternating stenosis is frequently noted. When the nasal spaces are materially increased in size beyond the normal it causes the disadvantages of atrophy and is even a greater defect than is stenosis. When the two nares are unequal in size, one being stenosed, the other is compelled to do the greater part of the work and may be so overworked that it can not properly fulfill its physiologic functions. While secreting only enough nasal fluid to properly humidify one-half of the air inspired, it is giving entrance to much more than half of the air required; hence this air is not sufficiently humidified and, as it enters in a larger column, it is likewise not so well warmed. Furthermore the increased volume of air entering tends to dry the mucous membrane to an abnormal degree and is therefore harmful.

Through the mobility of the *alæ nasi*, in combination with those slight growths upon the cartilaginous septum which are so frequently met with, a certain degree of anterior stenosis is as often observed, being usually more pronounced during inspiration than during expiration. Anterior nasal stenosis tends to produce posterior congestion, for, when present, the air in the postnasal space during respiration is alternately rarified and condensed, the same as though it were being operated on by an air-pump, hence a hyperemia is kept up, which in time may, result in posterior turbinal hypertrophies or posterior enlargements on the vomer. Varying air pressure in the postnasal space has long been recognized as being a frequent cause of Eustachian tubal congestion and catarrh. A stenosis of one nostril will frequently

cause a hyperemia of the other nostril, even though it be free from structural defect.

Connected with the nose by suitable openings are several accessory cavities, the perfect drainage of which is dependent on proper patency of the nasal meatuses and in fact of the entire nasal fossa. Physiologic research has established the fact that the most important function of the nose is to warm and humidify the air inspired. By being warmed the air is also slightly rarified. Of course it is additionally known that large particles of floating matter are caught by the hairs located near the external meatuses; that small particles of dust become attached to the mucous membrane through the tenacity of the nasal secretion and are in due time blown into the handkerchief; also that noxious vapors and gases cause sudden swelling of the turbinals, increase the flow of nasal secretion and often provoke protective sneezing.

In a healthy adult nose the quantity of the nasal secretion approximates one pint each twenty-four hours, being watery in character and of a specific gravity of about 1.015°. The quantity mentioned, one pint, is none too great to properly humidify the large quantity of air inspired. Taking for an average eighteen respirations per minute we have 1,080 per hour, 25,920 per day, 9,467,280 per year, and so on through life, and, as at each breath in the adult male there is taken into the lungs on an average one pint or twenty cubic inches of air, we have twelve and one-half cubic feet per hour, 300 cubic feet per day and 109,575 cubic feet per annum, or enough to fill a cistern sixty feet square and over thirty feet in depth.

In order that this vast quantity of air may easily pass through the nose and be properly prepared for the lungs, it is essential that the nasal fossæ be free and unobstructed by deformities. If the requirements as previously given are fulfilled, viz., there being in every case a sufficient space between opposing surfaces, and in no case two opposing surfaces touching each other, the entering air will freely pass through all parts of the nasal fossa, including the deep recesses of the meatuses, so that every part thereof will be thoroughly and perfectly ventilated and, as a result, the nasal secretion will be continuously evaporated so there will be no opportunity for it to thicken and become a catarrhal discharge.

In addition to the prevention of evaporation through contact of two opposing surfaces, drainage is likewise at the same time impaired. Growths upon the septum, even when no contact exists, by destroying the symmetry of the passage interfere with drainage, particularly when the patient is in a recumbent posture, and in this way cause, through the accumulation of secretions at such points, a thickening thereof, which in turn prevents the required evaporation.

A second result of the touching of parts in the nasal passages is the production of a condition of inflammation of the membrane which in time becomes chronic, and which changes the character of the secretion, rendering the evaporation thereof more difficult, and thus increasing the tendency to catarrhal decomposition and discharge.

Through the increased sensitiveness associated with such inflammation we often have an explanation for the manifestations of hay-fever, asthma, etc., which, regardless of any concomitant uric acid condition, are best relieved by such surgical steps as will insure perfect intranasal ventilation and drainage.

The excitation of cold, or of dust, or any other

irritating quality of the air being inspired, causes a swelling of the turbinals through a congestion of the capillaries of the same, which capillaries are larger than those in other parts. By being so congested the increased supply of blood gives increased heat and, furthermore, through the swelling the lumen of the passages is reduced in size, causing the air to pass through under great pressure and in a thinner column, so that it may be more thoroughly exposed to the heated turbinals. Simultaneously with the swelling of the turbinals, the nasal secretion becomes greater in quantity, so as to better humidify the air and attract the dust or cause its precipitation. Furthermore, evaporation of this secretion is more rapid, owing to the increased rapidity of the air current.

The ophthalmologist ever has in his mind the emmetropic eye, though such eyes are rarely to be met with. The refracting of abnormal eyes, and the surgical, or gymnastic correction by prisms, of muscle inequality or strain, are merely efforts to cause the defective eye to more nearly resemble the emmetropic standard. In the same way the duty of the rhinologist is, on the same principle, to cause the defective nose, as nearly as possible, to become patterned after the ideal standard, and in this way we have the key to the cure of nasal catarrh.

Chronic nasal catarrh is chiefly a structural disease and its cure generally consists in the removal of hypertrophied or pathologic tissue.

Meyer was one of the first to make a decided advance, and one of great import, when he published the result of his studies of adenoid hypertrophy, showing its causative effect in the production of both postnasal catarrh and trouble of the ears.

In a small percentage of cases, nasal catarrh is due to a catarrhal or empyemic condition of some one or other of the accessory cavities, though in my experience such conditions are invariably associated with other nasal defects wherein either some degree of hypertrophy impairs the ventilation and drainage of the fossa, or else a condition of atrophy is present, and therefore, in either event, presenting a structural change.

Atrophic degeneration, if not a sequela of the hypertrophic condition, is frequently found associated therewith, so often in fact that it would seem to be ample proof that atrophy is frequently a late stage of that which began as a hypertrophy. A frequent cause of atrophy is the presence of septum growths, against which unyielding points the opposing turbinal is caused to press each time it becomes distended until, after years of such restraint, its normal contractile elasticity is impaired and, through the irritation long kept up, hypertrophy follows, which in time is succeeded by pressure atrophy. Thus we see the result of nature's awkward effort to remedy the hypertrophy and stenosis. While nature is ever trying to correct defects, her aims should be anticipated and her footsteps guided, else she may go astray. As the condition of atrophy advances, the nostril gradually increases in caliber until it becomes abnormally large, and hence there is lost, to a corresponding degree, the physiologic property of moistening and warming the inspired air. Such secretions as are present, being too dense to evaporate, become incrustated and decomposed and frequently are instrumental in causing the breath to be offensive. In the treatment of atrophic rhinitis, while a return to normal structural form is seldom attained, the condition is greatly benefited by

following out the line of practice recommended in this paper, viz., the correction of all hypertrophic conditions existing so that all parts of the nasal fossa, meaning in this case particularly the attic, shall be thoroughly ventilated and drained.

Perforation of the nasal septum, even though the turbinals remain normal, produces the equivalent of atrophic rhinitis to the extent of the size of the perforation, and is an unfortunate structural deformity, which in the present state of the art is incurable.

It is not within the scope of this paper to attempt the consideration of the remote or primary causes of deformities of the bony or cartilaginous tissues of the nose. Some of the causes of hypertrophy of the soft tissues have already been touched upon, and among others may be mentioned recurrent attacks of coryza, induced by climatic changes generally, and particularly by those frequent and sudden changes from heat to cold and from dryness to humidity, so continuously made by going in and out of our modern overheated and too often poorly ventilated residences and public buildings. Additionally, dietetic irregularities, the wearing of cotton instead of woolen underwear, and many other customs of latter-day civilization may be cited as predisposing causes.

In this paper only the present condition of chronic nasal catarrh is being considered, coupled with nothing more specific than the general principles of treatment.

The correcting of nasal deformities is much like the remodeling of an old house. With a sufficient amount of patience and perseverance on the part of the patient, and of careful and systematic work on the part of the surgeon, results satisfactory to both will in a very large percentage of cases be obtained. It is far better that nasal defects be corrected early in life, and as soon as recognized, for in this way the kindly help of nature will be secured, and at a time before she, through misguided efforts to improve, has unfortunately done damage which will be difficult to remedy.

When the laity, as well as the rank and file of the profession, fully recognize the great import of nasal deformity, it will be quite as customary to have the rhinologist examine and correct the defects of the nose as it is now to make annual visits to the dentist in order that the teeth may be kept in perfect repair.

Conclusions:

1. That chronic nasal catarrh is chiefly a structural disease.
2. That impairment of ventilation and drainage of the nasal fossa are the most important causative elements.
3. That the touching of apposing surfaces is one of the most important pathologic factors.
4. That the line of treatment is largely surgical and the chief object aimed at is to cause the defective nose to conform, as nearly as possible, to the shape of the ideal standard.

Paracentesis of the Tympanic Membrane.—Prof. J. Gruber incises for a collection of pus or serous fluid in the tympanum as for any abscess, and recommends his incision as the best, for several reasons. He commences in the upper posterior square of the tympanic membrane and carries the incision forward around to and through the lower posterior square, following the arc of a circle, about 1 to 1.25 mm. from the edge of the auditory canal, with the convexity turned toward the rear.—*Wien. Klin. Rundschau*, October 17.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

XVIII.—DISEASES OF THE THROAT, CHEST AND ABDOMEN.

(Continued from page 1165.)

Foreign bodies in the esophagus were oftener pushed into the stomach than removed. If the first attempts failed a pause was allowed to ensue, during which antiphlogistic methods, means for allaying spasms and ememas were applied. The old folk's way of dealing a strong blow with the fist between the two shoulder-blades was also used by surgeons. For the removal of foreign bodies a curved hook made of strong wire sufficed (J. L. Petit), or a sponge for needles and (fish) bones. The sponge drawn with strong threads against the end of a tube was inserted in a dry condition, then water was injected through the tube, the tension of the threads relaxed a little so that the sponge expanded and then pulled against the sides of the tube so as to securely grasp the impediment. The old so-called stomach-brush was in use then (Heister). This, a soft brush fastened to a wire, was originally intended for freeing the stomach from mucus; it was moved upward and downward until no more mucus appeared. For propelling foreign substances downward, a whalebone to which a sponge was attached (J. L. Petit), and oil injections were used. Forcibly thrusting down the obstruction Lentin considered utterly inadmissible and recommended large pills of butter, dumplings and oil. An infinite number of forceps and ligatures were invented; Eckoldt constructed a whole instrumentarium of throat protectors, throat cages, throat sacks and throat buttons. That Habcot on account of great spasms of suffocation in connection with a foreign substance impacted in the esophagus was compelled to employ tracheotomy has been mentioned before. The last remedial agent that remained was the operation known as esophagotomy. First recommended by Verduc (1611), it seems then to have been used by Stenosen (Taranquet, Monnod). For the removal of a foreign body, Goursault (1738) made the first artificial opening of a man who had swallowed a bone by an incision into the most prominent part of the neck. Only once more during the past century was the operation of esophagotomy performed, by Roland for a similar purpose. Theoretically surgeons gave much time to it. Guattani in 1772 furnished the first complete description of it, designated the proper place for incising, made several operations on animals and saw that the wound healed easily. He advised an incision from the trachea to the sternum a little toward the left side, pulled the edges of the wound apart with dull hooks, then thrust his instrument into the interior on the left beside the trachea between the muscles, and so exposed the esophagus. If the foreign substance could be felt, the incision was made in that spot, otherwise the esophagus was carefully opened and with the aid of scissors on a hollow probe distended upward. In order to obtain a larger aperture and to prevent an injury to the nervus recurrens and the arteria thyroidea inferior, Eckoldt (1799) proposed an opening between the lower parts of the sterno-mastoid and thence to penetrate into the interior.

Foreign bodies that had made their way into the stomach and into the alimentary canal were often gotten rid of by making the patient swallow oily and mush-like foods and liquids. Schmucker in one case counted 120 needles, 150 nails, besides hairpins, pieces of glass, etc., which had been expelled through stools. If the offending body or bodies could not be pushed down and so pushed out of the system, an operation of gastrotomy had to be performed. It is known that one was successfully made on the peasant Grünheide of Koenigsberg. He had used the handle of a knife nineteen centimeters long to tickle the pharynx so as to cause vomiting, when he swallowed it. The members of the faculty examined him, after a prayer to God the patient was strapped on a board. The registrar of the faculty marked the place for the incision with a piece of charcoal, whereupon the surgeon, Daniel Schwabe, with a lithotome cut an opening of four fingers' breadth, and about a hand's breadth to the left of the umbilicus. After half an hour, fainting spells ensued and the patient was released from the board and then again bound to it. Attempts to draw forth the stomach with a pair of forceps in order to open it, failed. Then a thread was passed through it; by order of the registrar a hole was cut into it and Schwabe drew out the knife with the forceps. Five sutures were required, a bandage with warm balsam and recovery. The Leyden Museum still preserves the portrait of the peasant of Koenigsberg. The operation was performed in the past century by Hübner (in Rastenburg before 1720), and by Frisac (in Toulouse, 1786?), also on account of a knife in the stomach.

Much mystery surrounded the disease known as *goiter*. Formerly *struma* and *scrofula* were considered synonymous terms, and then also writers confounded goiter with scrofulous tumors of the neck. The physiologic import of the thyroid gland was unknown. According to Fodéré (1792), its principal function consisted in moistening the inner, ever dry surface of the larynx, due to the currents of air passing through it; hence it kept the windpipe moist by its own secretion. That author desired to have air and liquids injected into the gland through the air passages that communicated with the thyroid gland (Haller). Consequently the immediate cause of goiter remained doubtful. It was credited to melted snow water, the frequent enjoyment of chestnuts and similar foods (Gautier), and to water saturated with selenite; on the other hand Fodéré considered damp and warm air one of the main causes of goiter, and cretinism a disease closely allied to it. Others attributed its origin to carrying burdens on the head (Wichmann), while Richter, who discredited all these causes, believed it due mainly to the accumulation of mucous liquids in the thyroid gland and its neighboring tissues. Sometimes the swelling was restricted to a flap of the gland or also to the cellular tissue, while the gland itself retained its contracted condition (B. Bell). There was a kind of goiter known of which the distention was caused by air forcing its way in from the trachea, or resulted from the aneurysmatic enlargement of the arteries and veins (Gautier, 1794). Only with recently developed goiters and at the most up to the thirtieth year of life, could medicated treatment be successfully applied. It was considered essential that the patient retain the medicines in his mouth for some time before swallowing, so that they might be directly conveyed into the thyroid gland by

the absorbents of the mouth. The principal remedy was burned amber; besides this calcined egg shells, soap, sulphurated potash, extracts of digitalis, sea water, change of locality, and various other remedies were used. External treatment consisted of a continuous rubbing of the tumors with dry cloths, fomentation of cold water, spiritus mindereri, volatile salve, camphor, etc. Sympathetic remedies (rubbing with the hand or the leg of a dead person) still flourished in the first half of the century; even the royalty of France and England were supposed to have power to heal goiter. An operative interference was reserved for large old goiters. If the swelling was soft it was punctured (J. L. Petit) or split, the pus squeezed out and then, in order to prevent further accumulation of the same, the cellular tissue between the gland and the skin was destroyed (Fodéré). Based upon their experience that occasionally large goiters heal spontaneously through the suppuration, Heister, and afterward Klein, successfully drew a seton through the swelling. Morean advised the tying off the tumor. In case of aneurysmal goiter the carotid was tied above and below it. The use of ligature in goiter was suggested by Johann Muys in 1629, who said: "The veterinary surgeons cut off the artery which produces goiter and thus it is extirpated; and perhaps this method may be effectually used with mankind." Not until 200 years later was this ligature method attempted with goiter, at first unsuccessfully by Blizard, then by Ph. von Walther successfully in 1814. Regarding the complete extirpation of the same, the first attempts of the past century were not encouraging. Kaltschmidt in performing the operation, injured the carotid and his patient died before his eyes. Gooch tells us that a surgeon, who was generally very fearless, could not complete the operation on account of the violent bleeding, and consequently lost his patient after a week. In attempting a second extirpation the same surgeon could again not staunch the flow of blood, but saved his patient by applying a digital compress for a week. Then a few successful operations by A. F. Vogel (1771), Freitag (1778) and by Theden, became known; the subject of the one performed by the latter was nine inches wide, seven inches long and grown together with both carotids and the larynx. Desault was also successful in extirpating (1791) a small but firmly grown struma, and made it a rule to immediately tie the small vessels, for the present lay bare the art. thyroid., make punctures around it and then cut through it. In spite of the knowledge of successful attempts made, Heister would not hear of the operation, deeming it too difficult and the bleeding too extensive. He rejected it as soon as the swelling occupied the usual broad basis, when by means of the pressure of the goiter difficulty in breathing and deglutition and venous stagnation ensued, and then absolutely on cosmetic principles. Also B. Bell operated on only small swellings and contented himself by using the palliative method for the large ones, because the operation was too dangerous on account of the great flow of blood. The doubts expressed by the surgeons were exaggerated by the remarks of the physicians, as, for instance, Wichmann's: "The undertaking to extirpate goiter is just the same thing as if one undertook to cut off a patient's neck." J. L. Petit dared to remove a goiter weighing ten pounds; it was eight inches in width and intergrown with several of the large vessels; Forestier also (1791) suc-

cessfully removed several neck swellings, which seemed to be epidemic in Flanders.

In order to determine the extent of the penetration in *breast wounds* caused by a thrust the experiments with the vibrations of a flame, a feather, with an injection, and above all, with emphysema, were tried. If these did not disclose the true nature of the injury, the diagnosis was discontinued, as a penetrating wound without the immediate internal organs being impaired requires no other treatment than a non-penetrating one. A sounding of the breast wound was permitted only when the greatest care was exercised and this was done in the position in which the injury had been sustained; and a continuous probing to ascertain whether internal parts had been injured was decidedly rejected on account of its uselessness, the formation of new passages, and on account of inciting a new flow of blood. Desault, Richter and B. Bell raised serious objections and Foulmart opposed sounding in all cases. A penetrating wound without symptoms of internal injuries was bandaged quickly and simply with charpie. A plaster to prevent contact with the air seemed unnecessary, for, according to Richter, the air in the thoracic cavity, if capable of being exhaled and inhaled without difficulty, was not such an impediment in breathing as was generally imagined. If emphysema were employed at the same time, it would necessitate a distension of the wound. In treating wounds in the lungs it was especially important to avoid inflammation and suppuration or else to reduce them. These wounds Richter also bandaged quickly and superficially, rejected all kinds of plugging of the wounds, boldly bled his patients (Le Dran fifteen times, Schmucker for a whole week every six hours) and, up to the time of the prospective healing, prescribed cold compresses, cool air, the utmost quietness and, if connected with coughing spasms, opium and phisics. Heister, on the other hand, warmed the atmosphere by live coals on a tripod before applying the bandage. The lung that had fallen forward was immediately pushed back; only mortified portions were cut off or tied off. When the blood entered the pleura, for which occurrence Heister did not give a single definite symptom, it was drained as speedily as possible, during his time, or the operation paracentesis was performed. But as considerable quantities of blood might be absorbed (Ravaton), the advice was given to aim at resorption rather than draining the blood, whereby the internal hemorrhage is increased (Sharp). When, however, it smelled foul, thoracentesis was the better operation to resort to, and that without delay. G. Van Swieten highly recommended it. If the wound was in the lower part of the breast, the patient was laid on the side in question and was allowed to breathe deeply, or the blood was sucked out. For this purpose there were different kinds of syringes with three-cornered, round, perforated projections, special sucking apparatuses, as it were (Ludwig); there were also elastic catheters (Theden), and various other instruments. In France, wounds after duels healed so marvelously that the sacrament was refused to those who recovered, as they were so evidently the "devil's own." If the blood had already coagulated so that the discharge was stopped, repeated injections of warm water or non-stimulating liquids (barley water) were made with the greatest possible care. For arresting the flow of blood from the *arteria intercostalis*, numerous new methods appeared. Special ligature needles (Gerard, Goulard, Heuermann)

and a hook (B. Bell) were suggested, or the artery was compressed by means of dossils (Bilguer), cushions (Leber), or by a linen bag filled with charpie (Lassus); and sometimes the artery which had only been clipped was cut in two parts and then the ends were compressed (Theden), and various other methods were proposed.

The *opening of the thoracic cavity*, usually termed "the operation for empyema," which was so skilfully described by Hippocrates, was generally considered an easy, simple and safe operation, and was therefore warmly recommended (Heister, Morand, Lassus). Not only hemorrhages in breast wounds, also those after a fracture of the ribs and violent concussions of the lungs warranted the operation, as well as the collection of purulent matter. Yet there was no prospect of a complete cure, if the source of the suppuration was not found and drained. To make the operation dependent upon external intumescence, B. Bell rejected it and thought himself justified in so doing by the general symptoms observed. A third principal indication was hydrothorax. Great success in this operation of thoracentesis, which had so long been neglected, was observed by Morand, who was full of its praises. Unfortunately, the diagnosis was so uncertain that but few could make up their minds to use it. Fluctuation was considered as one of its surest symptoms. The patient as well as the surgeon felt it if they placed one hand on the ribs near the sternum and with the other struck the back; it could even be heard if the patient shook himself. Treccourt compared the sound to that of the water in a half-filled bottle when violently shaken. But also in doubtful cases the operation was permitted, if carefully performed. There was much wrangling over the place for the opening. At first the trocar was thrust into the thorax at the lowest spot between the second and third false ribs, about the breadth of the hand from the spine (Heister). This method was then done away with on account of possible injury to the diaphragm and the space between the sixth and seventh ribs, in a line with the shoulder, was pierced with a knife (Bromfield, Bell, Richter). Others did not confine themselves to a certain spot, but operated where it seemed most convenient (Warner), or first shifted the skin to prevent the air from entering (H. Bass). In order to avoid injury to the lungs and the intercostal artery, the intercostal muscles were gradually severed, the pleura having been bared before, and then the point of the knife was boldly thrust into the fluctuating spot. If the pus could be felt, the opening in the pleura was made rather small, as was always the case when only water was to be tapped. This was done very slowly, not all at once, and the wound was kept open by inserting a wick, a small silver tube (Heister) or a piece of tape (Richter). In empyema, injections of a decoction of cinchona were used (Hemmann). Whether the opening in the thoracic cavity ought to be done with the knife or the trocar, whether a tube should be inserted or not, were subjects of many disputes. Bell and Richter considered the tube superfluous in dropsy in the chest, and rejected the trocar because no one could know beforehand whether the lungs and the pleura had grown together. Heister, Morand and Camper, on the other hand, preferred the trocar, which, if thrust in obliquely, they believed, prevented the air from penetrating.

Abscesses in the lungs were fearlessly and successfully opened by B. Bell. If sure of the diagnosis, he

insisted upon the operation, no matter how deeply the abscess was situated in the lungs. He made an opening into the thoracic cavity, two to three inches in length, inserted his finger to find the abscess, and in two cases he had to thrust in his lancet into the substance of the lung to the depth of a finger before the pus came. Nearly half a pint of matter was drained and the patients saved. Richter believed that, unfortunately, the diagnosis, which is based on the seat of the pain and on the fluctuation, was safe enough to allow the opening of the abscess in rare cases only and that a prospective cure did not exist unless the abscess had formed accidentally and the strength of the patient was in good condition. And yet he approved of the operation even if the abscess in the lung had already burst open in the bronchi and the patient emitted pus and showed signs of consumption, an operative interference might be ventured upon in case the symptoms were less plain, as the abscess is often more correctly located during the operation. There was no doubt in Richter's mind that it occasionally averted tuberculosis. He already presented ideas of a *mechanical treatment of phthisis pulmonaris* which at the present time, is again being variously ventilated. He proceeded from the idea (de phthisi pulmonali operatione chirurgica sananda) that the difficulty in healing abscesses in the lungs was largely due to the continuous admission of the atmospheric air and the tedious discharge of the pus. Since in the usual horizontal position of the patient the matter did not readily drain and the abscess was always filled with the same, the general rule for abscesses should be followed in connection with the lungs; for instance, if there is difficulty in discharging the pus, a counter opening ought to be made. Therefore, besides the horizontal position, he advised emetics, inhalations, artificial issues, but principally a counter opening. Of course a recovery could only be expected if the phthisis pulmonaris was due to a local cause in a usually sound body. The difficulty was with the diagnosis regarding the seat of the abscess; and it seemed to him that the symptoms of an open abscess not alone indicated an operation but also those of a vomica. He is thought to have achieved good results with counter openings as shown by the following extract: "Of all consumptives the entire chest should be frequently examined and if the surgeon note anything to justify him in making an opening, he should do so without hesitation. This by no means increases the violence in the disease; but it might occasionally effect a cure if the patient has not become exasperated and the phthisis pulmonaris is the result of a benign local cause." Suppurations and extravasations into the anterior mediastinum required a trephining of the sternum, which then, in caries of the breast-bone, but not in reduced fractures, was warmly recommended by French and German surgeons. J. L. Petit had often trephined the sternum, in one case even three times, and cut out the costal cartilages. Larger pieces of carious ribs had been successfully cut off at the same time (Gooch, Acrel). A collection of air in the thoracic cavity indicated an opening of the same, but only if there was a simultaneous fracture of the ribs, seldom in penetrating breast wounds. The operation was also recommended by Bourdelin in extravasations of the chyle after wounds in the thoracic duct; but the observations thereto are missing.

The *paracentesis of the pericardium*, first proposed

by Riolan (1653), was at times considered life saving, at any rate harmless (Bell, Richter) in dropsy, the diagnosis of which was based upon fluctuation between the third and fifth ribs with every beat of the heart. A puncture was made between the fourth and fifth ribs with a small trocar (Senac) and the water allowed to flow off only after short intervals. Once Desault, Dubois and Sue could not agree whether heart failure gave rise to dropsy of the pleura or of the pericardium. Desault, for this purpose, opened the thoracic cavity between the sixth and seventh ribs opposite the apex of the heart, felt a fluctuating sac, which he incised and then he felt the heart like a conical body beating against his finger. The section proved the error, that the sac was not the pericardium, but it lay between it and the lungs and the heart stuck fast to the pericardium, which was filled with blood in various places. Successful attempts at paracentesis were not known in the preceding century.

For *paracentesis of the abdomen* in ascites such great enthusiasm was manifested that medicated treatment was pushed into the background. It was deemed most important to perform the operation as early as possible. Richter saw more harm done by medicaments than good and thought the operation an easy, quick and surely successful, painless and safe method. He was displeased that so often it was deferred until all sorts of urinary remedies and purgatives undermined the constitution and the abdomen was badly swollen. An operation should always be performed as soon as a fluctuation can be felt (Le Blanc, B. Bell). Even if regarded as a mitigating remedy, the puncture possessed many more virtues than the medicines; and, at times, effected a radical cure, when the serum had again accumulated, if not made too late, but is often and in close succession repeated. Desault punctured thirty-two times and that within a week, until no more relapses ensued; Mead and Schmucker made from fifty to seventy perforations and thereby preserved the patient's life for several years. According to A. Monro, the puncture was made in the spot where the fluctuation could be plainly discerned, to the left in the middle of a line drawn from the umbilicus to the spina ant. sup. The place of perforation, however, was variously chosen. The navel (Petit, Chopart, Desault), linea alba (Sharp), the lateral region of the abdominal cavity (Heister, Bell, Richter), the vagina (first recommended by Henckel, Watson), the rectum (Allan, Sabatier), the scrotum with simultaneous congenital hydrocele (Le Dran). The common trocar retained the preference given to it and instruments which were modifications of it (flat, double-edged point according to Bell), as well as the suggestions to first puncture with the lancet and to insert into this a trocar with a dull point (Cline), or to employ the lancet alone. All alleged improvements of the trocar Richter considered poor, also the injections (diluted red wine according to Hale's, lime water according to Martin's idea) recommended to be used after the puncture in order to prevent the serum from again collecting, these good physicians disregarded. The fear of a rapid and total evacuation of the fluid was looked upon as unfounded, if from the beginning of the operation the abdomen was uniformly compressed and afterward a pressure by means of a bandage or napkin was brought to bear upon it (Cheselden, Mead, Fothergill). There to Monro invented a particular kind of "compression belt." Hunter and

Cline had the misfortune to injure the arteria epigastica. Operative interference by puncture was also recommended in tympanites of the abdomen (Combalusier 1747, B. Bell).

Whenever in a penetrating abdominal wound, the finger could be inserted, sounding was not resorted to. The wound was immediately closed up by plaster strips, or the suture, so as to avoid any contact with the air, and the patient was freely bled. A piece of sound intestine that had fallen forward was at once put back and the wound was distended if necessary. For this purpose many useless, complicated instruments had been invented (le Dran, Morand, Petit). In establishing the abdominal suture, as much of the peritoneum was caught as of the skin and muscles; the thread was begun an inch from the margin and the lower corner of the wound was left open; B. Bell, however, sewed up the whole wound. In case of extravasations in the abdominal cavity, which were mostly found in clots and never spread over the entire cavity, a portion of the wound was allowed to remain unstitched and cold applications were made to distribute the blood. But if, besides the irritating conditions, there was a fluctuation felt and there was

discharge of urine, bile and excrement, a puncture with the trocar was required as soon as possible. Three different methods were pursued in the treatment of intestinal wounds, the portion that had fallen forward was stitched, an artificial anus was formed, or everything was left to nature. She could not directly close the wound, but effect an adhesion of the surrounding parts, thus covering up the wound. In stitching the intestinal suture, the wounded part had to be fastened with a thread close behind the abdominal wound, so that the contents were discharged toward the outside and not toward the inside. The sutura ansata with one thread (several according to B. Bell) was preferred to the Kürschner suture and to the many other new inventions. The method of Ramdohr, a surgeon in the mountains of Zellerfeld, who inserted the upper end of the intestine into the lower and by means of the suture secured it close to the abdominal wound (made known by Möbius in 1730) was greatly favored. Antiphlogistics and daily enemias were prescribed for a few days until the removal of the stitches. Nature, it is true, worked amazingly in many cases, although occasionally an anus præternaturalis, always a contraction, remained.

SOCIETY PROCEEDINGS.

The Berlin Lepra Congress.

General Report of the Berlin Lepra Conference.

OBSERVATIONS ON CONTAGIOUSNESS OF LEPROSY.

Prof. K. DEHIO of Dorpat said: Hansen and Looft already contend that the maculo-anesthetic form of leprosy is less dangerous as to contagiousness than the tuberculous form, and my own experience in Livonia compels me to agree with them. My disciple Lohk has quoted in the parishes of Kielkond and Ansküle, on the island of Oesel (c. f. r. Compare Lohk, epidemiologic researches on leprosy and the etiologic relations of its forms, *Arch. of Dermat. and Syph.*, 1897), forty-eight cases of lepra tuberosa, eleven cases of lepra anæsthetica and two cases of lepra mixta. Among the forty-eight tuberculous cases there are thirty-six, that is, 75 per cent., which in all probability have caused further disease and consequently had contagious effects. Among the thirteen cases of lepra anæsthetica and lepra mixta, on the other hand, there is not a single one which allows even the suspicion that it has caused further

disease. This fact is the more important as Lohk, at the time of his researches, was quite unaware of the innocence of lepra anæsthetica, and believed it to be as dangerous as lepra tuberosa. There can therefore be no question of a positive presentation of facts. The popular opinion which develops and establishes itself in the course of the centuries, and which in regard to the causes of disease, so often hits the mark, is also on my side. In Oesel at least, where leprosy belongs to the diseases well known to the people, the peasant considers lepra anæsthetica as not being contagious at all. While the tuberculous leprosy patient is shunned by the whole world, the anæsthetic leper is feared little or not at all. There are many even among the common people who believe that lepra maculo-anæsthetica is a disease *sui generis* and has nothing in common with the tubercular leprosy. I personally know only three or four cases where leprosy is possibly, or at least might be, attributed to the intercourse with anæsthetic lepers, while I know by the dozens, evident contamination through tuberculous lepers.

My opinion therefore is: Lepra tuberosa is a contagious disease; but lepra maculo-anæsthetica, though caused by the lepra bacillus and the lepra virus, is in itself contagious only in a small measure or only temporarily.

The massed appearance of the lepra bacillus in tubercular leprosy and, on the other hand, the difficulty in finding the bacilli in the maculous and anæsthetic form, is perfectly in accord with my opinion.

If I am right, this might be of great practical importance. As we do not so far possess any cure for leprosy, the only possibility for combating it lies in strict isolation within the leproseries, so that the diseased may be prevented to transmit the evil to other men. But if lepra anæsthetica is not contagious, or very little, we may perhaps show some mildness in the treatment of the latter.

By this means the combat against leprosy would become much cheaper, but would also for many of these people lose its terror and assume a more humane appearance.

Dr. HELLAT of St. Petersburg said: In the question of optional or obligatory isolation, the social conditions and popular ideas of every country must be considered. To shoot sparrows with heavy ordnance is not practicable. If in a country the people are enlightened enough to understand the danger of free intercourse with lepers, or if it goes so far as to be convinced of it, then optional isolation might expect sure, perhaps even full success. But if, as happens with us, the written word does not exist for the people (they do not read the newspapers), where fraternization and genuine communism are in so high degree at home, and where at the same time religious habits overrule every other inclination (on Easter morning everybody in Russia kisses the other on the lips, even the Emperor, with the words, *Christos Voskies*, Christ is risen), optional isolation would be only a half measure and perhaps a totally futile one. Here only compulsory isolation can be relied upon.

First International Congress of Neurology, Psychiatry, Medical Electricity and Hypnology.

This congress met at Brussels in September with a large attendance including many names well known in this connection. The increasing importance of cerebral surgery as the physiology of the cortex becomes better known was emphasized: also the satisfactory results obtained by surgical intervention in epilepsy when the lesion is clearly defined and can be completely removed. Numerous communications were presented on the subject of electrotherapeutics, and the necessity mentioned of the establishment of standards for the reaction, and the characteristics of excitation. Professor d'Arsonval's "high frequency" current was recommended by several, and its beneficial effect in obesity, etc., reported, but Regnier denied its superiority to franklinization in diabetes and neurasthenia (*Vide JOURNAL* page 762). The question of criminal suggestion elicited contradictory discussion, as the Nancy school believe that the hypnotic subject is irresponsible and can be made to commit any crime by suggestion, while Milne-Bramwell denies this and states that the conscience or sense of propriety is still alert and will prevent the execution of any act in the hypnotic state, which the subject would not commit in his normal condition. Liegeois (Nancy) asserted that in every person in a condition of induced somnambulism, an actual automatism can be produced by verbal suggestion, even to the extent of committing murder or other crimes, while perfectly unconscious. A woman or girl can be violated without knowing it. The author of the suggestion is the only criminal and the only one to be punished. He adds that there is a remedy for this state of affairs: Every man, woman and child should

be tested by some reliable, competent person to discover his or her degree of susceptibility to hypnotic influence. If profound somnambulism can be induced, then the suggestion must be impressed that he or she can not be hypnotized by any one nor by any means in future. The subject is thus morally vaccinated, as it were. Milne-Bramwell does not consider the crimes suggested in the laboratory any test as to the actual commission of crimes outside, as he believes the subjects have always a realizing sense of the pretended character of the acts and advises questioning them more frequently. In regard to the therapeutic value of hypnotism and suggestion, he asserted that it varies with the duration and gravity of the disease and the mental instability of the subject. He reported good results in moral insanity, alcoholism, morphinomania, cocaineism, hysteria, hiccough, hysterical trembling, neurasthenia, insomnia, migraine, chorea, obsessions, incontinence of urine, facial neuralgia, amenorrhœa, dysmenorrhœa, menorrhœgia, deafness, seasickness, acute and chronic rheumatism, constipation, hyperhidrosis and eczema. He traced the history of hypnotism, showing the influence of Braid in its evolution and called attention to his thirty-six works, which should not be overlooked by the student of this science. He also endorsed Delbœuf's theory in regard to the secondary or subliminal conscience in hypnosis, which is able to modify the organs and functions not under the control of the will, and is analogous to that of the lower animals. In spite of the insufficiency of this explanation, the conception of hypnosis which it implies is more correct than the assumption of the automatism of the subject. He added that the death of Professor Delbœuf is deplored by all the workers in the field of hypnotism. Few since Braid have had such a clear conception of the mental and moral condition of the subject, or have done so much to unmask the deceptive appearances of laboratory crimes and experiences. His explanation of the possible origin of the curative effects of hypnotism, in organic lesions, constitutes a scientific and original advance full of promise for future research. We add a summary of Bernheim's views presented at the Moscow Congress, for comparison, as he is one of the leaders of the Nancy school:

Suggestibility is a physiologic property of the human brain; the tendency of the brain to realize all the ideas accepted by it. Every idea accepted is a suggestion. Hypnotism is not a special state: it is the setting into activity of suggestibility, with or without sleep. Suggestion can make some persons commit crimes, either by instinctive impulsion, by hallucination or by perversion of their moral sense. Suggestion can not destroy a robust moral sense nor create it when it is absent: it develops existing germs of good or evil. Suggestion, that is, the idea wherever it may come from, plays a part in almost all crimes. Congenital weakness of the moral sense, and great suggestibility facilitate criminal suggestion. A wrong or criminal deed may be committed in a somnambulistic condition of hetero- or auto-suggestive origin. False testimony may be presented in good faith from fictitious souvenirs evolved by auto-suggestion. There is no such thing as absolutely free will. It is impossible to appreciate the moral responsibility in most cases. Society has only the right of defense and prophylaxis. Education should intervene and neutralize vicious germs and oppose coercive suggestions to natural impulses. A new psychotherapeutic treatment was described by Aimé of Nancy, which consists in strengthening the therapeutic idea by representing it in action to the patient. The idea, incarnated by voice, gesture and action, stimulates the psychic cells and through them the nerve elements, and the contagion of example and limitation starts the therapeutic action and enables the patient to throw off the opposing ideas accumulated in his brain. This psychic dynamogenics has been found especially valuable in neurasthenia of the aboulomania type, in psychopathy with deficient ideation, and in ideomotor dynamic troubles of traumatic or emotive origin, many of which resist hypnotic suggestion and all other treatment.

The broad scale on which the Congress was planned has been much commended. Among the other speakers were Eulenburg of Berlin, on "Exophthalmic Goiter," which he considers still belongs to the domain of internal medicines, and is caused by a qualitative and toxic alteration of the fluid secreted by the glands; Mendelssohn, St. Petersburg, "Pathogenesis of Reflexes"; Van Gehuchten, "Muscular Rigidity in Nervous Affections," and Sancte de Sanctis, Rome, "Psychoses and Dreams." Professor Thomsen of Bonn, called attention to the long duration of the incipient stages of general paralysis and the value of the prodromal symptoms for its early recognition and differentiation from cerebral syphilis and neurasthenia (Argyll-Robinson's and Westphal's signs, flitting opthalmoplegia, disturbances in articulation, atrophy of the optic nerve, paralytic or aphasic attacks, etc.). The next Congress will be held at Paris in 1900.

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Continued from page 1169.)

FROM SEWAGE TO DRINKING WATER—A STUDY OF THE NATURAL PROCESSES OF SEWAGE PURIFICATION AND OF THE MEANS WHEREBY THEIR EFFICIENCY CAN BE INCREASED,

by Col. GEO. E. WARING, Jr., M. Inst., Commissioner of the Department of Street Cleaning of the City of New York.

He said: Where circumstances permit the discharge of sewage into the sea or the strong current of a great river not used as a source of domestic supply, is usually the simplest and least expensive method of disposal. The great majority of inland towns remote from streams, are confronted with a problem daily growing more urgent and complex. General introduction of water-supplies, then the overlavish use of that water, have made necessary a sewerage system to remove the foul floods. By furnishing the proper conditions the sewage of the largest city can be freed from impurities and the water can be passed on as pure as when first received. This is the exposure of the sewage to the reducing action of bacteria for a certain time. Our chief efforts must be directed to the furnishing of oxygen to each particle of sewage at all stages of the operation. If oxygen be absent or insufficient, disintegration begins by the germs of putrefaction, which break up the organic structure, but which allow the nascent elements to recombine in offensive compounds. The disgusting changes in sewage stored are the result of putrefaction consequent upon imperfect aeration. We secure the aeration by spreading the sewage in a thin layer upon a tract of land so that every drop is exposed. The land must be well drained to allow the escape of water and the liquid must be applied intermittently. Usually the period of rest and aeration must be twice as long as the period of use. One acre of ground will purify the waste of 500 to 1,500 people. When sufficient land can not be had, recourse is made to intermittent downward filtration. Its principal essential is a porous soil. The work is carried on both above and below the surface. Thus we can pass the liquid at a higher rate of speed. One acre of well-constructed filtration-beds will care for the sewage of 1,500 to 5,000 people. The writer in 1894 tested the theory at Newport, R. I., as to forcing air through the filters. Tanks filled with broken stone and gravel aerated by an air-blast from a blower at the bottom was built. Sewage containing the normal impurities of fresh domestic wastes, and the putrid overflow of old cesspools escaped within four hours of its entrance, odorless, tasteless, colorless and sparkling. Chemic analysis showed it better even than the city supply. The impurities which had been removed were not stored in tanks, for they too remained sweet and clean, without any change of filtering material during the whole five months of the experiment, and when taken apart showed no sign of organic material: the gravel was as clean as the day the filter was built. All the filth had been consumed and resolved into atmospheric nitrogen, water, carbonic acid and nitrates. The limit of capacity was never reached. A rate of application was attained showing that one acre of artificially aerated filters would purify the sewage of over 50,000 people. This plant was removed and set up to treat the waters of the West River much polluted by waste from a large woolen mill: it worked admirably. Last February he took charge of Willow Grove Park, Philadelphia. Soon after its opening as a pleasure ground it was found necessary to arrange for the disposal of the sewage. Lavatories and toilet-rooms were scattered over the grounds, a large restaurant added to the waste, dairies and ice cream pavilions added their waste, with the sewage from the car bar, etc. The liquid is stronger than the average of town sewage: total 80,000 to 100,000 gallons daily. The only water course near was a small stream feeding a lake and a lily pond. Its maximum dry weather flow was through a five inch pipe: at times its bed is dry. Thence it enters another pleasure park forming a pond for boating and fishing. The only land available was a mile away, higher than the park, involving the laying of a long force main and constant heavy pumping. The soil is stiff heavy clay, not well suited for irrigation, and absolutely unfit for downward filtration. The latter process would have involved the construction of an acre of filter beds with material from a distance. Filtration with forced aeration was adopted, requiring one-eighth of this area. It was impossible to deliver the sewage by gravity. The flow is collected in a receiving well of 12,000 gallons. The essential feature of this well is a series of screens to withhold rags, paper, corks, etc. Two screens are used, the outer coarser, of five-eighths inch vertical iron rods with half inch openings between them, permanently fixed across the entrance to a masonry chamber surrounding the suction-

pipe through which the well is emptied. The second screen is a frame of galvanized flat iron, diagonally braced and covered with iron netting of one-quarter inch. This slides into channel iron grooves built in the masonry a few inches behind the first screen. A second pair of grooves is provided close to the first so that another fine screen can be lowered whenever one needs removing. One of these will pass sewage without clogging, for six or eight weeks. From this well the sewage is pumped to a distributing tank and led by gravity to the filters. The valve is adjusted so that under normal conditions the sewage will accumulate in the tank during the day to escape at night when the sewage is slight. Thus a more or less constant flow is maintained. The process of purification comprises the mechanical removal of suspended solids by deposition and their subsequent destruction by bacterial action; then the dissolved impurities remaining in the clarified liquid are attacked and purification is complete. The first operation is performed by filters which we call strainers; shallow rectangular tanks with concrete floors covering each an area of 675 square feet. Floors are covered with a system of channels made up of hollow Raritan tile laid loosely with open joints which collect water and distribute air. An opening in each tank at the floor level controlled by a valve communicates with a chamber which is constantly full of air under light pressure applied by a blower. While a filter is in operation, this opening is closed by shutting a valve. Each strainer is divided into two compartments built not from the floor of the tank but upon the tile so that liquid and air can pass freely from one to the other. The false flooring is covered with a thin layer of large broken stones to protect the joints against the entrance of finer material and each compartment is filled to 30 inches with broken stone of one-half to one inch in diameter. The sewage enters the upper compartment, passes through the filtering material under the diaphragm wall, and rises in the lower compartment, overflowing into a collecting channel. The movement is slow so that all suspended matters are deposited upon the filter within three inches of the surface of the stone of the compartment. The action is purely mechanical. Gradually the deposits interfere with the freedom of the flow and the sewage begins to back up in the receiving compartment, the increased head counterbalancing the increased resistance. This condition is accompanied by no deterioration of the quality of the effluent. The clarification is usually a little better at this stage than when the filter is clean, for the accumulation of sludge on the surface of the receiving compartment acts as a finer filter, and prevents the passage of even the most minute particles. The resistance becomes so great that the sewage threatens to overflow the walls of the receiving compartment. The flow is then turned into another strainer and the decomposition begins anew. Now the valve in the bottom of the strainer is opened, the liquid contents drain away, passing back to the receiving well for further treatment. The amount returned to this well is considerable, for the filters are drained but seldom and the quantity at each is small. As soon as the liquid of the tank has escaped, air from the blowers enters the unsealed opening, rushes through the distributing channels which cover the floor and, escaping through the joints, rises in the filtering material, supplying to every part of the mass the oxygen needed for bacterial activity. Oxidation begins immediately. Each particle of filth is attacked by the reducing organisms, consumed and resolved into gases or soluble mineral compounds. As the supply of oxygen is abundant and constant, the bacteria multiply, and long before the next period of use the entire accumulation of filth disappears, leaving the filter clean and able to pass sewage as freely as when new. This alternate choking and cleansing proceeds indefinitely. With proper care, especially in the exclusion of silt, the work will be uniformly good and no renewal of the filter be needed. There are three of these strainers, any two in alternation are sufficient. As the sewage leaves the strainers, it is free from suspended matters, has a slight opalescent cloudiness and a perceptible odor of urine. It still contains all the dissolved impurities of the sewage. These are removed by passing it through a second filter called the aerator. Here, filtration and aeration are carried on constantly and simultaneously and the whole area is normally in constant use. The floor of the aerator is covered with a series of channels to collect and remove the purified water and distribute the air from the blower. These channels are covered with a thin layer of coarse broken stone which supports the next and main layer of three feet of crushed coke, from which all dust has been removed. Over the coke is placed a six inch layer of coarse broken stone packed with finer stone at the top, the whole covered with six inches of coarse sand lightly compacted with a broad wooden rammer. This retards and distributes the flow. The liquid passes slowly, trickles down in thin films over

the particles of filtering material, escaping through a trapped outlet at the bottom. It is in constant contact with a current of air from blower, rising through the valves, passing through the vent tiles which perforate the blanket of sand in each of the four divisions of the aerator area. The time required for the percolation is one hour. The bacteria are stimulated to their maximum activity by the abundant supply of air and are ransacking each drop for food. Before the water reaches the bottom, the dissolved organic impurities are destroyed and the only trace of its recent foulness is a high percentage of nitrates. The regeneration is complete. At the Park named, the supply of water is abundant, the purified sewage is collected as it leaves the aerators and drained to an effluent soil, connected by a pipe with one of the smaller lakes. Here the water is stored for use and pumped to an elevated tank, thence piped to sprinkle roads, flush closets, urinals, etc. It is clean and wholesome and, save for sentimental reasons, might be used in the lavatories, the restaurant and the drinking fountains. In all processes of bacterial oxidation, the maximum of efficiency is reached only after a certain period of use. The organisms must be given time to multiply and spread. The daily attendance at this grove varies from 100 to 30,000 daily. A similar but smaller plant has been constructed at Homewood, South Brooklyn, L. I., for the City and Suburban Homes Co. of New York to purify the sewage of one hundred houses and which for years will have no other outlet. The process of bacterial oxidation in these filters is identical in theory with that of irrigation. Only in the former, artificial aeration supplies to the entire mass the conditions which in irrigation are confined to the surface alone. In other words, the introduction of air under pressure makes it possible to concentrate in cubical form, in a single tank, the effective area of a whole acre of irrigation field.

The operation of the system is simple and any intelligent laborer can easily learn to control it. It consists mainly in judicious distribution of sewage and air and the occasional raking over of the filter bed. One man can care for a large plant. Where sewage can flow to the filters by gravity, the wages of the attendant and the cost of running the fan are the only expenses. The filters once built and filled are practically indestructible.

"Investigation of Water Supply by the U. S. Geographical Survey," was presented by F. H. NEWELL, hydrographer, U. S. G. S., Washington, D. C. He outlined the work of the U. S. Geographical Survey in making a thorough examination of the geologic structure, mineral resources and products of the national domain. . . . The Division of Hydrography was created in 1888. From that date the work has gradually extended and now embraces practically three classes of work. The first consists of the measurement of streams in various parts of the country and the determination of surface supplies in lakes and rivers. This necessitates operations carried on through several years and at widely separate points. It includes the examination of reservoir sites, especially upon the public lands and the feasibility of using these for increasing the water supply. . . . The second class of investigations is purely geologic. It consists in examination of underground waters and artesian well conditions. Operations are mostly confined to the western half of the United States, where the deep-seated sources of supply of pure water have the greatest value. The third class consists in preparing reports upon the best methods of utilizing the water resources and these include a wide variety of subjects, as storage, pumping, irrigation, filtration, etc.

The papers on "Tuberculosis" were thoroughly discussed. Dr. L. F. FLICK of Philadelphia said: To stamp out the disease we must remove people from the presence of the contagion. Hospitals for consumptives are imperatively demanded. This would soon reduce the death rate, as we see everywhere when people are removed from the constant exposure to the emanations of those afflicted. He believed that often there was in butter and milk a microscopic organism resembling the bacillus tuberculosis but not identical with it, and which many examiners took for that bacillus.

Miss LYDIA RABINOWITSCH of the Woman's Medical College detailed experiments made by her with butter and milk. In milk she found from 20 to 30 per cent. of these bacilli. In eighteen samples of butter she had not found one bacillus, but had found a micro organism which resembled it.

Dr. H. M. BRACKEN, secretary of the State Board of Health of Minnesota, read a paper on

TYPHOID INFECTION.

Over 1,800 examinations of blood after the Widal-Johnston method have been made at the laboratory of the Minnesota Board of Health during the past ten months, and while the serum diag-

nosis quite uniformly has been borne out by the clinical diagnosis there have been cases where the blood gave marked reaction with the first of typhoid fever symptoms, but where the clinical symptoms quickly disappeared and there was a prompt return to health. There have been cases where the serum reaction has persisted for a time after recovery and such cases are stumbling blocks to the physician. How can we explain these facts? May I suggest the possibility of typhoid infection without the classical typhoid fever? Certain individuals have a natural immunity to the disease. Others have acquired it, the result of disease in the past. Still others become immune in a manner quite similar to that by which we produce artificial immunity, namely, by constant exposure to an infection, too small in quantity, however, to produce the specific disease. Those individuals who are constantly using water with the germs of typhoid fever may escape, while the newcomer soon succumbs. Still further, we know individuals constantly using contaminated water may at one time be able to resist infection, and at a later period become infected though using the contaminated water in the same quantity and manner in both cases. In the light of the foregoing facts may it not be possible for an individual to receive such a degree of infection as will produce the early symptoms of the disease and for the system to develop an antitoxin so promptly and in such an amount as to cut short the procession of the disease? Thus to prevent the completion of the classic typhoid fever, it would seem that an unusually marked reaction to the serum test with the early appearance of such symptoms and the prompt subsidence of all followed by health would bear out such a proposition. It would seem, with an early and marked Widal reaction, as though the conditions of the blood producing such reaction might have some bearing on the degree of resistance of an individual to infection and this would suggest the possibility of the reaction being one of immunity rather than of infection. This I know is contrary to the teachings of Widal and others, but it is safe to say that the consensus of opinion is yet unsettled as to the relations of serum reaction to immunity. . . . The serum reaction as a rule appears earlier with younger than with older cases; half of the second and third positives being among children, though they numbered only one-seventh of the total positive reactions. . . . If it is true that serum reaction obtains earlier with children, that reaction is marked and the mortality is lower it would seem as though this had some bearing on making the reaction as one of immunity rather than of infection. Quite a number of cases of adults on record show marked serum reaction early and was followed by a rapid subsidence of the typhoid symptoms.

"Hydrants; Closed Fountains," was presented by Dr. EMILIO ZERTUCHE, delegate from the State of Pueblo, Mexico. He exhibited a hydrant which he believed was the proper form to use, closing off the water completely.

(To be continued.)

PRACTICAL NOTES.

The Neglect of Revaccination.—Jasiewicz (*Jour. de Clin. et de Thérap. Infant.*) recommends more frequent revaccinations and cites the case of twenty-three children under 6 years of age where the successes were seven in number, or 35 per cent. He believes that it protects from other infectious diseases as well as variola.

Placenta Previa Centralis.—A typical case is described by Von Weissen in the *Cbl. f. Gyn.*, No. 22, in which the placenta was attached to a large proportion of the cervical wall, the cervix mucosa forming a part of the decidua serotina. After extraction of a dead child delivery of the placenta was extremely difficult, owing to adhesions. Death followed four days later from sepsis. — *Wien. Klin. Woch.*, July 29.

Auto-intoxication as a Predisposing Cause of Infection.—Poehl (*Wien. Med. Woch.*) gives as the main causes of auto-intoxication: Diminished alkalinity of the blood due to acidity of the tissues from overexertion or other causes; insufficient supply of oxygen; abnormal fermentation processes in the intestine; poisoning from without by bacterial or other agencies; retention of metabolic processes. Many of these conditions, he says, can be detected by an examination of the urine, and in support of his views relies upon elementary proportions. He

holds that the resisting power of the organism depends very largely upon the manner in which its internal or tissue respiration is carried on and avers that he has never examined a case of infectious disease in which this has been normal.

Mycosis of the Pharynx.—Castex removes with Duplay's forceps the small tenacious white patches as they develop, after the patient has gargled with a hot 1 per cent. aqueous solution of resorcin. Ten sittings will complete the cure in obstinate cases. The most diverse micro-organisms were found in some cases, and none in others. The etiology is very obscure. It seems to affect debilitated persons with previous throat inflammations, most frequently women between 15 and 30 years of age. — *Journ. de Méd. et de Chir.*, 68th year, No. 20.

Early Symptoms of Puerperal Infection.—Slight elevations of the temperature (37 to 38.2 degrees, axilla), usually once a day, sometimes more frequently, separated by intervals of lower temperature; the pulse more rapid, even when the temperature is not elevated, 80 and above. The sleep at night is also an important indication, as good sleep denotes a more favorable prognosis, while insomnia in connection with higher temperature and more rapid pulse, with a sensation of chilliness in the back, trunk or limbs, and a change in the lochia, as decrease, suppression, fetidity, indicate approaching infection. — *Gazz. d. Osp. e d. Clin.* of October 21.

The Danger Point in Anesthesia.—As anesthesia progresses, the corneal reflex is abolished and the pupil contracts to a point. The moment the pupil reaches this point, the anesthesia is profound and the chloroform should be suspended. If the pupil begins to dilate again slowly and gradually, more chloroform will reduce it again to a point. But if it suddenly dilates rapidly, this is a signal of impending immediate collapse, and every effort should be made to facilitate respiration. Gradual dilation of the pupil from the punctiform state is the natural arousing from the anesthesia, but brusque, rapid dilation to its maximum is the danger signal. — *Journ. de Méd. et de Chir.*, October 25.

Ichthyol-glycerin Tampons in Chronic Vaginal Gonorrhoea.—Certainty and cure can be attained in the puzzling cases in which the absence of the gonococci and the persistence of the trouble lead us to doubt our diagnosis, by tamponing the upper portion of the vagina with 10 per cent. ichthyol-glycerin, preferably just before or after a menstrual period. The mechanical irritation of the tampon, the softening effect of the glycerin and the influence of the ichthyol, cause such an increased secretion that the cocci are dislodged in the depths and brought to the surface and the epithelium peeled off. A dry tampon is inserted, with iodoform later, and the vagina is then ready for the argentum nitricum. Bodenstein explains the advantages of this tamponing in the *Deut. Med. Woch.* of October 14, as he has used it in fifty cases with the best results and no inconveniences. He recommends, in the preliminary irrigation, to allow air to pass through the tube before the liquid begins to flow, which will distend the vagina and smooth out the folds.

The Morphin Habit as a Legal Defense.—A kleptomaniac in one of the British courts plead guilty and her counsel assured the bench that she was in no want of money, but had sufficient means to enable her to live comfortably, and asked that she be treated leniently on the ground that the theft was due to the effects of the excessive use of morphin. According to the testimony, she had consumed ninety-six grains of morphin in a single week. The magistrate suspended judgment, upon the defendant giving security in £50 to appear for sentence when required. De Quincey's daily consumption of laudanum was nine ounces and there is a case on record where 120 grains of opium were taken at once without producing death. The tolerance of opium and its salts proves in reality much more than old women's fables, and instances of enormous doses are in the possession of nearly every family practitioner. A poisonous draught of laudanum can not be measured by cases on record.

No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, DECEMBER 11, 1897.

THE PRESIDENT'S MESSAGE.

The President in his message gives the following statement based upon report of the Secretary of the Treasury:

The recent prevalence of yellow fever in a number of cities and towns throughout the South has resulted in much disturbance of commerce and demonstrated the necessity of such amendments to our quarantine laws as will make the regulations of the National quarantine authorities paramount. The Secretary of the Treasury in the portion of his report relating to the operation of the Marine-Hospital Service calls attention to the defects in the present quarantine laws and recommends amendments thereto which will give the Treasury Department the requisite authority to prevent the invasion of epidemic diseases from foreign countries, and in times of emergency like that of the past summer will add to the efficiency of the sanitary measures for the protection of the people and at the same time prevent unnecessary restriction of commerce. I concur in his recommendation.

In further effort to prevent the invasion of the United States by yellow fever the importance of the discovery of the exact cause of the disease, which up to the present time has been undetermined, is obvious, and to this end a systematic bacteriologic investigation should be made. I therefore recommend that Congress authorize the appointment of a commission by the President to consist of four expert bacteriologists, one to be selected from the medical officers of the Marine-Hospital Service, one to be appointed from civil life, one to be detailed from the medical officers of the army, and one from the medical officers of the navy.

In the natural order of things under the present system, the bureau is the custodian of all papers and documents relating to any matter under consideration.

There seems to be no question but that something is necessary to perfect the health service, whether it should take the shape of increasing the powers of the Treasury Department, or whether to create an independent bureau, utilizing the existing machinery and having at the head of the new department a professional man, is for Congress to determine. Theoretically the chief of the Marine-Hospital Bureau is supervised by the Secretary of the Treasury; practi-

cally he is under no supervision at all, as the Secretary of the Treasury does not know the technique of the question at issue. There is nothing in the message incompatible with the recommendation of the AMERICAN MEDICAL ASSOCIATION, and even if there were incompatibilities it is Congress that enacts the laws. The report of the Secretary of the Treasury shows the number of sailors treated during the year, the cost of conducting this branch of the department, and gives the total number of deaths by the yellow fever epidemic.

The placing of this excellent service in a new Department of Health whereby orders would be received from a medical man acting in part for a council representing the whole country, would be of infinite benefit and would insure the necessary co-operation in case of epidemic. The AMERICAN MEDICAL ASSOCIATION Bill provides for semi-annual consultation with the State Boards of Health, thus making thorough harmony and co-operation between the Government and State. As it is, it is not at all likely that this or any other Congress would pass a bill increasing the powers of the Government in the matters of inter-State quarantine.

It will be noticed that the recommendation of the President refers simply to increasing *quarantine* powers; not a word is said on the subject of co-operation with State boards or of adding to the hygienic functions of the Health Department. As a matter of fact, quarantine is the smallest part of the business.

The recommendation for a commission of experts to visit Cuba is always a good one. We have had many such recommendations and many commissions. The English in Bermuda, the Portuguese in Brazil, the French in Martinique, several times the Spanish in Cuba, and our own National Board of Health Commission in Cuba in 1880, are familiar examples of these commissions and their work. Besides these there have been individual investigators almost without number; but in the meantime shall the voice of our Southern Coast be heeded, and either move Ship Island quarantine or surround its anchorage with an adequate naval patrol?

TRANSIENT HEART MURMURS.

The *Lancet* in its issue of Nov. 13, 1897, summarizes an annual address to the Northwest London Clinical Society delivered in October by Sir WILLIAM BROADBENT. The main points dwelt upon are irritable heart and transient murmurs heard over various cardiac and pulmonary areas, with the differentiation of these functional and temporary conditions from organic and permanent disease. Candidates for the public service have sometimes, it is stated, been refused their commissions on wholly inadequate grounds. According to Sir WILLIAM the candidate presents

himself for examination in a state of extreme nervous excitement, his pulse rapid, perhaps irregular, and his cardiac impulse violent and even diffused beyond the right sternal border. Murmurs which sometimes cause rejection simulate closely a soft systolic mitral, but are heard only during inspiration or when the chest is full, and are due to compression of the overlapping lung by the heart during systole. Pulmonary murmurs may depend on bulging of the conus arteriosus against the chest wall; they disappear when the lung is interposed on deep inspiration. Sometimes bruits are heard, not only in the course of the ordinary mitral regurgitation, but over the greater part of the lung. In such cases there is usually pleural adhesion. The criterion of pseudo-mitral disease is absence of displacement of the apex beat and of accentuation of the pulmonic second sound or undue right ventricular impulse, together with absence of symptoms.

Medical examining boards in the United States have already met with experiences of this kind, which should lead to caution lest injustice be done. A board convened at West Point, N. Y., Aug. 20, 1894, reported ten cadets as having become affected with heart disease while at the Military Academy and as being physically disqualified for service, but recommended continuance at the Academy for a probationary period of six months. They were kept under special medical observation in accordance with the directions of Surgeon General STERNBERG, and the report of the medical officer who carried out these instructions, rendered June 23, 1897, when the last of the cadets concerned had become commissioned officers, showed that in nine the heart was free from structural lesion and that there was no symptom of mechanical derangement of the circulation nor of heart strain. In the one case in which the bruit persisted a medical board considered the condition not incompatible with the exigencies of the military service. The conclusion was reached that in all except the last mentioned case the murmur heard in each individual at the time of the examination in 1894 was due to "a temporary irritability of the heart caused by the nervous excitement attending the ordeal of examination." One of these young men, while the subject of medical observation became notable in the athletic events of the Academy, and in March 1897, was awarded the prize for all-round athletics, having won the greatest number of prizes in the individual contests.

These cases convey their own moral.

Twenty-five years ago the Editor of the JOURNAL examined a young carpenter for a Life Insurance Company and was about to reject him, as there was a distinct heart murmur, but he demanded another examination and two days later when perfectly quiet the murmur had subsided so much as to be scarcely audible. At this writing the applicant is entirely well and to all appearance bids fair to become a septuagenarian.

THE PURPOSE AND NATURE OF ACUTE INFLAMMATION.

The leucocytes in acute inflammation not only act as phagocytes and as carriers of bactericidal substances that are secreted or liberated on disintegration, but the presence of leucocytes within formative cells is usually interpreted as signifying an additional supply of food for the rapidly growing cells. KLEBS¹ and RANVIER,² in particular, lay stress upon this rôle of the leucocytes. In addition to its bactericidal, diluent and irrigant action the exudate also furnishes the proliferating cells with abundant nourishment. The precipitation of fibrin in inflammatory exudates can also be regarded as beneficial in so far as the fibrinous adhesions often seem to circumscribe the action of the bacteria. The inflammatory proliferation of the fixed tissue cells may be regarded as not only regenerative but as an effort to build a protective wall between the bacteria and the healthy tissue. The experiments of AFANASIEFF show that healthy granulation tissue is a powerful barrier against general infection, the action of its serum and its cells being destructive to bacteria. Here are rehearsed some of the means to counteract harmful agents, protect the organism, and effect healing. As the same principles are seen in response to injury, in defense and in repair in all animals and in practically all kinds of injury, no line can be drawn separating one set of responsive and reparative phenomena as inflammatory from another set a little differently constituted as not inflammatory. The common mode of origin, the similarity of the changes though combined in differing proportions and the recognizable tendency in these changes to protect and repair justify fully the modern teaching introduced largely by METCHNIKOFF³ that the inflammatory processes are essentially *adaptive, protective and reparative*.

And yet it can not escape notice that the protective and reparative tendencies of inflammation are limited and imperfectly controlled. The reaction is not always in proportion to the strength of the "irritant." The adaptations to the pathologic conditions created are imperfect, as shown by "the excesses, disorders and failures incident to inflammation." The exudation may, as ADAMI⁴ says, possess but little bactericidal power or it may carry the bacteria outside the area of primary invasion. The leucocytes and other cells, instead of destroying, may undergo destruction; they may incorporate bacteria but not destroy them, and the bacteria, as in the case of tuberculosis, may continue to multiply; the fixed cells may form imperfect material for repair and continue to multiply excessively; the resulting cicatricial tissue may lead to serious functional disturbances after the harmful agent has been destroyed and repair completed. The

³ Pathologie comparée de l'Inflammation, 1892.

⁴ Allbutt's new System of Medicine, 1896.

inflammatory reactions do not respect the relative functional and anatomic importances of the organs, but create new conditions that *per se* are dangerous. It will suffice to call attention to occlusion of the larynx in consequence of violent inflammatory reaction, fatal cerebral compression on account of excessive serous exudation in inflammations of the leptomeninx, the contraction and functional disturbances of the valves of the heart from the fibrous tissue produced in repair after endocardial infections, and the overgrowth of connective tissue in the chronic inflammations. These disastrous consequences of inflammation, examples of which can be multiplied, can not always be regarded as unavoidable in order that it could fulfil the purpose of overcoming or diminishing the effects of the primary injury. Hence KLEBS¹ concludes that inflammation is an increase in the reactive changes beyond the degree necessary for restitution. It is an adaptive and self-preservative, and yet often harmful and wayward, process that requires the active intervention of man. Consequently, inflammation, from the clinical standpoint, is harmful: from the pathologic or biologic, a struggle for self-preservation. Inflammation is the reaction of the tissues to local injuries calling forth protective and reparative measures: an imperfect pathologic adaptation often leading to consequences that *per se* are dangerous and defeat its purpose.

HEREDITY AND MENTAL DISEASE.

It has been a matter of general belief amongst the alienists that without predisposition of some kind there would be but comparatively few cases of mental disease. But predisposition in this sense means not only brain weakness or ancestral taint of insanity, but every form of physical or mental deficiency that rendered its subject to any extent unequal to the special condition of stress that produced the mental failure. In this sense any individual of the lower races or of savage or barbarous tribes, and to a lesser extent, of the uncultured and primitive populations of the higher races, so far as he is capable of being affected by the more complex condition of the highest civilization, is mentally handicapped and the more liable to succumb to conditions that are harmless to mental health in others better fitted by culture and evolution and especially by the hereditary accustomedness to these special phases of modern life. It is this that, in part at least, brings about the rapid extinction of savage tribes too suddenly introduced to an advanced civilization; besides the diseases and vices introduced among them they suffer from a loss of psychic *morale*, a sort of national apathetic melancholia, which saps their vitality and hastens their decay. It is this also that fills our asylums with immigrant foreigners who, accustomed to a simple uneventful peasant life in an old established civiliza-

tion, are suddenly forced into the struggle for existence under severer competition and in less primitive states of society.

It is therefore not necessary to assume that a direct heredity of insanity is the leading etiologic element in its great extension in modern times; there are other competent factors to largely explain the phenomenon. It is nevertheless a fact that the common notion that insanity is to a very great extent directly inherited, has an ample basis of truth. Asylum medical officials are constantly reminded of this in their daily experience, and asylum statistics offer abundant evidence. One of the latest inquiries into the subject is that of Dr. W. C. KRAUSS, who analyzes the statistics of the New York State hospitals for the insane in the last issue of *Medicine*. He shows that the reports of these institutions give a percentage of 25.38 for the year ending Sept. 30, 1896, and for the eight years since 1888 a slightly lower one of 23.56 of hereditary tendency to insanity in those admitted, including not merely those in regard to whom facts could be obtained, but those in regard to whom no data were obtainable. The figures therefore signify that in about a quarter of the whole number of insane committed there was direct testimony as to an insane taint. But since 1888 the total number of admissions was 41,141, and in regard to 16,914 of these no data as to heredity were obtained. Deducting these the percentage was 35.7 of those of whom some facts could be obtained, and as he admits that there may be some objection to this method of figuring, he assumes that the statistics of one asylum where the proportion of cases without family histories was the least, that at Middletown, can best be taken as giving the true index of heredity as far as the New York hospitals for the insane are concerned. The percentages here are 35.2 for the year 1895-96, and 30.99 since 1888, the unknown cases being practically a negligible quantity—only 172 out of 2,394 admissions since 1888. The proportions here also agree approximately with those of the United States census of 1890, as given by Dr. KELLOGG in his recent textbook on insanity, viz., 31.38 per cent.

It should be kept in mind in estimating the value of these figures that there is a considerable possible, and we may say almost inevitable, source of error in the most carefully collected statistics of this nature—that due to ignorance, family pride, etc. It is always possible that family histories are incompletely given in respect to direct or collateral heredity of mental disorder, as every one who has attempted to collect such data can testify. Very significant facts of collateral heredity are not infrequently innocently withheld, the parties not recognizing their connection with the case. They are also often unknown to those giving the history, and there is beyond this also a certain amount of actual suppression of facts. Insanity is not a very satisfactory thing to have recognized as a

family taint, and there are many who are more than simply willing to conceal it, and to give out the impression at least that its occurrence is purely accidental and unusual. This tendency exists and has to be reckoned with to a certain extent in estimating such statistics as are afforded by asylum reports. Just how much percentage ought to be added on this account, it is hard to say, but it should be an appreciable one and should make us accept the figures as under rather than over the truth.

An homologous heredity of insanity is, however, not by any means the only form to be considered; inebriety, various forms of nervous disorder, and even chronic infectious diseases like consumption, and a host of degenerative conditions appear to alternate in hereditary transmission with mental disorders, and if all these are considered it is doubtful whether we could find any large proportion of the insane who are free from hereditary taint, if indeed we could find any such. Even restricting the responsible heredity to the more marked and serious cases of these disorders we still have such a predominance of their occurrence in the antecedents of the insane as to justify the belief that some kind of degenerative heredity is rather the rule than otherwise. The existing causes of insanity, more especially the so-called moral causes, have, as a rule, little effect on a brain that has no taint of morbid heredity.

Thirty per cent. of all cases of insanity with a heredity of direct or collateral mental disease in asylum statistics signifies a still larger proportion in actual fact, and this again is probably equaled or exceeded by that of heredity of other pronounced degenerative defects. The common belief, which has also good support from high alienist authority, that heredity is the chief cause of insanity, may therefore be considered as well founded on fact.

PHARMACISTS IN THE ARMY HOSPITAL CORPS.

Two or three years ago the American Pharmaceutical Association appointed a committee to work for the fuller recognition of pharmacists in the Army and Navy of the United States, and a bill drafted by this Committee was introduced in Congress providing for a reorganization of the Hospital Corps of the Army. To show in this connection, the high appreciation in which the pharmacist is held in European armies a series of articles were published under the direction of the Chairman of the Committee. From the article on the pharmacists in the French Army, we learn that the Inspector ranks as a Major-General, principals of the first class as Colonels, principals of the second class as Lieutenant-Colonels, with Majors and Aide-Majors ranking as Captains and Lieutenants; and, that although they are the subordinates of the Surgeons "*they have the same income, almost the same uniform and the same marks of honor as the surgeons of the*

same respective ranks." The italics are intended evidently to invite comparison with the enlisted status of the hospital stewards in this country. The bill drafted by the Committee does not, however, purpose making high ranking officers of the stewards. It merely provides that the Hospital Corps, outside of its enlisted men, shall consist of pharmacists who shall not be enlisted but appointed to position by the Secretary of War, and that "upon the passage of this Act all hospital stewards now in the United States Army shall be placed on the list of pharmacists with the rank, pay and privileges of the same, etc."

The Committee does not appear to have studied the constitution and organization of our Army Medical Department and Hospital Corps. The analogues of the pharmacists of European armies are not, in the United States, the hospital stewards but officers of high rank in the Medical Department assigned to the special duty of providing medical and hospital supplies for the troops. One is stationed in New York City, one in St. Louis and one in San Francisco. Surgeon General STERNBERG in a letter which appears in another part of this issue defines the position and duties of the hospital stewards and states how pharmacists, under existing regulations may enter the service.

EFFICIENCY IN HOUSEHOLD DISINFECTION WITH FORMALDEHYDE AND THE AUTOCLAVE, AND WITH A MINIMUM OF INJURY TO FABRICS.

Dr. E. H. WILSON, Director of the Hoagland Bacteriological Laboratory, Brooklyn, reports a satisfactory degree of success in the use of formaldehyde gas generated by means of the TRILLAT autoclave. ROUX, BAUDET, TRILLAT and others have assisted in working out a method of evolving formaldehyde gas from formalin. Formalin, or formol, is a saturated (40 per cent.) solution of the gas in water. If a quantity of solution is mixed with an equal quantity of a 5 to 10 per cent. solution of calcium chlorid, it will be found that the boiling point of the mixture is considerably above 100 degrees C. (212 degrees Fahr.), and the most favorable temperature for evolving formaldehyde gas is between 95 degrees and 100 degrees C. Thus, nearly all the gas is evolved before the mixture begins to give off steam. Moreover, it prevents the polymerization of the gas into trioxymethelene. The following is a partial description, and directions for the use, of the TRILLAT autoclave:

The apparatus is packed in two cases, one of which is the autoclave case containing autoclave with gauge thermometer, two handles and a tin case containing two outlet tubes and a wire to clean same. In the case of accessories is a special lamp and small can containing alcohol to light same; copper can for the formochlorol; tin can for kerosene; cotton wadding for stuffing cracks in windows, doors, etc.; pair of spectacles to protect eyes.

The TRILLAT autoclave: The vessel of the appar-

atus is made of heavy copper, which is silver-lined and has a capacity of about one and one-half gallons. The remainder of the apparatus is mostly brass, highly polished and carefully finished. The cover of the autoclave, which rests on a rubber band so that it can be tightened to avoid any leakage, is equipped with a pressure-gauge, a sleeve in which the thermometer is placed and a stop-cock by which one regulates the escape of formaldehyde gas. The apparatus is heated by means of a special lamp, the flame of which is fed by kerosene vapors. By a small screw one can regulate the heat and by using the pump occasionally one can increase the heat.

Formochlorol is a saturated solution of formic aldehyde and a neutral or indifferent mineral salt and absolutely free from methyl alcohol. When heated under pressure, formaldehyde vapors are evolved in a non-polymerized condition. Before putting the formochlorol in the autoclave, it should be well mixed so as to distribute any precipitate which may be in the same. This deposit is not an impurity, but on the contrary is one of the essential parts of the solution.

Full directions as to the procedure and the methods of bacteriologic testings, too long to be quoted here, are given in an article by Dr. WILSON, in the *Brooklyn Medical Journal* for November. One experiment was done May 27, 1897, in a room having 1,165 cubic feet, with 1,250 c.c. of formochlorol and four hours exposure. The organisms used in this test were those of anthrax, diphtheria, typhoid fever, etc. No moist cultures were used, as it was intended to make the experiment correspond as closely as possible to actual working conditions and in practice we are seldom called upon to disinfect articles that are not dry. The formalin mixture remaining in the autoclave was carefully removed and measured. It amounted to 2,300 c.c. and contained 9.27 per cent. of formaldehyde corresponding to 213.2 grams. As the original mixture contained 500 grams, 286.8 were present in the chamber, and as the capacity of the chamber is 10,188 cubic meters, each cubic meter contains 28.11 grams of CH_2O . This corresponds to a volume per cent. of 1.93, or in round numbers 2 per cent.

This experiment proves that, under the conditions adopted, 2 per cent. is sufficient to disinfect anthrax spores in the middle of a mattress, a very severe test, and, on this account, it is recommended that 2 per cent. be the minimum of gas allowed. As regards the temperature and the vacuum, the experiment shows that a temperature of 65 degrees C. is high enough, and that a vacuum of at least half an atmosphere is desirable. It will be seen that the temperature exercises a marked effect on the disinfection, and the failure of the first experiment, where a much larger percentage of gas was used, must be attributed to the low temperature at which it was conducted.

This method, therefore, gives a convenient and satisfactory disinfection of goods that would certainly be injured, if not ruined, by the use of steam.

The advantages of the autoclave over the lamps are at once apparent: 1. It produces a large volume of the gas. 2. Rapidity of application. 3. It is constantly under observation and located outside the room. 4. No damage to disinfected goods.

The experiments with lamps previous to this apparatus have been instructive. As long ago as November 1895, we began at the Hoagland Laboratory a series of experiments with this gas. At that time ADNET, in Paris, had devised the first of the lamps.

We sent for one, and after the usual delay we obtained a lamp from ADNET, and, using that as a model, we had a lamp constructed containing more burners. ADNET's was a single-burner lamp, something like a student's lamp, having a receptacle for the methyl alcohol and a cone of platinum gauze on the other side. This lamp made a very bad odor in the room, but it was difficult to tell how much was due to the formaldehyde and how much was due to the unoxidized methyl alcohol. We placed it in an ordinary clothes-press, such a closet as one ordinarily finds in a sleeping room, so that all of the cultures exposed to the action of the lamp were within five feet of the burner. The result was, we could not, no matter how long we left the lamp in, succeed in killing dry diphtheria cultures; we did succeed with moist cultures, but the dry ones always survived. Then we had a lamp made with four burners, and after that one with eight burners, and we took that out to the Kingston Avenue Hospital and put it in the isolation pavilion and tried the same cultures there, and we drove everybody off the grounds, with the exception of the test-organisms, and we came to the conclusion that lamps were impracticable and rather dangerous for use in the Health Department, because very often such a lamp, in the hands of an unskilled or careless man, if put in a room and started might set fire to the house.

It is true that very many manufacturers are now engaged in the production of these lamps. I think within a month we have received as many as a dozen circulars from different manufacturers in regard to these lamps and they make extravagant claims for them, which on careful investigation I am sure will not be borne out. I would suggest a scheme which seems to me is a very feasible one, and one which could be readily carried out: That the Health Department furnish to physicians who desire to do such disinfection a package of test-organisms and let them put it in the rooms with their lamps and return the package to the laboratory, and learn the next day whether their disinfection was efficient or not. I think that this would settle the question of lamps very shortly.

This apparatus which I show you is imported, and the duty brings the cost of it up; it costs \$100; but I received a circular today from a firm in New York, who manufactures an apparatus almost like this. It seems from their prospectus to be very efficient. It is in three sizes, the smallest size costing \$30 and the largest for hospital use, \$100. The one for \$30 has about the capacity of this one.

CORRESPONDENCE.

Reminiscences of a Recent Visit to the Twelfth International Medical Congress at Moscow, Russia.

CAMBRIDGE, MASS., NOV. 26, 1897.

To the Editor:—The International Medical Congress at Moscow, August 19-26, was under the high protection of His Majesty, the Emperor Nicholas II. and the August Patronage of His Imperial Highness, the Grand Duke Sergius Alexandrovitch.

There were held three general sessions, which took place in the Grand Théâtre Impérial. Admission to a session was by card, which was issued by the committee having the matter under control. The number of delegates and registered members was so great that the invitations had to be limited to the

seating capacity. Most of the members, however, had during one or more of the three sessions an opportunity of witnessing the manner in which the general work was conducted. I was fortunate in receiving a card that admitted me to all the exercises. The opening session was the most important, on account of the presence of the Grand Duke and the high officers of the Imperial Court. The introductory discourse and address of the welcome given by the President of the Committee of Organization, Prof. N. B. Sklifosowsky, was in full accord with his ever watchful and sympathetic audience. The report of the Secretary-General, Prof. W. K. Roth, on the progress of the work of the Congress, on the large number of valuable contributions that had been promised and the unprecedented number of delegates that had already registered commanded the closest attention and approval. It was indeed a moment of supreme delight to have the opportunity of observing the dignity and, if I may be allowed to say, the grandeur of the man who for nearly three years past had performed that Herculean task of carrying on by the most skilful use of the French language, the extended correspondence necessary for the success of such an international meeting as was then taking place at Moscow.

The official addresses of the representatives of the various governments were an interesting feature of the opening session. The address of Prof. Virchow on "Die Rolle der Gefässe bei Entzündung" was the occasion for rapturous applause. The speaker's very presence stirred the soul of the Congress and added a charm to the great gathering that will not soon be forgotten, and though he had passed his 76th milestone, the quick flash of his eye, the merry play of his countenance, his keen wit and engaging manners, recalled to mind our student days when his work entitled "Cellular Pathology as Based upon Physiologic and Pathologic Histology," was regarded as the highest authority on the subject and was read with almost as much interest as a novel.

An address entitled, "The Classification and Surgical Treatment of Acute Peritonitis," was delivered before the second general session by our countryman, Dr. Nicholas Senn. The address was interesting and instructive and impressed the hearers that Dr. Senn was a thorough master of the subject with which he was dealing.

Perhaps one of the most brilliant efforts made by any speaker was that of Professor Lannelongue, who had for his subject "Surgical Measures to be employed in Tuberculous Cases." The speaker exemplified in his address the fact that the French vernacular was well adapted for the highest flights of "soul-ravishing eloquence."

The address of Professor Leyden of Berlin entitled, "Ueber die gegenwärtige Behandlung der Tuberculösen und die staatliche Fürsorge für dieselben," was looked forward to with perhaps more than ordinary interest, from the fact that he had been identified in some measure with Professor Koch in an endeavor to solve the question as to the best method of treatment for tuberculosis. As far as I could understand his address, which was delivered in German, he did not regard the use of tuberculin as a specific; the Professor relied more on climatic influences, upon the advantages of a residence in elevated centers where there is an abundance of sunlight and fresh air free from moisture. In cases, however, where the patient is feeble and there is much febrile disturbance and profuse hemoptysis, high altitude would be, for the most part, contra-indicated.

The addresses of Professor Krafft-Ebing of Vienna on the "Etiology of Progressive Paralysis," of Professor Metchnikov of Paris on "The Pest," of Professor Robert of Barcelona on "Certain Pathologic Characteristics of the Human Economy," of Professor Lombroso of Turin on "New Horizons and New Applications of Psychiatry," of Professor Loukanov of St. Petersburg on "The Inanition of the Cell Nucleus," and of

Professor Lauder Brunton of London on "The Relations between Physiology, Pharmacology, Pathology and Practical Medicine" also met with warm response and would compare favorably with the great productions put forth by speakers on similar occasions.

There were in attendance, including the women, upward of 10,000, of whom, according to the Secretary-General, 7,500 were delegates and registered members. More than half that number were from Russia. Germany sent upward of 800. The number of Austrians was nearly the same, while the number of French exceeded 400. Italy's quota was not far from 300, and England's list of delegates, notwithstanding the great attraction of the meeting of the British Medical Association at Montreal, Canada, was nearly as large as that of Italy. Sir William MacCormac and others of her illustrious members of the profession were in attendance. Scandinavia, Holland, and the remaining European countries were well represented. Delegates appeared from China, Japan and other Asiatic regions, and also from South America. Mexico sent Professors Licéaga, Lavista, Heréra, Noriéga, Carbajal and fifteen other delegates. The number of representatives from the United States was 124, of whom 37 were delegates from the AMERICAN MEDICAL ASSOCIATION: of this latter number there were from Cambridge besides myself two of our most worthy and eminent physicians, Dr. John L. Hildreth and Dr. Edmund H. Stevens. The closer sympathy or nearer touch in which were brought our American delegates and their gracious ladies and pleasing friends is to be counted as no inconsiderable part of the pleasure realized in journeying to such a distant meeting, the Mecca scene of our profession.

The number of papers presented to the Congress was not far from 1,000; the work was divided into twenty sections. The Section on Surgery had a large attendance. The titles of 140 papers were entered. Such names as Macewen of Glasgow, Doyen of Paris, Roux of Lausanne, Beck of New York, Czerny of Heidelberg, Ollier of Lyons, Israël of Berlin, Championnière of Paris, Oppenheim of Berlin, Murphy of Chicago, Tauber of Warsaw, and Preobragensky of St. Petersburg, when arrayed with those of many others no less illustrious, ought to be sufficient to indicate that good work was accomplished.

Surgery of the lungs was a prominent theme for consideration. In cases of abscess and gangrene of the lung, pneumotomy was regarded as sometimes indicated. The occurrence of cases of large tuberculous cavities in which there are distressing or immediately dangerous symptoms may sometimes demand incision and drainage for relief. In some cases of such disease, resection of one or more of the ribs in order to secure proper drainage was deemed advisable. Dr. Jacob Frank's demonstration of his "New Absorbable Intestinal Coupler" as a substitute for the "Murphy Button" attracted much attention.

The Section of Obstetrics and Gynecology, in which I registered, occupied the larger share of the time at my disposal. In this Section the titles of seventy papers were on the program. Professors Makóiev and Snóguirev of Moscow were the principal managing officers and were associated with thirteen members of the Committee of Organization. Seven secretaries were appointed to facilitate the work of the Section. The meeting of this department took place in the spacious hall on the second floor of the old University. It was a brilliant gathering; on the walls near the main desk hung a magnificent painting in oil of the Emperor, while on the right was also an exquisitely finished picture of a former empress. Behind this stand for the various speakers was placed a sounding board which improved the acoustic properties of the hall. At a long table sat the managing officers of the Section, the various members of the committee, the honorary presidents, prominent speakers and invited guests. The secretaries' table was on the right and the reporters' table on the left. The other members

and those who came to witness the proceedings occupied seats outside of the enclosure. The number in attendance was for the most part always sufficient to fill the hall to its fullest capacity. The Chairman, Professor Snéguirev of Moscow, began his address by taking for his motto that beautiful saying of Malgaigne, "Verité dans la science, moralité dans l'art." His reference to Raphael's Sistine Madonna was most happy; he affirmed that the beauty and health of the woman with the child in her arms, as personified by the artist, was no mythical or unrealizable representation; it is a perfect type of healthy and beautiful womanhood. It is the duty of science to contribute to such an end; we must therefore care tenderly for the child if we would preserve the race of mankind. By studying the phenomena of nature and assisting woman in conserving her energies, mutual love and respect will be strengthened and thereby her rights be increased and her duties materially lessened. In the paper on "Symphyseotomy," by Professor Varnier of Paris, the author remarked that the operation was no more dangerous in properly selected cases than were other recognized obstetric procedures. The operation could be resorted to in those cases in which the child was alive, the dilatation of the os and cervix was complete, the membranes were ruptured and the efforts at expulsion insufficient to effect delivery owing to the disproportion between the fetal and the maternal structures. The author's experience appeared to warrant him in saying that perfect restoration of the parts, after a resort to this means for relief usually took place by primary intention. The operation could without incurring permanent inconvenience be had recourse to, if necessary, several times on the same woman. The paper was ably discussed by Zweifel of Leipzig and Borsi of Genoa. The question relating to the advantages of colpotomy in cases of inflammation of the adnexa, of displacements and of neoplasms of the uterus was ably discussed by Candela of Valencia, Doyen of Rheims, and Dübresen and Martin of Berlin and Farza of Barceloua.

Surgical treatment for peritonitis was another favorite subject for consideration. The discussion was carried on by Martin of Berlin, Winckel of Munich, Christovich of Salonica and Noriega of Mexico. The consensus of opinion was favorable to a timely resort to operative procedures. Serotherapy, when employed in puerperal septicemia, was endorsed by Bar and Wallich of Paris, and Weinstein of Odessa.

"The Comparative Value of Different Operative Methods in the Treatment of Uterine Cancer and as the Means of Preventing Return of the Disease" was the subject of a paper by Winter of Berlin, and was freely discussed by Goubarev of Moscow. In this connection Doyen of Paris, took for his theme "Total Extirpation of the Uterus," and Landau of Berlin had for his paper, "Total Etirpation of the Uterus by the Abdominal Method." He also presented a report on 500 cases of total extirpation by the vaginal method with varying results. Among other speakers who discussed different themes were Peau of Paris, Wedorodoff and Goubarev of Moscow, Ott of St. Petersburg, Apostoli of Paris, upon the application of a new galvanic current (ondulatoire) to be employed in gynecology. Of the other speakers who presented papers on discussed subjects were Torre of Rome, Leopold of Dresden, Müller of Bern, Olshausen of Berlin, Weugebauer of Warsaw, Borav of Moscow, Cameron of Glasgow, Hennig of Leipzig, Pinard of Paris, Simpson of Edinburgh, Woltchini of Moscow, Rosner of Cracow, Twesternark of Stockholm, Colderini of Bologna, and Cholmogoroff of Moscow. "Perineorrhaphy, Immediate and Secondary," was the title of the last speaker's paper.

During the discussion of the several subjects the managing officers of the Section, Professors Makéiev and Snéguirev, were active in arranging matters that would expedite the work, while the honorary presidents were called upon in turn to preside and to control the discussion according to the manner that

had been determined upon by the committee. In the consideration of questions of operative technique beautifully prepared diagrams and drawings upon the blackboard were freely brought into requisition. The discussions ranged upon a great variety of topics growing out of the subjects presented in the papers, and were carried on by the several speakers in a most earnest, courteous, and dignified manner.

All the work accomplished tended to unite in kindly feeling the members one with another, and to render the meeting a scene of memorable occasion. After a speaker had taken part in the consideration of a subject that was not in his paper, he was presented by one of the secretaries with a card and pencil, that he might note down the leading points of his argument; this part of the regulation was strictly observed and was carried out to good advantage.

At 4:30 p. m. on August 24, the work of the Section was brought to a close. After a few words complimentary to the officers and the Committee of Organization, by Winckel of Munich, Torre of Rome, and others, the parting benediction was given by Professor Makéiev and by the chairman, Professor Snéguirev. It could not be otherwise than a season of pleasure to draw near the men whose names have in works of great importance, been so long familiar to us, and to see them facing each other, not with the purpose of advancing a dogmatic theory, but with a sincere desire to assist in the elucidation of that truth which would be of the highest advantage to suffering humanity.

The dinner given at the opening meeting of the Section by Professor Snéguirev and M. Schélapoutine, the founder of the Institute Gynécologique de Moscow, at Pocrowsky-Fili, was a most enjoyable occasion. The distance was some seven versts or three kilomètres from the Barrière de Dorogomilowo. The place was reached by carriage and in driving it was necessary to pass beyond the house (Koutousovskaiä Izba) designated by an inscription and celebrated for the Council which was, under the presidency of General Koutousov after the battle of Borodino, during the French invasion in 1812, there held for the purpose of determining the expediency of evacuating the city of Moscow.

The dinner was followed by addresses and the rendering of vocal selections. It was attended by the officers and the committee of the Section, invited guests, and hostesses, Madame Schélapoutine. Dr. Parvin and myself were, I believe, the only Americans who were present. As we returned at a late hour, by moonlight over the winding roads, through groves, open fields, and along the Moskva River, Moscow in the distance with her thousands of brilliant lights illuminating her many domes and pinnacles, and with her other semi-oriental adornings, had the appearance of a fairy city and presented a view that was most enchanting.

No one who is versed in the affairs of nations can doubt that the future of Moscow will be most favorable to her development, and that when the railway construction, which is being extended on a gigantic scale through Siberia and other parts of the Russian Empire, has been completed, this ancient capital will, by the importance of her situation, become one of the greatest emporiums of the eastern hemisphere.

The Institute of Gynecology has recently been constructed and was founded, as before remarked, by M. Schélapoutine in memory of his mother. A visit to the institution showed that the buildings were well situated and equipped with modern appliances and conveniences; that the appointments were excellent and the work carried on would compare favorably with that accomplished in the best hospitals of other places. Moscow has been famous for its institutions for promoting the different branches of medical science and for extending relief to the unfortunate, through the liberality of its hospitals, dispensaries and *cliniques*.

The Imperial Foundling Hospital is the largest infant asylum

in Europe; it affords an annual refuge to 17,000 abandoned children and occupies 81,800 square meters of land. It has for its number of inmates, including attendants, 7,000.

The Section dinner given at the Chasseurs Clubhouse, at Rue Wosdvienska, on August 25, was the occasion for another pleasant reunion. Most of the Sections had dinners during the same evening; the speeches and toasts following proved most entertaining and the opportunities that were there presented for conversation and kindly greetings have, as regarded by many, been rarely surpassed. At the close of the third general session addresses appropriate to the occasion were, as done in some of the Sections, delivered by the president and by prominent members from different countries.

The next congress is to be held in Paris in 1900. Professor Lannelongue was chosen president of the Committee on Organization and Professor Chauffard, Honorary Secretary-General.

In regard to the nature and character of the work accomplished by the Congress there can be no question as to its great importance to humanity and to the profession generally. There may have been encountered embarrassment by the use of some of the various languages that were officially allowed in the reading and the discussion of papers, but this feature could not have been a serious drawback to one who was acquainted with the general principles of subjects. The fact as already intimated, that so many noted delegates from France, Germany and other countries were present and took prominent part in the consideration of the work, is evidence that the meeting must have been productive of far-reaching results.

The committee of Russian dames having the approval and support of the Grand Duchess Elizabeth Feodorowna, and the advantages of the position of their ubiquitous president, Madame Sklifossowsky, are deserving of great credit for their arduous endeavors in planning and carrying out, on a most magnificent scale, a series of entertainments for the visiting bodies to Moscow. The features of these entertainments were of a social, historic and artistic nature, and were thoroughly enjoyed not only by the fairer sex, but by the gentlemen.

In closing I might say that the medical gentlemen of Russia have long since been recognized by the faculties of other leading nations; they have always been in close sympathy with the great merchants and with the commercial interests of their country. They used to good advantage their influence in securing the large appropriation from their government, beside contributing freely of their own substance toward bringing the work of the Congress to a most successful issue. They extended a most hearty welcome to their visitors. Their courtesy was phenomenal and their solicitude for the welfare of all is indeed worthy of emulation. The following from Dr. Leusser-Lissingen's "Farewell to the Congress of Moscow," expresses my feelings in regard to my visit in Moscow:

"Wahrlich, schwer wird's mir zu scheiden,
Gar zu gerne war ich hier.
Lass mein Herz sich nochmals weiden,
Heilige Stadt, an deiner Zier!
Lebe wohl, mein trautes Moskau,
Märchenschöne Kremelstadt!
Niemand wird mein Herz vergessen
Was es hier empfunden hat."

AUGUSTUS P. CLARKE, A.M., M.D.

"Treatment of Inevitable Abortion."

BLOOMINGTON, ILL., Dec. 1, 1897.

To the Editor:—I read with interest, and with a large measure of approval, the concisely stated contribution of Dr. H. P. Newman on the "Treatment of Inevitable Abortion," in our JOURNAL of 27th ult. A paper on the subject of abortion before any medical body, or village society, or an international gathering, invariably elicits a spirited discussion, plainly indicating that there yet remains much to be desired in the management of such conditions.

The diversity of views usually expressed, tending all the way from a dull, blameable conservatism to dangerous radicalism, further indicates that all methods are unsatisfactory at times, disastrous often, and that the desired middle ground of action has not been reduced to a formula, embracing every probable situation. A careful analysis of Dr. Newman's article indicates clearly enough that he believes in and practices the rather advanced radicalism, and defends his position by his own results and the general tendency of the times in his direction.

The immediate danger, as stated by him, is hemorrhage; the degree of danger increasing with each day of gestation. To the third month, or rather to the time of definite formation of the placenta, the danger from hemorrhage is slight, but the remote probabilities of chronic metritis, subinvolution, salpingitis, etc., are considerable. Now when dangerous hemorrhage follows an interrupted pregnancy, there is no time lost in calling the doctor, and he in turn loses none in checking it, and in the vast majority of cases succeeds. In calculating from whence come the great number of unfortunate victims of the "remote probabilities" that throng dispensaries and gynecologic hospitals, we seldom take into account the large proportion that have never had treatment of any kind. From motives of concealment, economy and shame many women never consult a medical attendant, thereby losing the opportunity of preventing just such conditions as named above, and which the sensible treatment of Dr. Newman would avoid. Hence, from whatever point we view this matter, control of hemorrhage, avoidance of chronic pelvic disease, or sepsis, we inevitably reach the conclusion that far better results can be expected from this real conservatism of Dr. Newman than from the dangerous conservatism of chance. It may be depended on with positive certainty that the uterine contents, after the rupture of the amniotic sac, will be infected from the vagina within a very few hours, and a rational plan of treatment immediately suggests a clean, sterile uterus, and as that desirable condition is within reach of any skilful practitioner, there is but small excuse for the waiting plan. Those who advocate it never leave a woman with a leaking uterus, possibly a fetid one, without wishing the contents evacuated, and with the half fear that the inevitable tampon is simply blocking the way. Why then be burdened with this apprehension? The contents can be easily and safely gotten rid of, and why not have at least the satisfaction of seeing the source of danger where it will do no harm?

If hemorrhage is the urgent symptom, immediate emptying of the womb is conceded to be the prime necessity, and everybody does it and generally with gratifying success. If the hemorrhage continues and the uterus is not contracting promptly, pack it and pack it well with sterile gauze. You will not be doing your duty unless you do this. It matters but little whether the curette is large or small, dull or sharp, so you use it sensibly. You may not use the curette at all, and depend on thorough packing for the double purpose of controlling hemorrhage and separating the secundines from the uterine wall. In removing this packing you are many times rewarded by the expulsion of the embryo, sac and placenta at the same time. This is a pleasing result and you know then you will have no curette dangers to be afraid of. You have not only checked a hemorrhage, but you have lessened the chances of fatal septicemia and of an infected uterus and the consequent "remote probabilities" so woefully damaging to multitudes of women.

There is another point in Dr. Newman's paper which is not quite clear and possibly a trifle contradictory. He classes hemorrhage among the *immediate* dangers and further on goes deliberately about its control with the same preparatory technique that he does in a vaginal section, bath, sterilization of genitals, starvation for anaesthesia and "free catharsis."

This usually takes twelve to twenty hours, and what about the hemorrhage *ad interim*?

In the main I consider the method outlined by Dr. Newman as sensible and practical and that it will meet the requirements in most cases, while at the same time it is so simple and rational that every general practitioner could skilfully carry it out in every necessary detail.

When, however, the embryo and its envelopes and placenta are not diseased and there has been an accidental rupture of the sac, we are confronted with "inevitable abortion" and I can hardly indorse the use of the curette unless there is actual or impending hemorrhage to a dangerous degree. The placenta and membrane are very firmly attached and dip deeply down into the uterine tissue, and a degree of force would be requisite to dislodge them that is not within the limits of safety.

There may be wandering abdominal and loin pains, but the uterine contractions are not sufficiently strong to expel the conception. In this condition it has been my practice for years, to moderately dilate the cervix with Goodell's or Palmer's dilator, remove any presenting fragment and thoroughly pack the womb with sterilized gauze, leaving a fairly close packing in the external canal. Then institute Dr. Newman's preparatory toilet and at the end of twenty or twenty-four hours, when the gauze is removed, in nearly every instance, the uterine contents will easily and bloodlessly pass away. In the event they do not you are then prepared for curettage.

As the paper of Dr. Newman treats only of "Inevitable Abortion," there need be here no reference to the wandering and mostly irrelevant discussion that followed.

507 Greisheim Building.

FAYETTE DUNLOP, M.D.

The Status of Hospital Stewards in the Army.

Letter of the Surgeon-General of the Army to a Committee of the American Pharmaceutical Association.

WAR DEPARTMENT, SURGEON GENERAL'S OFFICE,

WASHINGTON, Dec. 1, 1897.

MR. GEORGE F. PAYNE, Chairman of Committee, American Pharmaceutical Association, Atlanta, Ga.

Dear Sir:—I have received your letter of November 29, also communications from pharmacists in various parts of the country, urging me to support the bills which have been introduced relating to the status of hospital stewards in the army.

There is a misapprehension on the part of pharmacists with reference to the position of hospital stewards. These non-commissioned officers have many other duties quite as important as those connected with the dispensing of medicines, and at our larger posts they usually do not give personal attention to the preparation and dispensing of medicines. This is done by an acting hospital steward, or at times, by a detailed private of the hospital corps. While we require hospital stewards and acting hospital stewards to pass an examination which includes some knowledge relating to the action and doses of the principal medicinal agents, we do not ask for any great proficiency in the art of the pharmacist. This is not essential, inasmuch as our medicines are largely supplied in the form of tablets and pills, and our tinctures and fluid extracts are purchased from the manufacturers.

It is quite as important for us that the hospital steward should have experience in the control of men, in the making out of official papers, in the drill of the hospital corps and in the general management of the post hospital. These things he learns by coming up through the ranks from the position of private in the hospital corps to that of acting hospital steward and finally hospital steward. This method enables us to ascertain his qualifications and to estimate his character and capacity before he is finally appointed to the highest position. A graduate in pharmacy would not be competent to fill the position of hos-

pital steward unless he had had this previous experience.

I shall, therefore, not support any bill which proposes to appoint graduates in pharmacy directly to the position of hospital steward. But a graduate in pharmacy who desires to attain that position can enlist in the hospital corps with a view to promotion, and his education and knowledge of pharmacy would give him a great advantage over all competitors in obtaining a detail as acting hospital steward, and subsequently an appointment as hospital steward. Nor do I think it would be in the interest of the service to make hospital stewards commissioned officers. Their present position is a most honorable one. They are highly respected by the officers of the army, and the position is eagerly sought by educated young men. Any reasonable proposition which may be made with reference to an increase in the pay of hospital stewards will receive my hearty endorsement.

Very truly yours,

[Signed]

GEORGE M. STERNBERG, M.D.,
Surgeon-General United States Army.

The Coming Meeting of the Association at Denver.

TECUMSEH, MICH., Nov. 29, 1897.

To the Editor:—The editorial in the JOURNAL of November 20, under the heading "Influence and Environment of Medical Men," is well worth the perusal of every member of our profession. The article alluded to particularly points out the absolute necessity and special benefit these National gatherings have on the physician who attends them, irrespective of his home surroundings.

The author further states that, "The coming meeting should bring out two thousand physicians." But should it not bring out five thousand?

If the Committee on Transportation can obtain the same railroad rates that are given to stockmen's conventions, butcher's conventions, political conventions of all sorts and shades, Christian science and similar crank conventions, we should have at least five thousand physicians at the Denver meeting, instead of two thousand, as anticipated by the JOURNAL.

Respectfully yours, J. F. JENKINS, M.D.

A Water Company Sued.

MILWAUKEE, WIS., Dec. 4, 1897.

To the Editor:—Some years ago there was an epidemic of typhoid fever at Ashland, in this State. The water-supply was furnished by a company, and it was believed that the epidemic was due to the contaminated water taken from Chequamogon Bay. The water company extended its pipes, and later put in a filtration system, which has resulted in giving pure water. In the meantime a Mrs. Green sued the company for the death of her husband, and claimed damages amounting to \$5,000. This case was recently tried at Stevens Point, the case being taken from Ashland on a change of venue; much expert evidence was produced on both sides, and the jury decided in favor of the plaintiff, giving her \$5,000 damages. This was done in spite of the fact that the only evidence produced that the man died of typhoid fever was the symptoms given by the attending physician. No autopsy was made nor no bacteriologic examination of the discharges from the bowels whatever. The case will be appealed to the supreme court.

U. O. B. WINGATE, M.D.

Correction.

HOT SPRINGS, ARK., Nov. 26, 1897.

To the Editor:—On page 1065 of your JOURNAL, in the discussion of the paper by Dr. C. A. L. Reed, entitled "Gall Stones in their Relation to Cancer of the Gall Ducts," in the last line on said page the reporter makes me say that I had

"seen cancer of the *uterus* unmistakably produced by gall stone infection." Of course there is a mistake in this on the part of the reporter. It should have been "liver" instead of "uterus."

Yours truly, JAS. T. JELKS, M.D.

The Late Prof. Harrison Allen.

PHILADELPHIA, NOV. 30, 1897.

To the Editor:—Will you kindly insert the following notice in your paper? At a meeting of the Philadelphia Neurological Society, held on November 22, the following action was taken:

WHEREAS, The Philadelphia Neurological Society has heard with great regret of the death of Dr. Harrison Allen, it desires to offer its sympathy to his family and to give expression to its sense of the great loss which has been sustained by science and the medical profession. Dr. Allen was deeply interested in neurology, not only as a human and comparative anatomist, but also in various practical directions, as indicated by his valuable contributions to this Society and other medical bodies.

CHARLES W. BURR, President.

WILLIAM G. SPILLER, Secretary.

PUBLIC HEALTH.

Department of Public Health Bill.—At the semi-annual meeting of the Oklahoma Territorial Association held in the city of Oklahoma, Nov. 18, 1897, the following resolutions offered by Dr. C. D. Arnold of El Reno, were passed without a dissenting voice:

Resolved, 1, That this Association desires to express its sympathy for the AMERICAN MEDICAL ASSOCIATION and its organ, the JOURNAL, in their untiring efforts to induce Congress to create a National Department of Public Health, and heartily endorse the Association Bill approved by the American Public Health Association, at its late meeting in Philadelphia.

Resolved, 2, That this body request the Oklahoma Delegate in Congress, the Hon. J. Y. Callahan, to use his influence in passing the bill; and further, that each member of this Association endeavor to at once procure a copy of said bill and familiarize himself with all its valuable features, and write to such representatives in Congress as he is personally acquainted with in the States, urging them to support the Bill.

Resolved, 3, That a copy of these resolutions be sent to the Hon. J. Y. Callahan, one copy to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, one filed with the transactions of this Association, and (as amended by Dr. G. E. Kesby) each member be supplied with a copy.

J. A. HATCHETT, President.

F. S. DEWEY, Secretary.

Health Boards and the Public Weal.—The determination of the New York Health Department to destroy a building as "not fit for human habitation and not capable of being rendered so" has been upheld by the Appellate Division. On the appeal, only the pleadings, decision, and exceptions thereto and the judgment were before the court, the appellant's counsel contending that the grounds specified in the decision were insufficient to warrant it, and that consequently no consideration of the facts was necessary. Justice Barrett, giving the opinion of the court, holds that, under the amendments of 1894 and 1895, to Section 1022 of the code, all that is necessary for the court is to state the grounds on which the issues have been decided; and whether the conclusions of law are justified by the evidence can not be decided on appeal where there are no distinct findings of fact and where the court has not the evidence before it. Averments were distinctly made in the petition in this case which, Justice Barrett said, if proved in their entirety would establish the fact that the condemned building was a public nuisance and that it should be abated. The court must assume, upon the record, that the judgment was rendered upon adequate proof of every fact so averred in the petition.

A New Disinfecting Steamer at the Quarantine Station of New York Harbor.—The health officer of the port of New York, Dr. A. H. Doty, has added to his equipment a disinfecting steambot, the

James Wadsworth, with an improved method for the application of steam. The latter is described as consisting in the exhaustion of the air in the chamber so as to produce a partial vacuum before the steam is admitted, and it is found that, all other circumstances being alike, a temperature of 240 degrees, that of the steam in the chamber, is reached in the interior of a mattress or like article in less than three minutes with the vacuum, though without it from ten to fifteen minutes are required. The oven is constructed with double walls and is encased in a jacketing of asbestos, which so prevents the loss of heat by radiation that the room in which it is fixed is not perceptibly warmer than others in the vessel or building. The special feature, however, is the steam exhaust, which consists simply of a powerful jet of steam coming directly from the boiler, where a pressure of sixty-five pounds to the square inch is maintained, passing across the mouths of 1½ inch pipes connected with the chamber of the oven and with the space between its inner and outer walls. A similar pipe communicates between the chamber and the outer air and the steam is admitted by one of 2½ inch in diameter, furnished with a regulating nozzle by which the pressure may be reduced to fifteen or twenty pounds, which is sufficient for a temperature of 240 degrees in the chamber. All these pipes are provided with stop-valves. The operation, after articles to be disinfected have been introduced and the doors securely closed, is to set the steam exhaust to work until the manometer or steam gauge indicates a pressure in the chamber and surrounding wall space of not more than twenty inches, a partial vacuum which is attained in about one minute. The valves are then closed and the steam pipe opened, when the superheated vapor entering under a pressure of two atmospheres, into the rarefied atmosphere of the chamber, penetrates the densest fabrics and stuffed or packed goods, raising their temperature throughout to its own in three or four minutes. Ten minutes at 240 degrees destroys bacilli of plague and anthrax, however protected, with absolute certainty, so that in fifteen minutes from the commencement of the process the steam may be turned off, when the steam exhaust is again set in action, though on the chamber only, until the former vacuum has been restored; then the air inlet is opened and the exhaust still acting draws such a powerful current through the chamber that in two or three minutes every trace of moisture has been removed and wearing apparel may be resumed within less than half an hour of its having been given up, an interval clearly none too long for the bath and cleansing of the persons of the wearers.

A Dangerous Intramural Cemetery.—The necropolis of Liverpool is situated in about the center of that city. Although it occupies a space not much larger than a good-sized city block, it receives hundreds of interments yearly. In the five years ending January, 1896, 2,255 bodies were added. The largest number of interments appear to take place at the necropolis. No notice is required to be sent to the sanitary department when these interments take place, but occasional visits are made to this burial ground. Here there is an arrangement of tiers, separated by a course of flagging, and with brickwork between each coffin. The walls between the vaults are four and one-half inches in thickness, and a stone flag covers over the top course of the coffins, about two feet six inches below the surface of the ground. The vaults contain about thirty-six coffins, and it is probable that, within an area ten yards square, there will be over 300 bodies of adults and children. Interments in this greatly overcrowded graveyard not only take place in family graves and vaults, but new graves are also being opened. The approximate number of interments (not including still-borns) which have taken place in the cemetery since it was opened is 82,341. There is said to be accommodation for 2,160 more bodies, besides graves already sold, but which have not yet been fully utilized. The inhabitants of the houses

abutting on the necropolis have, as a whole, occupied them but a short time. Many of them complain of offensive smells, which they believe come from the cemetery. In many instances the occupiers also state that their houses are infested with mice of a peculiar light fawn color, which they believe come from the cemetery. Some light may be thrown upon the probable condition of the subsoil in this city graveyard from the following extract from a report by an inspector of the city engineer's department. It will be noticed from this report that the offensive condition described was in that part to which material from the burial grounds would be most likely to gravitate. It was not found in the sewer nearer the surface. "The sewer in West Derby Road is what is known as a rock sewer and is cut in the sandstone. It is about fourteen or fifteen feet below the surface, and is between two and three feet in width. This sewer was undergoing reconstruction in 1889. The bottom was very much worn and 'liners' were to be put in. The top is arched over with brick, and the sides were to be cased. When opposite to the necropolis in West Derby Road, a large quantity of black jelly was found adhering to the side of the sewer nearest the necropolis, the other side was the natural color of the rock. When this material was touched or pricked, it emitted a frightful stench. The opinion of the other men and myself was that it came from the burial ground. One of the men at work was taken seriously ill, and died while the work was in progress. The other men objected to work there. The jelly was scraped off, and several coats of cement put on to try and keep the stuff from oozing through. There is also another sewer in West Derby Road which runs above the preceding one at a slight angle. This sewer is only about nine feet below the surface, and is supposed to drain the burial ground. The vaults in the burial ground are about fourteen or fifteen feet deep. This sewer is of similar construction to the other and was reconstructed at the same time. None of the jelly material was found in this sewer. None of the material was found in the Everton Road sewer, which is about nine feet below the surface. The jelly was only found in that particular length of the sewer outside the necropolis."—(From report of Dr. E. W. Hope, Health Officer of Liverpool for the year 1896.)

ASSOCIATION NEWS.

Section on Diseases of Children.—At the Jubilee Meeting of the AMERICAN MEDICAL ASSOCIATION a motion was made, in the Section on Diseases of Children, that the ASSOCIATION endorse the organization of the American Pediatric Society. The discussion on this subject was as follows:

Dr. COOK—There are many people who desire to study pediatrics as a specialty and it seems to me they should have that privilege. Therefore I move that the organization of the American Pediatric Society receive the endorsement of this Section of the AMERICAN MEDICAL ASSOCIATION.

Dr. FOSTER—From the remarks Dr. Love made yesterday afternoon I gathered that the idea was for the membership of that society to be rather select. I understood from his remarks that it was to be confined to teachers of pediatrics, barring out a certain number of us poor fellows who might possibly like to belong to it and like to attend it otherwise than just as *visitors*. If the teachers form a society they have a right to do so, but it seems to me with that restriction such a small meeting as this should not bind the Section to any such endorsement.

Dr. COOK—The lines have to be drawn somewhere to form the society, and it seems to me the hospital connection in that line gives one the privilege of belonging to the society.

THE CHAIR (Dr. LARRABEE)—Dr. Cook is right. Perhaps it would be better for the Chair to state that he has some knowledge of the preliminary organization of this Association and that the qualification of membership is that the party must be connected with some institution for the treatment of children or be a full professor of pediatrics, or that he should have been in the past a professor or should be at the time attending an institution where children are treated.

Dr. I. N. Love of St. Louis—I rise to place before the Sec-

tion the subject of the organization of a national pediatric society. Some steps have been taken toward securing such an organization. I have thought that if this body would pass a resolution, stating that it is the sense of this body that such a society should be organized, it would be helpful. Such an organization should be thoroughly national in its character and should limit its membership to those who are or have been active instructors in pediatrics. Such a body would then be authoritative and its scope would be such as to secure representative membership in every State in the Union, making it a thoroughly national body, not what some of our so-called national bodies are, an aggregation of men from one part or another of the country. We do not, and one should not, desire to have the membership among those not engaged in the work. I think a recommendation from this body that such an organization should be established would dignify it and strengthen it.

SOCIETY NEWS.

Western Surgical and Gynecological Association.—

DENVER, COLO., Oct. 1, 1897.

To the Surgeons and Gynecologists of the West:—The next meeting of the Western Surgical and Gynecological Association will be held in this city December 28 and 29. It is the purpose of the members of the Association, and of this Committee, to make this meeting one of unusual interest, and the papers and attendance promised indicate that the effort will be successful. This Association is the surgical society of the West, and must become to the West what the Southern Surgical and Gynecological Society is to the South. To this end it is desired that the many able and skilful surgeons and gynecologists of the West be brought to this meeting and enlisted in the organization for scientific work.

We are so much cut off from the scientific societies of the East and South that it is imperative that we create for ourselves a society that will foster among us the true scientific spirit and give us a better knowledge of each other.

If you are doing surgical or gynecologic work, and can by any possibility arrange to be at this Denver meeting, do so by all means, it will be representative of the best and most advanced surgical skill among us and you can not afford to be absent. If you have a paper you would like to read, write to the Secretary at once and ask for a place on the program, but make your plans to come to Denver on December 28, and at least contribute by your presence to the success of the association. We need you; you need us. A banquet will be given the visitors by the physicians of Colorado, and every effort will be put forth, to make the stay of each individual as pleasant and profitable as possible.

Committee of Arrangements at Denver: Drs. W. W. Grant, Chairman; C. K. Fleming, Secretary and Treasurer; L. E. Lemen, T. H. Hawkins, Leonard Freeman, W. B. Craig, W. A. Jayne, H. G. Wetherill.

The Albany Medical College Alumni Association.—The third annual meeting of the Albany Medical College Alumni Association of Greater New York was held December 3 at the residence of Prof. Wm. H. Thomson, M.D. Preparations were made for the third annual banquet to be held Jan. 20, 1898, and the following officers were elected: President, Horace Tracy Hanks; vice-president, John J. Van Rensselaer; secretary, Warren C. Spalding; assistant secretary, Edward F. Quinlan; treasurer, Henry H. C. Muller; governors, William Stevens, Frederic Loughran, S. E. Armstrong, Howard J. Wood, New York, and H. B. Maben, President Albany Medical College Alumni Association, member *ex officio*.

Societies.

The following meetings are noted:

Illinois.—Chicago Medical Society, December 1. The Chicago Pathological Society, December 3, the address being by Dr. George M. Sternberg, Surgeon-General U. S. A., on the "Etiology and Pathology of Yellow Fever."

Iowa.—North Iowa Medical Society, Calmar, December 4.
Michigan.—Saginaw County Medical Society, Saginaw, December 1.
Massachusetts.—Thorndike Medical Club, Boston, November 29.
Missouri.—St. Louis Medical Society of Missouri, December 4.
Nebraska.—Lincoln Medical Society, November 28.
New York.—The Medico-Chirurgical Society of Central New York, Syracuse, December 2.
Ohio.—Cleveland Medical Society, November 26. Lucas County Medical Society, Toledo, November 19. Pickaway County Medical Association, Circleville, December 1. Sandusky County Medical Society, Fremont, December 2.
Pennsylvania.—Delaware County Society, Chester, November 19. Lancaster City and County Medical Society, December 1. Pittsburg Academy of Medicine, December 2.

NECROLOGY.

J. C. EASTMAN, M.D., Hampstead, N. H., November 27, aged 86 years 7 months. The Doctor was graduated from Dartmouth in 1837. In August, 1861, he was appointed surgeon of the Fourth Regiment, New Hampshire Volunteer Infantry, with the rank of major. He was in service with the regiment at Washington, Annapolis, Port Royal, Hilton Head, St. Augustine and Jacksonville until 1863, when he resigned. Dr. Eastman was one of the oldest members of the New Hampshire Medical Society, of which he was president in 1860; a member of the Rockingham Medical Society, also of the AMERICAN MEDICAL ASSOCIATION, and was one of the three representatives from New Hampshire to the International Medical Congress held at Philadelphia in 1876. Dr. Eastman was twice nominated for councillor for his district; was a delegate to the convention which nominated General McClellan for the Presidency. In 1849, while a member of the legislature Dr. Eastman introduced the bill entitled "An Act Providing for the Establishment of Public Libraries," which became a law under the signature of Governor Dinsmore, and New Hampshire was the first State in the Union to empower towns and cities to maintain free public libraries by taxation as a result of the passage of that bill. Dr. Eastman was largely instrumental in the building of the Nashua and Rochester Railroad and served as a director.

AUGUSTUS HUEHNE, M.D., New York Medical College (now extinct) 1858, died at his home in Kingston, N. Y., December 2. He was born in Hanover, Germany, about seventy-seven years ago, but came to New York in 1852 and there engaged in the drug business, finally to become a general practitioner of some forty years standing. Among his survivors are two sons, both physicians.

JAMES OLMSTEAD, M.D., Yale 1874, died at the Grenoble Hotel, New York City, December 4, aged 48 years. In 1877 he received an appointment at the Connecticut Hospital for the Insane, Middletown, Conn., of which he became superintendent in 1886. He never lost a day from duty until he came to New York for treatment two weeks before his death. He left a widow and one child.

JOHN E. WHITESIDE, M.D., Medical Department of the Pennsylvania College, Gettysburg (now extinct) 1847, and a practitioner for fifty-three years, died at Atlantic City November 25, aged 74 years. His home was in Philadelphia.

WILLIAM N. GILCHRIST, M.D., died at the Windsor Hotel, New York City, December 3, age 74 years.

CHARLES T. ALLEN, M.D., Minneapolis, Minn., November 28.—Lafayette Campbell, M.D., Chillicothe, Iowa, November 29.—Hiram S. Crandall, M.D., Leonardville, N. Y., of cancer of the stomach, November 29.—Edward Livingstone Welling, M.D., University of Pennsylvania 1860, died at his home in Hennington, N. J., November 29, of cardiac disease, aged 63 years.—Paul Güterbock, M.D., Privat Docent of surgery in Berlin, with rank of professor, at the age of 51 years, and whose work in surgery of the urinary organs was notable.—

Aurelio Silvestri, M.D., Lecturer in Ophthalmology in the Florence School of Medicine.—Arthur Scheffer, M.D., formerly Professor of Chemistry and Medical Physics in the University of Kieff.—H. Daniels, M.D., Privat Docent of Psychiatry, St. Petersburg.—George H. Goodyer, M.D., Toledo, Ohio, November 26.—Fred H. Kauwertz, M.D., Milwaukee, Wis., found dead in his office November 25, aged 28 years.—William J. Kernan, M.D., Albany, N. Y., Albany Medical College 1891, November 26.—Robert S. Lewis, M.D., Culpepper, Va., November 28, aged 68 years.—J. C. W. Moore, M.D., Concord, N. H., November 28, aged 60 years. The Doctor was a graduate of Dartmouth Medical College, and on the breaking out of the Rebellion enlisted in the Seventh New Hampshire Regiment and was discharged in 1863 on account of promotion to the Eleventh New Hampshire, in which he served throughout the war as assistant surgeon.—J. R. Sparkman, Plantersville, S. C., aged 82 years.—Thomas Stillwell, M.D., Fremont, Ohio, November 30, aged 82 years.—William P. Taylor, M.D., Abingdon, Md., November 23, aged 46 years.—Edward W. Welling, M.D., Pennington, N. J., November 29. He was graduated from Princeton in 1857 and a few years later from the University of Pennsylvania. During the Rebellion he served as a surgeon under Colonel McAllister, and last year was appointed surgeon at the Soldiers' Home at Hampton Roads.

BOOK NOTICES.

Hand-Book of Materia Medica, Pharmacy and Therapeutics, including the physiologic action of drugs, special therapeutics of disease, official and practical pharmacy. By SAMUEL O. POTTER, A.M., M.D., M.R.C.P., London; pp. 900. Philadelphia: P. Blakiston Sons & Co. Price \$4.50. (From Edward Speakman, medical bookseller, Chicago.)

This edition is one-eighth larger than its immediate predecessor, and is almost a new book, although retaining the general plan and special features which have proved so acceptable in previous editions. Ninety-seven pages have been added and many new articles in the Section on Materia Medica.

A patent thumb index has been placed in the book for the convenience of the reader at the commencement of the several departments of the book.

From our examination we are satisfied that notwithstanding the numerous works on the same subject now on the market the work of Dr. Potter will be found in the front ranks. We regret to see the rather unfriendly tone of Dr. Potter for the decimal system of weights and measures, although in the sample prescription, page 506-507, simple rules are given for metric prescriptions, but they are nowhere incorporated in the text, nor in the general formula.

Dr. Potter writes well, his language is precise, correct, and his opinions are his own, and have been carefully matured.

Manual of Gynecology. By HENRY T. BYFORD, M.D. Second edition, containing 341 illustrations; pp. 596. Philadelphia: P. Blakiston Sons & Co. 1897. Price \$3. (From Edward Speakman.)

The first edition of Professor Byford's book appeared in 1895, and a few changes in the text were therefore required, but a large amount of new matter has been added to this volume, which has been simplified and by devoting several "parts" each of carcinoma, sarcoma, and cystic tumors. Some of the chapters have been rewritten. Marginal notes have been added throughout the book.

In its new form the book will be more popular than ever. The work will be found fully up to date.

A Practical Treatise on Diseases of the Skin. By JOHN V. SHOEMAKER, M.D., LL.D. Third edition, revised and enlarged with chromogravure plates and other illustrations. Pp. 894. New York: D. Appleton & Co. 1897.

The first edition of Professor Shoemaker's book appeared in 1888, and the second one in 1892; many changes have occurred in the pathology and etiology of the treatment of diseases of the skin, a number of new preparations have been introduced and the most important of them that have been thoroughly tested are noticed in the work. A short account has been

given of mycosis fungoides and actinomycosis, neither of which diseases appeared in the former editions. The conclusions reached by the latest investigators in symptomatology, diagnosis and etiology treatment have been added to the volume.

The illustrations are excellent and in general we must say this edition fully merits the support and consideration given its predecessors.

Skin Diseases of Children. By GEORGE HENRY FOX, A.M., M.D., with twelve photogravure and chromographic plates and sixty illustrations. Pp. 166. New York: William Wood & Co.

A series of illustrated articles on certain skin diseases which occur in infancy and childhood, appeared in the *American Journal of Obstetrics and Diseases of Women and Children*, and are now published in book form. Some additions have been made to most of them and as the work now stands it will be found to be one of the most useful treatises on the subject that has appeared, one of which will be useful to every practitioner.

We observe with pleasure that the metric system of measures has been adopted in the formulæ recommended in the book. The illustrations are excellent.

Hutchison and Ray's Clinical Methods. Clinical methods, being an introduction to the practical study of medicine. By ROBERT HUTCHISON, M.D., M.R.C.P., Demonstrator of Physiology in London Hospital Medical College, and HARRY RAINY, F.R.C.P., F.R.S.E., University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. Handsome 12mo, 562 pages, 137 engravings and 8 colored plates. Cloth, \$3. Lea Brothers & Co. Philadelphia and New York.

Although the author modestly disclaims that the book is a clinical diagnosis, yet as a matter of fact it is so, for it describes those methods of clinical investigation by which the proper application, and correct diagnosis can alone be arrived at.

The work includes chapters on case taking; general condition and appearances as applied to the alimentary system and the abdomen; circulatory system; the blood; respiratory system; the uricæ; the skin; the nervous system; eye; ear; throat; nose; locomotory system; clinical examination of children; examination of pathologic fluids; clinical bacteriology.

The work is finely illustrated and has an excellent index.

Spinal Caries. By NOBLE SMITH, L.R.C.P., London. Second edition; pp. 153. Smith Elder & Co., 50 Waterloo Place, London. 1897. Price 5s.

This is a practical treatise on inflammatory diseases of the spinal column. It is accurate, pains-taking and up to date. The work is a valuable addition to surgical literature. This edition, while very little changed from its predecessor, has been improved by the correction of some errors and description of new instruments. The methods of supporting the diseased spinal column are thoroughly and wisely discussed.

Mastoid Abscesses and Their Treatment. By A. BROCA, M.D., Paris, and F. LEBET-BARON, M.D., Paris; translated by HENRY J. CURTIS, B.S., M.D., London; pp. 268. H. K. Lewis, 136 Gower St., London. 1897. Price 6s.

This volume is a translation of a memoir on suppurations of the mastoid process and their treatment, which was originally published in 1895 after having been awarded the Meynot prize by the French Academy of Medicine. The eleven colored illustrations are from Mr. R. J. Godlee's paper of the "International Clinics," volume 2, 6th series. The work is an excellent one, both in the original and in the translation, but for an American reader it was really unnecessary to translate the Centigrade scale into the Fahrenheit.

The Medical News Visiting List for 1898. Seal grain leather, \$1.25. Thumb-letter index, 25 cents extra. Philadelphia and New York: Lea Brothers & Co.

This visiting list is published in three forms: the weekly list, dated for thirty patients; the monthly, undated, for 120 patients per month; the perpetual, undated, for thirty patients weekly per year. The list contains much data of use to the physician and many blank pages. Each style is a well-shaped book with pocket, pencil and eraser.

Proceedings of the Seventh Annual Meeting of the Association of Military Surgeons of the United States at Columbus, Ohio, May 25, 26 and 27, 1897. Edited by JAMES E. PILCHER, M.D., Captain Medical Department U. S. Army. Pp. 694. Columbus, Ohio: Erwin Printing Company. 1897.

This volume includes the minutes of the meeting, reports of the various officers and the papers read at the annual meeting.

It is only fair to the editor to say that this work is not only larger than its predecessor but very much better printed and better edited.

The Society is flourishing and every qualified officer in the National Guard should become a member.

The New Mexico Medical Society. Sixteenth annual meeting held at Albuquerque, N. M., May 12 and 13, 1897. Paper; pp. 12.

This is a report of the sixteenth annual meeting, and also contains a brief history of the Society, lists of officers and members, and the by-laws of the Society.

MISCELLANY.

"**The Laryngoscope.**"—Beginning January, 1898, a foreign edition of *The Laryngoscope* will be published by John Wright & Co., London, England.

A Medical College Burned.—The Tennessee Medical College, Knoxville, Tenn., was burned December 3. The building was comparatively new and cost \$25,000, contents \$12,000.

Hospital for Cornell.—William R. Sage of Ithaca and Dean Sage of Albany have presented to Cornell University the residence of the late Henry W. Sage for a students' hospital and besides equipping it will endow it with \$100,000.

Foreign Medical Students at Paris.—The recent regulations restricting the privileges of the Ecole de Médecine have all been rescinded, and the old order of things restored. Foreigners can now enter and matriculate as in the past.

Compliment to Professor Senn.—A public reception was given to Prof. Nicholas Senn, on December 8, at the Newberry Library, in recognition of his generosity to that library through donations he has made. The medical profession of the city were invited and largely attended. Nearly every physician of prominence was present. Speeches were made by President W. B. Blatchford, Dr. Fernand Henrotin and Professor Senn. The occasion was a memorable one in connection with library movement in Chicago.

Cerebral Complications of Actinomyces have been observed by Bourquin and Quervain, a meningitis and encephalitis, which are invariably fatal, as the parasite always continues its invasion. Treatment with potassium iodid is ineffectual at this secondary stage of the disease. The symptoms are those of other cerebral abscesses or chronic lesions of the brain.—*Jour. de Méd. et de Chir.*, October 25.

Large Bequests to Massachusetts Charities.—Many worthy institutions in Boston are remembered in the will of Eliza Ann Collins, widow of Jeremiah Collins, which was filed for probate in Dedham in November. The Home for Aged Couples and the Home for Aged Women, Boston, will each receive \$10,000; Perkins Institution for the Blind and Massachusetts Charitable Ear and Eye Infirmary, Boston, \$5,000 each; Massachusetts Society for the Prevention of Cruelty to Animals, \$15,000; and the Home for Aged Men, \$10,000.

Total Abstinence and Life Insurance.—Emory McClintock, a life-insurance actuary, has made a very careful examination of the records of all policy holders of his company, classifying them as abstainers and non-abstainers. The main results of his examination are summed up by him as follows: "Upon those who on entering stated that they abstained from alcoholic beverages the maximum expected loss was \$5,455,669 and the actual loss was \$4,251,050. Upon those who stated otherwise the maximum expected loss was \$9,829,462, and the actual

loss was \$9,469,407. These abstainers show, therefore, a death loss of 78 per cent. of the maximum and the non-abstainers 96 per cent."

Size of Bullet Judged from a Wound. In a homicide case, the surgeon who attended the deceased prior to his death testified that he examined the gunshot wound which caused the death, and that he had examined gunshot wounds in the past, and taken bullets therefrom, and knew the size of the bullets making these various wounds, and that the wound in question was inflicted by a 41 or 44 caliber bullet. This evidence, the supreme court of California, in the *People against Wong Chuey*, holds admissible. It says that the witness was sufficiently versed in the subject of gunshot wounds and the respective size of bullets to give evidence of the character here adduced.

Etiology of Chorea.—Prof. Cesaris De Mel announces that he has discovered a lanceolate encapsulated diplococcus in a case of typical chorea, extremely pathogenic for guinea pigs, in which it determines a hemorrhagic hyperemia, with diminished fibrin and no edema. The histologic lesions in the nervous system of the case and in the viscera of the animals showed that the effect was more toxic than septic, and with an elective action on the vessels. This announcement sustains Prof. Leroux's theory that chorea is a syndrome determined by some infective or toxic agent on a soil prepared by an inheritance of neurotic and arthritic tendencies. In this case the degenerative lesions considered specific by other authors, were absent.—*Gaz. degli Osp. e delle Clin.*, August 22.

The Sixtieth Anniversary of the Birth of Photography was celebrated in France recently by the erection of a statue to Daguerre in the small town where he was born. To the scientist Arago is due the honor of recognizing the value of the new invention and presenting it to the world, and rarely has an inventor reaped such instantaneous fame as fell then to Daguerre. With the application of collodion, the daguerreotype disappeared and modern photography took its place, with the sun now supplemented by the Crookes' tube, which has added photography to the medical sciences and rendered it one of the most important subjects presented at the various medical congresses this year.

Virchow's Fiftieth "Docent Jubilee" was celebrated November 6th at Berlin by his friends and pupils, who hailed him as *Preceptor Mundi*, and reviewed the work accomplished during his fifty years professorship with veneration and pride. The congratulations were the more cordial as he had been compelled to leave the lecture room the day before from a slight indisposition, which however proved transient. He deprecated the excess of honors that have been showered upon him lately, observing that he seemed to himself like a tree whose leaves had been stripped off to enable it to present a better appearance. He remarked that if he had succeeded sooner than others in establishing a school, it was because he early recognized the fact that one can not do everything himself, and he had organized a solid phalanx which had been strong enough to withstand opposition and lay foundations broad enough for future development. He announced in conclusion that he had succeeded in convincing the government of the necessity of a new building for the pathologic museum, which was now assured.

A Liability Without Contract. A firm of wholesale druggists in the province of Quebec received an order for bismuth from an apothecary, but by mistake sent him antimony. A dose of antimony, in a prescription calling for bismuth, was consequently administered to a sick woman with injurious effects, and a suit for damages was brought against the firm from which the apothecary obtained the antimony. The trial court decided that the firm were responsible for the injury. The superior court of Quebec held that there was no such relation between the original vendors of the drug and the injured per-

son as to render the defendants liable, but that the real responsibility lay with the apothecary. The provincial court of queen's bench took the contrary view, saying that, although there was no contract, there was a liability. On November 12 the defendants applied to the Judicial Committee of the Privy Council in London for leave to appeal to that tribunal (which is the court of last resort for colonial cases), and special leave was granted. The final decision will be awaited with interest.

Foreign Body in the Air Passages.—Nordman describes his experience when summoned to a child dying of suffocation from having "swallowed something." All efforts to find the foreign body were in vain. Tracheotomy was performed without results and respiration had ceased, although the heart was still beating. Artificial respiration was kept up with frictions and injections of ether until more than an hour and a half had passed, when suddenly a small balloon appeared at the tracheal opening, having been distended and forced upward by the artificial respiration. It was easily extracted and found to be one of the toy whistles consisting of a wooden part, 2.5 cm. by 8 mm., and a small balloon 2.5 cm. by 2.5 cm., which had lodged beyond reach in the right bronchus.—*Journ. de Méd. et de Chir.*, October 25. Another case is reported in which the child had inspired a smooth slender glass object, but instead of performing tracheotomy as indicated, Bonnus attempted intubation first. In a few moments the object was expelled in a fit of coughing, a new and suggestive application of intubation.—*Presse Méd.*, October 30.

The Physical Bases of the Antiparasitic Treatment of Wounds.—An interesting series of experiments at the Institut Pasteur prove that there are other factors to be taken into account besides a sepsis and antiseptics. The absorbent nature of the dressings, the position of the wound, and the condition of the atmosphere favor the absorption of microbes, or the reverse, proving in many cases the most effective weapons in the struggle of the organism against the micro-organisms. The physical processes involved are evident when a small roll of gauze is placed astride on the edge of a glass of water, one end touching the water and the other outside, below its level. The water is drawn up into the gauze and soon begins to drip from the other end. If a drop of methylene blue is placed on the gauze the stain will only affect that part of the gauze beyond it, even if that end of the gauze is raised. If strychnin is sprinkled on a wound in mice, it is absorbed and the animal dies, but if charcoal, magnesia, or some similar substance is sprinkled first, or soon after the strychnin, it is not absorbed by the tissues. Intoxication can also be arrested by applying a moist dressing even after the first symptoms have appeared. Similar experiments with putrid matter, anthrax spores, septic blood, etc., show that the microbes do not find an entrance if absorption and evaporation draw the current outward, but if it is checked by stagnation of the secretions, or any cause, the micro-organisms find their way in.—*Semaine Méd.* November 10.

Increased Charitable Accommodations on Blackwell's Island, New York City.—Mayor Strong and the Commissioners of Public Charities have opened eleven new buildings in connection with the almshouse on Blackwell's Island. Commissioner Faure said that at the time of his appointment over five hundred of the inmates were obliged to sleep on the floors for lack of accommodation and that many of those lodged in the top stories could watch the stars through holes in the roof, which freely admitted the snow or rain in stormy weather. There was no water in several of the buildings and no lavatories except makeshifts. Filth covered the floors until the physicians refused to enter one ward unless it was cleaned. He then gave a report of the manner in which the department has expended the million dollars which had been allowed it for improvements, stating that since Jan. 1, 1895, no less than fifty-three new buildings had been erected. In addition to the eleven at

the Almshouse, these included fifteen at the Infants' Hospital on Randall's Island, five at Bellevue Hospital, four at the City Hospital, Blackwell's Island; four at Fordham Hospital, the new Harlem and Gouverneur Hospitals, and the Lodging House for Homeless Men. In delivering the keys of the buildings to the mayor, Dr. Stephen Smith, the new president of the board, said: "Not one dollar of all that million has been spent for filigree or decoration, either on the interior or exterior."

The Paris Academie de Medecine.—Among the communications of minor importance received by this body in the last few months (the others have already been mentioned in these columns), the report of the transmission of mumps to a dog, a Russian hound who lapped up his master's sputa, aroused considerable interest, although some incredulity was expressed by some other members as to the identity of the dog's affection. The pathogenic rôle of dust has also been emphasized there again recently, and several instances related in which epidemics were traced directly to the dust in the cracks of the floor in barracks, etc. Impermeable floors for such places were advocated. Frigoro therapy was lauded again by Cordes, as the result of ninety-six experiences proves it a powerful stimulant of cellular nutrition (*Vide JOURNAL*, Vol. XXVI, p. 548). Doumer reported the efficacy of the high frequency current in the treatment of painful fissures of the anus and in hemorrhoids. Vaquez described a myocardiac apoplexy discovered at the necropsy, to which he ascribes the sudden deaths during parturition of women affected with mild, chronic heart trouble. He considers it a valuable contribution to the question of sanctioning marriage in cases of known heart disease. Boeckel reported an operation for an inguinal hernia which was found to contain the appendix with the spermatic cord adherent and a loop of the cecum, suppurated and gangrenous. He did not close the artificial anus until three weeks later; perfect recovery. He recalled in this connection an operation, published in 1892, in which he found a matrix and tube in a hernia on a man. Lancereaux communicated a study of the cirrhosis of the liver in habitual drinkers, which forty years of observation have convinced him is not caused by the alcohol, but by the potassium salts in wines treated with plâtrage (calcined gypsum). Laborde disputed his statements, adducing as one of his arguments that in America, where wine is not drunk, and "le whisky" is the principal source of alcoholic consumption, hepatic cirrhosis is frequent. He added that cerebral cirrhosis has also been noted in America by Duplay, who has called attention to this hitherto overlooked lesion. Another interesting communication was in regard to a patient who had suffered much inconvenience from a floating kidney, and finally decided to purchase an appliance to control it. On her way to the city, a ride of several hours by rail, she felt all her discomfort vanish and returned home cured, without purchasing. The cure lasted two or three years when the former inconveniences returned, but again they were cured and this time permanently to date, by taking again the same trip by rail. The Académie expresses disappointment that so few contributions, only three, have been received in competition for two of its most important prizes.

The Vivisection Question.—On November 27 "Vivisection" was the topic for discussion at the Woman's Club, Denver. The following letter was sent by Dr. Charles Denison, who was unable to attend:

DENVER, COLO., Nov. 26, 1897.

To the Woman's Club:—Lying before me is your invitation, received yesterday, to attend the meeting of the Reform Department and take part in your discussion of the subject of "Vivisection."

While I thank you for your kindness, I am constrained to tell you that I can not leave my office to attend, chiefly because I fear it would do no good, and again I might say something under the heat of the debate which would offend the ladies;

something perhaps which (you ladies understand how it is) might better be said, if at all, by inference, so as to avoid the direct charge of prejudice or ignorance.

For instance, if I were to explain that the Humane Society, whose general purposes are admittedly most worthy, had inaugurated a crusade against this so-called "vivisection," and directed much of its argument against my profession for its defense of the same, I should have to explain that only when cornered in a possible but very unlikely debate, would they admit that this word "vivisection" only refers to the cutting up of a live animal, and that an animal under an anesthesia is practically dead for the time being, even though automatically moving. Then of course I would be tempted (only tempted, please,) to show how some women, more easily lured to fanaticism than the rest of mankind, under the new stimulus of this reform age, had taken up the cudgel, and as there is so little of vivisection to attack, they must have the whole question in sight from A to Z, regardless of consequences.

It would not be enough for me to explain that during all my experience, since thirty years ago I commenced the study of medicine, I have seen but one case of vivisection in the limited sense of the animal not being practically dead. The experiment was made by Prof. Austin Flint of New York, and proved of great utility in that it showed to over two hundred medical students that a single drop of woorara poison, previously introduced in a large quantity through an artificial opening (made under chloroform) into a dog's stomach, and without poisoning the dog at all, will kill a dove instantly when this drop is injected under its skin.

If I should thus prove, by the experience of other physicians as well as my own, that this hue and cry about vivisection is a "will o' the wisp" which is a waste of our valuable time to follow, some one would undoubtedly advance the senseless and sensational articles written "by the yard" for the newspapers about the recent dissection of a cat in the Y. M. C. A. rooms. Then I would have to explain that the incident was not so horrible as pictured, and that the young men thus learned the existence and location of internal organs better than by any amount of book reading. Thus the discussion would naturally lead up to the great utility, even among women, of a knowledge of the anatomy and physiology of the internal organs.

Then very likely my argument would be met by a rejoinder of some bright woman, who happens to know something of anatomy, and I fear I would be tempted to put her to a test and ask her where her *spleen* was? She might very likely get ahead of me by claiming that, if I really referred to the organ below the left lobe of the liver, whether she had any *spleen* or not had nothing to do with the question, and retort that doctors did not know anything about the spleen anyway. Of course I would be "floor'd," so to speak; but in acknowledging the truth of the assertion I might rally a little by claiming that ignorance (of the function of the spleen) is a goon reason why more experimenting with animals should be made in order to attain the truth.

With so many ladies present, one could hardly help being personal, for if I were to refer, as an offset to the little vivisection really done, to the thousands of instances of cruelty to animals constantly occurring in both business and social life, I could not help wounding the feelings of somebody present—either the richly dressed woman whose finery is contributed to by the profits of the cruel practice of branding calves with huge red-hot irons, or the culinary critic who will go into ecstasies over a lobster bisque, never thinking that the animal was slowly tortured to death by lying in cold water which was then heated to the boiling point.

But, seriously, it does seem like the "irony of fate" that you women, whose children the medical profession are trying to save from death by infection and contagious diseases, should join the hue and cry against the very means which are just now proving to be the most successful in overcoming these very diseases. It is probably understood by very few of you that each of these infectious diseases is due to a specific cause, which can only be eliminated from the human system by means of a naturally existing or artificially created antitoxin in the blood of the affected person, and that thus far the chief and only reliable means of discovering these antitoxins has been by animal experiments performed with great pains in physiologic and bacteriologic laboratories.

In illustration I could mention here, for the lack of space to say more, the custom of experimenters to poison guinea-pigs with virulent tuberculin, diphtheritic or other poisons, that they may then neutralize these toxins and prevent the animals dying by the use of the proper antitoxin to the given disease. The advance of science is nowadays replete with this kind of evidence, and while it may take hundreds of guinea-pigs to establish such a cure, we claim that any discriminating person

ought to be willing to put the life of a little child against a million of these vermin, if necessary.

The fanaticism of some people impells me to relate, in this connection, the late experience of a brother physician in Philadelphia. A friend of his had three children, the two oldest of whom were attacked by malignant diphtheria. They were attended by a so-called "Christian science healer," who was put in charge, and both in due time died. The third child came down with the same virulent disease and the neighbors insisted on my doctor friend being called. He came and happily in time injected the new antitoxin for diphtheria, and the child recovered. The irony comes in when, less than two months afterward, this friend of his, the father of these children, comes to ask the doctor to attend with him a "Christian science" meeting! Do you wonder that doctors get very "tired" in view of such perverse conditions, and are moved to exclaim, with the poet Burns, "It's hardly in a body's power to keep at times frae being sour, to see how things are shared."

I am, with much respect,
Yours very truly,
CHARLES DENISON, M.D.

Denver.

THE DENVER AND ARAPAHOE MEDICAL SOCIETY.—At the regular meeting held November 23, Charles A. Powers read a paper entitled "Methods and Results in 450 Cases of Fracture of the Forearm Bones." Of these cases 429 had been under the author's care at the Chambers Street Hospital and at the New York Hospital, the remainder being gathered from private practice. After giving general statistics and diagnosis, the author divided his cases into classes: 1, of the radius; 2, of the ulna; 3, of both bones combined; each class being further subdivided into the fractures through the upper fourth, through the middle two-fourths, and through the lower fourth. Each of these nine classes was considered at length, with illustrative cases, methods, management and results. The latter were, on the whole, entirely satisfactory, although the author felt that under no form of management could an absolutely perfect result be attained in every case, especially in those fractures at the lower end of the radius known as "Colles." Dr. H. T. Pershing, in discussing the paper, emphasized the danger of keeping a splint on too long. He mentioned a case of injury to the shoulder which was followed by neuritis. Some one applied a splint which remained on for five weeks, with the result that the fingers became stiff, and although the patient has acquired some motion, it is very imperfect. Dr. Powers also reported the history of an interesting case of fracture of the skull and exhibited the patient: Male, 40 years old, struck in the head by a street-car. When seen by Dr. Powers there was no paralysis or anesthesia. There was a lacerated wound beginning on the right side about one inch above the middle of the margin of the orbit and extending up and back to the temporal parietal articulation. The depressed bone, measuring two and one-half inches in all directions, was removed; frontal sinus found to be open; the dura and brain lacerated. The wound was thoroughly washed, the scalp wound sewn up and the patient reacted well. It was found that there was a fracture through the posterior part of each maxilla and across the root of the nose thus loosening the whole face, which moved freely when the patient talked. No plate could have been inserted owing to the unclean condition of the wound. The patient presented a large depression on the right side of the frontal bone, which disappeared when the patient stooped. Ophthalmologic and neurologic examination showed no deviation from the normal. Dr. A. C. Godfrey exhibited two specimens of anomalies of the arch of the aorta as found in the dissecting room of the Denver Medical College. In one, the left vertebral came off between the common carotid and subclavian. In the other the arch of the aorta was found divided shortly after its origin from the left ventricle. One of the divisions, the right, gives off all the branches except the subclavian. The innominate artery, therefore, gives off the left common carotid in addition to the right common carotid and subclavian. Dr. Bane read a paper on "The Card Index System for Keeping

Records of Cases." Dr. Fern recommended the use of the card system in dispensaries where several students can take the histories of cases at the same time. Dr. J. N. Hall reported a case of splenic leukemia illustrated by microscopic slides in which the white and red blood-corpuscles were in the proportion of one to five.

THE DENVER CLINICAL AND PATHOLOGICAL SOCIETY.—At the meeting of the Society held November 12, Dr. Le Mond reported a case of a nun, 69 years old, who was injured by an explosion of a lamp. The accident was followed by glaucoma and later a cataract in one eye. The pressure having been relieved by an operation, hemorrhage followed and caused the loss of eyesight.

Dr. Leonard Freeman reported a case in which he operated for gallstones and none were found. Soon after the operation the patient commenced to vomit blood, and on the ninth day died. At the autopsy no cause for the bleeding could be found. Gallstones were found in the common gall-duct. Dr. Wetherill demonstrated an original device for classroom demonstration of the different layers of the abdominal wall. Dr. Hershey reported the good results he obtained from the use of atropin and cocaine in shock and morphin poisoning. Dr. Powers reported a case of appendicitis, with exhibition of specimen, which was complicated by a tear in the bladder wall.

HEALTH OF THE CITY.—The total number of deaths during the month of October was 67, representing a rate of 12.52 per 1,000 per annum. Number of days with 0.01 inch or more of rainfall, 6. Possible hours of sunshine, 345. Total hours of sunshine, 284. Mean barometer, 24.77.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from November 26 to December 8, 1897.

Capt. Norton Strong, Asst. Surgeon, is granted leave of absence for three months, to take effect Dec. 1, 1897.
First Lieut. Basil H. Dutcher, is relieved from duty at Ft. Leavenworth, Kan., and ordered to Ft. Grant, Ariz., for duty at that station.

RETIREMENT.

Major Joseph K. Corson, Surgeon, having served more than thirty years in the Army, is on his own application, by direction of the President, retired from active service this date, Nov. 30, 1897.

ORIGINAL ARTICLES.

VAN ARSDALE'S TRIANGULAR SPLINT IN THIRTY-THREE CASES OF FRACTURE OF THE SHAFT OF THE FEMUR IN INFANTS AND CHILDREN UNDER SIX YEARS.

A RÉSUMÉ OF THE DIFFICULTIES AND COMPLICATIONS
OVERCOME; WITH STATISTICAL TABLES EMBRACING
OVER 64,000 FRACTURES ILLUSTRATING THE
PERCENTAGE OF FRACTURE OF THE
FEMUR AT VARIOUS AGES.

Presented to the Section on Diseases of Children, at the Forty-eighth
Annual Meeting of the American Medical Association, at
Philadelphia, Pa., June 1-4, 1897.

BY A. ERNEST GALLANT, M.D.

CLINICAL ASSISTANT IN SURGERY, POLYCLINIC MEDICAL SCHOOL
AND HOSPITAL.
NEW YORK, N. Y.

Van Arsdale's triangular splint is made of thick straw or binders' cardboard, and adjusted in the following way. 1. Measure the length of the uninjured thigh from the middle of the groin to the end of the femur.

2. Outline upon the cardboard a figure resembling two spades (as seen on playing-cards), united at their points, the length of each of the four sections (A, B, C, D) to be equal to the length of the child's thigh (Fig. 1). The flanged portions to equal at the widest part the length of the thigh. Cut outlined figure with a knife or scissors.

3. Moisten cardboard on one side and fold on the dotted lines, lapping section A over D so as to form a triangle, and fasten together by two strips of adhesive plaster (Fig. 2).

4. Cover the abdomen and thigh with absorbent cotton, secure in place with a gauze bandage.

5. Flex the thigh and place the triangle therein so that one flanged portion embraces the thigh, the other lies upon the abdomen.

6. Secure the splint by muslin bandages carried through the splint, around the body and then around the thigh. To prevent lateral motion, take reverse or figure of 8 turns at the upper angle around the body and at the lower angle around the knee (Fig. 3).

7. Encircle the body and thigh with starch or crinoline bandages to fix the splint and prevent removal.

While one person can adjust the splint, it is better to have an assistant keep the thigh flexed against the splint, and to exert a certain amount of extension while the splint is being secured in place. In a child with a very prominent abdomen the upper bar (Fig. 2), made by overlapping A and D (Fig. 1), can be shortened so as to increase the flexion of the thigh and throw the body weight farther forward, allowing the child to sit down with greater ease and comfort. The leg must be bandaged from the toes up to the knee

to prevent any tendency to swelling, but not so as to prevent flexion of the knee.

This splint was first applied to Case 12, Table 5, and has been used on fifteen cases in Dr. Van Arsdale's department and on eighteen cases (including four cases in 1896) by Dr. Swinburne, or a total of thirty-three cases. In Cases 18 and 22, union with angularity had already taken place when brought to the dispensary, but the natural contour of the limbs was restored by the use of the splint for three weeks.

The rule followed has been to see the child at the end of each week, to examine the splint and if necessary to remove and replace it, and finally take it off at the end of the third week, when firm consolidation and cure were obtained in all the cases. To remove stiffness from disuse and restore muscular tone, friction was then applied morning and night to the limb, the strokes always being directed toward the trunk, never up and down. There was no appreciable shortening.

Dr. Swinburne's eighteen cases.—In response to my request in a personal communication, Dr. G. K. Swinburne writes: "Unfortunately, my records are very unsatisfactory and I must give my answers to your questions entirely from memory. None of my cases, so far as I can remember, were over 3 years old. The two youngest cases, one with accompanying fracture of the humerus, occurred at birth and were brought to me within a few days. Almost all occurred in the middle third; two-thirds were transverse; one-third were green-stick; none oblique. Angularity always occurred with the apex of the angle pointing forward. Triangle left on three weeks as a rule, sometimes removed as early as the end of the second week; changed once a week. I remember only three cases as congenital or occurring at birth. The others were due to violence, but could not obtain satisfactory answers from those accompanying the child. No shortening in these cases at time of discharge. Effect on development later I have never been able to note. This method has been always satisfactory as regards cleanliness, but requires careful watching to avoid angularity. Extension does not seem to be necessary in these cases."

Frequency at all ages.—That fracture of the femur at all periods of life is a not uncommon occurrence is well shown by Bruns' analysis in decades of 3,986 fractures (Table 2), and the statistics of various authors tabulated by Gurlt¹ (Table 1) giving a total of 64,979 fractures, of which 5,051, or 7.8 per cent., were of the femur.

In children under 10 years.—The frequency of fracture of the femur in children seems to be a matter of wide difference among the various observers (Table 3), varying from 36.4 per cent. (Beck²) to 4.5 per cent. (Packard³). The latter states that the low percentage may be accounted for by reason of the unwillingness of parents to send their children to public

institutions; a large proportion of cases are treated at home. Gurlt⁴ was unable to account for the apparent rarity of this accident, as shown by the London hospital statistics, 1804 to 1862, until in 1877 he added the fracture tables from the out-patient departments. Summing up the cases in Table 3, gives us 1,599 fractures in children under 10 years, of which 296 were fractures of the femur, an average of 18.5 per cent.

Eastern and Good Samaritan Dispensary.—The work of the Eastern and Good Samaritan Dispensary shown in Table 4, gives a résumé for the nine years ending Dec. 31, 1895. If we divide the total number of children under 10 years (254,036) by the total number of fractures of the femur at the same age, we find but 1 in 6,250 children. Again dividing the total number of fractures in children (343) in Van Arsdale's division (surgical) by the fractures of the femur (26) gives 1 in 13, or 7.5 per cent. fractures of the femur to all fractures in children under 10 years old.

Age.—The youngest child to which the splint was applied (Table 5) was but six weeks old, and the oldest 5½ years. This perhaps accounts for the low percentage, as no doubt many children between the ages of 6 and 10, being too heavy to carry in arms, were taken to the hospitals or treated at home.

Sex.—Of the twenty cases in which the sex was recorded, five were girls and fifteen boys.

Fig. 1.—Diagram showing outline of splint, to be folded on the dotted lines. Each section to equal the length of the child's thigh.

Fig. 2.—Diagram, splint folded, fastened by rubber plaster, flanges bent to embrace the thigh and abdomen, ready for adjustment.

Comparative tables.—Table 6 shows the wide difference in the number of fractures in the same location which may come under the care of two surgeons, as illustrated by the number of fractures of the clavicle, Beck² 7.3 per cent., Van Arsdale 50 per cent., while of fractures of the femur the former had 36.4 per cent. and the latter 7.5 per cent.

Extreme opinions.—On referring to the literature on fracture of the femur in children, one is at once struck by the wide variance as to the relative importance of the way to handle these cases. Owens⁵ states that broken thighs in children always do well; extension and counter-extension are not necessary, for there is no overlapping, and all that is necessary is to keep the little patient at rest and protect the limb from disturbance. He naively adds: There is no better way than by Thomas' hip splint. Whatever be the kind of apparatus selected, it must not hurt nor require frequent readjustment, nor become spoiled from being wetted or soiled. Holthouse⁶ took a somewhat similar position when he said that it is seldom necessary to do more than encircle the thigh

from the knee to the hip with soap plaster spread upon leather, care being taken that it is not applied too tightly.

Difficulties.—On the other hand, when we recall the numerous apparatuses made use of, or read the statement of Stimson⁷ that the practical difficulties in the way of the usual dressings have seemed so great that some of the most experienced surgeons, Paget and Callender, have discarded them entirely and treated many such fractures without splints, the child being laid on a firm bed with little or no head pillow, with the broken limb, after setting, bent at the hip and knee and laid on its outer side, we must conclude that the subject is worthy of careful study.

Starr⁸ points out the difficulty of maintaining the fragments in apposition, due to the restlessness and the necessity of frequent removal of the dressing, due to soiling and irritation with chafing and excoriation.

Vertical extension, writes Kummel,⁹ was first successfully tried in 1877 in Berlin, in the department of Dr. Schede, and has been exclusively used in femur fractures in case of children 1 or 2 years old, and further in those of 3 and 4 years when, on account of the soiling of the bandages, horizontal extension was not practicable. Disturbance of the circulation in the vertically raised leg does not appear in case of such young children. His tables show that several children, while in the extension bandage, passed through scarlatina, measles, pertussis and convulsions,

Fig. 3.—Showing Van Arsdale's triangular splint in position. Note the wide space between the dressings and the excretory passages.

and some succumbed after infectious disease, but none as a consequence of continuous resting upon the back. This optimistic view is refuted by Jacobus,¹⁰ who complains that with the vertical extension hypostatic pneumonia could not be prevented.

Though Hamilton's¹¹ double thigh splint for children does not confine to bed and permits of moving from place to place, it requires frequent changes in order to maintain cleanliness and prevent excoriation.

“Physiologic doctrine.”—Hamilton refers to Percival Pott as the first to oppose the treatment of fractures on the old lines, when he brought out his remarkable treatise on fractures and promulgated what has been called the “physiologic doctrine,” the peculiarity of which consisted in its assumption that the resistance of those muscles which tend to produce shortening can be sufficiently overcome by posture without aid of extension; and, for example, in case of broken femur, it was only necessary to flex the leg upon the thigh and the thigh upon the body, laying the limb afterward quickly upon the outer side upon the bed.

Von Wahl¹² concludes that since the use of exten-

sion in young children is not possible, treatment is without exception limited to the use of splints. Thin grooved wooden splints generally suffice, well padded and kept in place by a roller bandage, frequently changed to prevent excoriation and dermatitis. He evidently recognizes the value of the "physiologic doctrine" when he writes, if it were possible to devise an inclined plane which would secure both legs in semiflexion and leave the excretory passages free, such a proceeding would be much more rational simply because it is impossible to extend the thighs of the little ones and coapt them to straight splints, and it is consequently hardly possible to abolish the deformity. Happily, such deformity disappears spontaneously in most cases; and even shortening is equalized by increased longitudinal growth more frequently than is generally believed.

Referring to simple muscular relaxation, Erichsen¹⁴ recommends laying the child upon its outer side, flexing the thigh to nearly a right angle with the body, and the leg upon the thigh, and supporting the limb in this position by an angular wooden or leather splint extending from the hip to the knee or outer ankle, and by a short wooden thigh splint.

Schutter¹⁵ commends the plan of Henke¹⁶ of flexing the thigh upon the abdomen, and fixation by strips of rubber plaster carried around the back, the two ends overlapping on the under surface of the thigh, reinforced by a strip of cardboard bent at an angle and placed in the popliteal space to support the leg.

Diagnosis.—The diagnosis, von Wahl¹³ considers, is rendered sufficiently certain by the pain, the inability to walk, the shortening and crepitation. He adds: I would merely mention that in young children an angle or bending of the limb, with anterior convexity, is observed, while in older children an external lateral convexity or angle-formation takes place. The reason for this probably lies in the fact that children under 18 months age have not, as a rule, fully extended their thighs, and in the dorsal decubitus maintain a flexed position of the thigh on the pelvis. The weight of the leg carries the lower fragment downward, while the psoas and iliacus muscles draw the lower one upward.

Seat of fracture.—In the forty-four cases here reported the seat of the fracture was located at or above the middle of the shaft, with convexity forward. This confirms the experience of von Wahl,¹³ that it is found to occur most frequently in the middle or at least near the middle of the shaft. He remembers only once having seen a fracture above the condyles. Bitter's¹⁷ cases were also at the middle and junction of the middle and upper third.

Direction of fracture.—Holthouse⁶ found in children, especially infants, that the bone is not infrequently broken transversely or nearly transversely, or it is serrated or denticulated so that complete displacement is much less frequent, and Erichsen¹⁴ believes the bone is usually broken transversely in young persons. Gross¹⁵ states that the obliquity of the fracture of the thigh in young children is generally less than in adults, and cases are met with in which they are nearly transverse.

Nature of fracture.—In rachitic children the fracture is always incomplete or green-stick, though Starr⁸ believes that most cases are of the green-stick variety.

Cause of fracture.—Swinburne recalls three cases of "congenital" fracture out of eighteen cases, one with the humerus also broken. That intra-uterine fracture

may occur, Hornidge⁶ considers proven by the results of autopsies made by Chaussier who found as many as forty-three and even 112 fractures in the same fetus, depending of course, on imperfect development of the bones or congenital rachitis. Fractures due to external violence or muscular contraction may occur in the healthy fetus. Of Beck's² ninety cases, one was the result of intra-uterine injury, one occurred during labor and a third was due to muscular action.

Most authors agree that the majority of fractures of the shaft of the femur are due to direct or indirect external violence.

Time for consolidation and cure.—Kümmel⁹ in children, removed the bandages (Schede's vertical extension) after three weeks. Hamilton¹¹ releases the child from his box in four to five weeks. Holthouse⁶ kept the child in bed four weeks and considered it cured on an average in six to eight weeks. Erichsen¹⁴ deems five weeks necessary for firm union in children under 10 years. Gritti,¹⁹ with the horizontal weight and pulley, obtained consolidation in a majority of thirty-eight cases under 7 years on the twentieth day, with a minimum of eleven days in one child, at 1 year, and a maximum of sixty days in a rachitic child.

In all of the cases so treated, the Van Arsdale splint was finally removed at the end of the third week and the child cured.

Shortening.—Whenever we undertake to ascertain the amount of shortening in a limb which has been fractured and union restored, the natural variations in the length of the two limbs in the same person must not be forgotten. Garson,²⁰ from the measurements of seventy adult skeletons, found the left femur longer in forty-seven cases with an average preponderance of 3.8 centimeters, the right femur longer in twenty cases, average preponderance 2.9 centimeters, and nine in which both femurs were of equal length.

As the result of a careful study of the cases of Warren, Buck and others, Hamilton¹² believes that in fracture of the shaft of the femur occurring in children or in persons under 15 or 18 years of age, the bones may often be made to unite with so little shortening that it can not be detected by measurement; but it must not be forgotten that with children especially, it is exceedingly difficult to measure very accurately, and Erichsen¹⁴ finds that in children union may almost always be procured without any shortening of the bones. But a slight diminution in the length of the limb is in reality of no consequence and gives rise to no inequality in gait; the pelvis, by the obliquity it assumes remedies this. It is only when shortening exceeds one-half or three-quarters of an inch that it is important and occasions deformity.

Lengthening.—The carefully tabulated cases of Kümmel⁹ show, in twelve cases ranging from six hours after birth to one year, that consolidation was completed in from seventeen to fifty-eight days, in all without shortening, except in a boy of ten months who on the twenty-second day of the treatment was attacked with measles, and on the forty-third day discharged at the request of his parents. In this case there was one-half a centimeter lengthening of the femur.

In sixteen children between 1 and 2 years old, consolidation was complete in from 17 to 159 days. In the case requiring 159 days, rachitic, there was one centimeter shortening. In three cases there was a lengthening of respectively one, one and one-half, and one and three-quarters centimeters. In twelve cases

between 2 and 4 years old, consolidation took place in 24 to 123 days; ten firm consolidations without any shortening. One (3 years old) showed some sloughing in the middle of the femur; discharged on one hundred and twenty-third day with no shortening. One healed in thirty days, with two centimeters lengthening.

With the above statements in mind the surgeon will do well to remember the advice of Nélaton,¹² that a fracture of the body of the femur with an adult is always a grave accident, especially on account of the shortening which it is almost impossible wholly to prevent. Accordingly Boyer recommends to the surgeon, from the first day, to announce to the parents of the patient the possibility of such accident.

Non-union.—D'Arcy Power²¹ collected seventy-one cases of ununited fractures in children under 10 years; seven of the clavicle; nine of the humerus; the leg forty-two; the forearm one, and the femur twelve. The very frequent failure of operative measures to effect union is well illustrated from the fact that firm bony union was secured in but six out of these seventy-one cases. He attributes non-union to: 1. *Errors in diagnosis*; a, in congenital fracture, and quotes a case reported by F. Smith in which during a long labor all the long bones were fractured. All united within six months except the right femur; b, in greenstick, sub-periosteal or fractures in fat children. 2. *Carelessness* on the part of parents in seeking skilled advice, or nurse drops the child and is afraid to report the injury, the fracture remaining untreated. Careless splinting or fixation; the injury left to take care of itself. The results of his careful investigations are that the prognosis for subsequent union in children is bad. The ends may be resected, but if there has been much wasting of either end this may prove useless. Fibrous union with artificial support will do for the upper extremity, but only amputation for the lower limb. The prophylactic measures which he insists upon are early diagnosis, maintenance of perfect apposition and immobilization, careful supervision and readjustment with close attention to details.

Advantages.—By the application of Van Arsdale's triangle in fracture of the shaft of the femur in infants and young children:

1. Overlapping is prevented by the flexed position of the thigh, relaxing the muscles.
2. The fragments are held in perfect apposition owing to the nice adjustment of the splint to the thigh, and complete immobilization in whatever position the child may be in.
3. Frequent readjustment is unnecessary, as the dressing is not soiled by the excretions, nor are chafing and dermatitis met with.
4. Complications due to confinement in bed in the dorsal decubitus, such as hypostatic pneumonia and vulvovaginitis are avoided and the liability to concurrent disease prevented.
5. Loss of flesh and strength does not occur, as the child is well and happy; it can nurse at the breast, sit on a chair, play on the floor, even learns to crawl about, sleep on either side, in fact lives a perfectly natural life with the one exception, inability to walk.
6. Under these conditions we are justified in expecting rapid, firm consolidation in three weeks without shortening, and non-union will be rarely if ever met with.
7. For older children and adults the triangle can be strengthened by the use of plaster-of-paris, the flexed

position of the limb being the best for maintaining the fragments in apposition, the most comfortable for sitting or lying and other necessary functions, and the most convenient for getting about on crutches.

Conclusions.—1. That of all fractures at all ages, fracture of the femur amounts to between 7 and 8 per cent.

2. In children under 10 years old fracture of the shaft of the femur is not a common injury.

3. Of all fractures under 10 years, it represents about 18 per cent.

4. It is most often located at or above the middle of the thigh.

5. It is most commonly caused by direct violence.

6. The line of fracture is usually transverse, or nearly so, with convexity forward in very young children, and with some outward lateral deviation in older children.

7. As a prenatal accident it has been met with, and does occur during labor.

8. With appropriate treatment adapted to the age of the child, shortening can be practically prevented.

9. In Van Arsdale's triangle we have a simple means for overcoming the many difficulties, preventing complications, and for securing a perfectly normal limb.

DISCUSSION.

Dr. J. A. LARRABEE of Louisville—Those of us who were out to the Children's Hospital and saw the display of this method were impressed by its utility. I know I was particularly impressed with it because I have had great difficulty, as all of us no doubt have had, in maintaining position in children under 5 years of age. The last case was the worst I have had; it was a child in an Irish family and a wild sort of a boy. I think I applied four dressings inside of four weeks. The plaster-of-paris lasted just about two days, and then I used the creoliu plaster, which lasted about four days. Whoever treats fracture at any age will always find he is in hot water until the case is discharged, for we can not be certain what the result will be. The very points met by this splint are the ones I wanted to meet if I had had a device to maintain the limb in position so the child could sit up in bed. These children are bound to get up and any splint apparatus renders them very filthy and they frequently become excoriated. I think the method just presented is one of the happiest thoughts that can be. It is so simple in construction. With a simple piece of cardboard and adhesive plaster you are ready to treat these cases.

THE APPLICATION OF THE AMBULANT METHOD IN FRACTURE OF THE LEG IN CHILDREN.

Presented in the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JAMES PORTER FISKE, M.D.

INSTRUCTOR IN ORTHOPEDIC SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSISTANT SURGEON, ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT. NEW YORK, N. Y.

I wish to call attention to the possibility of applying the ambulant method to leg fractures in children, and to discuss the method used and results obtained in fractures occurring in children from the age when they first begin to walk up to the age of puberty, say 14 years. This was discussed, in a measure, by the writer at the New York Academy of Medicine, Jan. 11, 1897, and reported in the *Medical News* Feb. 13, 1897.

When we consider how trying a long confinement is to the young and growing child, how rapidly a general muscular atrophy develops, how easily the onset of anemia presents itself, how insidiously a latent cachexia may develop, the possibility of auto-infection occurring at the site of trauma, we realize to some extent the risks of keeping our fracture cases in bed. A method which admits of a child with a broken leg to be up and about during the first week, and by so doing not only tends to preserve the general condition of the patient, but "promotes a healthy and rapid union of the fragments" (Hartley), should commend itself to all.

Simplicity as regards the form of apparatus used, the weight or cumbersomeness of such apparatus, the use or non-use of crutches and the dependence of the surgeon on the instrument maker, all have to be considered in determining what is the best method of treating fractures of the leg, and after a considerable

experience and trials, as regards various methods, I am in favor of the general use of the ambulant plaster-of-paris cast, requiring as it does only a few ordinary roller bandages and a few plaster bandages properly applied. As to the ultimate result in regard to the position and union of the fragments, this method has no advantage over any other method which maintains a perfect reduction of the deformity and affords the necessary protection to the injured limb.

That this ambulant method was practicable to children of all ages was first brought to the mind of the writer by the after-treatment in a case of double bow-legs corrected by osteoclasia. In the summer of 1893 I performed an osteoclasia in a three year old child for double bow-legs, and after correction both legs were put up in plaster of paris extending well up on the thigh. At the end of a week I called to see my little patient, whom I was surprised to find walking about. From that time I have always encouraged this class of patients to walk early, and found as a rule that they were able to walk nicely from the seventh to tenth day after operation. We were already applying this method to simple fractures in older children, and later the ambulant method was carried out most successfully in several osteotomy cases.

How soon should the ambulant cast be applied? is a question often put to us. I believe the earlier the better unless there exists some contraindication. If we can apply an ambulant cast before the occurrence of edema or effusion it is a decided advantage. The value of the early application of the plaster cast has frequently been demonstrated both by the writer and Dr. John McG. Woodbury in the Roosevelt fracture service, and I need but refer you to our statistics of these cases published in the *Medical News*, Feb. 13, 1897.

The same general principles apply in the treatment of leg fractures as in fractures in any other part of the body, and our first duty is to reduce any existing deformity, our second to maintain such reduction by the immediate application of some retaining apparatus, and our third to elevate the limb. This can all be accomplished in most cases by the immediate application of the plaster cast, and at the same time we are adding more effectively to our patient's comfort than by any other means, the comfort of the patient being in direct proportion to the amount of fixation and protection afforded the injured member. We at times meet cases where the reduction of the deformity is difficult, due usually to muscular spasm or obliquity of the fragments, and in these cases we administer an anesthetic and then accomplish complete reduction of the deformity.

The ambulant plaster-of-paris cast is applied as follows: After reduction of any deformity the limb is held by an assistant, the foot being flexed to a right angle, and the foot and leg are bandaged with a muslin roller from the toe-tips to and surrounding the tuberosity of the tibia. This bandage, as well as the cast, may extend in children well up on the thigh, but the effectiveness of the cast as a walking splint depends largely on how firmly it grasps and supports the enlarged upper end of the tibia. Over the muslin roller we apply our plaster bandages in the same manner, building it stronger about the ankle and also at its superior circumference, where in walking it largely supports the weight of the body. No padding is used, the splint exerting equal pressure at all points. A considerable experience in the use of plaster dress-

ings is requisite to have the cast applied in an efficient manner. It has been thought that as the tuberosity of the tibia is not developed to the extent of adult life, the ambulant cast is not applicable to children. This view is entirely erroneous, as I have successfully applied the ambulant cast to all ages and in various conditions, not only fractures of the leg, but in tubercular disease of the ankle joint, after clubfoot operations and after operations about the ankle joint, including resection of the ankle joint, and also in osteotomy cases involving both tibia and fibula.

This then is the truly ambulant method, the patient walking on the injured limb without the aid of crutches, the weight of the body being transmitted from the tuberosity of the tibia to the upper circumference of the plaster cast. As I have stated elsewhere, the advantages of this method of treatment are that the patient is kept up and about, less muscular atrophy occurs, there is less stiffness of adjacent joints, the period of after-treatment is considerably shortened and the general health of the patient is maintained.

Though at some time during convalescence the ambulant splint should be called into play in every fracture of the leg, there are certain fractures and conditions complicating fractures which may prevent the early use of a walking cast. The existence of edema, abrasions, marked effusion or considerable obliquity of the fragments all call for some delay. In compound fractures or where we have any abrasion, we must wait sufficiently long to determine the absence of any infection. Where there is obliquity of the fragments the ambulant cast should not be employed until the fragments are thoroughly glued together in their proper position and ossification has commenced, *i. e.*, about the tenth day. All simple fractures seen early where there is no tendency toward displacement, with absence of edema, call for the immediate application of the ambulant plaster-of-paris cast.

Without presenting any extensive statistics, I will report two representative cases showing in a measure the wide range of cases which can be treated by this method.

Case 1.—Simple fracture middle third of tibia.—F. B., age 6 years. This case was reported to the New York Academy of Medicine, January, 1897. Dec. 11, 1896, while coasting on the snow, he ran into a cart and fractured the tibia just below the middle third. He was taken to Roosevelt Hospital and the leg put up in plaster. He was referred to me one week later, when the dressing was removed and, as the leg was in good condition, the ambulant cast was applied. He reported to me the next day, and as everything was in order, he was instructed to walk. In a few days he not only walked with ease, but rode his velocipede daily.

Case 2.—Osteotomy, Trendelenburg operation combined with orthrodesis.—Louisa Neuman, age 14 years. When very young she had an attack of poliomyelitis anterior, and since then the muscles of the right leg have been paralyzed. For years she has had a flail foot and at present, when she walks, with each step her foot is thrown out and the internal malleolus touches the ground. No apparatus could correct this deformity of years' standing, and fixation of the ankle joint by orthrodesis was advised. This was consented to and the patient was operated on August, 1896. The ankle joint was opened by an external incision and the entire articular cartilage removed. Upon replacing the foot the vicious position of extreme valgus could not be corrected, so the superior third of the inner portion of the astragalus was chiseled away, but this did not correct the deformity sufficiently. Wishing to preserve as much of the tarsus as possible, I determined to fully correct the deformity by the Trendelenburg method, removing a wedge from the lower third of the tibia, performing a linear osteotomy on the fibula and then turning the foot inward until it was in the proper line. This procedure was entirely successful and the foot, leg and thigh encased in plaster. Convalescence was uneventful and on the eleventh day dressings were removed, stitches taken

out and the ambulant plaster cast applied up to the tuberosity of the tibia. This patient commenced to walk on the fourteenth day, and was discharged six weeks after the operation.

I need only add that after operation and complete correction in clubfoot in children who are old enough to walk, as well as in many cases of tubercular disease of the ankle joint, we have used the ambulant cast with the greatest success.

THE EARLY RECOGNITION AND MANAGEMENT OF DEFECTIVE DEVELOPMENT IN CHILDREN.

Presented in the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY LOUIS FAUGÈRES BISHOP, A.M., M.D.

Chairman Section on General Medicine, New York Academy of Medicine; Secretary Section of State Medicine, American Medical Association; Member Neurological Society, Etc.
NEW YORK, N. Y.

Too long has the treatment of the defectively developed mind been postponed beyond the age of infancy, and often are individuals thus affected relegated to the hopelessly idiotic group, without a careful study of the possibilities of each. The very poverty of our knowledge of the subject challenges study and investigation. The great variations in degree make it difficult to recognize in early childhood the mildest forms, and the worst cases are so bad that they offer no encouragement to treatment. The cases that require the greatest attention are those in which we can hope to rescue the individual from the class of useless idiots, and by intelligent education place him as an humble member of the productive classes.

The etiology of idiocy has always been a source of speculation. Most lay people and many medical men fall into the habit of concentrating their attention too much on the size and shape of the brain. We have chosen the term defective development rather than idiocy to emphasize the fact that the trouble is quite general throughout the whole economy. The cause of this deep-seated vice of development lies further back than the premature ossification of the bones of the cranium, further back than an unusual smallness of the heart, further back than any noted change in the size and shape of the brain cells, or the number of tangential fibers. The cause to be sought is some force that has influenced that factor, which in our ignorance we term life. Heredity is a strong factor of insanity or imbecility, existing, according to the statistics of Martin W. Parr of Pennsylvania, in 38 per cent. The cases of idiocy due to infantile cerebral disease, such as hemorrhage, are examples of arrested development due to a definite gross lesion. We prefer to consider the more uncomplicated cases in which the defective development can not be traced to accident, infantile cerebral palsy, or the cerebral complications of the exanthemata. The early recognition of defective development is not at all easy. Children differ much as individuals in different families, and also are very strongly influenced by their surroundings. The keenness of their special senses also plays a strong part in rapidity of the mental development. A slight defect of hearing or eyesight in a young child will influence and retard development in a marked degree. I have a number of times had occasion to point out that an apparently idiotic child was only defective in sight or hearing. Curiously enough, however, some of the children who on careful exam-

ation prove to be markedly defective, have every appearance of being the brightest children. Probably the most troublesome cases and those that are the most difficult to improve are the active, restless and physically strong. It is impossible to fix the attention of these children and they are absolutely lacking in that power of plodding work that often does so much for some dull cases.

One of the saddest things that can happen to a defective child is that he should be placed under the educational influences of a large school in competition with children of normal abilities. Under such circumstances, as time goes on, a defective child gradually drops farther and farther behind until finally he is associated with children much younger than himself. This breeds discouragement, recklessness as to behavior, and mortification of spirit, or what is just as bad, callousness. The defective child should be trained with a definite view of accomplishing the possible. If the child is almost imbecile the training should commence in a purely physical direction, and the child should be taught to perform at first a few definite acts, as a trade, or certain household duties. The capacity of the child must always be borne in mind. The defective child must be taught many things that in others come from observation and example. The defective child is taught with great difficulty the care of its clothing and the minor civilities of life that to a bright child come almost without teaching. More difficult and more serious even than the development of mind is the development of character. Stubbornness and perversity of disposition are more often a manifestation of defective development than they are of an inheritance of strong characteristics from the parents. The defective child is unable to subdue its own personality and unable to recognize the authority of others. The question of how to meet this difficulty is of very serious import, and will tax to the greatest degree the tact and intelligence of those who have the responsibility of its training. But the principles applicable to the defective child are not different from those of education in general. Indeed, the study of the defective has often thrown light upon the whole field of education. Severity is certainly wrong. The principle so strongly advocated by Spencer, that the child should be allowed to suffer the consequences of its previous acts are applicable to a degree, but a defective intelligence renders extreme application impossible. Undoubtedly the most rational treatment of such children is to disregard as much as possible all previous acts and perversities of temper, and by constructive efforts in the directions of those abilities and faculties that the child has to counteract as much as possible the evil tendencies. The question of responsibility is not easy to decide, but certainly the defective child is not to be held accountable for those acts that are evidently the outcome of its condition. The symptoms of the defective do not always differ in quality from the ordinary defects of most children. It is more a difference of degree. A child subject to occasional outbreaks of ungovernable temper, or even frequent perversity of will, should not be decided to be defective; but when this is accompanied by the extreme restlessness of manner, the inability to fix the attention, and perhaps physical signs, the diagnosis is easy to one of any experience. With the history of a cause or the presence of recurrent convulsions, the diagnosis of defective development may be certain. The close study

given, of late years, to the development of children by intelligent mothers, nurses and educators, who from time to time meet to consider the interests of children, may throw light on the normal and abnormal child's mind that may in the future make the very early recognition of defective development easier. At the present time it must be based to a large extent upon a balancing of probabilities and upon the ripe experience and the trained judgment. Fortunately there is nothing in the management or treatment of the defective child that would in any way prejudice the future of a child, in the case of a mistaken diagnosis. On the other hand much harm can be done to the prospects of development if the defective child is wrongly managed in its earlier years, and its condition only recognized when the manifest difference from its fellows becomes evident through the application of an educational system that has already worked upon it the greatest hardship.

THE CARE OF THE BABY'S EYES IN THE PERAMBULATOR.

Presented in the Section on Diseases of Children, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY MARY E. BALDWIN, M.D.

NEWPORT, R. I.

The matter to which I call your attention, the baby's eyes in the perambulator, is one epoch in the life of many children that seems absolutely to have been ignored. I say many children! The very poor are not luxuriating on wheels. They have a possible contact with mother earth, or with a pavement. Again they get the air on the hip of an older sister. Children born in the other extreme of worldly position are not so often in a baby cab.

In the maternity, the nursery and in the school, the young eyes have received intelligent attention with preventive suggestion and remedial treatment.

The first bright spring days are hailed by invalids and almost anybody's baby is then given a breath in the fresh air. The invalid is apt to have a veil, colored glasses, a close carriage, a sunshade, etc. For this outing the baby of fairly well-to-do parents in America may have in order of time the third special outlay for sweet daintiness. The toilet basket and the Christening robe have or have not preceded. The perambulator with its umbrella top may be the first real treasure the parents secure for the baby. It is as important as the coming-out dress of the *débutante*, or the first dress suit. What is it? Of rubber tires and the various springs, I will not speak. Would that many adults might have had an outing some glorious morning in the past three months in an enlarged baby cab. This means an intense white reflex from the blanket, much farther from the eyes than could possibly be arranged for the baby. An ever changing parasol is professedly protecting from wind and sun. What does this creation of lace and flummery really do? The average parasol for the baby cab is covered with figured white lace, or thin white material that is gathered. The lining may be fairly opaque and of neutral tint. Often the covering is of such a combination of texture and color as to give through it, in bright sunshine, a mottled light. The edge is finished by a fringe or by a ruffle, something that can wave and flop, and usually it does this so that it not only gives a changing object before the child, but at the same time

throws the sunshine or light of varying intensity into the face.

With the joltings from various causes, including the curbstones and the temper and thoughtlessness of the attendant, the parasol top and a white blanket to give a reflected light, there is a sorry combination. If my picture does not appeal to each one of you, I beg you to call upon your memory and put your eyes in the place of the baby's. If your attention has never been arrested by the squinting babies, will you not observe them in their perambulators?

During the short, cold and comparatively sunless days, the young child is apt to be kept indoors. The adult likes a breath of spring warmth, and gets it with an outing for the baby. From the shaded room to the unshaded street the transition is greatest for the infant, during the spring months. When summer heat comes, the care-taker will seek the shady side of the street or the protection of trees.

The ocean beach with the near sand and the far reach of sky and dancing water needs consideration, if the baby, well or sick, is to be sent to it.

Without actual demonstration, it seems most probable that an obscure etiology may often be traced to the conditions to which I have had the honor of calling your attention. Does not the probability assume so much the aspect of a certainty as to demand a widespread protest and warning. This is my reason for wishing even at this hour to enlist your interest. Grant you I certainly do, that this touches a most fruitful means of gratifying the vanity of the younger or the older mother or even of the devoted father. Twenty-five years ago, imagine if you can the horror with which we would have looked upon a dozen well-bred daintily dressed children wearing black stockings. Put a dozen daintily dressed children on the street today with white stockings and they will attract every eye.

If the parents are convinced that danger threatens the babies from the present vanities of their cabs they will accept a remedy, a prevention; make the prevention a fad, a fashion, and all is accomplished. Taking for granted that every doctor will be convinced as soon as his own eyes have been taken for an imaginary outing with those of the baby, every baby carriage will soon be dressed in opaque and soothing color, with no tilting canopy, flying frill or sharply reflecting robe.

DISCUSSION.

Dr. J. J. TAYLOR—Usually the iconoclast lays the way for the reconstructionist, but sometimes we have the iconoclast and the reconstructionist in the same individual. The Doctor has destroyed our baby carriage, but she has also given us some idea as to the proper kind of a baby carriage.

Dr. BALDWIN—I am very glad of the opportunity to speak of the remedial measures, although I can not say I have sufficiently formulated them not to be open to some modifications. I am told the English cabs have a top that shoves down, a good deal like the street cabs in America. Occasionally I have seen those in America. They are usually in some dark color. I am told, also, that the English cab has a dark colored robe. I think we seldom see a physician here riding with a white lap robe. Recently, in speaking on this subject, a physician said, "O, you will never get our mothers to dress their children in green." But I do not believe the mothers can keep the top of the perambulator in such a position as to be of any advantage to the child. I think a cover that will give a steady light is much better. I would have no lace and no frill that can be constantly changing its position. In the nursery we have been told the children should not be given things near the eyes, and that the light should not come into their eyes directly, and that

at no time should they be employed with anything small. But the very first season, when the child goes in the perambulator, these rules are lost sight of. I would take away the irregular light, I would plant no flapping thing on the carriage, and I would have no white light reflected into the infant's eyes.

THE INFLUENCE OF OUR SCHOOL SYSTEM ON THE HEALTH AND DEVELOP- MENT OF THE CHILD.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. STUVER, M.Sc., M.D., Ph.D.

Member Colorado State Medical Society (Vice-president 1894),
American Medical Association, International Medical
Congress (Berlin); Active Member National
Educational Association.
RAWLINS, WYO.

The strength, happiness, prosperity and stability of nations and races almost entirely depend on their hereditary heritages and their ability successfully to adapt themselves to their environment.

The whole history of man's development from the earliest times conclusively proves that his highest welfare is conditioned on the harmonious development of all his powers, physical, intellectual and moral, and that when one or more of these have been slighted or neglected, he has paid a dear penalty for such neglect.

Glancing down through the ages, we behold untold misery and innumerable wrecks caused by the violation of this inexorable law of nature. Here we see ignorance or disregard of sanitary laws followed by pestilence, disease, lowered vitality, degeneration and extinction; there we behold licentiousness, debauchery and immorality in all its varied forms, produce a similar result. Nor are the most striking examples taken from savage or barbarous peoples, but furnished by the greatest and most powerful nations the world has ever known.

The observance of these developmental laws raised Greece to the pinnacle of intellectual greatness and physical perfection; their violation reduced her to an insignificant dependency and to a position of subordination, which she is now making a gallant effort to overcome. Physical, intellectual and moral integrity made Rome the mistress of the world and the Roman name honored and feared everywhere, but the loss of the virtues which made her great was the signal for her downfall, and now there remains only the name of her former power, grandeur and glory.

Such examples as these should cause us, as a nation, to pause in the midst of our wonderful career and consider some of the dangers that threaten us, and at the same time carefully examine our bulwarks of defense and see whether they are in a condition to resist any or all attacks that may be made against them.

We have always boasted, and justly too, of our National system of popular education, and repose greater confidence, as a means of defense, in the intelligence, freedom and patriotism of our people, than in immense standing armies and monster iron-clad ships. While nearly all will admit that our public school system is a strong bulwark of defense, and has been a potent factor in molding our National character, developing our institutions and promoting our material welfare, still the question naturally arises, have these results followed as the consequence of our educational methods, or have they been largely due to the

inherent force of character, mental acumen and physical integrity of the hardy pioneers who laid the foundations of our Nation, and to whom is due much of our greatness as a people?

The highest happiness and welfare of a nation or a people is in direct proportion to the highest happiness and welfare of the *great* majority of the individuals who compose it; and the greatest welfare of the individual depends upon the inheritance of a strong, well balanced organization and the symmetric and harmonious development of all his powers; in short, in order to attain the most complete living he must be perfectly adjusted to his environment. To accomplish these results an educational system must provide, in the first place, for a strong physical organization on which to work. Sanitary, hygienic and dietetic laws should be thoroughly understood and their principles carefully inculcated. Every parent and teacher should be strongly impressed with the truth that a "sound mind in a sound body" is a *sine qua non* in every case, if enduring results are desired or expected. Every one, and especially teachers, should understand that plain, nutritious and unstimulating food, an abundance of sleep, and plenty of free, unrestrained exercise in pure air, away from the formality and routine of the schoolroom, where the spontaneous activities are given free play, are of the greatest possible value to the child. They should not only know, but put into practice, the truth that proper food, plenty of oxygen, and frequent periods of relaxation in which to rest and change the activities of the brain, are of infinitely greater value to the child than the details of geography or history, or the memorizing of rules of grammar or arithmetic, frequently drawn from principles they do not understand. Then, too, teachers and all those who have the direction of the intellectual and moral training of children, should have a clear and comprehensive knowledge of the laws and principles underlying and governing the development of the brain, as well as the mental and moral faculties of the child. They should know that the brain of the child, as compared with that of the adult, contains a larger percentage of water, is more unstable, more easily irritated, and that as a consequence, long continued, monotonous work not only fails to strengthen it, but, on the contrary, weakens the mind, besides producing irritation of the brain, with a lowering of the vital powers and retardation of the physical development. They should understand that the motor centers, which preside over and control muscular movements, act much as storage batteries, that is, they store up nerve force, which is almost constantly being discharged and producing muscular movements. The proper development of the muscular system being the foundation on which muscular strength and integrity depend, nature has wisely, by the automatic discharge of nerve force, to a large extent removed muscular development from our volitional control. We might just as well try to compel a normal, healthy child to stop breathing, as to remain quiet for any great length of time. The nerve force accumulating in its motor centers has just as specific and important a function to perform as that which regulates the activity of its respiratory organs. If teachers understood this fundamental physiologic truth, together with the fact that the inhibitory brain centers, as well as the paths of association which connect them with the motor centers, are in an undeveloped condition, thereby necessitating the discharge of nearly all nerve

force in muscular movement, and that when the attempt is made to frustrate this provision of nature the effort at inhibition not only requires much brain power, which should be used in quiet thought and study, but that it produces irritation of the brain and weakens the mind, they would not commit the very common error of trying to compel young pupils to concentrate their attention on one subject or remain quiet for a long time.

Teachers who understand the natural order of evolution of the faculties can assist nature in directing the mind in proper channels and help strengthen and develop the various mental powers at the proper time and in the proper manner. Activity is the normal healthy condition of the human mind, and if this activity be properly directed mental work should be a constant joy, a source of the greatest pleasure and happiness to the learner. Show me a school where the pupils dislike their work, where everything is regarded as a disagreeable task and evaded or performed as a matter of routine, and I will show you a school where dreary drudgery and dead formalism have taken the place of generous enthusiasm and noble aspirations; where the laws of mental and physical growth are outraged and the moral nature is being warped and distorted, and in charge of that school you will find a teacher entirely unfitted for his or her work and who is lowering one of the grandest vocations to the level of a mercenary calling.

Every educator should appreciate the fact that in its development the child is an epitome of the development of the race. It passes through savage, barbarous and semi-civilized phases of development with many of their attendant impulses and passions before reaching that culture and refinement represented by our best civilization. In view of all these facts the proper training and education of a child is a most difficult thing and demands on the part of the teacher natural ability for the work, a thorough education and careful professional training, besides an accurate and comprehensive historic knowledge of the mental and moral evolution of the race and a careful observation and study of these faculties in the child.

While educators are being profoundly stirred on this subject and "child study" is receiving much attention and creating great interest, still the fact remains that the great mass of teachers know very little about it; indeed, it is a deplorable fact that the great majority of teachers in our public schools have never had adequate professional training of any kind (only about 15 per cent. have taken a course of training in normal schools, see *Forum*, April, 1896, page 179), and many lack that thoroughness of education necessary to make them first-class teachers. Under these conditions, is it any wonder that the courses of study formulated and the methods of instruction pursued have been either injurious, barren of results or failed to produce that highest good which should be the aim of all education.

To obtain a consensus of opinion on the influence of our school system on the health and development of the child, I addressed to about one hundred and fifty of the leading educators and physicians of the country the following questions:

1. Do you think our present comprehensive course of study is best calculated to develop the highest physical and intellectual powers of the child?
2. How long do you think continuous school sessions should be?
3. What is the longest time that should be devoted to a sin-

gle recitation? *a.* In primary grades; *b.* in grammar grades.

4. How often should pupils have recesses or periods of relaxation?

5. Which do you think are more beneficial, open-air recesses with spontaneous play, or formal indoor exercises consisting of calisthenics, etc., and why?

6. To what extent does the practice of denying pupils the privilege of attending to the calls of nature or of punishing them for the exercise of this privilege (by making up for the time so lost, etc.) exist in the schools? *a.* What do you regard as the moral effect of such a practice on the child? *b.* What physical evils may or do follow it?

7. What effect does "home" study, outside of school hours, have on children, and especially on girls during puberty?

8. What should be the outside limit of such study for: *a.* grammar school pupils; *b.* high school pupils?

One hundred and five answers were received: Sixty-nine from educators, including college presidents, professors in colleges and normal schools, superintendents of city schools, principals of graded schools and others eminent as educators; also thirty-six from physicians who occupy professorships in our leading medical colleges or have distinguished themselves as general practitioners or specialists whose work is among children, or who have large opportunities to observe the effects of school work upon the health of those who have recently passed through or who are now pursuing a course of study in the schools of the United States. As you will notice, the answers come from all sections of the country, and as a consequence the results of the investigation which I herewith subjoin, do not possess a mere local significance.

Answers to No. 1.—Sixty-three of the sixty-nine educators answered this question as follows: Yes, fifteen; no, twenty-nine; doubtful, eighteen, with one no to first part and yes to the second part.

Prof. Joseph Baldwin, LL.D., Austin, Texas: No. Many modifications are demanded.

Prof. Edward Brooks, LL.D., of Philadelphia, Pa.: Yes. The course in the elementary schools is not too comprehensive and does not interfere with the physical development of the child.

President George Stockton Burroughs, LL.D., of Crawfordsville, Ind.: No. Too many subjects are handled at once: the physical neglected.

Prof. William A. Cate, M.S., of Fountain City, Tenn.: Too many studies are carried at one time. I do not find so much fault with the comprehensiveness of the courses of study, however, as I do with the everlasting cramming in teaching.

President Alston Ellis, LL.D., of Fort Collins, Colo.: No. Course of study in higher grades too pretentious.

President Charles W. Eliot, LL.D., of Cambridge, Mass.: Courses are now in stage of transition, are being revised and enriched and will result in a comprehensive and better course.

Principal J. M. Green of Trenton, N. J.: I do not. I think it contains too many subjects, as generally laid out.

Supt. J. M. Greenwood, A.M., of Kansas City, Mo.: In general the schools are overcrowded with studies.

President G. Stanley Hall, Ph.D., of Worcester, Mass.: It needs great reconstruction.

Prof. Mark W. Harrington, LL.D., of Seattle, Wash.: Probably best for pupils treated collectively. Better means could be applied to pupils treated individually.

Supt. L. H. Jones of Cleveland, Ohio: I am a believer in liberal and comprehensive course of study.

A. A. Johnson, D.D., of Laramie City, Wyo.: Yes, if proper attention is given to hygiene and physical exercise.

Prof. Joseph W. Mauck, LL.D., of Vermilion, S. D.: I believe it would be better if less comprehensive and more intensive; more thorough grasp of a few subjects and less distraction and anxiety from a multiplicity of studies.

President George L. Osborne, LL.D., of Warrensburg, Mo.: The early part of the course deals too much with books and not enough with nature. It is also defective in its cultivation of the power of expression.

William H. Payne, LL.D., of Nashville, Tenn.: There is a tendency to injurious high pressure.

Col. F. W. Parker of Chicago.: There are a great number of courses of study and few are adapted to the growth of the child.

Mrs. Frances E. Ramsey of Westport, N. Y.: Emphatically, no! There is danger of superficiality as well as physical degeneration through feeding the brain at the expense of the body.

President Charles Super, LL.D., of Athens, Ohio: I do not, most emphatically.

Nathan C. Schaeffer, LL.D., of Harrisburg, Pa.: Everything depends upon the teachers employed.

Charles F. Wheelock, B.S., of Albany, N. Y.: No. We teach too much and permit the child to develop too little.

Rev. F. R. Wotring, D.D., of Berthoud, Colo.: No. Too much pouring in and not enough drawing out, though there has been a great improvement in recent years:

President Irwin Shepard, A.M., Ph.D., of Winona, Minn.: Yes, if wisely administered.

Thirty-five physicians answered this question (No. 1) as follows: Yes, two; no, thirty-two; doubtful, one. The following are some of the opinions expressed:

Prof. Henry M. Brown, M.D., of Cincinnati: Not by any means; too hard on the nervous system.

Prof. N. P. Dandridge, A.M., M.D., of Cincinnati: No. I regard our public school system as defective in many ways.

Prof. N. S. Davis, M.D., LL.D., of Chicago: No; because it taxes the mind with too many studies and prevents thoroughness in any.

George M. Gould, M.D., of Philadelphia: Not by any means. Our modern system of education is the offspring of vanity and sin, for which our future world will justly curse us.

Prof. C. H. Hughes, M.D., of St. Louis: No. It is too exhaustive, overtaxes the perceptive powers and dwarfs the reflective. The tension on the physical centers is beyond their responsive powers and powers of body and endurance.

Prof. Frank Parsons Norbury, M.D., of Jacksonville, Ill.: I am opposed to the present method of conducting primary grades, very large classes and crowding together.

Prof. C. D. Palmer, M.D., of Cincinnati: No. One of the most serious effects of our modern school education, especially in the more advanced grades, is the multiplicity of studies crowded into any course, for the result is that a very imperfect and superficial information is obtained with nothing done in a thorough manner. A few things learned well are infinitely better than many learned superficially. Bad habits of mental training are induced by skimming over branches. Good habits of study and strength of mental discipline come only from thoroughness.

Prof. Theophilus Parvin, M.D., LL.D., of Philadelphia: I do not believe in a common education for

boys and girls. They have or ought to have different work or calling in life and the education should not be the same in many departments of study. Of course, it follows that co-education can not be. On moral grounds, too, I am unfavorable to such education. Not only sex but the individual is disregarded in our system of public education.

Prof. Thad. A. Reamy, M.D., LL.D., of Cincinnati: No. They are not taught to think and observe.

W. H. Short, M.D., of La Grange, Ind.: There are too many branches in one grade: too much required in all grades, especially primary grades, e.g., arithmetic contains too many written exercises and examples which never occur in business, and fractional numbers of large and unusual terms which weary and bewilder, and when written analysis is required a child of only average ability, in almost every case, is compelled to accomplish this at home. If we had teachers of discretion who would cut out half of the text-book and instead give the classes, simple practical business questions, both mental and written, much would be gained. Instead of some conception of the simplest laws of mathematics, children are misled with rules and puzzled by hard questions until they neither know what they are trying to learn nor what powers they are trying to use, and so in other branches. *Too much attention is given to details.*

Henry Ling Taylor, M.D., of New York City: Not as I am acquainted with it.

Henry E. Tuley, A.B., M.D., of Louisville: The curriculum in the public schools in this city is very good.

De Forest Willard, M.D., of Philadelphia: Fewer branches would yield better results.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: I think there is too much study from books and too little from nature.

Wm. Jay Youmans, M.D. (Editor Popular Science Monthly), New York City: No. It includes too much, forestalling the exercise of the thinking faculty. I am not an admirer of our school system as now organized. It is artificial to the last degree; while healthy development, both bodily and mental, is a natural process that is oftener defeated than promoted by the school.

Augustus P. Clarke, A.M., M.D., of Cambridge, Mass.: Not for the average child.

Prof. Leonard Freeman, B.S., M.D., of Denver: No. There is too much systematic study and too little systematic physical culture.

Prof. J. A. Larrabee, M.D., of Louisville: The course of study and requirements between eight and twelve years is too laborious, exacting and voluminous.

Answers to No. 2.—One hundred educators and physicians answered this question, and while there is considerable diversity of opinion among them the average length of a session without outdoor, open air recess, advocated, is from one to one and one-half hour. Many insist that the sessions should be shortened and more time given to physical culture.

Answers to No. 3.—Just one hundred answers were likewise received to this question, and while there is considerable divergence between them, the great majority advocate recitations, in the primary grades, of from ten to twenty minutes in length, and in the grammar grades from twenty to thirty minutes. It is urged, very justly too, by many of the respondents that the length of the recitation should be governed to a large extent by the subject, the method of instruc-

tion and the kind of teacher in charge of the class; that a good teacher would be able to maintain the interest of the pupils for a longer time and attain good results, while under the charge of a poor teacher, this interest would not be secured, they would soon tire and be more injured than benefited.

In this connection I desire to insist that whenever the children of a class in their efforts to follow the recitation, become tired, or it requires a strong effort of the will to keep their attention on the work in hand, it is time to stop. If this limit be exceeded the unstable brain will be injured and infinitely more harm than good be done. The custom of requiring pupils of 11, 12 or 14 years of age to spend two hours or more continuously on a single recitation, review or examination of one subject as is sometimes done, is not only a gross violation of all mental laws and is *prima facie* evidence of ignorance or heartlessness on the part of the teacher, but is at the same time barren of results; because it is a well established fact that impressions made on a tired brain are very evanescent in character and the effort required to concentrate the attention in such a condition has a very enervating effect on the mind.

Answers to No. 4.—The importance of relieving the strain on the brain and allowing it to equalize its energies; that is permitting the stored up nerve-force of the motor centers to discharge itself in muscular activities while the higher brain centers are resting and accumulating force to carry on their proper work, is being recognized by the best educators and physicians who advise frequent periods of relaxation and play.

In response to this question I quote the following:

Prof. Joseph Baldwin, LL.D., of Austin, Texas: Every hour.

Prof. Edward Brooks, LL.D., of Philadelphia: Each hour to once in each half daily session, according to grade.

Pres. Chas. W. Eliot, LL.D., of Cambridge, Mass.: As often as once an hour in all grades.

Supt. J. M. Greenwood, A.M., Kansas City: Two regular recesses of fifteen minutes.

Pres. Geo. L. Osborne, LL.D., of Warrensburg, Mo.: Very young pupils at least once in thirty minutes; upper grades once per hour.

Pres. G. Stanley Hall, Ph.D., of Worcester, Mass.: If practicable, a little every hour.

Supt. L. H. Jones, of Cleveland, Ohio: Once in about one hour.

Prof. G. W. Patrick, Ph.D., Iowa City: Every hour.

Col. F. W. Parker of Chicago; A short period, between every two recitations, of music and gymnastics; fifteen minutes outdoor play in the morning session.

Mrs. Frances E. Ramsey of Westport, N. Y.: After each recitation if practicable.

Prof. W. J. Stevens, M.A., of Carthage, Mo.: At least every forty-five minutes.

Prof. Wm. H. Smiley, A.B., of Denver: Best work would be done with opportunity for free movement every hour for five minutes.

Pres. Z. X. Snyder, Ph.D., of Greeley, Colo.: Every hour or so.

Nathan C. Schaeffer, LL.D., of Harrisburg, Pa.: Twice each day and noon intermission.

Prof. Irwin Shepard, A.M., Ph.D., of Winona, Minn.: Every hour.

Pres. Alfred Holbrook, of Lebanon, Ohio: Every hour a short recess of ten minutes.

Prof. N. S. Davis, M.D., LL.D., of Chicago: Once in the middle of each daily session.

Prof. J. T. Eskridge, M.D., of Denver: Every hour, or at most every two hours.

Geo. M. Gould, M.D., of Philadelphia: Every hour.

I. B. Parkins, M.D., of Denver: At least once in afternoon and forenoon.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: In the middle of each session.

Elizabeth K. Matthews of Des Moines: At the close of every lesson or study period.

Answers to No. 5.—In the whole range of educational subjects there is no question more fraught with important consequences to the child than that of proper sanitary surroundings and ample provision for healthful outdoor exercises. As previously indicated the brain of the child is unstable and easily irritated; nerve-force rapidly accumulates in the motor-centers and unless frequent opportunity be given for its discharge in muscular movements, the attempt to inhibit the movements by will power, will not only set up irritation of the brain, make the child peevish and unamiable, injure its health and interfere with its proper physical development, but will at the same time weaken the mind and defeat the very object for which long sessions are intended, viz., the accomplishment of the largest amount of work in a given time.

Oxygen is necessary to produce nerve-force (Spencer: "Principles of Biology," Vol. I, p. 50), to stimulate the respiration and the circulation of the blood, to develop the muscular system and to destroy the poisons constantly accumulating in the body. No room with from forty to sixty pupils can be occupied much over an hour and the air be fit to breathe without dangerous draughts being created; consequently, pupils should have a fifteen minute, open air, outdoor recess in the middle of each long session. During this recess the windows should be thrown open and the room thoroughly ventilated, the foul emanations eliminated and the air vitalized. This outdoor exercise is best for the child because it removes him from the monotony, formalism and routine of the schoolroom and enables him, yes, compels him to inhale full draughts of nature's life-giving element, pure air, to free his system from accumulated poisons and spontaneously to develop his powers and adjust himself to his environment. A properly conducted recess not only increases the sympathy and fraternal feeling between pupils, increases their physical strength and enlarges their intellectual and moral horizons, but draws them closer to Mother Nature, the source from which to derive inspiration. The recess too gives pupils an opportunity to attend to the calls of nature which under other conditions would be neglected, because, as pointed out by Durante (*Medical Age*, Oct. 10, 1896, p. 601) "the sigmoid flexure in children is of much greater length than in the adult; the nervous forces also are not yet as well regulated; so the child does not feel the need of an evacuation" and, therefore, children are more apt to put off or disregard these calls of nature than they are to abuse their privileges if permitted to leave the room whenever necessary.

The recess too, to a large extent, prevents withdrawals from the room during the school sessions and in this way much disturbance is avoided and good order promoted. The objection to the recess on the ground of immorality is, in my opinion, not well founded, because there is much greater danger of

immoral practices being carried on when a few pupils are excused from the school at the same time during the sessions than when all are let out together at the general recess. I do not wish to be understood as being opposed to calisthenics and gymnastic exercises. On the contrary, I regard them as of very great value and deserving of a place in every school. What I do wish to insist on, however, is that they should be used in connection with, but not displace, the regular outdoor recess. In the advanced sheets of his new work, kindly sent to the writer, the distinguished author and educator, Prof. Joseph Baldwin of Austin, Texas, writes as follows:

PLAY AND GYMNASTICS.

Play is eminently hygienic.—"Recreation makes the best work possible. The kindergarten by utilizing play has made a large contribution to the well being of the race. Work fatigues, exhausts the brain cells; play is recreation for it is free, spontaneous activity. It breaks the spell of work and care. From infancy to age play is a boon to all workers. A self while taking recreation relaxes effort and roams fancy free. Thus the tired brain is given time to recuperate. The men of thought as well as the men of action, double their efficiency by taking regularly helpful recreation."

School work is education when pupils are fresh.—"Drudgery hurts and does not help. Work and then play is the divine plan. We may easily quadruple the value of our schools by studying to keep the pupils fresh. Strong men find recreation a necessity; how much more must immature pupils play as well as work and thus grow. He who helps to lead the school world to play wisely deserves to be crowned as a benefactor."

Recess at the close of each hour is the perfect economy. "The hygienic and educative benefits of the hourly recess are incalculable. Young children soon become fatigued and so we make their periods of work very brief. The periods of work are lengthened as the pupils advance. The fatigue limit is a great practical study. Much may be done to keep pupils fresh by having easy work follow difficult work. Change rests, but frequent periods of absolute freedom are indispensable. In schools of the future it is believed a recess of ten minutes will be given at the end of each hour."

Play in open air is most hygienic.—"Suitable play grounds with the best play-provoking facilities may safely be counted among the most hygienic agencies. All real play is essentially free and spontaneous, yet at no time is a wise supervision more important than during play. Hurtful plays may be discouraged and the most helpful plays fostered. The teacher feels the play impulses and so guides by suggestion without abridging freedom and spontaneity. Well ventilated, well lighted and commodious play rooms for use during inclement weather are remarkably helpful when the supervision is judicious. However great the cost, these play rooms pay largely in increased pupil vigor."

Systematic physical culture is indispensable. "In our best schools physical culture goes side by side with mental and moral culture. Graded physical exercise gives pleasure, gracefulness and vigor. During the pauses pointed suggestions are given in practical hygiene. The gymnastic exercises when adapted to the pupils and well managed are educative as well as hygienic. They develop habits of exact obedience.

train pupils to work in harmony with others and give artistic command of the body. *Gymnastics require considerable will effort, and hence do not take the place of the spontaneous plays of the recess.* (Italics ours.) The Germans emphasize systematic gymnastics but neglect play. The English exalt play but neglect systematic physical culture. The Americans and the French after the fashion of the Greeks, emphasize both play and gymnastics."

In contrasting romping and calisthenics Prof. Frank H. Hamilton (see *Lancet-Clinic*, Oct. 31, 1896, p. 477) speaks as follows: Calisthenics may be very genteel and romping very ungentle, but one is the shadow, the other the substance of healthy exercise. Girls need health as much, nay, more than boys. They can only obtain it as boys do, by running, tumbling; by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars let down and be turned loose like young colts.

Out of 105 answers to this question all except four strongly advocate out-door exercise or a combination of calisthenics and the old-fashioned recess. Following are some of the replies received:

Henry S. Baker, Ph.D., of St. Paul: In city schools calisthenics are infinitely better.

Prof. J. E. Brate, A.B., of Postoria, Ohio: The former; they tend to relieve necessary formality of room and give nature's best tonic, pure air.

Prof. Warren Darst of Ada, Ohio: Open air, better air, usually more hearty, freer minds, more restful, therefore more free from restraint. Cultivate a free spirit favorable to free institutions, more self-control and self-reliance among pupils.

Prof. C. C. Enigh of Fort Collins, Colo.: Out-door, wild, free, innocent, natural play at what pleases the individual pupil best. Calisthenics require close attention.

Pres. Alston Ellis, LL.D., of Fort Collins, Colo.: I favor both, the open-air recesses preferred. Calisthenics at close of recitation.

Pres. Chas. W. Eliot, LL.D., of Cambridge, Mass.: I would insist on both. If I could have but one I would prefer recesses with spontaneous play.

Prof. L. C. Greenlee, A.M., of Denver: Open-air recesses: 1. Pure air. 2. Not so fatiguing. 3. More natural to child, and relaxation more complete.

President Graves, A.M., Ph.D., of Laramie City, Wyo.: Open-air recesses and all pupils, unless real invalids, should be obliged to go out every time. I do not believe there is anything like getting good oxygen into the lungs and getting the benefits of sunshine.

Supt. J. M. Greenwood, A.M., of Kansas City, Mo.: Open air; no indoor recess can take the place of the regular old-fashioned spontaneous recess.

J. H. Miller of Lincoln, Neb.: Out door, if possible to have close supervision as in country schools; if otherwise these are dangerous to morals and not needed, as children have nothing to do but play before and after school.

Supt. J. H. Millspaugh, A.B., M.D., of Salt Lake City, Utah: Open-air recesses. Freedom and spontaneity are essential to perfect relaxation, yet rightly directed calisthenics will serve a purpose not met by recesses.

Pres. Geo. L. Osborne, LL.D., of Warrensburg, Mo.: Open air with spontaneous play properly directed. Greater freedom, better health conditions, better results. Calisthenics may be introduced for variety

and systematic exercise with a view to regularity of movement and discipline.

Prof. John H. Philips, A.M., of Birmingham, Ala.: Both essential: first must be had, second should be; first, health: second, physical grace and strength.

* Prof. W. B. Powell, A.M., of Washington, D. C.: The latter, because the exercise can be directed to known wants. The child has free undirected exercise enough without this.

* Miss Estelle Reel, State Superintendent of Public Instruction, Cheyenne, Wyo.: Open-air recesses, because more helpful.

† Prof. Wm. H. Smiley, A.B., of Denver: Open-air recesses with spontaneous play. The child, instinctively, unless abnormal, will harmonize his bodily organism with his environments better than any one can do it for him.

Pres. D. E. Sanders of Fort Scott, Kan.: Open air. Greater freedom, purer air, more interest.

Pres. Z. X. Snyder, Ph.D., of Greeley, Colo.: Open air by all means.

James Russell Parsons, Jr., and Dr. Roland Keyser of Albany, for Board of Regents, New York: Recess with play, because it affords complete and natural recreation.

‡ Albert E. Winship of Boston: I doubt the utility or necessity of a recess. Indoor recreations, singing, calisthenics, etc., would seem all sufficient.

§ Pres. Irwin Shepard, A.M., Ph.D., of Winona, Minn.: Open-air recesses once each session and calisthenics between recitations.

¶ S. Henry Dessau of New York City: Open air by all means. It restores oxygen to blood and gives vent to pent up energy.

Prof. Chas. Dennison, A.M., M.D., of Denver: Open air always in pleasant weather.

Joseph Eastman, M.D., LL.D., of Indianapolis: By all means open-air recesses with spontaneous play. Exercises by rule keep the mind on a strain. Chest expansion is better facilitated by outdoor exercise and chest expansion determines the capacity of any individual for physical or mental exertion.

Prof. F. Forchheimer, M.D. of Cincinnati: The former. We know that the air in schoolrooms is not the best, therefore as much fresh air as possible.

Prof. I. B. Perkins, M.D., of Denver: Always outdoor. Indoor exercises are of little value; fresh air is what they need.

Prof. Henry Sewall, M.D., Ph.D., of Denver: A combination of both. Calisthenics should be practiced in the open air when possible and are then preferable if one mode of recess must be chosen.

P. A. Walling, M.D., of Park Rapids, Minn.: Open air and plenty of it. Reasons: This gives greater freedom and allows the minds to come in touch; also it brings out the slow ones, does away with the idea of a recitation as the set exercises are apt to be viewed.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: Open air and spontaneous play because of better ventilation and because there is no tonic like pleasure; a task is no pleasure.

Wm. Jay Youmans, M.D., of New York: Freedom in the open air because it is natural and superior to any artificial arrangements that can be devised.

Prof. Augustus P. Clarke, A.M., M.D., of Cambridge, Mass.: My experience leads me to doubt very much the pretended benefits of calisthenics and gymnastic exercises, which serve to make the pupil be more like a machine than a living being. Outdoor exercises; they favor spontaneous activities.

Harriet E. Garrison, M.D., of Dixon, Ill.—Open air. The machine system of our schools is crushing out spontaneity from children.

Hon. John J. Lentz of Columbus, Ohio: Open air for reasons that must be obvious.

Pres. Alfred Holbrook of Lebanon, Ohio: I would prefer both alternately enjoyed. Indoor exercises when weather is inclement.

Elizabeth K. Matthews of Des Moines, Iowa: By all means the outdoor. The child gets the benefit desired, perfect freedom without restraint, hence normal development.

Prof. J. A. Larrabee, M.D., of Louisville, Ky.: Primary grades, five minutes recreation in school-room after each recitation. For all grades, fifteen minutes recess in the middle of the forenoon and afternoon sessions. Morning session to begin at 8 A.M. and close at 12 M.; afternoon session to begin at 2 and close at 4 P.M., thus enabling all children to go home for dinner. The recesses, except the recreation above mentioned, should always be outdoors, untrammelled and unrestrained. The windows of the rooms should be thrown open in pleasant weather. Calisthenics and all rhythmic exercise, whether by system or music, tend to continue thought and brain exertion and is not therefore complete relaxation.

(To be continued.)

ABNORMAL RESPIRATION IN INFANTS FROM OBSTRUCTION IN THE UPPER AIR PASSAGE.

Presented to the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY JAMES J. CONCANON, M.D.

PHYSICIAN FOR DISEASES OF CHILDREN, NORTHWESTERN DISPENSARY;
LARYNGOLOGIST, ST. BARTHOLOMEW'S CLINIC; ASSISTANT
SURGEON, N. Y. EYE AND EAR INFIRMARY.
NEW YORK, N. Y.

Normal infantile respiration in sleep is quiet, noiseless, save for the soft low inspiratory murmur, always nasal, chiefly diaphragmatic. During the first month its rhythm is irregular, there are frequent pauses and at times it is deeper, as in the Cheyne-Stokes variety. Its rate varies from 30 to 45. At the end of the third year it is regular and has a rate of 24. The rhythm is changed by very slight impressions. The movements seen are the ample ones of the abdomen, the lesser ones of the thorax and those of the nasal alæ. There is no drawing in of the fleshy portions of the thorax, the mouth is closed and the act of nursing can be completed without interruption.

Widely differing in its symptoms from that due to pulmonary or bronchial affections, abnormal respiration from obstructions in the upper air tracts is more difficult to trace to its cause, but is more amenable to treatment. Many fatal cases have shown that errors of diagnosis are common. Only recently has it become generally known that nearly all cases of croup are true diphtheria. Deaths from foreign bodies in the larynx or trachea, or from growths therein, could have been prevented had these not been mistaken for croup.

There exists hardly any other affection so dangerous and distressing to the patient, alarming to his family, or trying to the physician as obstructive dyspnea; nor is there any in which treatment is more effective. In

no other condition is the skill of the surgeon or the ability of the physician so evident. Antitoxin is the greatest medical triumph of the nineteenth century, and intubation and the recognition and removal of obstructive growths are amongst the most brilliant of surgical achievements. Occurring with great frequency in early childhood, respiratory obstruction may be regarded as one of the most important of pediatric subjects. The condition may last for moments or for years; life may be ended by it in a few moments or made unenjoyable for months or throughout its whole duration.

The symptoms, effects and treatment vary according to the nature and degree of the obstruction, and with its situation, which may be in the nasopharyngeal, the pharyngeal, or the laryngotracheal portion of the air tract. The first of these divisions extends from the anterior nares to and including the retronasal space; the second, from the level of the palate to that of the larynx; the third, from the mouth of the larynx to the lower end of the trachea. Briefly, impediments in the nasopharyngeal portion cause mouth-breathing; in the pharyngeal, snoring, and in the laryngeal stridulous respiration.

Of the three, that last mentioned is by far the most important.

LARYNGEAL OBSTRUCTION.

Laryngeal obstruction figures largely in infantile mortality. Phonation being one of the principal functions of the larynx, an altered or lost voice will be one of the earliest symptoms of obstruction.

The larynx being also the gateway of the respiratory regions, its partial closure interfering with the influx of air soon causes dyspnea with laboring inspiratory movements and noisy breathing.

Causes and symptoms.—The causes of laryngeal dyspnea in infants are numerous. Dividing them into six groups, it will be convenient to study, first, their nature and symptoms, and afterward their diagnosis and treatment.

Malformations of the larynx may cause congenital aphonia, hoarseness or dyspnea. There have been found membranous webs joining the vocal chords, and elongations of the arytenoid cartilages, preventing proper closure of the glottis and giving rise to whispering voice. The epiglottis in infants is folded longitudinally, approximating the aryteno-epiglottic folds. In some cases this causes so much narrowing of the entrance to the larynx, as to give rise to what has been called chronic infantile stridor, which is accompanied by crowing inspiration that at times becomes shriller as the dyspnea increases and again subsides to the low-pitched stridor which is always present even in sleep. One case of this affection has been under the author's observation since birth. Although there is a great improvement, noisy inspiration with occasional attacks of dyspnea exist still, the child being 3 years old. Even slight congestion may be very dangerous in these cases.

Laryngeal growths are nearly always papillomatous in infancy, fibroma being rare and myxoma and cysts rarer still. The last named are sometimes found on the epiglottis. Growths give rise to dys- or aphonia, cough and dyspnea. The number and intensity of the symptoms depend upon the size, situation and character of the tumor. Granulations from tracheotomy wounds may be a cause of obstruction. With pedunculated subglottic growths the symptoms may

be intermittent. Systemic effects, anemia and failure of development from imperfect respiration are present in proportion to the duration of the obstruction.

Foreign bodies according to their nature, size and location, give symptoms varying from the mere sense of their presence to the most distressing dyspnea or instant death. In infants they nearly always cause dangerous stenosis, although in out-of-the-way places they may be present for a long time without giving rise to any pronounced symptoms, but may at any time cause fatal obstruction from edema or displacement. Pointed bodies, pins and fish-bones, and prickly ones, as sand-burs, usually fasten themselves in the larynx. Fish-bones may be fastened across the glottis without serious symptoms unless edema occurs. Pieces of meat or other food, vomited or swallowed, entering the larynx are perhaps the most dangerous and frequent of foreign bodies ordinarily met with in infants. Smooth, roundish bodies, such as small glass beads, buttons and fruit stones may pass into the trachea. Bronchial glands have also been found therein. If these do not pass into the bronchi they may remain loose in the trachea, a source of great danger from being subsequently wedged into the glottis.

Inflammations of the larynx, idiopathic or caused by the exanthemata, malaria, aphthæ, erysipelas, pertussis, typhoid, influenza, syphilis, tuberculosis, urticaria, erythemanodosum, pemphigus, traumatism, cold, inhalation of steam or of caustics and foreign bodies cause edematous, membranous, spasmodic or cicatricial stenosis.

Cicatrices are the result of congenital syphilis, sometimes of inhaled steam or caustics. Stenosing infiltration is extensive in syphilis, burns and tuberculosis. Spasmodic stenosis may result from congestion or inflammation, the local condition acting as an irritant to excite closure of the glottis.

Membranous exudates occur not only in diphtheria but also with scarlet fever, influenza and aphthæ.

Stenosis depending upon causes that act through the laryngeal nerves are frequent in infancy, at which period the controlling centers are undeveloped and motor response to all irritations is very active. Apart from the spasm occurring with congestion or inflammation of the larynx, reflex spasm may be due to dentition with its slight cough, pertussis with its inspiratory dyspnea, or to tetany or rickets, which are not seldom fatal. Other reflex causes are mediastinal tubercular glands, retro-esophageal abscesses, or hypertrophied thymus gland pressing upon the recurrent laryngeal nerve. Others yet are foreign bodies in the ear, nose or tonsils. Adenoid growth of the nasopharynx and elongated uvula are not infrequent causes. In some cases of rickets these spasmodic attacks of dyspnea are easily excited. One case happened in the author's practice where tetany and laryngismus stridulus coexisted. An attack fatal in half a minute, was caused by feeling the pulse. In chorea the inspiration has a peculiar wavy character which may be due in part to the intermittent contractions of the laryngeal muscles. Paralysis of the larynx often follows diphtheria and may be a cause of severe continuous dyspnea. Unilateral abductor paralysis gives dyspnea upon exertion only. It may result from compression of the recurrent laryngeal nerve. Suffocation from particles of food is likely to happen.

The pressure upon the larynx or trachea of retro-esophageal abscesses, enlarged cervical glands, hyper-

trophied thymus gland or foreign bodies in the esophagus may be causes of fatal dyspnea, as may also the peritracheo-laryngeal abscesses described by Massei.

Diagnosis.—Notwithstanding that the diagnosis of some of these laryngeal causes of dyspnea is often a matter requiring no small degree of ability, it would be more often successful if it were generally known that the examination of the larynx in infants is not at all so difficult as has been believed. It is not, as in the case of adults, a matter of training the patient, but one of gentle force, properly applied. Probably not one physician in fifty examines the infant larynx. Direct and laryngoscopic examination of the larynx should be practiced until skill is acquired. No one can be considered an adept in the treatment of diseases of childhood who is not proficient in the employment of modern methods for the diagnosis and treatment of the diseases and abnormalities of the upper air-passages. No careful physician commences the treatment of an infant without examination of at least the fauces. In three-fourths of the cases, as we get them, the upper air-passages are involved. With the patient's head well back and the tongue drawn forward, by means of the little finger placed beside the epiglottis, or better yet, with the spatula of Escat, the knobbed forks of which fit into the sinus pyriformis, the larynx can be opened to laryngoscopic and, in many cases, to direct examination.

In the diagnosis and treatment of the first three classes of causes of stenosis, malformations, tumors, and foreign bodies, laryngoscopy is indispensable. Acute stenoses have diverse causes but symptoms much alike. Moreover, the history is often obscure. While unobserved the infant may have swallowed a pin or button, or inhaled steam from the spout of a kettle and can not or will not give an account of it, hence, examination of the larynx is necessary for intelligent treatment. Bodies in the trachea may give symptoms easily mistaken for those of croup. The laryngoscope will often fail here and then recourse must be had to the Roentgen rays, which method, cryptolaryngoscopy, has been successfully used for the location of foreign bodies in the air tracts and esophagus.

Inflammatory conditions are distinguished from others by the presence of fever, the symptoms of the causative disease or the history of the causative accident. It is well to remember that with stenosis occurring in the course of acute diseases, the Klebs-Loeffler bacillus can often be found. In very severe stenosis occurring in the course of measles or scarlet fever, it is much better to administer antitoxin at once, which will often serve not only to cure but in so doing will indicate the true cause while awaiting further confirmation of the bacteriologic examination. Stenosis from inhalations of steam or other irritants can be ascertained by examination of the fauces and epiglottis, where their action is quickly manifested, urgent dyspnea and dysphagia coming on rapidly as the result of extensive swelling.

Spasmodic dyspnea is most frequently found in connection with rickets, of which disease laryngismus stridulus is but a symptom, whose presence makes the diagnosis easy. Absence of fever and transitory character point to the affections being functional. The various reflex causes already mentioned should be sought out.

The causes of compression should be remembered.

When present they are, as a rule, easily found. Abscesses may at first be difficult to discover. In some cases it is not easy to ascertain the seat of the obstruction, for bronchial dyspnea may closely simulate laryngeal or tracheal dyspnea. The laryngoscope, X-rays, auscultation and percussion may be necessary.

Treatment.—In dealing with laryngeal and tracheal obstruction there are four agents that must often be used—used with a skill that all should try to acquire, namely, the antitoxin syringe, the O'Dwyer tubes, the laryngeal forceps and the knife. Intubation, tracheotomy and, certainly the use of forceps for the extraction of foreign bodies and the removal of growths should be first practiced on the cadaver. Malformations, tumors and foreign bodies, while considered to belong to the domain of laryngology, often give rise to a dyspnea that brooks no delay, and with which the physician who is called in the urgency of the case must be prepared to deal.

Congenital glottic webs are divided by means of the laryngeal knife. The stridor due to the peculiar infantile shape of the epiglottis generally disappears at the third or fourth year.

Tumors are usually removed by evulsion or crushing, with the aid of the laryngoscope and local anesthesia. Tracheotomy may precede or accompany these measures. Laryngotomy is employed only as a last resort, but may be necessary in young infants where death from suffocation is imminent. Intubation may in some cases be employed for temporary relief.

Foreign bodies, if they can not be removed by means of the laryngeal forceps and mirror, may require tracheotomy, and usually do in infants; the high operation for bodies in the larynx and the low one for those in the primary bronchi. The administrations of emetics and the reversal of the patient's body, as formerly practiced are dangerous, for if the foreign body be in the trachea, it may become wedged in the glottis. Inflammations may render necessary scarification, intubation or tracheotomy. They are best treated by applications of ice from the beginning. Derivatives and antispasmodics may be required to check accompanying spasm. The best remedy is probably codein, of which one milligram may be given at a dose to a child one year old, or morphin one-third of a milligram. Congenital syphilis requires mercurial inunctions and the internal administration of syrup of iodid of iron. When in the course of any of the acute diseases mentioned, a progressive, urgent dyspnea, accompanied by anemia and asthenia arises, it is best, as before remarked, to administer antitoxin at once, for nearly all such cases will prove to be due to the presence of the Loeffler bacillus. Prompt use of the serum will arrest the stenosis and render intubation unnecessary. Often, however, that operation will be required, not only in membranous but also in edematous, spasmodic and cicatricial stenosis. The tubes can be retained for long periods, a week or more without injury, those of hard rubber are best for long retention. Tracheotomy is not often required. For the relief of aphthous stenosis, Massei considers the ordinary catheter the best instrument. It can be used often and for brief periods to relieve the stenosis and detach the masses of oidium albicans. This instrument is invaluable for any form of dyspnea where the O'Dwyer tubes are not at hand. Cicatricial stenosis may render necessary repeated dilatation, prolonged retention of tubes or tracheotomy.

Aside from the treatment of the predisposing systemic condition, spasmodic stenosis is relieved by chloroform, codein, chloral, bromids and other antispasmodics and by the removal of adenoids and other excitants. Intubation or catheterization will sometimes be indispensable.

Pressure stenoses are treated by removal of enlarged glands, evacuation of abscess, and sometimes intubation or tracheotomy.

PHARYNGEAL OBSTRUCTION.

In the pharyngeal region hypertrophied tonsils, peritonsillar abscesses, retropharyngeal abscesses, elongated uvulæ, cicatricial contraction and the presence of foreign bodies, are causes.

Hypertrophied tonsils, although often congenital, rarely gives much trouble before the second year. They cause snoring, imperfect articulation, dysphagia and offensive breath. Often concurrent adenoids add their symptoms. If the tonsils nearly meet they should be excised; if they project but slightly, they should be let alone. Peritonsillar abscesses should be opened just outside the upper edge of the tonsil. Foreign bodies are to be carefully sought for and removed. The epiglottis has been found fastened down by pins and fish-bones. Cicatricial stenosis from syphilis sometimes occurs in infancy. The soft palate may become adherent to the pharynx, so as to completely shut off the nasopharyngeal tract. Operation is not then very successful. Elongated uvulæ may cause reflex cough and need removal. The palatopharyngeal space may be so narrow as to impede respiration.

The one very important and often fatal obstruction met with in this region is retropharyngeal abscess from suppurating lymph nodes or vertebral caries. This disease belongs to infancy, three-fourths of the cases occurring in the first year. Influenza is perhaps the most frequent cause. Sometimes it follows scarlet fever. The symptoms are fever, prostration, dyspnea, pain, dysphagia, aphonia or dysphonia, the cry being of a peculiar guttural character. Inspiration is accompanied by a very characteristic snoring sound which attracts the attention of the examiner, to whom the fauces and pharynx appear normal where the abscess is low. The abscess, although bulging most frequently directly behind the mouth, may be hidden above the palate, latterly by the faucial pillars or below, opposite the larynx. In all cases of infantile dyspnea where the diagnosis is not clear, the pharynx should be explored with the finger. Called once to intubate a nearly suffocated child, considered by two physicians in charge to have laryngeal stenosis, the author found a large abscess at the level of the larynx. Incision gave prompt and permanent relief. These are often dangerous cases. Death has occurred from the slight increase of obstruction due to the insertion of a mouth gag preliminary to operation. If not found and evacuated, the abscess may kill by eroding large blood vessels or by bursting into the larynx. Starvation and dyspnea usually kill. In scrofulous children the abscess may refill many times. In such cases general hygienic treatment and the administration of small doses of calomel for long periods has given the best results.

The abscesses of Pott's disease are of rather rare occurrence and long duration. They surely refill. Occasionally they can be opened externally and should be.

NASAL OBSTRUCTION.

Passing now to the study of abnormal respiration from obstruction in the nasal and retronasal spaces, we find effects and symptoms of another order. Not from interference with the free entrance of air to the lungs does the patient suffer, but because of interference with the passage of air through organs designed for purifying; warming and moistening it preparatory to its reception by the delicate organs through which it is assimilated; for such is the function of the mucous membrane of the nasal chambers, whose superior half, moreover, depends upon the air current for the stimuli of the myriad olfactory impressions conveyed by its nerves and so necessary to mental development and the enjoyment of life. Just as the digestive organs prepare food for absorption do the nasal passages prepare air.

Since the free passage of air is necessary for maintaining an equal atmospheric pressure on both sides of the tympanic membrane, impeded nasal respiration must cause imperfect hearing.

Again, the nasal chambers and antra modify the phonatory vibrations that pass through them. Their obstruction therefore renders imperfect vocalization inevitable. Not only is mouth breathing present and audition, olfaction, articulation, respiration, and consequently growth and development of mind and body seriously impaired, but the lungs, ears and eyes are rendered prone to catarrhal inflammations. Anemia is almost constant.

The effects of nasal obstructions are now becoming generally recognized. No one now doubts that the early relief of this condition enables a stunted backward child to grow and develop marvelously, reaching a perfection impossible without it. Indeed, the recognition and treatment of this condition should be a national care, for it means higher racial development. All familiar with the extraordinary improvement in a child after the removal of adenoid growths, will readily admit this. The peculiar physiognomy of some backward races, the Esquimaux for instance, is believed to be due to the presence of these last-named growths during childhood.

Causes.—Apart from malformations, the most important of which are absence of the septum and floor of the nose, which render respiration abnormal, and imperforate or extremely narrow nostrils, any of the following causes of obstruction may be congenital: Complete or partial occlusion from exostosis, ecchondrosis and deviations of the septum, hypertrophy of the turbinated bodies, bony cysts of the middle turbinated, polyps, abscesses of the septum. Frequent causes are, foreign bodies, fractures, diphtheritic membranes, syphilitic lesions and what is not at all rare, and yet has received little or no mention so far as the author knows, in the literature of the subject, collapse of the alæ nasi.

The acute inflammations are but transient.

In the nasopharynx is found by far the most frequent and important cause of nasal obstruction in infants, the so-called adenoid growths. Although often present in the new-born, it is toward the end of the first year that they are generally found. They are idiopathic or the result of acute infectious inflammations, especially influenza, a disease which few children escape during its prevalence.

Symptoms.—An infant having nasal obstruction from any cause presents an expressionless face, with open mouth and flabby folds, stretching down from

the alæ of the generally flattened and running nose. This has been called the veiled face of adenoids. Deafness, otitis, mutism, anemia and eye affections are often present. The voice has a dead, nasal character, that of cold in the head. Snoring, restlessness, night terrors, inability to nurse are always present in cases of large growths. Postnasal, laryngeal, bronchial, aural and conjunctival catarrh are frequent accompaniments. Not only is nasal obstruction often the reflex of very distant irritants, but it may be the cause of apparently widely separated affections, such as enuresis. Fits of crying and continued frowning indicate headache. The mouth-breathing infant is generally anemic, puny, ill-developed and frequently affected by diathetic diseases. The rachitic are frequently mouth breathers; while predisposing to other diseases, the presence of nasal obstruction causes infants ill from any cause to do badly. An interesting case was recently reported in the *New York Medical Journal* of a child which having complete nasal obstruction from birth, with inability to nurse, died when one week old. At the autopsy the turbinated bodies were found congested to such an extent as to cause complete occlusion. Surgical treatment had not been attempted.

Diagnosis.—The first diagnostic procedure should be an examination of the nasopharynx; for adenoid growth will be found in four-fifths of the infants with chronic nasal obstruction. In a few seconds the physician's index or little finger slipped behind the palate, over the vomer and down the posterior pharyngeal surface, will not only have met the soft, pendant, easily bleeding masses, blocking the posterior nares, but will be found blood stained when withdrawn. In infants under six months, such examination being impossible, an applicator armed with a cotton nob introduced behind the palate or through the nose, touching the masses ever so gently, causes them to bleed, showing their presence. Anterior rhinoscopy requires some practice before a reliable diagnosis can be made of the obstructions in the nasal chambers. A novice in rhinology is most likely to fail in even so simple a matter as distinguishing a red fleshy hypertrophy of the inferior turbinated body from the gray oyster-like polyp of the middle turbinated. Nor can he easily determine whether it be a growth or a deflection that affects the septum.

Intranasal obstructions are, however, comparatively rare in infants. Abscesses of the septum have been found five times in the author's practice. It is easily recognized by the bilateral bulging of the septum. The probe detects bony or cartilaginous growths that completely or partly occlude. Collapse of alæ should always be thought of before a speculum is introduced. Unilateral occlusion with purulent discharge often means the presence of a foreign body, such as a shoe button or grain of corn. In diphtheria the anterior nares are usually excoriated and covered with a gray pellicle. The Loeffler bacillus is always present. The membranes may be confined to the posterior part of the nose and retronasal space.

Treatment.—Apart from the finding and removal of the reflex and other causes, when general treatment fails, hypertrophy of the turbinated bodies are reduced by the galvanocautery or snare; exostosis and echondroses are drilled through with the electric trephine. Bone cysts and polyps are snared away. Abscesses opened and foreign bodies removed by means of forceps or hooks. Syphilitic lesions require mercurial inun-

tions and thorough cleansing. Nasal diphtheria demands prompt injection with antitoxin, in large doses and repeated until the membranes cease to recur. This form of the disease indicates not only its virulence, but that the patient is non-resistant. When collapse of the alæ exists it is treated by means of springs or frames that maintain the form and size of the nostril.

Practically, however, the treatment of nasal obstruction in infants means removal of retronasal adenoid growths. The operation requires but a few seconds of time and no anesthetic. Cutting forceps and Gottstein curettes are employed. For growths on the posterior wall of the retronasal space the latter is the best. The forceps better reach the high growths which hang into the posterior nares and cause most of the obstruction. To prevent the injuries to the vomer, uvula and Eustachian tubes, which often occur with inexpert operators, and to guide the instrument into proper position for effective work, the author has devised a plate of peculiar shape which fits over the open jaws of the forceps and, when introduced, over the posterior edge of the vomer, also enables the operator to bring all the growths within the blades. This instrument accomplishes the operation at one application. Only when there are extensive posterior growths a single sweep of the curette may supplement the forceps. The latter instrument has the advantage that the growths are always brought away with it, while with the curette they are usually swallowed.

Hemorrhage nearly always ceases in a few moments. Three fatal cases have been reported. To check it, pledgets of cotton, saturated with solution of acetate of aluminum, should be drawn up into the nasopharynx by means of cords passed through the nose, and tied over the columella. Salt water irrigation, thrice daily for two or three days, is the only after treatment. Over two hundred cases have been treated in this way in dispensary practice with no evil effects whatever. The operation is invariably successful.

Rachitis, rhinitis, chorea, reflex cough, eye troubles, deafness, malnutrition, laryngismus, laryngitis, enuresis, night terrors and aprosexia will often resist the most careful treatment until the accompanying adenoids are removed, when convalescence will be rapidly established.

Having thus briefly dealt with the important subject of dyspnea in children under three years of age, it may be permissible to emphasize: The importance of laryngology in pediatrics; the facility with which the larynx may be examined even in infants; the necessity for ascertaining the condition of the upper air passages in all children, and for the removal of obstructive adenoid growths; the many causes of nasal and laryngeal dyspnea in infants, amongst which drawing in of the nasal alæ, sprue, inhaled irritants and foreign bodies are often overlooked; the frequency of retropharyngeal abscesses, necessitating digital explor-

ation of the pharynx; that the bacillus of Loeffler is often the cause of laryngeal stenosis in acute diseases. and demands prompt use of antitoxin; that these helpless little beings, who can not, often will not, give a history, should receive the benefit of all modern methods in diagnosis that they may enjoy normal respiration.

PUERPERAL INFECTION.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. E. COWLES, M.D.

LOS ANGELES, CAL.

As this does not pretend to be an exhaustive treatise on puerperal fever, so-called, I will make no apology for slighting certain parts of the subject: and if I seem to wander too near the boundary line of the undiscovered, it will not be for the sake of the theorizing, but with the desire to draw, from reasonable inferences, certain conclusions that may assist in our every-day work. In regard to a choice of name for the puerperal condition now under consideration, there is not entire unanimity among medical men. Garrigues objects to the term puerperal fever, principally on the ground of its expressing only a symptom and in exceptional cases not even that, as he states there is sometimes no fever at all. Metria, he thinks too vague, and septicemia too strong a term for mild cases; therefore, he prefers the term "puerperal infection" and while admitting that it refers more particularly to etiology, he thinks it may also stand for the pathologic process, just as "cold" is used by the laity and profession also for both conditions. He claims for it the great advantage of pointing out that the disease comes from without, thus impressing on us the necessity of taking measures to prevent it. Puerperal infection, then, being the most available term in the present state of our knowledge, may be used as a general term, and the words septicemia, pyemia, etc., may stand for peculiar and grave states of this infected condition. The time-honored name, puerperal fever, may be retained also for association's sake, even if we can not find any rational basis on which to rest its claims, looked at from the standpoint of a purely scientific classification. As to the identity of the causes of surgical and puerperal infections, about which there has been so much discussion in times past, I believe the consensus of medical opinion of today is on the affirmative side of the question. In view of the accumulated experience of the most enlightened physicians of the last two decades, aided by the revelations of the microscope and the results of bacteriologic research, all tending to establish beyond the peradventure of a doubt, the identity so far as cause is concerned, of the two conditions, it should be hard indeed to find an advocate of the dual theory. The idea of identity, as I understand it, is not that the two conditions are dependent on a particular kind of germ, the poison *sui generis* of Barker, but that they are both dependent on the presence of germs, be they all of one kind (if it were possible), or of many kinds, and that there may be as much similarity, or, if you please, identity, between a given case of puerperal infection and surgical infection as there would be between two cases of surgical infection all the time allowing for the greatly differing conditions of the two cases. For, as Lusk expresses it: "In the puerperal state it is necessary to take into account the blood changes

induced by pregnancy, the effects of shock and exhaustion in protracted labor, the frequency of hemorrhage, the deep situation of puerperal wounds, the presence of clots, decidua and dead tissues in a state of disintegration or decomposition, the ease with which deleterious substances are absorbed by the wide lymphatic interspaces, the serous infiltration of the pelvic tissues, the exaggerated size of the lymphatics and veins, and the proximity of the peritoneal cavity;" and, therefore, he concludes "that the differences between surgical and puerperal septicemia are due to differences partly structural and partly physiologic in the wounded surfaces exposed to septic contamination, but that the two conditions are not only analogous but essentially one and the same process."

That the puerpera is much more liable to infection than any surgical case will hardly be denied, for "it is a fact independent of all theories."

Blood clots and decidual shreds most certainly furnish good material for infection, but from experiments made by Prudden, a detailed account of which was given in the *New York Medical Record* of Jan. 25, 1890, he conclusively shows that, whereas, all the other body fluids have more or less germicidal effect, amniotic fluid, on the contrary, proved to be such a good culture-medium that typhoid bacilli planted therein almost quadrupled their number in six hours after implantation.

Etiology.—The query as to what is puerperal fever is answered by a practical obstetrician as follows: "It is a disease due to a poison coming from without, the cause of which seems to be produced by certain microbes. That the severe cases are due to septic organisms is proved by the fact, that by antiseptic measures we succeed in preventing the disease and if it has made its appearance they have great power in conquering it. Another proof is, that microbes have been found in such numbers and under such conditions that they must be regarded as intimately connected with the disease—but this properly belongs to the bacteriologist."

That scientist adds: "Emphatically, yes. Bacteria *are* connected with this disease as causal factors." When asked for his reasons for such a statement he reminds us that, following Tyndall, a number of investigators have proven beyond a doubt "that bacteria do not arise by spontaneous generation anywhere," thus establishing the law *omnis cellula e cellula*, the only law, so far as I know, without an exception. "This being true, as well as the fact that bacteria have never been found in the body in a state of health their presence there in disease must be ascribed to an entrance from without and the finding of suitable conditions for their development after this entrance has been effected. Therefore we can confidently affirm that bacteria or their products are the exciting causes of such affections as the pyemias and septicemias."

Pasteur and Doleris give as results of their work, four varieties of bacteria occurring in cases of puerperal infection, which they classify as follows: 1. Cylindric bacteria or bacilli, developing into large filaments about the time of the death of the patient and called *bacteries septiques*, and commonly found in malignant septicemia. 2. Micrococci in chains, called streptococci. 3. Diplococci, especially occurring in pyemia, as the micrococci pyogenes. 4. Micrococci occurring singly or in irregular masses. From the nature of the subject and the difficulties

surrounding it, it is impossible at this stage of investigation, to associate any one or several of the different species of micro-organisms, as causing a definite array of symptoms in any given case of septic trouble, except to say in a general way that the most serious infections are due to the bacilli and streptococci. "If we have chills and a rise of temperature to 40 degrees C., we may assume, almost with certainty, the presence of the streptococcus." So far, the following bacteria have been found in causative relation to, or thought capable of causing puerperal fevers, viz:—The streptococcus pyogenes of Passet; the streptococcus erysipelatis of Fehleisen; the streptococcus septicus of Nicolairer; the staphylococcus pyogenes aureus of Rosenbach; the staphylococcus pyogenes albus; the staphylococcus pyogenes citreus of Passet; the staphylococcus pyogenes circus albus of Passet; the bacillus coli communis of Escherich; the bacillus saprogenes of Rosenbach; the bacilli of rabbits and mice septicemia; the bacillus pyogenes fetidus of Passet; Noeggerath's saprocyte and others.

As to the modes of entrance of these poisons into the system, unquestionably the vast majority of cases are infected through a solution of continuity, at some point or points within the genital tract, but there are a few cases on record that can only be reasonably explained upon the supposition that the germs gained admission through the respiratory or digestive tracts; but the percentage of these cases is so small as hardly to merit consideration.

Pathology.—As infection may cause a septic vulvitis, vaginitis, endometritis, salpingitis, ovaritis, peritonitis, lymphangitis, phlebitis, pleuritis, pneumonitis, etc., so will be added the special pathology of one or more of these inflammations, as they exist, plus the peculiar pathology of the particular bacteria present, such as pus, diphtheritic membranes, etc. It is thought that, where the round bacteria exist in great quantities, you are apt to find emboli and infarctions, ending in metastatic abscesses characteristic of pyemia and so frequently found in the liver, kidneys, spleen, parotid gland and other glands; or, if the more virulent bacilli predominate, we are told that the only pathologic change, sometimes observed, is a very coagulable blood and at other times an excessively fluid state of the blood, each condition supposedly due to the chemic action of the animal alkaloids produced by the germs.

Mortality and prognosis.—We are all familiar with Max Boehr's statistics and the report of the Berlin Society, and since we gather from them that before the period of antiseptic midwifery 10 to 15 per cent. of all deaths occurring in women, during the period of sexual activity, was due to childbed fever" and that at a later period with imperfect antiseptics this appalling mortality was reduced to 4 per cent. at the New York Maternity Hospital and later to a quarter of 1 per cent. with a more perfect system, we can praise the Lord that he put it into the minds of men to study this much neglected subject.

In addition to this great saving of life antiseptic midwifery, as Garrigues tells us, has reduced morbidity from 25 to 3 or 4 per cent. The prognosis of puerperal infection depends upon the *character* and amount of poison absorbed in the particular case under consideration, together with the character of the tissues or organs involved. As a material help to prognosis and treatment, a microscopic examination of some of the cervical discharge should be made by an expert microscopist.

The symptoms of puerperal infection may be as varied as its pathology. They may vary from a slight headache, anorexia and mild fever for a few days, the so-called milk fever, to a case with severe and prolonged chill or recurring chills, rapid pulse, high temperature, sweet breath, dusky or jaundiced skin and anxious face of acute septicemia, soon terminating in collapse and death. The local inflammation, as a peritonitis, may impress its symptoms in a given case. Again, we may have an array of symptoms characteristic of pyemia, with such sudden rises of temperature followed by profuse sweating and marked remissions of temperature, as often to be confounded with malaria. If it is true that micro-organisms have the power of producing animal alkaloids, with properties as varied and with effects as marked as are characteristics of those vegetable alkaloids with which we are familiar, such as atropia, aconitia, etc., then it should not appear strange, if we should note symptoms in certain cases similar to those produced by large or toxic doses of these powerful medicines. Bearing this possibility in mind, we should be on the alert for symptoms caused by these little understood but none the less real and potent substances. In case of a sudden collapse and death (and who of us have not heard of such during supposed puerperal convalescence, with a death certificate given of "heart failure") due, perhaps, to the leucomain analogous to aconitia, secreted within the individual herself where we were giving aconite in large doses, to know of the possible presence of this leucomain, might save us from unmerited reproach and qualms of conscience.

Prophylaxis.—By far the most important consideration during the lying-in period is to obtain as conscientiously perfect asepsis as is possible and no amount of trouble either to the accoucheur or attendants should be declined to secure this *sine qua non* to the puerpera. "For here if anywhere, a man is weighted with responsibilities of a momentous nature, even such as he is called upon to sustain in no other social, professional or individual capacity." I maintain that considerations of delicacy or false modesty as in the past, should not be allowed such paramount importance, as to prevent such a careful aseptic toilet of vagina, vulva and contiguous parts as an up-to-date surgeon would order given as a preliminary to a vaginal hysterectomy.

If the obstetrician is not sure that the nurse knows how to scrub out and disinfect a vagina thoroughly, he should do it himself, after all hair has been removed from around the vulva, and order antiseptic pads changed *pro re nata* or frequently, both before and after the completion of labor.

A word of explanation as to the necessity and importance of this cleansing should be impressed on the puerpera herself, and a caution as to keeping her hands away from the cleansed parts should not be overlooked, as every observant accoucheur can testify. The writer rigidly adheres to Garrigues' rules "for and in such cases provided" and he thinks he has cause for gratulation and gratitude, as in from 1,200 to 1,500 cases attended by him, he has had no death from puerperal fever and but few cases of morbidity. In 1870, writing on this subject, I used the following language: "While I do not use the intra-uterine douche as a routine measure, I know of no good reason why it should not be done, and if, as seems certain, liquor amnii is such a good culture-fluid for bacteria, it would seem but in the line of common prudence to

wash it away and by the same process and at the same time, get rid of placental shreds and blood clots, generally recognized as sources of danger. Besides, the hot uterine douche assures good uterine contraction, and I believe it is but a question of time, until this excellent prophylactic measure will be advocated ex cathedra, as correct practice after every delivery, at least where there is no trouble about having satisfactory antiseptic arrangements. Until then, I shall consider the surgeons a step in advance of the obstetricians."

I notice that Alexander Duke, of Cheltenham, England, writing to the *Medical Press and Circular* of London, in September 1895, states that he thinks "that an antiseptic treatment in midwifery would be seldom required, if the aseptic were more attended to, one of the most important plans being thorough flushing of the *entire genital tract* directly after labor. Those who have not taken the trouble on themselves to thoroughly wash out the uterine cavity directly after labor, the time when it can be best and easiest accomplished, can have little idea of the amount of débris which, if left behind, must take a considerable time to be expelled and is certainly likely, to say the least, to prove a source of danger to the lying-in patient."

A prophylactic caution that should be observed in every case, is to examine rarely and not to introduce the finger within the os in ordinary cases. When it is absolutely necessary, follow it with an antiseptic douche, also express placenta by Credé's method. Squibb's fluid extract of ergot in half teaspoonful doses, or one-thirtieth grain of strychnia, three times a day for five or six days, as well as immediate suturing of any laceration worthy the name, is important prophylactic treatment.

I shall make no apology for thus having dwelt at length on the most important part of this very important subject. I must say in passing, that I have had great comfort in postpartum douching of the uterus, in using a thick-walled, properly curved, glass tube, nine or ten inches long and as large as the thumb, which I think could be improved by deeply fenestrating the outer curve at its distal end for four or five inches.

Treatment.—If proper attention has been paid to prophylaxis, there will seldom arise a necessity for other treatment, but I believe that once in a great while one will run across a case of autogenetic infection from a ruptured pus tube or abscess sac, ovarian dermoid or other abnormality within the pelvis. In such cases evidently celiotomy with careful toilet of the peritoneum and drainage would be the remedy. In case the genital tract has been infected, I am an earnest advocate of early and very careful curettage and swabbing the uterine cavity with iodized phenol, without irrigation, but insufflating boric acid and packing lightly with iodoform or acetanilid gauze; or, what I sometimes like better, sew into the cervix a perforated one-fourth of an inch glass tube and fill the vagina with iodoform gauze. If, in spite of this treatment, faithfully tried, general infection ensues, it would certainly be proper to inject hypodermically the antitoxin serum appropriate for the preponderating germ present.

The most modern treatment of general septicemia is that of hypodermic injections of creosote recommended by Frank of Cologne. Its administration is said to be attended with remarkable results, rapidly reducing the temperature from 104 degrees F. to normal.

The solution that I have used in 20 minim doses, three or four times in the twenty-four hours, consists of equal parts of pure beech-wood creosote and sterilized camphorated oil. It is a beautiful, light amber colored liquid with only a slight smell of creosote and its injection does not seem to be attended with any disturbance or reaction. Failing in this special treatment, coupled with strongly supportive and stimulating general remedies, if the uterus and adnexa are thought to be a hotbed of infection, one would be derelict in his duty, if he did not give the patient her last chance by removing them; and I would most earnestly urge the vaginal method where possible, as causing less shock and securing better drainage.

ANTI-STREPTOCOCCUS SERUM.

BY C. P. THOMAS, M.D.

SPOKANE, WASH.

During the last four months we have used this new remedy eight times, and notwithstanding that the cases treated were of very severe nature, the results have been so universally good that I feel it a duty I owe to the profession to report them.

I will be unable to give a correct clinical report of the cases, for no notes were kept, but they are sufficiently recent I hope to make them plain to you from the mental picture which I still have.

Mrs. A. was being treated by Dr. Button for acute cellulitis of the arm following an infection of a slight wound on the finger. She came to him after having been treated indifferently for two weeks, with a much swollen arm considerably distended with pus. Her temperature at this time was not very high. Under strict asepsis, free incisions were made into the arm, much pus evacuated, and the arm enveloped in a moist bichlorid dressing. Three days later, a violent erysipelatous condition came on, the temperature rose to 104 degrees, the patient suffering great pain; she was almost pulseless and death seemed imminent. She was given 10 c.c. of Marmorek's anti-streptococcus serum and also the usual stimulating treatment; and on his return twelve hours later, the Doctor found the temperature to be 100 degrees, and she continued to improve until complete recovery took place.

Mr. B., who was under the care of Dr. Byrne, came into the hospital the second or third day of the disease with acute erysipelas involving one entire leg; place of inoculation, a small varicose ulcer. The entire leg was swollen and from the knee down the limb was almost black with edema. His temperature was 106 degrees and he was unconscious. He was given 10 c.c. of the serum in the evening, and next morning his temperature was nearly normal, tongue moist, the swelling subsiding, and he went on to a rapid recovery.

The third case was also under the care of Dr. Button, and was one of acute suppurating appendicitis, in which we flooded the general peritoneal cavity with pus during the operation by the breaking of a very thin wall of protective membrane. Twelve hours later the patient showed great restlessness and other symptoms, well known to abdominal operators, of beginning peritonitis. He was given the usual dose of the serum and all these unpleasant symptoms disappeared and he made a rapid recovery.

The fourth case was a boy of 14 years of age, with acute obstruction of the bowels, who had recently

been operated on for an abscess of some sort in the region of the vermiform appendix. He came under my care forty-eight hours after the attack began, with a high temperature, greatly distended abdomen and every indication of acute peritonitis. The abdomen was opened in a line with the old scar, which was parallel with Poupart's ligament and about an inch above it, adhesions broken up throughout the intestines, mesentery and omentum, the appendix removed, an operation done for the cure of the incisional hernia, which was very marked and the wound closed without drainage. All parts of the abdominal viscera showed marked evidence of acute inflammation. He was given the serum injection at once and recovered.

The fifth was a case of erysipelas beginning in an axillary abscess which involved the skin and muscles of one entire side of the chest. He was also greatly prostrated and suffering from a very high temperature; one injection of the serum was given him, with the same results as the others.

The sixth was a case of ruptured pus-tube of probable specific origin, which also had the usual high temperature, tympanites and great prostration. She was operated on through the vagina, the leaking tube removed and the general cavity thoroughly drained with rubber tubes and gauze. She was given at the time of the operation, the usual dose of serum, and although she was greatly improved, the next day it was repeated and her recovery has also been uneventful.

The seventh was a case of a large leaking pelvic abscess. The patient was in worse condition than any of the others, the bowels greatly distended, and very tender on pressure; she was vomiting persistently and there had been no passage for three days. Up to this time, she had been under the care of a colleague and given the opium and saline treatment. She was given the serum and immediately opened through the posterior fornix and about a pint of foul smelling pus evacuated from the abscess cavity. Both it and the general peritoneal cavity were thoroughly irrigated and drained. At the end of twelve hours her bowels moved with but little effort, the vomiting gradually subsided, and she is now almost recovered.

The eighth was a case of acute sepsis coming on about nine days after a very difficult labor, in which she was severely lacerated. She was irrigated and curetted two or three times before being sent in from the country, but her temperature remained high and there was some distention of the abdomen. She was given the serum treatment after the temperature had remained up for four days, all intra-uterine treatment stopped and, within twelve hours, the temperature became almost normal and remained so for ten days, when she was again suddenly taken with a chill and very high temperature, which resisted all constitutional treatment for three days, when she was again given 10 c.c. of the serum. The next day it was found that her temperature was not so high and there was some bogginess in the posterior fornix. The serum was repeated, the fornix opened and drained of a small accumulation of serum, and the uterus again thoroughly curetted, considerable placental tissue being removed. The following day she still had a very high temperature, showed evidence of the most profound toxemia and the serum was again given, and from this time on she continued to improve, the temperature remaining normal after the eighth day. This case would doubtless have been subjected to a hysterec-

tomy by some of our advanced surgeons, but I consider her in a much better condition than if she had lost her uterus.

While it is true that some of the above reported cases might have recovered without the serum, considering the fact that so eminent an operator as Dr. Nicholas Senn has just admitted that out of over fifty operations for general peritonitis which he has done, not one has recovered, it appears to me that much credit must be given the serum in these cases. This represents my entire experience with the serum and I have used only that which was prepared by the Pasteur Institute and obtained from their branch house in Chicago, the Pasteur Vaccine Co. It comes in single bottles of 10 c.c. each, and is given with the antitoxin or ordinary hypodermic syringe.

URTICARIA, A THERAPEUTIC NOTE.

BY BERNARD WOLFF, M.D.

ATLANTA, GA.

The list of remedies suggested for the relief of urticaria is already so voluminous that I would have some hesitation in further adding to it, were I not thoroughly convinced of the value of phosphate of soda in the treatment of this common complaint.

I have used this drug for the past year in quite a large number of cases, and with such uniform success that I have come to regard it as absolute master of the disease, and have ceased to have any of my former misgivings of my ability to promptly relieve the patient.

In acute cases in adults my plan is to give dram doses of a supersaturated solution of phosphate of soda, *i. e.* sixty to eighty grains to the dram, the salt being dissolved in its own water of crystallization. This is to be repeated every three hours, and in addition the following antipruritic lotion is recommended:

R	Pulvis Calamin	aa	ʒi ss	6
	Zinc. Oxid.		ʒ ss	2
	Acid. Carbolic		ʒ ij	64
	Aq. Calcis		ad ʒ iv	128

This is to be applied frequently and freely. The dose of the salt may be appropriately reduced in the case of children, and the quantity of carbolic acid in the lotion diminished. The effect is prompt, within a few hours the acute symptoms subside, and in from twelve to twenty-four hours the eruption ceases to appear.

In the chronic type of the disease the relief afforded is equally prompt, but recurrences are apt to follow. The remedy should be given in doses of one dram or more after meals, and should be persisted in until all tendency to recurrence of the attacks has disappeared. Patients do not acquire a tolerance for the drug and therefore, it may be administered in unchanging doses for as long as is necessary without any injurious effect.

The remedy is especially applicable in urticaria of gastro-intestinal origin, and is consequently applicable to fully 90 per cent. of all cases.

Sodium phosphate is regarded as one of the most reliable hepatic stimulants and intestinal antiseptics, and its curative influence over urticaria is probably based upon this physiologic action.

The Paris Hospitals.—It is stated by the correspondent of the *Medical Press and Circular* that the hospitals of Paris need the expenditure at least of one million pounds to make them habitable, and a further outlay of another million to make them what they really ought to be.

ACNE ROSACEA TREATED BY INTRADERMAL INJECTIONS OF FORMALDEHYDE.

BY J. T. McSHANE, M.D.
INDIANAPOLIS, IND.

The patient, an unmarried lady 30 years of age, has suffered from acne rosacea, with pustulation and papulation for about ten years. The entire face was involved with redness, most marked over cheeks and nose, and always worse during menstruation. The patient is well nourished but has suffered from nervousness and despondency, perhaps due largely to her necessary isolation from society on account of the bad appearance of her face. She has been under the professional care of several first-class physicians and all the usual means of treatment have been resorted to, but without avail.

I decided with the consent of my patient to use intradermal injections of formaldehyde in the strength of 1 drop of the 40 per cent. solution to 100 drops of water. These injections are attended with a stinging pain which the patient compares to the sting of a bee. One-half to one minim was injected in each point selected, care being taken to pass the needle into but not under the skin. In a few moments a spot about the size of a 10-cent piece, immediately surrounding the point, presents an elevated surface resembling urticaria. A sufficient number of injections were made at each treatment to thus affect the whole area of the disease and the treatments repeated at intervals of one week. The results have been most gratifying, and now, after three months' observation and treatment, the face is normally white with little or no tendency to recurrence of the disease.

26 East Ohio Street.

OVARIAN CYST.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY A. M. CARTLEDGE, M.D.
LOUISVILLE, KY.

I desire to report a rather unique case. The woman from whom this cyst was removed was 37 years of age and lived in a hovel a great distance in the country. I saw her May 13 and operated the same day. The tumor had been growing for thirteen years, and for the last four years very rapidly, so that she was unable to assume the reclining posture for more than a year and a half. The circumference at the umbilicus was seventy-nine inches. The woman was five feet four inches in height and well formed, except that she was very much emaciated from carrying this enormous cyst. Twenty-four gallons of ovarian fluid were removed before she was placed in position to be anesthetized. After that she was placed on her back and ten additional gallons of fluid withdrawn. The adhesions to the anterior parietal wall were terrific. Many ligatures were used and the operation consumed about two hours under unfavorable circumstances. The woman survived the operation fairly well, leaving the table with a pulse of 114. On the fifth day she had a normal temperature and a pulse of 108. Beginning with the sixth day symptoms of intestinal obstruction developed and she finally died. The fluid withdrawn weighed 240 pounds and the sac 5 pounds.

WRITE TO US for a copy of Department of Public Health Bill.

LENSES FOR THE STUDY OF THE SCISSOR MOVEMENT, CONIC CORNEA AND SPHERIC ABERRATION WITH THE RETINOSCOPE.

BY JAMES THORINGTON, M.D.

Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine, etc.
PHILADELPHIA, PA.

As the scissor movement, conic cornea and spheric aberration, as recognized by the retinoscope, are so difficult of demonstration, except in the individual patient, the writer has had made three lenses which will illustrate these conditions respectively, when placed in front of his schematic eye; and thus the beginner in retinoscopy may have the opportunity to see, know and study these important and interesting manifestations, before proceeding direct and in comparative ignorance to his patient.

Figure 1, is a plano-concave cylinder of 2 D., mounted in a cell of the trial case and to one half of its plane surface is cemented (at the same axis) a plano-convex cylinder of 4 D., thus making a combination lens, one-half of which is a -2 D., and the other half a +2 D. Placing this lens with its axis at 180 degrees, before the schematic eye at emmetropia (zero) and the observer at one meter distance

Thorington's Schematic Eye.

with his plane retinoscope, the two light areas, so characteristic of the scissor movement, with their straight edges and dark interspace may be seen approaching each other from above and below (and the dark interspace disappearing) as the mirror is tilted in the vertical meridian.

Figure 2 is a section of thin plane glass mounted

as in figure 1, and has cemented at its center a small plano-convex sphere of 3 D., whose base is about 4 mm. in diameter. Placing this lens in front of the schematic eye at emmetropia (zero) and reflecting the light from the plane mirror at one meter, there will be seen in the pupillary area a small central illumination which moves against or opposite to the movement of the mirror, and a peripheral ring (at edge of the iris) which moves rapidly with the movement of the mirror; between these two light areas is a dark ring. This is the retinoscopic picture and movement of the light areas, so indicative of conic cornea. It is also an exaggerated picture of negative aberration.

Figure 3, is made similar to figure 2, except at its center is ground a -2 D. sphere of about 4 mm. in diameter.

Placing this lens in front of the schematic eye at emmetropia and the observer seated as before and with the plane mirror, he sees in the pupillary area a central illumination which moves *slower* than the peripheral area (at the edge of the iris) which moves rapidly, both areas moving *with* the movement of the mirror.

After the observer has carefully studied these pictures, it will be obvious that changes other than those mentioned, can be made with these lenses and he should proceed to note them, by: 1, changing the focus of the schematic eye; 2, by placing both the convex and concave spheres in combination; 3, by varying his distance from the eye; 4, by placing a concave cylinder in front of the double cylinder at an oblique axis, thus getting the picture of compound irregular astigmatism; 5, by placing a concave cylinder of 1 D., in front of the convex sphere and developing astigmatism with the conic cornea, which is the usual condition. It is also obvious that the scissor movement can be produced by a prism which is made to cover one-half of the pupillary area, but the resulting picture is not as satisfactory for demonstration as that given by the combination lens referred to in figure 1. The instrument is manufactured by Messrs. Wall & Ochs of Philadelphia.

120 South Eighteenth St.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

XVIII.—DISEASES OF THE THROAT, CHEST AND ABDOMEN.

(Continued from page 1219.)

Abscess of the liver required surgical treatment when it presented a fluctuating swelling on the outside. It could make its way through the diaphragm and appear outside on the thorax (Petit, Morand) or break through into the lung (Fourcroy), the intestine (Bajon) and stomach, and then heal. Generally it appeared on the lower short ribs, but seldom between the abdominal muscles and the iliac bone, in the right hand groin region, above on the inner side of the thigh (Bajon), where the diagnosis was very difficult. Also a well filled gall bladder was delusive and could be mistaken for an abscess in the liver. This was often and successfully opened; the sooner it was done the more certain was the cure, for there was no dependence on a spontaneous breaking of the

same on the outside. Later the pus could separate the adhesions between the liver and the peritoneum and flow into the abdominal cavity. The abscess was opened with a rather large lancet, not by cauterizing, which would be apt to make the aperture too large. Schwartze had to pierce two inches deep before he reached the pus. When this smelled foul, camomile tea and honey were cautiously injected. A fistula might remain or death ensue from consumption. *Opening the gall bladder* was taken into consideration in fistulas and great accumulations. To effect a cure of the fistula it was usually necessary to extract the gallstones which caused the same, but only if the patient suffered excruciating pain. By means of catgut or a chisel the opening was enlarged until it admitted the finger, on which the forceps was introduced for the extraction. In this wise Zacharias Vogel of Lübeck had performed "one of the very finest of operations." In swellings of the gall bladder, which attained such a size sometimes that they were mistaken for encysted dropsy, an attempt to force the bile into the duodenum by gentle rubbing was made upon the presence of inflammatory symptoms. If it failed, the bladder was opened with the trocar according to Petit's mode of procedure, a very harmless interference as, on account of the inflammation, adhesion was assured and the tube was allowed to remain for a few days. Without a simultaneous inflammation it was not permissible to open the gall bladder, for fear of the probable adhesion with the abdominal wall. In order to produce the inflammation the peritoneum was exposed, spread with caustic, and after a few days the bladder was pierced.

A partial *extirpation of the spleen* was achieved by Ferguson. For twenty-four hours the spleen protruded from a wound and a portion of it was gangrenous. Around this piece, weighing three and one-half ounces, a piece of twine was placed; then it was cut off and a large, violently bleeding artery was tied. The remaining portion of the spleen was replaced, the threads hanging out of the wound wore off after ten days and the patient was soon cured.

We will now speak of *hernias*, in the study of which a lively interest was manifested. Their history is especially glorified by the names of J. L. Petit, Arnaud, Garengot, Morand, Pott, Guenz and Richter. The latter arranged the scattered material in his classical book in such a brilliant manner that his work was the authority on the above subject until A. Cooper's time. As early as the beginning of the century, attempts were made to scientifically explain the mechanism of the formation of ruptures, and to end the strife whether the nature of hernia was due to displacement of the peritoneum or to rupture of the same. The latter idea was the more prevalent one. German surgeons manifested but little interest in these researches. Heister did not know for which opinion to decide, compared the different views expressed, and produced authorities for the one and the other. Wideman (1719), a lithotomist and cataract curer in Augsburg, expressed himself more clearly and earlier than Heister, saying that "in reality no tear exists, only a distention, discharge and obstruction are found." The first scientific attempts were made by Rencaulme ("Essai d'un traité des hernies." Latin edition, 1721; French, 1762), who looked upon the rupture portals as fissures, from which the outer membrane of the peritoneum along the vessels, which protrude from the abdomen, continues as a divide; the

peritoneum is always well and unimpaired, if not maltreated in some peculiar way. His theory was more fully executed in detail by Garengot (1732), whose writings enjoyed a great circulation. But he as well as Arnaud had experienced, that after a violent thrust or great exertions the peritoneum burst and thus a rupture ensued without a hernial bag. Soon there appeared in Germany, almost simultaneously, the works of Günz, Mauchard and Vogel. Günz reproduced Garengot's theory, furnished exact anatomic descriptions of various sheaths for the different ruptures, described also those into the oval orifice. Mauchard tried experiments to ascertain the possibility of displacing the peritoneum. Vogel is credited with the important remark that strangulated hernia does not necessarily lie in the inguinal ring, but often in the hernial sac, even in the protruding viscera at times; I have not found the place in his book where it says so.

Regarding the treatment of reducible hernia, we have read, in the second chapter, of the outrageous malpractice carried on by the lithotomists with the radical cure. In the middle of the century Sharp and Günz favored the "king's suture," a method so-called because by sparing the generative organ its procreative power would be preserved and thus save subjects for the king. Vitriol was recommended by Renton for cauterizing, and in the year 1774 was again used by Maget and his friend Gauthier, who caused a great sensation with his ill-reputed writing. In it a thorough cure of all ruptures, no matter how large, was assured, taking for granted that they had not grown to any of the organs or the walls; but the details of the operation were concealed. The Académie de Chirurgie used its entire authority against the same; and above all others, A. Petit, who accused Gauthier of the famous de la Condamine's death; also Bordenave opposed him, although it appeared that both of these men were somewhat the victims of envy and jealousy. A third method of the radical cure consisted not only in compressing the neck of the hernial sac but to produce a counter-irritation to incite an adhesion. This was accomplished by means of a truss with a hard pad which was tightly put on the tumor and allowed to remain until intense pain ensued; then a softer pad was substituted. The closing of the neck of the hernial sac could be achieved by operative interference, if its anterior surface was scarified to cause an inflammation and then closed by a light weight truss. There was also a method extant to separate the hernial sac from the cellular tissue of the testicle and tie it close beneath the abdominal ring or return it into the abdominal cavity (Petit-Arnaud). Subligation Schmucker deemed the most reliable method of the radical cure and, on account of employing this in an operation on the body physician Zimmerman, became involved in a quarrel with Richter. The radical cure was often successfully carried out by Acrel, but he, like Petit and Sharp, saw patients die with it. He asserted that in many old ruptures the abdominal ring had been so greatly distended, that the best truss could not keep back the rupture, while by means of the operation, the same, if it could not be closed, could at least be sufficiently narrowed to permit of the use of the truss afterward. Operative interference in reducible hernia was opposed by Pott, B. Bell and Richter. The last surgeon rejected it entirely, with a few exceptions, having known the easiest, simplest and quickest operation to end fatally; and according

to J. L. Petit's view, it was more dangerous than in strangulated hernia. Of course, Richter admitted the possibility of obtaining a complete cure with the aid of a truss and caustic and scarification of the neck of the hernial sac, yet all methods were uncertain and perilous. For the opponents of the radical cure there existed no other method but the truss, for the shape and application of which Richter's directions were very accurate. The inelastic rupture bands, which were very popular for a time, he absolutely rejected, and he had no use for the movable pads. The truss should always be put on by the surgeon the first time and then worn by the patient day and night. There was a difference of opinion regarding ruptures in children. Mohrenheim advised not to use the truss, the child being too weak to stand it; besides, the band would ever be wet through with urine. He gave wine with sal ammoniac, had enemias administered daily and saw the hernia disappear gradually. Pott, on the other hand, ordered every child, however young, to wear a truss of feathers; he thought the prevalent idea that it was impossible for a child to wear one, erroneous.

In strangulated hernia we follow especially Richter's methods. The cause of the strangulation was most frequently located in the abdominal ring, which, consisting of sinews that were continuations of the m. obliq. ext., might become constricted. A second cause, probably first observed by Saviard, arose from the constriction of the neck of the hernial sac due to the thickening and callosity of the same (resulting from pressure caused by the truss, Monro), also an aperture in the hernial sac, sustained through injury (Garengot); or a partition wall in the same (Mohrenheim) could constrict the intestine; likewise the omentum becoming twisted with a portion of the intestine and driven into a pre-existing hernia (Callisen), or the hardened omentum pressing upon the intestine (Pott). Often the excrement was the cause of the strangulation. Richter distinguished an inflammatory strangulation, one caused by excrement, and added a third, the spasmodic. In this, the symptoms, with their intermissions and exacerbations, were mitigated by quieting remedies. It was often very difficult to determine the cause of the strangulation, which could also be conditioned by acrid bile and worms, and yet the success of the cure depended upon it. "Rational treatment of strangulated hernia requires far more knowledge and skill than an operation," Richter proclaimed to the surgeons.

There were various curious methods of taxis. One of the most favored was to tie up the patient to a strong man in such a way that his knees rested on the shoulders of the latter, the body hanging down from him (Sharp, Morand, Louis). The pressure, at first mild, was gradually increased, continued for a long time, and in inguinal ruptures was effected from below toward the top and from the inside toward the outside against the abdominal ring. Another manipulation consisted in pressing all parts of the entire rupture toward the inside toward the center of the swelling; a third method was to draw out the rupture and unfold the intestines; particularly was this used when there was an accumulation of fecal matters. The fourth manipulation, especially adapted to small ruptures, was to place one or two fingers at the side of the neck of the hernial sac on the abdominal ring and gradually press them back into the cavity of the abdomen.

Richter demanded that the taxis be continued for

an hour, but called attention to the exaggerated desire on part of the surgeons to continue the pressing in the following words: "Although I am free from being inclined to absolutely reject taxis, I must confess, pursuant to my experiences, that I think less of that manipulation than do the majority of the surgeons who consider it the principal method; and I am convinced that it is often harmful, seldom successful, but if successful seldom effects a complete cure. Rarely have I seen that a highly dangerous form of strangulated hernia could be returned into the abdomen, and in cases where it was returned, so many other remedies had assisted to mitigate the conditions, and after the preceding fruitless attempts the rupture retreated so unexpectedly and easily that I was always inclined to believe it would have gone back after a few hours, of its own accord." Likewise Pott did not strictly rely on the taxis, as at times it could be successfully employed after a week, and in other cases death ensued the same day. Desault considered it of great value never to employ the taxis immediately after the strangulation, as had been the general custom, but to precede the same by baths and softening poultices; furthermore it should be carried out very gently, since after vigorous manipulations the operation usually ended fatally. "There is always hope in a rupture that has not been touched before the operation." Unfortunately nearly every consulting physician who had been summoned allowed the tumor to pass through his hand, pressing it with great delight. If the entire hernial sac, the neck of which was constricted, with the intestines had been returned into the abdominal ring then the strangulation could continue. This fact had been observed by le Dran, la Faye and Arnaud, who produced dissections to prove the same. Louis, on the other hand, considered this reposition impossible on account of the firmness of the cellular tissue between the hernial sac and the testicle, and on account of the abdominal ring being too narrow; in short, he was very much in doubt about it, because he did not understand the matter. This vexed Richter and he replied: "If everything that we can not explain is not true then 100,000 truths which are daily before us would be false and we would no longer have the sun. But if in spite of this fact Mr. Louis continues, and because he can not comprehend the matter declares it an impossibility, and thereby intimates that the aforesaid three surgeons had fabricated their observations, then he is guilty of great impudence, and I, for my part, must confess that I by far more appreciate the experience of an Arnaud, the greatest authority on hernia that ever lived, than all the theories and over-refined reasonings of Mr. Louis, and that to me the trustworthiness of a le Dran and la Faye is of greater importance than all the assertions of Mr. Louis."

Various internal and external remedies are used to assist the taxis. Mild purgatives (Epsom salts according to le Grand's directions, or a decoction of herb. nicotian. and rhubarb) were recommended by Richter in strangulations due to excrement and worms, but he advised against them in case of inflammations. Pott, however, did not think much of purgatives, because the constipation resulted from the constriction of the hernia, therefore the treatment must be directed toward the latter; according to Bell's and Wilmer's ideas they caused more harm by irritating the intestine and increasing the vomiting. Among the injections the one of tobacco smoke was thought the best, especially in spasmodic strangulations. It is said that

Heister was always so successful in employing it that he never found an opportunity to perform the hernial operation. Yet there was a difference of opinions. While a few obtained good results but seldom from the use of the tobacco enema (B. Bell), or rejected it altogether and used water instead (Latta of Edinburgh), others were full of its praise (Pott, Wilmer, Richter). The last surgeon demanded that the smoke of a good and strong tobacco be blown into the hernia for at least an hour. For "this is the most common error on the part of surgeons in strangulated hernia: they like the frequent changes in methods and do not use one persistently, and yet there is seldom one that affords a speedy relief; generally we gain our purpose only by persistence." Injections of cold water and vinegar were also recommended (Theden). Of the antispasmodic remedies, the tepid baths chiefly assisted the taxis. It was always the first method employed by Desault; the baths were given two or three times daily, lasting for hours at a time. With the aid of warm baths, poultices and plain injections. Desault saw serious strangulations disappear without necessitating a taxis. Then linimentum volatile was rubbed in and poultices of camomile and linseed applied, for internal use ipecacuanha and poppy juice were given. General bleeding to the verge of faintness was the method resorted to in inflammatory strangulations, which was rejected by a few who did not see the taxis succeed through the exhausted condition (Wilmer, Alonson). Warm poultices, especially indicated by spasmodic and fecal strangulations, Richter ordered put over the entire abdominal region, not on the rupture alone. Many parties opposed the same (Pott, Monro, B. Bell, Wilmer and Keate). They did not think much of the poultices because the effect produced did not penetrate deeply enough, because the intestines were distended and the swelling increased. Pott even believed that the faith in them on account of the irretrievable loss of time had killed more people than saved them. Instead of warm poultices cold compresses were advocated. These (according to Richter) "incited the intestines to greater activity, thereby distributing the excrement and flatulence, contracted the blood vessels, freed them from the impeding fluids, reduced the size of the rupture, mitigated the pain and assisted the return of the hernia into the abdomen." The rupture and the limbs were suddenly treated to a shower bath of ice-water (J. L. Petit, Arnaud), or poultices of ice were made (Monro, Richter, Schmucker, Theden). Also by means of sugar of lead, water mixed with vinegar (B. Bell), by a solution of sal ammoniac (Wilmer), and evaporation of ether on the rupture (Hughes), frigidity was produced. Richter thought it contra-indicated by serious inflammation and violent pain, and by spasmodic strangulation, but wished this method only as a last recourse for a few hours when all others had failed.

When all methods proved of no avail, the operation became a necessity. But when was it to be performed? To designate the proper time, Sharp considered a more difficult task than to accomplish the operation, and Pott held the opinion that there was probably no subject in surgery which required greater power of judgment, more firmness and care than was necessary to determine the period beyond which it would be dangerous to defer the operation. By the majority of the German surgeons the operation of herniotomy was carried out too seldom and too late.

They experimented principally with internal and external remedies in the hope of diffusing the hernia, and tried everything imaginable. Thus, precious time was wasted, the symptoms increased in intensity and then came gangrene or mortification. The reason for this delay is found in the fear of resorting to the knife. It was otherwise in France, where, in the 90's, herniotomy was performed unusually often and the taxis seemed to have been neglected. Desault is credited with the honor of having revived herniotomy. At one time eleven whom he had operated on died in succession, while at another time fourteen patients similarly treated survived the operation and recovered. All good surgeons were convinced that it was best to operate immediately if the symptoms did not abate after applying the usual remedies for several hours. Pott asserted that if the operation was performed at the proper moment it would always fulfil the desired purpose, and believed himself justified in saying that not one case out of fifty would prove fatal if the operation be performed carefully and in good season. B. Bell wished all treatments energetically applied, but never longer than three or four hours, to be followed at once by operative interference; every minute of delay increased the danger. This principle was followed in Germany by Heister, Bilguer, Steidele and Richter, who said: "It is better to interfere too early than too late. The operation is in itself not dangerous nor very painful. The danger is not the result of the wound, but is generally caused by the length of time it is deferred. As soon as the hernia becomes so painful that a slight pressure can no longer be borne, no time must be lost and the operation must be performed, partly because the rupture is already highly inflamed and the danger of gangrene not far distant, and partly because the palliative methods are of no more use. . . . The smaller and the more recent the hernia, the more tightly constricted is the strangulation, the more pressing the danger. . . . When all methods vigorously applied have been fruitless the operation should be made without delay. The strangulation is worse tomorrow than it is today; hence, tomorrow these remedies will avail less than today." Pott reasoned similarly and said that no one can tell when a hernia becomes mortified. For several days the strangulated intestine might remain well and then again it might be gangrenous within twenty-four hours after the protrusion. Steidele had a similar experience of finding a hernia mortified, although the symptoms were very mild, the fever scarcely perceptible and the pain endurable. The cause of Morand's exceptional success in herniotomy was that he never deferred the operation long and preceded it with a mild taxis two or three times.

Concerning the technique of herniotomy, the incision was made above the abdominal ring, penetrating to the bottom of the tumor (Louis). Opening the neck of the hernial sac was, since Garengot's time, universally believed to be necessary. Upon his and Mauchard's advice, the knife was held obliquely and the several layers of the cellular tissue separated by raising each one with a pair of forceps. Pott and Richter split the hernial sac upward, but not, as was usually taught, to the abdominal ring, but only within an inch or an inch and a half beneath the strangulation, only far enough for the finger to enter. As a living probe Richter considered the finger the safest means to prevent all injuries. If the hernial sac was very large, a portion of it could be cut

off; the ligature recommended by Günz, Pott disapproved of. Light injuries were not considered as dangerous by Richter as many others believed them to be; they could be returned without any symptoms. "I am not all inclined to induce the surgeons to become inconsiderate and audacious, but I think it is my duty to encourage them when I see them being instilled with fear without a cause." The mode of procedure of not opening the hernial sac and only distending the abdominal ring was a method already used by Franco, who was the first to operate on a strangulated hernia (1561), and by Paré, but was not introduced into the practice of medicine until later by J. L. Petit. Consequently it bears his name. He had practiced the method for more than thirty years, refuted all objections and laid great stress upon there being less danger, no contact of air, etc. He protested that he did not reject the opening of the sac in every instance, for there was no question that it was necessary in gangrenous hernia. Petit's method, however, was not generally adopted. With the exception of A. Monro, Vater, Acrel, Richter and J. G. Wagner, the method was rejected by all the surgeons of the various nations. They cared nothing about it on account of the intestine and the omentum adhering to the sac, the eventual mortified condition of these parts, also the easy relapses, and the putrid fluid of the hernia. Pott regarded this method very contemptuously, spoke of writers who mentioned things of which they had no experience, but what they produced one copied from the other; he had but little to say of it and did not consider it worth his while to subject it to an examination. Richter compromised matters by saying: "It has become a sort of duty in these modern times to reject this method absolutely and in all cases. The one has repeated the words of the other, no one heeding the inventor's purpose and the cases in which he recommends them. The reasons for not opening the hernial sac are truly striking, but they are by far not so good and demonstrative as many seem to think. Ordinarily there is too much praise and too much censure. This method is not practicable in all cases, nor can it be positively rejected in all cases. Besides, the inventor did not intend its general use; he recommended it in special cases only. The idea of the general utility of this method seems to have been forced upon Mr. Petit, and at the same falsely attributed to him so as to be able to reject it. I hold the opinion that this *modus operandi* ought not to be rejected in all instances but employed wherever it would be of use and advantage and be permissible under the circumstances." Contraindications to him were adhesions of the parts in the rupture; great thickness of the hernial sac, so great that on the outside of the same no instrument could be inserted for the distension of the abdominal ring; also, gangrenous hernia and strangulations in the neck of the hernial sac.

For extending the abdominal ring the incision was either made toward the navel (Heister, Garengot, Bertrandi, Richter), or toward the outside of the body (Sharp, Pott, la Faye). Desault was guided in operating by the position of the spermatic cord, for if, as usual, it lay behind or inside the sac, he enlarged the ring upward and outward; if it lay before or outside the sac, he distended the opening upward and inward. The instrument used for the distension was the simple scalpel with a dull and somewhat curved point (Richter), or the well known bistoury of Pott. For

this operation the French invented a number of useless instruments (Méry's winged sound, Morand's hernial bistoury, le Dran's hernial bistoury and other instruments). The knife was pushed in on the hollow probe, or on the finger, allowing it to press more than to cut. The distension sufficed, if it permitted the admission of the finger in the abdominal ring. Le Blanc and Arnaud wished to insert the finger and the hook, respectively, in order to distend the abdominal ring. This method was rejected by most of the surgeons. B. Bell considered it next to an impossibility, because Poupart's ligament was already so stretched that it was not capable of being distended any more, and Louis ridiculed such procedure. But Richter advocated the method in femoral hernia, so as to avoid the danger of injuring the epigastric region or the spermatic vessels: "I can not easily make up my mind to cut into the Poupart band in males, but will ever strive to widen the ring by this method. In inguinal hernia this method may be dispensed with, because then the cut can be made without danger, and yet the method ought not to be absolutely rejected." Intestines that had become discolored, either deep red, brown, or even black, could be successfully returned into the abdominal ring (Desault, Schmucker): only when they had become disgustingly mortified could they be treated as gangrenous hernia. After the reposition, Richter deemed it advisable to scarify and compress the neck of the hernial sac, thereby sometimes effecting a radical cure. After the operation a T-bandage and, during the entire treatment, dry charpie was applied, besides which fomentations were put upon the abdomen and mild purgatives as well as injections were given. If a part of an intestine had become gangrenous, it was fastened on the outside of the abdominal ring by means of a thread drawn through the mesentery; then the gangrenous portion was cut out and the sound portion repositioned. But if the mortification covered a large surface, joining of the parts was not to be thought of unless both ends of the intestines protruded from the abdominal ring, otherwise all was left to Nature. La Peyronie and Ramdohr invented special intestinal sutures; du Verger joined both ends over the dry trachea of a goose to one another, etc. J. L. Petit principally favored the idea that Nature alone effects a cure, for he had seen several gangrenous herniæ heal almost without artificial means; therefore he thought most remedies for joining superfluous, yes, even dangerous. Richter held the same opinion. In an intestinal fistula he ordered a common elastic truss worn and under the pad of which a sponge or wad of charpie was placed on the opening. There was much dispute in regard to the treatment of the abnormal omentum. The first method used was the ligature. Most surgeons favored cutting it off and rejected Arnaud's special method of tying it off. At the most it was allowed when greatly developed arteries promised violent hemorrhages in connection with the incision. The dead portion of the gangrenous omentum was cut out and then it was returned, or if this was not possible it was left lying in the neck of the hernial sac; also the hardened omentum was left alone and only the abdominal ring distended in order to raise the strangulation.

Space does not permit us to enter more fully into the various kinds of hernia. The true nature of the congenital rupture was first determined by Huller, and William Hunter improved upon his work. There

originated with Richter, for umbilical rupture in children, a bandage still used, which consisted of half of a nutmeg wrapped in linen, the application of which with the assistance of plasters and strips he described clearly enough, so that he alone merits the honor of the invention. For adults he suggested a special kind of umbilical truss. For the radical cure of hernia Desault resurrected the ligature heretofore recommended by Celsus, and prized it as a reliable painless as well as safe method in the tenderest age of a child; this mode he had successfully used more than thirty times in the Hôtel Dieu within eighteen months. In femoral hernia, in which Gimbernat thought the seat of the strangulation located in the crural curve of the m. obliq. ext., to avoid the epigastric region the direction of the incision should depend upon the position of the rupture. If situated on the inner side of the femoral vessels the incision was directed obliquely toward the linea alba (Günz, Camper, Richter) and as closely as possible to the inner angle of the fissure. If the hernia lay on pulsating vessels or outside of them, then the cut was made outward and upward in the outer angle of the fissure. Wilmer cut directly upward, while B. Bell made several small incisions. If the epigastrica was injured, which was considered a very dangerous matter, it was necessary to interfere very energetically to reach the vessel, compress the same by means of Chopart's forceps, or ligature in order to stanch the flow of blood.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated meeting, Oct. 15, 1897.

Dr. G. FRANK LYDSTON in the Chair.

The subject for discussion was "Hysteria," which was opened by Dr. BANNISTER.

DEFINITION OF HYSTERIA.

Dr. H. M. BANNISTER—The average conception of hysteria by those who have not given the subject more than casual attention is probably an indefinite one. It is considered as a condition without a very precise definition and into which may be thrown an infinity of morbid symptoms that can not well be referred elsewhere. The definitions that are given of it also show a considerable variety. Quoting only the most recent ones the following may be offered:

Lowenfeld says that it "is a general neurosis in which nevertheless a peculiar participation of the cortex or a primary predisposition renders possible a reference of a part of the symptom to the psychic sphere." Bartholow defines hysteria as "a functional nervous trouble characterized by various motor, sensory and intellectual disturbances, and by excessive variability in their seat and manifestations." Landon Carter Gray calls it "a peculiar increased reflex excitability of the cerebro spinal nervous system, possibly also of the sympathetic, with decrease of cortical inhibitory power." In one of the most recent text books, Dr. J. Hendrie Lloyd defines hysteria as "a psychoneurosis of which the physical symptoms are the most conspicuous, tending to disguise the mental phenomena and to simulate superficially the effects of various organic diseases."

Of those who consider the disorder more especially a psychosis in its pathologic sense, or a mental disease, following the example of Charcot, I will quote the following definitions: Moebius defines as hysterical "all those alterations of the body which are produced by ideas." Osler, quoting Moebius, gives as his definition "a state in which ideas control the body and produce morbid changes in its functions." Oppenheim's definition is as follows: "A mental disease that reveals itself not in intellectual disorders but in anomalies of character and emotion and conceals its real nature behind an almost unlimited number of physical symptoms."

It will be seen that in these definitions there are embodied two conceptions of the disorder; one that it is a neurosis, understanding by the term a disease of the nervous system of rather indefinite nature and pathology, and the other that it

is in the proper sense of the word a mental disease. All mental disorders depend upon the derangement of function of the organ of the mind, or the cortical substance of the brain. For myself I would adopt the view of those who consider hysteria a mental disorder and would offer as a definition, which I do not consider, however, as necessarily better than those that have been given, but simply as conveying my present conception of the condition, the following: Hysteria is the manifestation of an original or acquired degeneracy in an ill-equilibrated action of the various cortical centers, characterized by lack of inhibition and heightened suggestibility. Reduced to its simplest expression this definition might be stated as that hysteria is an undisciplined functioning of the cortex. This, however, is not a perfectly accurate condensation.

The essential of hysteria as a disease is a degenerative basis. Every one has in him or herself the potentiality of hysteric symptoms, and under special stress of circumstances any one is liable to manifest them. But it is only in degenerates, and in proportion to the degree of degeneracy that it becomes a disease.

RELATIONS OF TRAUMATISM TO HYSTERIA.

Dr. HUGH T. PATRICK—The questions of most practical interest regarding the relation of traumatism to hysteria are two in number: 1. Does traumatism cause hysteria? 2. If so, does hysteria of this etiology differ from that due to other causes? Each question is to be answered in the affirmative, with certain qualifications.

For any morbid influence to produce disease there must be a susceptibility or a vulnerability of the organism so proportioned to the noxious agent as to allow of its domination. This axiom applies to hysteria as naturally as to fracture, toxemia or vicious education. In current parlance, then, traumatism may be the exciting cause of hysteria. But there are many diseases in which the exciting cause constitutes practically the entire etiology. A violent blow properly administered will invariably break the human fibula, and the injection of strychnin in a sufficient dose will be uniformly fatal. In such instances, however, the fragility of the bone or the comparatively feeble resistance made by the nervous system to the overwhelming power of a poison can not be regarded as a predisposing etiology, because the strength and vitality overcome are up to the normal average vigor of our present physical status. Is the case of trauma and hysteria somewhat analogous? In brief, may traumatism cause hysteria in a normal person? I shall certainly not assert that this can not be, but I believe that such an occurrence must be of an extreme rarity and I can state positively that an indubitable instance has not come within my personal knowledge. To enunciate a rule, then, in answer to the first question, it may be said that traumatism may cause hysteria, but, as a rule, only in persons with a certain abnormal somatopsychic susceptibility. For the practicing physician it is of considerable importance to know whether this morbid frailty can be affirmed in individual cases. In my experience it can, if a fairly good history be obtainable. Evidence of nervous instability, of nervous symptoms out of proportion to the cause, or of foregoing outspoken hysteria will become patent to the expert inquirer.

In attempting to designate the distinctive traits of hysteria excited by trauma, if any such exist, the subject may also be approached by the etiologic gate. Whether or not hysteria be a well defined pathologic entity, the ascendance of the more striking features in each single case are largely determined by the nature of the exciting etiology and the circumstances of its application. It is true that "traumatism" covers a broad domain of physical and mental injury associated in a melange of infinite variety, and imperceptibly loses its identity in related morbid agents; still, in the ordinary course of human affairs, it possesses certain leading characteristics by which it is currently and readily recognized as a something apart. So the hysteria of traumatism, while it can be said to present no single pathognomonic sign and, in an absolute ignorance of the etiology, it can be asserted of no case of the disease that it has been excited by traumatism and by traumatism alone, yet as a group, the traumatic cases may be said to present a certain somewhat vague but perceptible facies and to evidence somewhat characteristic tendencies. The most prominent of these distinguishing features relate to localization, pain, the admixture of symptoms of neurasthenia, hypochondria or melancholia, the rarity of general convulsions, to tremor and backache.

In the nature of things a traumatism injures one part of the body more than others and in harmony with an etiology more or less locally defined in its application, the more salient symptoms of traumatic hysteria are apt to be local, the point of injury determining the place where the more obtrusive of these will be manifest. Hence, monoplegia, localized epasm,

isolated amblyopia and regional anesthesia are relatively frequent.

Almost a universal accompaniment of traumatism is pain, and hence it would be but natural to suppose that pain would be more constant and severe in hysteria caused by injury than in the same malady due to higher or more purely psychic influences. Experience has shown this to be the case.

As before noted, traumatism, with the immediately succeeding mental and bodily states, involves a most complex concatenation of pathogenetic influences and it is no wonder that the results are so widely discrete; the individual cases of consequent nervous trouble so atypical. In brief, with so mixed an etiology, a mixed clinical picture is inevitable, hence the anomalous so-called hysteroneurasthenia, hysteromelancholia, neurasthenomelancholia, etc. It is for this reason, I think, that the patient hysteric from trauma, is apt to show the ready exhaustion, agorophobia and irritable weakness of the neurasthenic or the depression and lack of courage of the melancholiac, or both.

Traumatism rarely causes a powerful and general mental commotion without the intrusion of particular bodily harm, which would probably explain, what I believe to be a fact, that general convulsions (hystero-epilepsy) are somewhat rarer in traumatic hysteria than in other forms of the disease; but it is not uncommon for a scar or point of injury to constitute a so called hysterogenic zone, pressure on which will cause a hysteric convulsion.

Tremor of some kind or another, often reaching in degree a marked shaking or jerking, is seldom absent in hysteria from trauma, and the relation of this symptom to the etiology seems clear. It is physiologic for a person physically or mentally shocked to tremble, especially after the moment of impact, when reaction and realizing consciousness supervene.

Finally, there can be no doubt that pain in the back, more or less spinal rigidity and tenderness along the vertebrae are more frequent in the traumatic cases than in others. The rationale of this prominence of back symptoms is obscure and I would not wish to speak positively on the subject, but I am quite willing to express a tentative opinion. The evidence tends to show that man was not always a biped; to stand erect is not always his prerogative. The dorsal and lumbar muscles and the vertebral ligaments are amply sufficient to maintain the perpendicular station under favorable circumstances, but they have not yet become equal to all the exigencies arising from modern civilization. The spinal column and its appendages are somewhat behind in the process of differentiation and specialization constituting development and thus remain a *locus minoris resistentiae*.

THE RELATIONS OF HYSTERIA AND EPILEPSY.

Dr. SIDNEY KUH—Both hysteria and epilepsy are degenerative diseases of the brain. Therefore, they both develop most frequently in those whose central nervous system is congenitally weak. In both diseases the exciting causes may be the same. Violent emotions; injuries; intoxication with lead, alcohol, nicotin, morphin; acute infectious diseases; certain constitutional diseases may precede the first symptoms either of epilepsy or of hysteria. The influence of menstruation, pregnancy, the menopause, venereal excesses, overexertion upon both neuroses has been known for a long time. But even as we study the etiology of the two diseases, the fundamental difference between them becomes evident. Who has ever heard that a faulty education, that idleness had caused the signs of epilepsy to appear, two factors which undoubtedly play a most important role in the causation of hysteria and afford a satisfactory explanation for the pronounced prevalence of the latter trouble among the female sex in most civilized nations as well as for the remarkable fact ascertained by Briquet, that hysteria is very much more common in those religious orders in which all day is devoted to prayer and pious thought, than among those nuns who are active in nursing and in other charitable work.

While epilepsy seems to be a disease that has found its victims among all races and at all times, hysteria is more probably a relatively recent acquisition of humanity, one that came only with civilization and one with which even today the more barbarous races have barely met. The similarity in the symptoms of the two diseases is due to the fact that both must be localized in the same portion of the nervous system, and that both are in the majority of cases due to a congenital weakness of those organs. Hence both the hysteric and epileptic character have certain traits in common with that of the degenerate, and until the secondary mental changes due to frequent epileptic seizures develop, the epileptic, the hysteric and the degenerate are mentally very much alike. If there is any difference between them, it consists in

the fact that in hysteria the exaggeration of self consciousness, emotionalism, craving for sympathy and exaggeration of suffering, are more pronounced than in epilepsy, that in the former trouble there is occasionally a great display of, usually misdirected, energy or of theatrical unselfishness, which does not occur in epileptics.

In both neuroses, psychic and motor symptoms occur simultaneously, but in epilepsy the motor, in hysteria the mental phenomena prevail. How strongly hysteria is influenced by the mind is shown by the occurrence of epidemics of that disease. It is true that the witnessing of an epileptic seizure in another person does occasionally produce a spasm in a predisposed individual, but who has ever heard of such epidemics of epilepsy as we read of in the history of hysteria in the Middle Ages and witness occasionally in our day in girls schools and cloisters. It is the psychic element, too, that is responsible for the frequent changes so characteristic of most cases of hysteria, while in epilepsy the symptoms, though most of them occur only periodically, are in the main constant and unvarying. In the so-called hysterio-epileptic seizure the mental element is evident in the "attitudes passionnelles."

In their effect upon the human organism the two diseases differ widely. Neither the single hysteric attack, nor a series of them produce the same disastrous results as the epileptic fit. In the one stupor, violent headache and complete amnesia usually follow the explosion: in the other amnesia is as rarely complete as it is incomplete in the epileptic, and mind and body appear none the worse for the preceding violent exertion. In the one we see a series of attacks, a *status epilepticus* accompanied by hyperpyrexia: in the other, attack follows attack with no elevation of temperature at all, or at the worst only a slight one. The one disease exists for a lifetime, without reducing the mental condition to a lower level than it was at the beginning of the trouble; the other often within a few years, reduces the sufferer to a state of pronounced dementia.

All of this tends to show that while both neuroses are due to changes in the same organ, the nature of these lesions must be totally different. Epilepsy is a disease which we are today hardly justified in counting among the functional maladies. For besides those pathologic signs due to degeneracy, as asymmetry of skull and face, malformation of palate, irregularity of teeth, adherence of lobules of ears, etc., which are common to all troubles arising upon that same basis, we find organic changes in epilepsy, such as we do not see in hysteria. Chassin, Féré, Bleuler and others have described hypertrophy of the neuroglia in certain parts of the brain, and one of these authors (Bleuler) states that this lesion, while distinct in the brains of all of his twenty-six cases of epilepsy, was not found in any of the fifty-four cerebra of non-epileptics. While there is some similarity in the etiology of epilepsy and hysteria, as well as in their symptoms, due to the fact that both neuroses are ascribed to the action of similar conditions upon the same organ, they are pathologically as widely different from each other as a diabetes insipidus is from chronic interstitial nephritis.

ABDOMINAL RELATIONS OF HYSTERIA.

Dr. F. S. COOLIDGE I can not believe that hysteria is caused directly by any derangement of the sexual organs. I believe, however, that certain derangements of the sexual organs by their repeated irritation can bring about such a state of the nervous system in a person who has a taint toward hysteria, that the taint becomes manifest and hysteria develops. You will remember that Stevens thought that eye strain was the cause of epilepsy, and that by cutting the muscles of the eye epilepsy could be cured. He failed in the majority of cases, but in some cases he was successful in relieving epilepsy by removing the exciting cause, the constant irritation of the nervous system, although the epileptic taint was still there ready to reappear should any other exciting cause manifest itself. So with reference to the abdominal and gynecologic relations of hysteria, I think in certain cases, if we can overcome the derangements of the sexual organs and do away with the constant irritation of painful menstruation, and other nervous phenomena incidental to them, we may often be able to materially relieve hysteria. But the old belief that hysteria was undoubtedly due to the sexual organs, and that the removal of these organs would cure hysteria, is passing away. Bushels of healthy ovaries, and tubes have been removed under that belief, and it is a fact that is yet running in certain localities. Recent statistics, however, disprove this theory. The most recent statistics I have seen are those given in the *Boston Medical and Surgical Journal*, in an abstract of a paper by Dr. Angelucci of Italy, who collected his statistics from asylums where the patients could be watched, and not where they were operated on in a hospital, then dismissed, or

discharged as cured, no further record being kept of the patients. He collected forty-one cases which were operated on for pure hysteria, in which healthy organs were removed for the purpose of curing the disease. Of these forty-one cases, seventeen became insane, ten became worse, eleven were unaffected by the operation and three were cured by it. In other words, nearly three-fourths of the forty-one cases either became insane or grew worse, and only three were cured. Of eighteen cases in which diseased sexual organs were removed, three became insane, six were not affected one way or the other and nine were cured. At the same time he collected six cases of pure hysteria in which a pretended operation was done, namely, a laparotomy, or possibly an incision not going through the peritoneum. All of these cases were cured.

It seems to me there is reason for this. In the first place, by removing the sexual organs, the ovaries and tubes, or the ovaries alone, there is brought about the menopause; and the menopause even in normal life produces what we might call a nervous shock, this shock extending over a period of some time causing a nervous condition which is of certain importance in the life of any woman. Not only does the menopause bring about a nervous shock in normal life, but if brought about early, by operation, the shock is augmented. This is one explanation why, in these cases of hysteria oophorectomy, with or without removal of the uterus, three-fourths of the patients are made worse. The operation produces a nervous shock in addition to the hysteria which is already present and makes the patient worse. In the case of unhealthy tubes and ovaries removed for hysteria, one-half are cured and the other half remain either unaffected or are made worse. In them we have dealt not with the true cause, but only the exciting cause of hysteria. In the six cases of hysteria in which a pretended operation was done, all of which were cured, we had the influence of suggestion.

So in any operation of this kind we have the value, on the one hand, of the influence of suggestion against, on the other hand, the bad influence of induced menopause, if I may so call it, and much in accordance with Angelucci's statistics, the feeling at the present time is that the suggestion caused by the operation is not of as great value as the harm done by removing healthy ovaries. My belief at present is that it is absolutely wrong to operate for the removal of the ovaries in cases of hysteria unless there is sufficient disease in those organs to warrant it, and it is only in those cases in which the diseased organs are presumably the exciting cause of the hysteria that such an operation is justifiable.

I have had one experience in removing the ovaries of a woman who had difficult menstruation. The hysteria at all times was marked, but particularly so at the menstrual period. She died of acute mania on the fourth day after the operation. It was a single experience, but it was to me a lesson.

To sum up: According to the present status of this subject, it is unjustifiable to remove healthy organs in cases of hysteria without any palpable disease of those organs.

AUTO INTOXICATION IN ITS RELATION TO HYSTERIA.

Dr. W. A. EVANS—By the term auto-intoxication I mean the poisoning of an individual by the poisons that he himself produces. It does not include poisons produced by bacteria or other organisms in any of his cavities, and whose absorption he does in some measure control. It does include products of incomplete digestion or incomplete assimilation, the incompleteness being due to his fault or condition. For example, if by change in intestinal epithelium proteoses are not converted into serum albumin, or if anti-peptone is not transformed by liver cells, intoxication results. It then does not include intestinal putrefaction. It does include poisoning with leukomains and with proteoses and anti-peptones. Auto-intoxication can produce hysteria. Hysteria can cause auto-intoxication. Auto-intoxication can produce hysteria by changing the anatomy and physiology of the higher nervous centers so that they lack "balance," or by upsetting an equilibrium rendered unstable by this or other causes. Hysteria can produce auto-intoxication by excessive leukomains production, *e. g.*, by violent nervous or muscular effort, or by diminished excretion, *e. g.*, hysteric anuria.

THE ORTHOPEDIC ASPECT OF HYSTERIA.

Dr. JOHN RIDLON It is more than likely that hysteria may simulate any disease or deformity in the province of the orthopedic surgeon. Personally, I have met with only the following: The hysteric spine may be mistaken for spondylitis or for scoliosis. In simulating spondylitis it may have a posterior curvature, but never a posterior angle. The spine may be more or less rigid, but the rigidity is rarely confined to the posterior curvature, and it is not equal in all directions, that is to say, there is often normal motion in one direction. The range of

voluntary motion is greater than the range of passive motion, especially if the patient's attention is directed elsewhere. Pain is usually local, whereas the pain of spondylitis is distant. Tender points along the spine are always, or almost always, found in the hysteric spine, and never found in spondylitis unless there be such local manifestations of inflammation as the development of an abscess. The hysteric spine is usually accompanied by other manifestations of hysteria.

When the curve of an hysteric spine is lateral it may be said to simulate scoliosis. In such cases it presents all the symptoms above enumerated, whereas a true scoliosis presents rigidity only after years of deformity, never presents local tenderness, and rarely either local or distant pain.

Simulating hip disease, it often presents very great rigidity without deformity, whereas in hip disease the deformity develops step by step with the rigidity. To passive motion, the rigidity of the hysteric hip is uncertain and shifting and has an elastic feel; the rigidity of true disease at the hip is always a fixed quantity at any single examination, that is, it is never more and never less, though it may be greater (or slightly less) at a second examination some days later. There is usually local tenderness, which is rare in true disease except during the formation of an abscess. The pain is usually at or about the joint; the pain in true disease is usually at the knee. Muscular atrophy is not present in hysteric hip; it is a constant symptom in true disease.

The same symptoms may be applied when differentiating disease at the knee. But at the knee the differentiation is not so easy, since in some instances there is present a puffiness and false fluctuation which closely resembles beginning tubercular synovitis.

The same may be said of hysteria at the ankle joint.

When hysteria affects the tarsus it is more likely to simulate talipes equino-varus than tuberculosis of that part.

When hysteric equino-varus is present the resemblance to the deformity resulting from infantile spinal paralysis is very great. Indeed, it may even imitate a congenital clubfoot except for the history. In both instances atrophy of the leg muscles, from disease in the congenital form and from paralysis in the paralytic form, is found wanting in the hysteric case.

In all diseases of hysteric deformity, profound anesthesia would seem to offer the key to the problem; but it should be remembered that recent deformity due to tubercular joint disease may disappear under profound anesthesia and, on the other hand, prolonged hysteric deformity may result in a structural shortening of the muscles on the concave side, which does not yield to even profound anesthesia.

There should be no difficulty in differentiating true wryneck from an hysteric condition in this region. In true wryneck the only symptoms present are those depending upon a structurally shortened sternomastoid muscle, whereas the hysteric condition closely simulates cervical spondylitis, from which it must be differentiated by the rules laid down in discussing spondylitis and the hysteric spine.

HYSTERIA AND ITS RELATION TO PREGNANCY.

Dr. C. E. PADDOCK—"The causes that directly determine the development of hysteria in an individual may be either physical or mental influences, or both. Of the two, the mental and moral influences are the more potent and the most frequent. The only disturbance common to all forms of the affection is that of cerebral functions, and we are not justified in looking beyond these for the primary development" (Gowers).

The physical conditions that may influence the development of hysteria are many, but disorders of the generative organs have always claimed the most attention. "Some morbid state of these organs is present in many cases, but the estimate that at least one-half of the sufferers from hysteria are free from such, is probably near the truth" (Jolly).

It is evident that whatever influence disorders of organs may exert, they are really the manifestations of the disease already in existence. As the term hysteria implies some uterine trouble, it is probably one reason why so much importance has been given to that organ in this relation. The etymology of the term is therefore misleading. To define hysteria, an accurate description of the individual with the ancestry and environments which surround the particular person seems necessary.

That hysteria is prevalent in all classes of society is apparent, but that heredity, education, climate and environment have their influence, there is no question. In the higher classes of society, idleness, social duties, dress, a sedentary life, furnish sufficient reason for the development of the disease. In the lower walks of life, unless it be among the dissipated and vicious, hysteria is seldom known.

In mild attacks hysteria may be controlled or modified by

the will, but when the hysteric habit has got control of a person, the least mental or physical fatigue may produce a fit of nervous excitement due to exhaustion of nervous force, and the patient is no longer able to control this paroxysm by will power. It is a mistake, therefore, to look at these cases as controllable. They can no more be influenced by the will and stopped than can an eclamptic attack. Hysteria occurring in the pregnant woman means more to the obstetrician than the same does in diseases in general. Pregnancy is considered a physiologic process, but only when it occurs in a woman free from disease. In every case of pregnancy when hysteria develops, I will prove to you a previous hysteric tendency.

The causes of hysteria in gestation are the same as in the non-pregnant woman. Authors generally agree upon this. "Playfair's System:" "A pregnant woman may suffer from hysteric convulsions, but this condition is identical with the same disease in the non-pregnant, and they are in no way special in their nature." "Gleson's Midwifery:" "Hysteria is quite common at the commencement of gestation and hysteric convulsions are most frequent at this stage. It does not differ from hysteria in the non-pregnant." Similar extracts may be taken from writings by Tarnier, Lusk, Galubin and others.

Professor Valenta, in the *Arch. Gynäkol.*, XLIX, Vol. 1, p. 189, 1895, reports a case of hysteria in first pregnancy. The patient was in the fourth month, was very hysteric, and wished to get rid of the child. The case threatened to pass from a nervous to a psychotic state. Abortion was performed. As soon as the membrane was ruptured all signs of hysteria ceased. There was an absence of any pathologic condition of the genitalia, but that there was a lesion somewhere is proven by the further statement that the case had been hysteric from childhood. Her father died of delirium tremens, and her paternal aunt was insane.

I can quote cases, in my own practice, of pronounced hysteric tendency, increased perhaps from psychic and physical reasons, such as maternal impressions, vomiting, etc., but in all these cases we do not have to look far for a cause.

From my own observations I formulate the following:

1. Pregnancy itself is not a cause of hysteria
2. Hysteria in pregnancy has the same primary formation as hysteria in any other form.
3. Heredity plays a very important part in its etiology, and the womb is no more a factor than any other organ which may be diseased.
4. Cases previously hysteric are not benefited by pregnancy, their offspring are alike hysteric and degenerate, and our social and moral obligations are not enhanced by bringing such children into the world.

HISTORY AND MEDICINAL THERAPEUSIS OF HYSTERIA.

Dr. GEO. F. BUTLER—The earliest medical conception of hysteria is presented by Shakespeare in *Lear*, when that king ere his madness says:

"O, how this mother swells up toward my heart,
Hysterica passio down, thou climbing sorrow,
Thy element's below."

In this, Shakespeare fully represents the old conception of Hippocrates, that hysteria was due to strangulation by the womb. To this strangulation, which resulted not from the womb moving about, but from some supposed reflex nerve performances akin to those utilized so lucratively today, were due, according to the Greek physician, six hundred and odd disorders of various types closely allied to those now ascribed to hysteria. As the male, in the hermaphroditic conception of the Greeks, was supposed to have a "spice of the mother," as the womb was called equally by Greek, Celt and Teuton, Hippocrates, like Shakespeare, naturally finds these disorders in men also; a conception that was supposed to be peculiar to the nineteenth century. During the centuries down to the sixteenth, many diverse notions of hysteria obtained, varying between the limits observed today. Rislau, Diemerbock and Bonnet attempted to establish, in the sixteenth century, that relationship between the female genitals and hysteria which has proven so lucrative to *jin de-si-cle* gynecologists. Nearly coeval with Shakespeare, Harsnet showed that when devils were cast out by miracle, the alleged devil was merely *hysterica passio*. About this time Dr. Jorden, in a treatise on "Suffocation by the Mother," strongly urged the reflex notions common to Hippocrates and modern gynecologists. In 1620 Lepois claimed a cerebral basis for hysteria. Indeed, during the sixteenth, seventeenth and eighteenth centuries, medical disputes as to the genital or reflex or cerebral origin of hysteria were as animated as at present. Sydenham, employing the term "animal spirit" for what would now be called nervous force, supported the cerebral side. Erasmus Darwin, the eminent clinician and neurologist of the eighteenth century, accepting the cere-

bral theory, anticipated many of the views of Brown-Séguard and Charcot. A fair idea of the views entertained by general practitioners of the eighteenth century as to hysteria may be gleaned from Smollett's description of the hysterical servant girl in "Humphrey Clinker." The girl displayed all the convulsive conditions and emotional outbursts supposed to be characteristic of the modern fine lady. This servant girl (being in Edinburgh, where the practice then, as in Chicago today, was to throw all garbage into the alleys), remarks: "A sweet savor comes from such a number of perfuming pans, but they say it is wholesome, and, truly, I believe it is, for being in the vapors and thinking of Isabel and Mr. Clinker I was going into a fit of asterisks, when this fiff, saving your presence, took me by the nose so powerfully that I sneezed three times, and found myself wonderfully refreshed, and this to be sure is the reason why there are no fits in Hadding burrough."

The peculiar effects here ascribed to odors survive in much of the medicinal therapeutics of hysteria today. Certainly the use of musk, castoreum, assafetida and the valerianates suggests the potent effect of stimulus to the olfactory anesthesia of the hysteric.

Medicinal treatment for centuries has practically ranged along the lines of the antispasmodics. In the early sixteenth, seventeenth and even eighteenth centuries, skatologic therapeutics of the type indicated by Smollett was not an uncommon phenomenon. Of this therapeutics the *mistura diabolium* of the first half of the present century was a sturdy survivor. Its essential ingredients of olfactory unsavoriness were added according to the taste and fancy of the prescriber and his sense of the exigencies of the case. The medicinal treatment of hysteria should be based on certain essential principles: The avoidance of excess in drugging; the avoidance of narcotics in order to prevent the formation of drug habits; discretion in the use of the bromids in order to avoid bromism and resultant debility; the careful use of cathartics that constipation with its frequent serious effects on the general, mental and nervous state of the patient may be avoided; counterirritants to protect the patient against local vasomotor results of auto-suggestion so frequent in hysteria.

For the relief of the vasomotor instability resultant in the various emotional states, zinc and other valerianates are often useful. Against this, and the erotism, camphor monobromate is frequently beneficial.

To secure slumber, whose non-existence should first be ascertained, trional, phenacetin and sulphonal, rather than chloral or morphin, should be used.

For the relief of the pseudo-anginas, glonoin or strychnin is of value. In the convulsions of grave hysteria, the hypodermic administration of apomorphia will often prove beneficial or glonoin, or the inhalation of amyl nitrite may prove equally valuable.

Hysterical aphonia and deafness have frequently been removed by amyl nitrite.

LOCAL AND GYNECOLOGIC PROCESS OF HYSTERIA.

Dr. W. H. RUMPF—Dr. Coolidge has said so much concerning the relations between hysteria and gynecologic diseases, that there is very little left for me to add. Undoubtedly, impairment of the functions or disease of the genital organs have a great influence upon the nervous system, and any derangement of these would naturally increase the neurosis that might be present. Any disease of these organs would be treated either locally or by operation according to the rules that govern us in our gynecologic work, whether hysteria is present or not. It is very essential to warn against unnecessary treatment when hysteria is present, and in many cases better results are obtained by mere suggestion and mental treatment than by actual operations.

(To be continued.)

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Concluded from page 1222.)

A BRIEF REVIEW OF THE WORK OF THE SAND FILTERS AT LAWRENCE, MASS.,

was a paper by H. W. CLARK, chemist in charge of the Lawrence Experiment Station. Up to 1875, the water of the city used for all domestic purposes was obtained from ordinary wells. In that year, however, a public water supply system was constructed and the water pumped to the reservoir and distributed to the citizens from the river at a point about one mile above the city. Nine miles up the river from the intake was the city of Lowell, having at that time a population of

85,000. The sewage of Lowell was and is still discharged into the river, and above Lowell are other cities and towns also discharging their sewage into the river. This water supplied to Lowell was then, from the first, beginning to be badly polluted, but was evidently purer than the average well water previously used, as shown by a considerable decrease in the death rate following its introduction. Gradually, however, typhoid fever became more and more prevalent, and finally the death rate in the city from this disease became the highest in the State, being about three times as great per 10,000 population as the average city of the State. The cause of the epidemics which prevailed during months when other cities were comparatively free from it was the polluted water-supply, and the question of a new supply began to be agitated. In the meantime, investigations in regard to the purification of Merrimac river water by sand filtration had been carried on at the Lawrence experiment station of the State Board of Health, and had resulted so satisfactorily that as early as 1891, the city was advised to construct a sand filter large enough to filter the entire water-supply, and in 1892 the city government made an appropriation for beginning its construction under the State Board of Health. In January following the starting of the filter, the number of cases of typhoid fever was nine, or one eighth as many as during the previous January. This fact is more striking when we note that in Lowell during this month there were ninety-nine cases, or three times as many as during the previous January. In January, 1896, there were six cases; January, 1897, two cases. A more satisfactory demonstration of the effect of the filter upon the health of the people of Lawrence can be made, however, by stating that in 1887 the deaths from typhoid fever were 12 per 10,000; in 1889, 13.75 per 10,000; 1890, 13.33; in 1891, 12.20; in 1892, 11.11. During 1893 the filter was built, and hence a portion of the year filtered water was being used. In 1894, filtered water was in use during the entire year, and the death rate from this disease was five per 10,000; during 1895, it was 3.07; 1896, 1.86, and the rate for the present year promises to be exactly the same as for 1896. Besides giving a water free from disease germs, the filter is also giving a cleaner water, more attractive and palatable and containing but 50 per cent. of the organic matter of the river water.

In the evening the Association was received formally by the Mayor, and were given an opportunity to go through the public buildings, which were brilliantly lighted for that purpose.

FRIDAY SESSION.

By invitation of the trustees and faculty of the University of Pennsylvania and by special permission of the students, the Association met in Houston Hall.

After the usual report of the Executive Committee, the nominations for officers for the ensuing year were announced: President, Dr. Charles A. Lindsley, New Haven, Conn., Secretary of the State Board of Health; first vice president, Dr. Benjamin Lee, Philadelphia, Secretary of the State Board of Health of Pennsylvania; second vice-president, Dr. John C. Shraeder, Iowa City, Iowa; secretary to fill the unexpired term of Dr. Irving A. Watson, resigned, Dr. C. O. Probst, Columbus, Ohio, Secretary of the State Board of Health; treasurer, Dr. Henry D. Holton, Brattleboro, Vt., member of the State Board of Health. Next place of meeting, Ottawa, Canada.

Mr. RUDOLPH HERING, C. E., of New York, reported on "Disposal of Garbage and Refuse." He made the statement that besides the reduction of the garbage to grease and as a fertilizer, or its total destruction by cremation, there is no other process the committee can mention as commendable from an economic or sanitary point of view.

Dr. C. O. PROBST of Ohio reported for the Committee on Transportation and Disposal of the Dead and favored the shipment of bodies previously prepared by a licensed embalmer, the body placed in a hermetically sealed casket. Dr. Henry Mitchell, Secretary of the State Board of Health of New Jersey, objected to this as creating a special class of workers to whom all such work would necessarily be referred. He offered a motion which was adopted, striking out licensed embalmer and inserting under the supervision of the provincial or State sanitary authorities.

Dr. MITCHELL presented the report of a committee to examine and report on the existing sanitary municipal organizations of the countries belonging to the Association with a view to mention those which had been most successful in practical results.

UNIFORM AND CO-OPERATIVE HEALTH LAWS.

was presented by S. P. HEILMAN, M.D., of Heilmantdale, Pa., Medical Inspector for the County of Lebanon, Pa. He said: "I appear before you today in a dual capacity as an officer of the State Board of Health of Pennsylvania and as a member of the Farmers' National Congress. At the recent session of this

Congress held at St. Paul a resolution was adopted favoring uniform and co-operative health laws, and a committee of three appointed to further the matter of the resolution. As a system of uniform and co-operative health laws applicable to all parts of the wide domain of our United States can hardly be thought of as attainable without the pre-existent establishment of a National Department of Public Health, headed by a Secretary of Health or a Commissioner of Health. Our committee assumes that that is what was really in view when the resolution favoring uniform and co-operative health laws was offered and adopted. You are aware that at the last meeting of the AMERICAN MEDICAL ASSOCIATION, held in Philadelphia June 1 to 4, 1897, a committee was appointed to draft a bill for a Department of Public Health and to define its duties, with instructions to present said bill to the United States Congress at the next meeting of the same. Such a bill has now been drafted by that committee. This measure, if presented to the United States Congress by an Association as distinguished and learned as the AMERICAN MEDICAL ASSOCIATION, seconded by the Farmers' National Congress (whose part in the matter has just been explained) and reinforced by this most distinguished American Public Health Association, more largely concerned in the matter than either of the two associations named, and by far the better judge as to the necessity for a department of public health, and whose deliberate avowal would be an invincible argument in favor of a department of public health, our committee respectfully submits, if presented with the recommendation of the three bodies named ought to go to the Congress of the United States with a force commensurate with the dignity, learning and influence of the bodies making the recommendation.

Some considerations on the "Hygienic Influence of Forests" by Prof. SALVADOR GARCIALDIEGO, Dean of the Medical College of Guadalajara, Mexico, was read by Dr. A. L. Gibon, U. S. N., retired.

The Executive Committee, as a part of its final report, recommended favorable action on the proposition to establish a National Department of Health; this caused much discussion before its final adoption.

Dr. P. H. BAILHACHE, U. S. Marine Hospital-Service urged delay and held it as improper for this an International Congress to take such action for one country, concerning which the others had no right to act. Whatever we of the United States might think of it, Canada and Mexico, a part of this Association, really had no right to give any advice.

Dr. A. L. Gibon opposed this view, and argued strongly in favor of the adoption of the report of the Committee.

Dr. E. O. SHAKESPEARE of Philadelphia, regarded this most important and action should be taken with proper consideration. The proposed bill was too long and in some places the language was ambiguous; he objected to the bill. He urged the return of the bill to the Committee for further consideration.

A vote was taken adopting the report as read, and the following resolution:

Resolved, That this Association reaffirms its urgent opinion, and petitions the Congress of the United States to organize and establish a National Department of Health, and orders a copy of this resolution to be transmitted to Congress with the report of the Committee on Health Legislation, and the accompanying papers.

THE PRESENT MORTALITY RATE IN DIPHTHERIA

was presented by I. NEWTON SNIVELY, M.D., Philadelphia. He said: The American Pediatric Society made the significant statement that, in its judgment, the results from the serum treatment of diphtheria would gradually further improve. The reasons given for this statement were that, 1, antitoxin is still frequently used too late, either from procrastination on the part of the physicians or objections on the part of friends; 2, it is given in a half hearted way and often in doses one-tenth to one-fourth as large as they should be. It has been frequently observed that the percentage of recoveries under antitoxin treatment has steadily increased from the beginning. The present mortality, the lowest ever recorded, is pronounced by most observers of large experience with the remedy, especially in private practice, as being entirely too high to represent the power of the remedy. He quoted from Holt the statement that from the most trustworthy statistics it appears that the actual mortality from diphtheria, including membranous croup, has been reduced at least one-half by the general adoption of serum treatment, and that in cases injected reasonably early the mortality is less than 5 per cent. The present mortality, all cases being included irrespective of the brand of antitoxin employed, or the day on which the serum treatment was introduced, was given as follows: General, 8 to 10 per cent.; general (antitoxin used reasonably early) 5 to 7 per cent.; laryngeal types, 21 per

cent.; operative laryngeal cases, 27 per cent.; non-operative laryngeal cases, 17 per cent.; number of laryngeal cases, requiring operation, 17 per cent.

The doctor then proceeded to show upon what a further reduction in the fatality from this disease must, in his opinion, depend. He observed that a study of the vast accumulation of reliable literature on the subject shows great improvement in three distinct lines: 1. In the production of the remedy, a more concentrated and potent product being now available. 2. The treatment is introduced earlier than formerly. 3. Appreciating more and more the efficiency and harmlessness of the remedy, the physician uses larger doses and, where repetition is found necessary, waits a much shorter time.

Speaking of improvements made in the remedy he observed what is now so generally conceded, namely, that the greatest improvement yet made has been in producing a much more concentrated product. The antitoxins now available to the profession vary in potency from 50 to 500 immunizing units to each cubic centimeter of serum. The major portion of the products range in strength from 100 to 200 units per cubic centimeter of serum. The most concentrated antitoxin in common use is that known to the profession as "Extra Potent" (Mulford's), containing 500 units to each cubic centimeter.

The advantages of concentration were then minutely pointed out. Such serums disturb the tissues but little because of the small quantity to be injected, they are quickly absorbed and always produce earlier results. The advantages of concentration in producing earlier and better results were compared with those of tinctures and fluid extracts over the infusions of the older pharmacopoeias. Only such products are recognized in the recommendations of the American Pediatric Society.

In the early days of antitoxin treatment it was proper to speak of obtaining results from a curative dose in from twenty-four to forty-eight hours. At present effects are expected in from twelve to eighteen hours, and are secured early in proportion to the degree of concentration of the antitoxin employed. The general employment of concentrated antitoxins of uniform quality will insure increasing success in the treatment of diphtheria and membranous croup.

The importance of care in the selection of antitoxin was then pointed out and the fact cited that examinations made by the Pennsylvania and Massachusetts State Boards of Health and the *Medical News* all show the presence in the market of serums of weak, variable and uncertain quality. The importance of eliminating such either by proper State authorities or by the careful practitioner was emphasized as essential, if the fullest powers of the remedy are to be secured.

Reverting to the hostility which some physicians still show toward the treatment, the doctor observed that the principles upon which the remedy is obtained and employed are now so firmly established both experimentally and clinically, that there would seem to be no reason why the entire profession should not accept them.

The importance of instructing the laity to report all cases of throat ailment early was emphasized and the reasons for the superior results from early antitoxin treatment pointed out.

Antitoxin must be employed as any other antidote in order to obtain the greatest possible results. At present no rule for dosage can be laid down except that the dose should always be graded to the severity of the case and that no dose of less than 1,000 units should be considered a curative dose. The importance of the initial dose as compared with any other that may be required in an individual case was clearly pointed out. Experience has explicitly shown that in severe cases one dose of 2,000 units will result in a larger percentage of cures than will three or four doses of 1,000 units each, given at intervals of from twelve to thirty-six hours. No maximum limit of dose has yet been ascertained and probably does not exist. Reports from large users of antitoxin show that at present curative doses ranging from 1,000 to 6,000 units are employed with excellent results.

The further increase in the rate of recovery from diphtheria will depend upon:

1. The production and use of only concentrated antitoxin.
2. The elimination from our market of all serums of variable, weak and uncertain quality, no serum of less than 200 units per cubic centimeter being accepted.
3. The general employment of approved serum, according to the best teaching of the profession.
4. By treating each case of the disease as speedily as possible, aiming to neutralize the absorbed toxins and arrest the disease.
5. By treating the constitution and the disease in the same way, namely, by meeting specific indications.
6. By guarding against fear and other undue exertions, psychic and physical, on the part of the patient.

7. By endeavoring, as physician, to maintain a reliable mental equipoise.

A vote of thanks was passed for the hospitality shown the members by the city authorities, the entertainments by the ladies and the pleasant entertainments by the Committee of Arrangements, etc. The officers elect were then installed.

On Saturday those who had not left the city were taken down the Delaware River to visit the State quarantine station at Marcus Hook, where they were provided with a luncheon, thence to Reedy Island, where the disinfecting plant of the Marine Hospital Service was exhibited and explained, returning to New Castle, Del., where a special train was in waiting by courtesy of the Pennsylvania Railroad, which carried the party back to the City.

NEW INSTRUMENTS.

EXCISION OF THE TONSILS FOR HYPERTROPHY WITH RECURRING TONSILLITIS.

A MODIFIED INSTRUMENT AND THE TECHNIQUE OF ITS USE.

Read by Invitation at the Meeting of the Will County Medical Society, Nov. 23, 1897.

BY E. R. LARNED, M.D.

Member Chicago Medical Society, Will County Medical Society, American Medical Association, Etc.; Lecturer to Silver Cross Hospital Training School.

JOLIET, ILL.

Excision of the tonsils in cases of hypertrophy, with frequently recurring attacks of tonsillitis, promises more for the patient's immediate relief, and affords a more certain cure, than partially removing the glands; and to facilitate this procedure I have devised a modification of the Ingals' or Bosworth cold wire snare, which has proven so satisfactory as to merit a description.

This changes the appearance of the instrument completely, as will be seen from illustration II.

The points embodied in this form of snare to which I wish to call especial attention are: *a*, The whole tensile strength of the wire is utilized instead of losing a good percentage of it by the friction at the proximal opening of the wire tube; *b*, the thumb-screw, with its double thread, acts quicker, easier and with more power than the milled nut used on the Ingals' snare. With this instrument complete excision of the tonsils can be made in only a little longer time than when using the ordinary tonsillotome.

The operation which this instrument was designed to facilitate is as follows: The patient complaining of attacks of quinsy each time a cold is contracted, is found upon examination to have hypertrophied tonsils.

This is a case where the ordinary partial removal would prove inadequate, if not actually adding to the patient's susceptibility to the recurring attacks of tonsillitis; nor would cauterization of the tonsillar crypts be of so much benefit. Frequently in these cases the tonsils are covered by the anterior pillars of the fauces and possibly this fact explains the frequent failure of tonsillotomy to permanently relieve the patient.

It is highly important that the field of operation be properly illuminated, and care be taken to select a room brightly lighted by a large window or a skylight, in which to conduct the operation. The patient is placed on a table parallel to and in front of the window. Back of the table a good-sized common mirror is placed, or held by an assistant, in such a manner that the light from the window is reflected to the head-mirror worn by the operator, who should be sitting between the patient and the window. By these means a strong light may be easily thrown on the field of operation and at the same time the operator's eyes are not confused by the bright light of the window. If the room is provided with a skylight, the light is

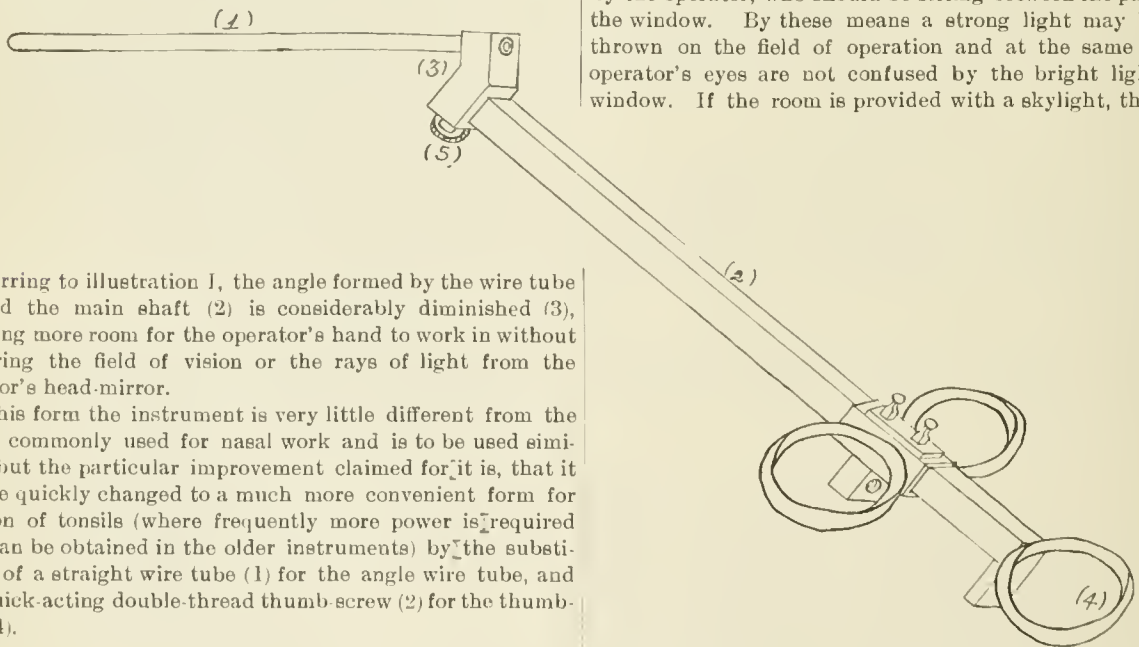

Fig. 1.—For ordinary work.—(Larned.)

Referring to illustration I, the angle formed by the wire tube (1) and the main shaft (2) is considerably diminished (3), affording more room for the operator's hand to work in without obscuring the field of vision or the rays of light from the operator's head-mirror.

In this form the instrument is very little different from the snares commonly used for nasal work and is to be used similarly, but the particular improvement claimed for it is, that it may be quickly changed to a much more convenient form for excision of tonsils (where frequently more power is required than can be obtained in the older instruments) by the substitution of a straight wire tube (1) for the angle wire tube, and of a quick-acting double-thread thumb-screw (2) for the thumb-ring (4).

Fig. 2.—For excision of tonsils.—(Larned.)

That this may be done, the wire tubes have been made interchangeable and held in place by a small set screw (5) and a place provided for the thumb-ring to be screwed into the shaft.

reflected in the same manner, by holding the large mirror at the necessary angle to reflect the rays from the skylight to the operator's head-mirror.

If neither window nor skylight is available, a common "bull's eye" lantern, or a bicycle lamp, can be made to answer very well, if a regular laryngoscope is not at hand.

The operation should always be conducted with the patient thoroughly under the influence of a general anesthetic, chloroform being preferred for obvious reasons.

The posture of the patient is very important. After the patient is thoroughly anesthetized, a Waxham gag should be used to keep the jaws well apart, and held by the anesthetizer; he is then turned upon his abdomen, the face projecting over the side edge of the table (not the end), about half way, the head and uppermost arm being held by an assistant.

If, as is usually the case, the tonsil is more or less covered by the anterior pillar of the fauces, it must be separated from its covering by passing a blunt hook between it and the pillar.

The undermost tonsil is now seized with a forceps, preferably one made for this purpose, or a bullet forceps, or even ordinary hemostatic forceps, and the wire loop of the *ceraseur* passed over the locked handles of the forceps, being careful to have it encircle the gland completely; then steadily turning the thumb-screw will completely remove the tonsil, frequently without the loss of a drop of blood.

Turning the patient with his face to the other side of the table and then turning the table so that the patient faces the operator again, the remaining gland, which is now undermost, is quickly removed.

The entire operation can be carefully done in from ten to fifteen minutes, not counting the time used in anesthetizing the patient. There is no danger from hemorrhage and the tonsillitis can not recur.

The after-treatment should consist of gargling once an hour, except during sleep, for two or three days following the operation, with rather warm water containing five drops each of carbolic acid and oil of gaultheria to the ounce.

A careful observation of the many little points of technique in this description makes the operation neat and satisfactory to the patient's friends and the operator.

The snare has comparatively few parts and may be thoroughly sterilized by boiling. The instrument and sketches are the product of my leisure moments, but any instrument maker can manufacture the snare by reference to the drawings.

426 Barber Bldg.

APARTMENT DISINFECTION.

The value of formic aldehyde gas in disinfecting is now generally recognized, but there have been many difficulties attending its efficient application. The volume used must be amply large and liberated with sufficient rapidity to overcome all the

disadvantages. Dry heated gas is of highest value because it is most penetrating and, having a specific gravity equal to that

of atmospheric air, mixes freely with air, thus producing its effects wherever air can penetrate.

In an effort to secure the best effects the following simple apparatus (shown in the illustration) has been devised. It consists of a Swiss heating lamp beneath a reservoir for commercial formaldehyde. Between these is a copper coil opening into the receiver and ending in a short gum hose, at the distal end of which is a thin feeding-tube. The opening from the reservoir into the tube is protected by a valve. When the tube is red-hot, the valve is opened to admit a small stream of solution of formaldehyde. This is instantly vaporized and the liberated gas and vapor intensely heated as it passes through the coil. The gas is not liberated under pressure, hence there can be no danger from inflammation or explosion. By means of the feeding-tube, an apartment is filled with gas through a key-hole or other suitable opening.

The apparatus is always on the outside of the apartment being disinfected, and is capable of filling an ordinary room within half an hour, so that one operator can easily disinfect as many as two dozen rooms per day, if not too remote one from the other. The apparatus can be obtained of H. K. Mulford Co., Philadelphia.

SELECTIONS.

The "Carlsbad Springs" of the United States of North America.

. . . The United States excels all other countries of the globe in the number and varying character of its mineral springs. . . . In the Thirty second bulletin of the United States Geological Survey (1886) there is an elaborate, and as far as possible, exhaustive report, prepared by Albert C. Peale, M.D., in which there are mentioned 2,822 localities, containing 8,822 distinct springs. Of the latter but 634 have been quantitatively analyzed, and 153 tested simply for the nature of their ingredients (qualitatively analyzed). Of these, 223 were being used commercially in 1896, 17 having been added to this number in 1890, which is the date of the last general report on the subject.

The figures as above given, incomplete as they are, demonstrate that while the number of springs which have been analyzed is less than a quarter of those of Europe, the sum total of those in the United States largely outnumbers those of that continent, as enumerated by Dr. Friedrich Raspe in his "Heilquellen Analysen." This author gives between 2,800 and 2,900 analyses of as many different springs situated in various parts of the continent of Europe. This great disparity is obviously due to the older civilization of Europe, and the greater facility and cheapness with which analyses are obtained there. Among the springs of our own country, with whose composition we are acquainted, and which, in spite of our youth, have been fully tested as to their intrinsic qualities as health restorers, there are a great many which may fearlessly take up the gauntlet and challenge the most celebrated health resorts of the Old World as to their value and efficacy in this direction. If Americans prefer European spas to the springs of their own land, it is doubtless due to their desire to travel "over the sea," the benefits of a voyage, or to lack of acquaintance with the resources of our country.

Among the oldest and most celebrated mineral springs and health resorts of Europe Carlsbad claims a prominent place, a claim readily granted by balneologic authors, as its springs have enjoyed for centuries a deservedly high reputation as a "resort for invalids and not for pleasure." . . . The hot waters here issue forth from a subterranean basin whose nature and contents have been plainly elucidated by Berzelius, who demonstrated "that the incrustations produced by the decomposition of the water in contact with the atmosphere has formed a roof, through which the waters below it forced them-

selves to the surface, at a temperature higher or lower according to the distance they had to travel beneath the shell before finding exit." There are quite a number of springs differing from each other mainly in the temperature at which they emerge from the earth, the range being from 115 to 162 degrees, with but slight variation in the nature or quantity of their solid contents. It will be sufficient, therefore, to mention the analysis of the most prominent, the "Sprudel," one gallon (58,329 grains) of which contains 326 grains of solid ingredients as follow: Calcium carbonate, 18.012; ferrous carbonate, .205; lithium carbonate, .152; magnesium carbonate, 10.404; manganous carbonate, .045; sodium carbonate, 77.003; strontium carbonate, .053; sodium phosphate, .028; potassium sulphate, 8.446; sodium sulphate, 146.558; sodium bromid, .015; sodium chlorid, 60.610; sodium iodid, .001; calcium fluorid, .186; alumina, .129; silica, 4.385. Total, 326.232 grs.

There are no less than eight known mineral springs in the United States for which the term "Carlsbad" is chosen to at once demonstrate their superior efficiency. . . .

"America's Carlsbad," the *Bowden Lithia Springs*, are situated among the granite hills of Northern Georgia, four miles west of Atlanta, at an altitude of 1,200 feet above the sea, with a mild and dry climate, whose temperature "rarely reaches 90 degrees in summer or goes below 40 degrees in winter." There are several springs on the grounds, which are encased, and used only partly for drinking purposes. The rest of their waters are pumped into a reservoir, from which the bath-house is supplied. "For the company has secured a competent physician, who is familiar with Hot Springs, Ark., to introduce the famous Hot Springs system of bathing at Lithia Springs." There are other arrangements for the comfort and benefit of the guests. A great stress is laid upon the presence of lithia in the water, and on this account it is most strenuously recommended as the water which "has been proven to be nature's remedy for rheumatism, bladder and kidney diseases." . . . A United States gallon of the Bowden Springs water contains 138 grains of solid ingredients, as follow: Calcium bicarbonate, 14.372; ferrous bicarbonate, .179; lithium bicarbonate, 3.706; magnesium bicarbonate, 2.395; aluminum sulphate, .442; calcium sulphate, 10.127; potassium sulphate, 1.221; sodium sulphate, .693; strontium sulphate, 1.013; sodium chlorid, 101.482; magnesium chlorid, 1.442; silica, 1.052. It is plainly observed that chlorid of sodium is the predominating substance in this analysis, and a water holding as small an amount of alkalies among its solid ingredients can not be classified with an "alkaline saline purgative water" like Carlsbad; it is a *saline water*. It appears now that neither the constituents of the springs nor the temperature of their waters bear any resemblance to the springs whose title has been assumed, but as it can not be presumed that the assumption has been wanton and without any cause, it may be surmised that the therapeutic effects from both have been such as to justify the Bowden Springs taking to themselves the name of the older, renowned watering-place.

The "*West Baden Mineral Springs*, the 'Carlsbad' of America" . . . are located on a tract of land nearly 700 acres in extent, where they are "surrounded by a series of majestic hills, under whose beautiful groves of noble forest trees the walks and grounds are sheltered." There are seven springs announced, which yield from 30 to 120 gallons per minute, and "this quantity is not perceptibly increased or diminished during the longest spells of wet or dry weather." It has a uniform temperature of 53 degrees F., during summer and winter, and "the quantity and temperature being uniform under all circumstances, gives a confidence, which experience in its use has verified, of its uniform strength and efficacy." . . . Although there are seven springs mentioned, the analyses of but four have been published, Nos. 1, 3, 5 and 7, of which the latter two have the largest amount of solid ingredients, 351 and 372 grains in one gallon, respectively. No 1 contains about 283 grains of solid matter. Below you find the analysis, by E. T. Cox, State Geologist, of No. 7, the largest spring in the valley. It contains, in one United States gallon, the following substances in grains: Calcium carbonate, 34.187; ferrous carbonate, 2.915; magnesium carbonate, 32.784; potassium carbonate, .635; sodium carbonate, 9.687; aluminum sulphate, 2.573; calcium sulphate, 86.011; magnesium sulphate, 43.798; potassium sulphate, .843; sodium sulphate, 28.857; calcium chlorid, 7.854; magnesium chlorid, 13.102; sodium chlorid, 108.318; total, 371.894 grs. The gaseous contents in one gallon are, in cubic inches: Carbolic acid, 8.296; nitric acid,

18.274; sulphuric acid, 4.205; oxygen, 6.147; sulphur, hydrogen, 9.987. According to this evidence, the water must be classed among the calcic waters with alkaline-saline properties, and should therefore be considered favorably in its comparison with Carlsbad water.

The "*American Carlsbad Springs*" are located at Nashville, Ill. . . . in altitude about 100 feet above St. Louis and 500 feet above the level of the sea. These so-called springs are actually artesian wells, which "after being bored yielded saline water in considerable abundance to warrant their commercial use." . . . The temperature of the water is 65 degrees F. It has been analyzed by Dr. Chas. Ludeking of St. Louis and W. F. Hillebrand of the United States Geological Survey, and contains in one United States gallon 260 grains of the following mineral substances: Sodium chlorid, 10.0; sodium carbonate, 27.4; calcium sulphate, 65.8; magnesium sulphate, 103.7; sodium sulphate, 53.0. This analysis places the water in the class of purgative waters, allied to the Carlsbad by its sodium salts. . . .

"The *Colorado Carlsbad Mineral Water Springs*" are located four miles east of Barr, a station on the B. & M. R.R., eighteen miles from Denver. . . . Two analyses have been made of the water, which differ from each other by about 5 per cent., and also in the arrangement of the probable constituents; one is by Prof. S. A. Lattimore of Rochester, N.Y., and the other by Prof. Karl Langenbeck of Cincinnati. S. A. Lattimore found in one United States gallon, 111.2 grains: Calcium carbonate, 2.144 grains; calcium sulphate, 26.429 grains; magnesium sulphate, 10.764 grains; sodium sulphate, 61.108 grains; sodium chlorid, 10.734 grains. Karl Langenbeck found in one United States gallon, 116.8 grains: Calcium carbonate, 18.657 grains; magnesium carbonate, 3.393 grains; sodium carbonate, 2.318 grains; sodium sulphate, 82.984 grains; sodium chlorid, 9.476 grains. Traces of substances can not be taken into consideration.

Both of the analysts have accompanied their reports with statements of the therapeutic value of the water, and while Professor Lattimore satisfies himself with declaring that it "bears in its composition a striking resemblance to the well-known Carlsbad water of Bohemia," Professor Langenbeck is more enthusiastic and positive in calling it "a water exactly of the Carlsbad and Franzensbrunnen type, although about one-third the strength of these." In their comparison of the Colorado spring they have neglected entirely one and the most important factors, to-wit: the temperature.

"*Hot Springs, S. D., in the famous Black Hills.*"—Its principal ingredients are the sulphates of calcium, sodium and potassium, together 65 grains, while the balance is divided among some other calcium and magnesium salts.

The "*Las Vegas Hot Springs*" are situated about six miles from the old town of Las Vegas, N. M., at an altitude of 6,767 feet, where "some forty springs bubble out of the hillside, varying in temperature from ice cold to boiling hot, but most of them ranging from 110 to 144 degrees F." The analyses of some twenty odd of these springs were made as early as January, 1882, when the water was collected and the temperatures taken by Prof. J. T. Lovewell, Washburn College, Topeka, Kan. He determined the carbonates of calcium and sodium, sodium sulphate, sodium chlorid and silicic acid, and mentions small quantities of magnesium and potassium and traces of lithium. Like in other localities where a number of hot springs are found to issue, the individual springs differ mainly in their temperature, but not very much in their solid constituents, which in this case, vary a fraction of a grain only in 10,000 parts, while the sum total of each of the twenty odd springs as mentioned above amounts to an average of 33 grains in a United States gallon.

A small, neat pamphlet entitled "The Land of Sunshine" mentions the analysis of one spring made by Walter S. Haines, M.D., Professor of Chemistry, Rush Medical College, in 1895, which is here selected as a sample, because it exhibits more details of the solid ingredients, and allows a more easy comparison with other known analyses. The following are the solid contents of one gallon in grains: Calcium carbonate, .89 grains; magnesium carbonate, .15; potassium carbonate, .28; sodium carbonate, 8.38; sodium sulphate, 3.35; sodium chlorid, 11.68; silica, 3.50; alumina, .10; volatile and organic matter, .32. Total, 31.65 grains. In the remarks which accompany his report, Dr. Haines states "that in many respects the springs resemble in chemie composition the waters of the famous ones of Teplitz and Carlsbad," which is correct, when we take into consideration only the relative proportion of the ingredients to each other, but when we compare the quantities of solids of the two different localities, we find that the Carlsbad springs contain about ten times as much solid matter as the Las Vegas springs. Otherwise there is really

a great resemblance between the analyses of the two waters, and in the light of the recently advocated doctrine of flooding and washing out the system, the Las Vegas as ten times the weaker might be taken for ten times the superior. While the springs are surely the principal attraction of Las Vegas, there are other prominent features which ought to make it a decidedly delightful health resort. Its high elevation, its dry and uniform climate and its situation on a large tract of land which is surrounded by high hills that form almost a complete circle and protect the valley against the cold north winds, and especially the sand storms, the plague of these regions. The mean annual temperature is 59.07 degrees F.; during the summer it rarely rises above 90 degrees F. The rainfall is less than one inch during the same time, and about twelve inches during the whole year with an average number of 326 sunny days. The nights are always cool and a blanket comfortable even in summer. The Hot Springs of Arkansas also aspire to be classed among the competitors of Carlsbad. . . . They are situated in 34 degrees 31 minutes N. latitude and 92 degrees 31 minutes W. longitude, at an elevation of 600 feet above the Gulf of Mexico. The climate is clear and beautiful, while the temperature rarely reaches an extreme in either direction, to render it uncomfortable. The sun passes down behind the west mountain early in the evening, giving a delightful long twilight and always insuring cool nights in summer. Its annual mean temperature is 76.67 degrees with lowest mean in January, 55.32 degrees, and highest in July, 95.48 degrees F. There are in all seventy-three springs which are discharged at a temperature from 77 to 157 degrees F. All of them have been neatly encased and their waters collected in one large reservoir, from which the hotels and the bath-houses are supplied with a daily output of 840,000 gallons. The water like that of many thermal springs carries in solution but a small quantity of solid ingredients. Prof. E. H. Larkin, in 1856, found eight and one-half grains to a gallon of water, which is still maintained as correct. He determined the proportion of its constituents, of which lime, silica and carbonic acid formed over 75 per cent. in almost equal quantities, the balance being alumina, iron, magnesia, soda, potash, chlorin and sulphuric acid to the amount of 15 per cent., and water and organic matter 10 per cent. It is obvious that if the quantity of solid constituents would decide the efficiency of a thermal spring, Hot Springs could not come into competition with Carlsbad and its 323 grains of solids in a gallon or about forty times the quantity of mineral ingredients. In all thermal waters, however, the natural high temperature is of the foremost importance, and should therefore be taken first into consideration. Thousands of sufferers stake their faith on Hot Springs every year, and have been rewarded for their confidence by being restored to health and activity. And it should always be remembered that if the high temperature be assisted by an almost absolutely pure water, its cleansing effect, whether it be employed for external or internal purposes, would be of the most intense quality. And if the dispensation of other medicines should be decided on, a purer menstruum could not be selected for their administration and even an artificial Carlsbad easily be prepared by the addition of the requisite substances. There is no doubt that the Hot Springs of Arkansas have the right to call themselves the "Carlsbad of America." *The Paraiso Hot Springs* are situated in California, 150 miles south of San Francisco, at an elevation of about 1,200 feet above the level of the sea, and nearly 1,000 feet above the valley. The temperature of the water is 118 degrees F., and the chief of its ingredients is sodium sulphate, although in decidedly less quantity than it occurs in the Carlsbad springs. However, a comparison of the analyses of the two springs makes it plain that there is a great similarity in the proportions of the active elements, and, therefore, we shall not antagonize the opinion of W. Anderson, M.D.: "This water is found to be very similar to the noted Carlsbad of Austria." According to his careful chemist analysis the water contains 61.45 grains in one U. S. gallon of the following mineral ingredients: Calcium carbonate, 1.30 grains; ferrous carbonate, .89; Magnesium carbonate, .75; sodium carbonate, 5.06; calcium sulphate, 6.45; magnesium sulphate, 1.10; potassium sulphate, a trace; sodium sulphate 34.60; sodium chlorid, 3.37; potassium chlorid, .32; aluminum chlorid, .56; silica chlorid, 2.90; organic matter, 4.15. Total solids, 61.45.—Abstract of a paper by ENNO SANDER, M.D., in the *Medical Mirror*.

How We Feel When We Die—In the *Review of Reviews* for September, 1892, is to be found an article bearing upon the above rather startling title, which is thus introduced to the readers of the magazine by its editor: "The July number of the 'Proceedings of the Society of Psychical Research' con-

tains a paper of surpassing interest by Mr. T. W. H. Myers, As it is appointed to all men to die, and as in the whole range of human literature there are hardly any authentic narratives as to how a man feels at the moment of death, the evidence in this paper is extremely interesting. Of the two narratives Mr. Myers gives us, the first is the most remarkable, although they are both exceedingly wonderful. The first was contributed by Dr. Wiltse of the *St. Louis Medical and Surgical Journal*. Dr. Wiltse is the authority for the statements which follow. . . . The second story is of a Huguenot minister, Bertrand by name. It is not so recent, but it is quite as remarkable in its way." Then follow the stories, which I shall give as briefly as possible, but verbatim. To begin with Dr. Wiltse's narrative: Dr. Wiltse "appeared to come to the moment of death in the last stage of typhus fever." He thus describes his experience: "I said to myself, 'I have died as men term death; I am about to get out of the body,' and I watched the interesting process of the separation of soul and body. By some power apparently not my own, the ego was rocked to and fro laterally, by which process its connection with the tissues was broken up. After a little time the lateral motion ceased and along the soles of the feet I felt and heard, as it seemed the snapping of innumerable small cords, when this was accomplished I began slowly to retreat from the feet toward the head. I remember saying to myself, 'now there is no life beyond the hips'; then, 'I am all in the head now and shall soon be free.' As I emerged from the head I distinctly recollect how I appeared to myself, something like a jelly-fish as regards form and color. I floated up and down like a soap bubble, until I broke loose from the body and fell lightly to the floor, where I slowly arose and expanded into the full stature of man. I seemed to be translucent and of a bluish color; as I neared the door I found myself clothed. I examined the fabric and judged it to be some kind of Scotch material, not handsome, I thought, but neat and good enough. . . . I discovered that a cord like the thread of a spider's web ran from my shoulders back to my old body, and was attached to it at the base of the neck. I stood and gazed at the couch I had just left and saw my own dead body. I noticed two women kneeling by my side, but had no conception of individuality; wife, sister or friend were as one to me. I could distinguish sex, but nothing further." He left the house and went out into the street, then he rose into the air, "upheld by a pair of hands," till he arrived at a narrow roadway, along which he walked for a while. At last he came to three great rocks barring the way, "and a voice spoke to him out of a cloud: 'Once you pass them you can no more return to the body.'" He desired to pass, but was stopped. He "became unconscious again, and when he awoke he was lying on his bed. He awoke to consciousness and soon recovered."

So much for the first story, now for the second. Pastor Bertrand was climbing a mountain with a party of students; feeling tired, he lay down to rest while the others proceeded, and was overtaken by "the sleep of the snow." He felt himself as if struck by apoplexy. His head was perfectly clear, but his body was powerless. He tells his story thus: "A kind of prayer was sent up, and then I resolved to study quietly the progress of death. . . . The sensation was not painful, but at last my head became unbearably cold, and it seemed to me that concave pincers squeezed my heart so as to extract my life. I never felt such pain, but it lasted only a minute and my life went out. 'Well,' thought I, 'I am what they call a dead man, and here I am, a captive balloon, attached to the earth by a kind of elastic string, and going up, and always up.' . . . When my companions return they will say, 'The Professor's dead!' They do not know I never was as alive as I am! The proof is, I see them now; the guide is stealing a leg of my chicken. 'Go on, old fellow, eat the whole if you choose, for I hope my corpse will never eat again! Hello, there is my wife going to Lucerne. Well, wife, good-bye!' I confess I did not call *dear* the one who has always been *very dear* to me. I felt neither regret nor joy at leaving her. My only regret was that I could not cut the string. Suddenly a shock stopped my ascension, I felt somebody was pulling the balloon down. My grief was measureless! When I reached my body I had a last hope, the balloon seemed much too big for the mouth. Sud-

denly I uttered the awful roar of a wild beast; the corpse swallowed the balloon and Bertrand was Bertrand again!" In other words, the exertions of his friends were successful in resuscitating him.

So much for the stories themselves, now for the comments of the *Review of Reviews*: "Both of these stories," it tells us, "agree in the consciousness of the apparently dead person that he exists apart from the body with which he was connected by a very fine line, the severance of which would complete the process of dying. . . . The moral of both seems to be that what we call dying is no more death than the changing of a suit of clothes is dying. . . . The ugly part of both stories is the comparative indifference with which the liberated soul regarded those whom it loved on earth. This, however, is so contrary both to experience and to reason, that it may be regarded as exceptional and due solely to the novelty of the situation, which in these cases had no time to pass before the process of dying was rudely interrupted."

Now I would ask: What "experience" is here meant? Not the ordinary experience of the living, surely, for that is quite beside the mark? And if, as the *Review of Reviews* tells us, the significance and importance of these narratives lie in their being almost the *only* revelations we have of the condition of the soul *after* leaving the body, it seems hardly consistent to accept the statements of the narrators as authoritative on some points, yet attempt to explain them away on others. Why, for example, should we be willing to believe on Dr. Wiltse's authority that the soul as it first emerges from the brain is "of the color and consistency of a jelly-fish," yet refuse to believe, on the same authority, that it no longer loves or even recognizes those dear to it in life? more especially, as this loss of natural affection is testified to by both of our witnesses. Indeed, this fact and the existence of some kind of elastic connecting cord between the almost liberated soul and its cast off body, are the only two points in which their experiences are identical. As regards the character of these revelations, they are as singularly devoid of dignity and weight as the "revelations" vouchsafed by so-called "spirits" at a "séance." The idea of a "disembodied soul" keeping watch upon a thievish guide in his appropriation of a chicken-leg certainly strikes one with a sense of incongruity, while the conception of such a soul habited in "a suit of some Scotch material" is so grotesque that the gruesomeness of the situation is altogether lost sight of in its absurdity! Indeed, there is a purely mundane tone about these experiences throughout, which stamps them as being emphatically "of the earth earthy."

The absolute accuracy of the stories, so far as they relate what the narrators believe to be their actual experiences, I shall not call in question; taking it for granted that they have been thoroughly sifted and authenticated before being presented as "facts" to the readers of the *Review of Reviews*. I must, however, express my surprise at the importance attached to them by that periodical. To me, they appear to belong precisely to the same category as those wonderful experiences related by patients who have recovered from a cataleptic trance, or to the stories told by drowning persons. They are undoubtedly very curious and exceedingly interesting, as, from the nature of the case, evidence of the sort must always be most difficult to secure, for even in those cases where disease has left the mind unimpaired, death is in most instances preceded by unconsciousness. Were it possible to collect sufficient data on the subject, the physiologist might be enabled to trace the underlying law governing the physical phenomena of death, and discover that certain differences of sensation mark the approach of death in different forms. Such knowledge, from a scientific point of view, would of course be most interesting. Had the article in question borne the title: "How we feel when we come as near death as we can come *without* dying," it would exactly have described the subject-matter; but its actual title "How we feel *when* we die," is, I maintain, a misnomer. Still, as I have said, these experiences are of value (always supposing them to be well-authenticated facts), but I utterly fail to see their importance as bearing upon the elucidation of the problem of "death." For death, as I understand it, is the absolute extinction of animal life; the utter and complete severance of the bond between the material and the immaterial parts of the nature. So long as one spark of vitality remains, so long as the potentiality of life exists, it is not death, but only a more or less near approach to death. And the nearest approach to death is not death. The *consummation* of the act of dying *alone* is death! Hence it is that, so far as penetrating the mystery of death is concerned, these "experiences," with all their interest, leave us precisely where they find us—profoundly in the dark!—Abstract from *Review of Reviews*, by H. E. BEHS.

PRACTICAL NOTES.

Etiology of Catarrh of the Upper Air-passages.—A writer in a Russian exchange mentions the universality of this affection, and emphasizes the resulting evils, especially in the young. He ascribes it largely to the fact that the mucous membranes are not supplied with the moisture required to keep them in normal activity, as soon as the weather compels us to heat our houses. The air is heated to a point when it would hold considerable moisture normally, but the little moisture in the cold outer air is dried out of it by the time it reaches our nostrils indoors.—*St. Pet. Med. Woch.*, October 23.

The Milk Diet in Kidney Lesions.—Dr. Ajello (*Blätter für Klinische Hydro-Therapie*) as quoted by the *Philadelphia Medical and Surgical Reporter*, does not believe that the milk diet is best for kidney lesion patients, but that, on the contrary, a "mixed" diet answers a better purpose in general. In his twenty-one cases he noted an increase in the quantity of urine in nine that were kept on a milk diet and eleven on a mixed diet. The albumin decreased in five cases and increased (quite considerably in some) in sixteen cases kept on milk. The urates diminished in ten milk cases, a rather unfavorable phenomenon. The phosphates diminished in seven kept on milk and thirteen on mixed diet.

The Action of X-Rays on Micro-organisms.—Bonomo and Gros have made researches in the military hospitals at Rome on this subject. They subjected cultures of various micro-organisms (*B. subtilis*, *B. tuberculosis*, *B. anthracis* and others) up to the third generation to the influence of the X-rays, applied vertically, for a period of about three hours each day. Some retardation or diminution of vitality, vegetative and pathogenic, was observed in every case: but the change was for the most part very slight except in the case of *B. anthracis*. With this microbe a well-marked diminution in motor activity, modification of chromogenic power and loss of spore-producing property was observed. With this, too, a complete attenuation of pathogenic effects was observed, so that the authors feel it might be possible through successful cultures exposed to the X-rays to make the *B. anthracis* innocuous. No such marked results were obtained with the other micro-organisms under the influence of the same rays. In every case such effects as were observed were more noticeable in the later than in the earlier cultures.—*British Medical Journal*.

A Pipe-stem Impacted in a Bronchus for Three Months.—The tolerance of the bronchi for large foreign bodies is well exemplified by the report by Francis (*British Medical Journal*, Sept. 25, 1897, p. 809) of a case in which a portion of pipe stem was impacted in the left bronchus for a space of three months. The patient was an army pensioner, who related that about a month before coming under observation, while standing quietly on the street smoking a briar pipe with a vulcanite stem, he was seized with a fainting fit and fell. On being raised from the ground by bystanders and recovering consciousness, he looked about for his pipe, but found that the shank was broken about an inch from the mouthpiece. The broken fragment could not be found and the man proceeded home, feeling little the worse for his accident. From this date he complained of pain more or less severe in the left breast with dyspnea on exertion and profuse mucopurulent expectoration. On examination there were heard a light systolic murmur and loud ronchi all over the chest, which was hyperresonant. A belladonna plaster and a stimulating expectorating mixture were prescribed. A short time afterward, while carrying a heavy weight about a hundred yards in a stooping posture, the man suddenly felt something move inside his chest and following a fit of coughing the long-lost pipe-shank dropped out of his mouth to the ground surrounded by a little coagulated blood and inspissated mucus, with immediate relief from the previous embarrassment of breathing. The piece of pipe shank measured one and one-fourth by one-half inch, and must have been lodged low down in the left bronchus.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, DECEMBER 18, 1897.

THE FREQUENCY OF DIABETES MELLITUS, AND
ITS RELATION TO DISEASES OF THE
PANCREAS.

There are a number of features in connection with the general frequency of diabetes mellitus, as well as with its occurrence in certain races and in certain classes that merit particular attention. Thus, for instance, it appears that the general frequency of this disease is steadily increasing, both in the United States and in the European countries, although the disease is as yet, at any rate, much less prevalent here than across the Atlantic.

The statistics of SAUNDBY¹ show that the mortality in the United States in 1870 was 2.1 to the one hundred thousand population; whereas in 1890 the death rate was 3.8 per hundred thousand. Now, these statistics show that diabetes in this country is gradually on the increase.

HARE,² in recently published statistics, also demonstrates that the frequency is on the increase. He points out that in thirty years, from 1850 to 1880, the mortality from diabetes in this country increased 150 per cent. in every hundred thousand deaths.

In Europe the mortality ranges between 5 and 9 to the hundred thousand. In the Island of Malta, where the mortality from diabetes is extraordinarily high, the census of 1891 showed a death rate of 13.1 to the hundred thousand. In Paris the death rate is gradually increasing during the last three or four decades, and in 1891 it reached 14 to the hundred thousand.

In the Johns Hopkins Hospital of Baltimore there have been treated, according to THOMAS B. FUTCHER,³

in all sixty-nine cases of diabetes mellitus, in the ordinary acceptance of the term in the medical wards and the medical section of the dispensary during the last eight years. During these eight years 45,636 medical cases have passed through the wards and the out-patient department, so that the diabetic cases comprise only .15 per cent. of all the medical cases.

It is well known that some races are especially liable to diabetes. Hebrews are especially susceptible, one-fourth of FRERICH'S cases being of the Semitic race. It is rare in negroes and Africans, and the Mongolian races are rarely affected in their own countries. Chinese are comparatively exempt. In the colored races the disease is apparently rare; TYSON⁴ has seen several cases, and of the sixty-nine cases of diabetes treated in the Johns Hopkins Hospital five were negroes.

The prevalent belief that persons living in the country are more exempt from diabetes than inhabitants of cities can not be traced back to any definite statistics; on the other hand, SAUNDBY¹ shows that for many of the counties of England this discrepancy does not exist.

The above statements, taken for the most part from FUTCHER'S article, indicate that the distribution of diabetes is very unequal. The same is also observed with reference to its occurrence among the various classes of people; thus wealth and culture are said to increase the liability to diabetes ten-fold. Statistics for London and Berlin show that the number of cases in the upper ten thousand exceeds the number of cases in the lower hundred thousand inhabitants. The same occurs in India, where the disease is much more frequent in the educated upper class than in the ignorant lower class.

In recent years great interest has been created in the part played by the pancreas in the causation of diabetes. For more than a century, however, it has been recognized that lesions of the pancreas may cause diabetes. In 1788 CAWLEY⁵ reported a case in which the pancreas was atrophic and contained calculi, but it was not until 1877 that LANCEREAUX⁵ described a special form of diabetes under the name of *diabète pancréatique*, associated with lesions of the pancreas. He stated that this variety was characterized by suddenness of onset, unusual malignancy and rapidly progressing emaciation, and a special tendency toward tuberculosis of the lungs as a complication. BAUMEL⁵ in 1882, advanced the view that all the cases of diabetes were due to the absence of a diastatic pancreatic ferment in the intestine, and he was the first to claim that pancreatic disease was the regular cause of diabetes. These observations seemed to leave no lasting impression until the discovery by MINKOWSKI and VON MERING that permanent diabetes mellitus could be produced experimentally in animals by complete removal of the pan-

⁴ Practice of Medicine, 1896.

⁵ Quoted by Fletcher, loc. cit.

creas, and it is now generally recognized that diseases of the pancreas are responsible for a certain number of cases of diabetes. There are some who claim that all cases of diabetes are due to pancreatic disease, maintaining that where there are no structural lesions, gross or minute, then there exists a functional disturbance of the gland; but there are others who believe there is no association between diabetes and changes in the pancreas. HANSEMANN⁶ analyzed the cases of diabetes which came to autopsy in the Berlin Pathological Institute during ten years, and the results follow:

1. Diabetes without changes in the pancreas, eight cases.
2. Diabetes without any information regarding the pancreas, six cases.
3. Diabetes with pancreatic disease, forty cases.
4. Pancreatic disease without diabetes, nineteen cases.

Of the forty cases in which the pancreas was affected, thirty-six presented atrophy, three fibrous induration of the organ, and one was a case of cyst of the pancreas.

WILLIAMSON⁷ has examined the pancreas in twenty-three consecutive cases of diabetes, and in only twelve was the pancreas normal. He also analyzed 100 cases of pancreatic lesions in diabetes, which he collected from the literature and found that in forty-eight it concerned essentially atrophic changes; in seventeen it concerned fatty degeneration; in seven, cystic transformation; in fourteen, chronic fibrous changes; in two, hemorrhagic pancreatitis; in three, suppurative pancreatitis; in eight, carcinoma of the pancreas, and in one, calculi were present.

In connection with this it is of interest to note that LEPINE⁸ maintains that the pancreas produces an active glycolytic ferment, which enters the blood and chyle and destroys a large part of the sugar before it reaches the liver, and that this ferment is absent, or greatly reduced in animals whose pancreas has been extirpated. More abundant evidence, however, seems to be required, according to FUTCHER, before this view can be fully accepted.

THE POLITICAL RESPONSIBILITY OF THE PHYSICIAN.

On various occasions heretofore the JOURNAL has endeavored to impress upon the members of the medical profession the utility and need of their taking a more active part in the government of this country, both as regards National and municipal affairs. The subject is one, however, that is not exhaustible by one or a few editorial utterances, and it is one that in some one of its many aspects is always demanding consideration. While the secular and religious papers are continually demanding the

co-operation of good citizens in political affairs to prevent their being controlled, as is too often the case, by the bad citizens, it is certainly not out of place for medical journals to call the attention of its readers from time to time to their responsibilities in this matter. This is the more justifiable and necessary from the fact that heretofore we have as a profession neglected our opportunities and sinned away our mercies, to use an old Scotch expression, far more than we can reasonably excuse ourselves for, and have suffered in consequence. Professional self-respect has not been preserved by this abstention from public affairs to any extent at all comparable to the damage it has received by the education of the public through our neglect, to consider all so-called professors of the healing art, quacks and charlatans of every kind, as equally deserving of popular favor and legal countenance with the educated and conscientious physician. Recent legislation and legal decisions in various parts of our country are witness to this fact.

The duty of our profession to itself has been already editorially pointed out in this journal, and is only reiterated here to keep up the interest in the reform that is needed. It has also been pointed out that we owe a duty to our fellows and that of all men the physician is his brother's keeper, and his responsibility as a citizen and voter is correspondingly heightened. As individuals we feel this responsibility, but as a collective body we are apt to be remiss and forgetful in this regard, and evils that we could prevent are allowed full play. The interest of a physician in good government is something more than that of merely a good citizen; he is himself a guardian of the public in their nearest and dearest relations, and as such he has it as his duty to do all in his power to protect his charge from all evil legislation or vicious maladministration of salutary laws. In the matter of direct sanitation alone, the value of medical knowledge in the forming and execution of the laws and municipal regulations, ought to be sufficiently evident to require no demonstration. A writer in a recent issue of a religious journal calls attention to the fact that the gradual reduction of the rate of mortality in New York City from 25.18 to 20 in the last three years saved 3,758 lives in 1895, 7,736 in 1896 and 9,920 in 1897, a total of 21,414 lives, due to better government and closer attention to sanitation. If such a saving of human life can occur in one case it can in others, and if it is to be brought about elsewhere, or generally, it will have to be through the co-operation of enlightened medical opinion acting on official ignorance and stupidity. So-called practical politicians are too generally ignorant and indifferent in regard to these matters, and the community as a whole can act intelligently only under medical supervision and advice. A sanitary issue is almost, if not

⁶ Zeitschrift f. kl. Medizin, 1894.

⁷ Med. Chronicle, May, 1897.

⁸ Quoted by Fletcher, loc. cit.

altogether, an unknown thing in our politics, and when it occurs it is handled, as a rule, along party lines and with all the disadvantages that such a course involves. Our legislatures are made up of lawyers and professional politicians without other visible means of support, together with a sprinkling of farmers and others who, though well meaning and generally honest, are apt to be prejudiced and misled on all matters that are without the limited range of their knowledge. If there are any physicians they are few in number and, as a rule, have not the influence that they should exert, even in matters that fall directly within their professional sphere, and in regard to which they should have a predominant voice. In Congress, as regards this special point of view, matters are no better; there has been, since RUSH'S time, no really eminent medical man amongst our National legislators—we have no VIRCHOW or VERGA in our Senate or House of Representatives. In the French Chamber of Deputies, there have generally been a number of physicians, and while the leading parts that some of them have taken may not have always reflected the most credit upon them, in medical questions they have often combined, and we do not hear of their inactivity when unintelligent legislation on medical and sanitary matters is proposed. The debates on medical matters in the British Parliament are of enough interest to be reported in British medical journals, and legislation in these matters is not left uninfluenced by professional action and information.

There is no reason why these conditions should not be attained in this country nor why, in our State legislatures especially, there should not be a working representation of the medical profession, who in all matters involving their special professional knowledge and the public health, should act together for the best interests of the community without regard to party lines. Were this the case we might expect a beneficial reaction upon the profession itself: there would be less recognition of quackery and more appreciation of genuine scientific medicine on the part of politicians and the public, and with this a more satisfactory status socially as well as politically. It would be a public benefit if we could have a few high-minded and able physicians to take part in National, State and municipal legislation in this country.

It is true that not every physician is fit to be a legislator and there are few probably that can afford it, and it is also true that some medical politicians have not been creditable representatives of their honorable profession. This, however, does not alter the facts we have stated, and further it does not at all affect the general question of the propriety of medical men recognizing their individual and collective responsibility as citizens, enlarged as it is by their special qualifications to judge and act in so many important matters affecting the public welfare.

MILITARY SURGEONS.

What's in a name?

This much: that the medical man of the military establishment has had his professional office limited in the popular mind to one, and that not the most important of his functions. As a "surgeon" he is supposed to lop off the limbs that the high intelligence directing the enemy's guns, and sometimes his own, has shattered, and, *ergo*, an amputating knife rather than a sword should be his distinctive badge of office; and *ergo*, again, a man whose badge is this has no fellowship in the military hierarchy.

The medical men of the military services have not acquiesced in this reasoning, but having been the under dogs in the fight, they have had to suffer and try to get strong, and the time has apparently come when they are strong enough to assert themselves and claim for their commissions the recognition and distinction merited by loyal service to the State from men of masterful acquirements in a profession requiring the highest order of ability—the very cornerstone of the military organization, without which the whole fabric would tumble to pieces.

The gun is useless without "the man behind the gun," and he is able and strong and intelligent as the military medical officer is empowered to select, domicile, feed, clothe and protect him from enemies within, as well as from those without, and when, rare event in his life, he may be disabled by hostile weapons, to repair and rehabilitate him.

The military surgeon is also military physician and especially military sanitarian. His forethought pervades the camp and ship, the regiment and fleet. Without him there can be no organized army and no disciplined navy. The military engineer may plan battles, the ordnance expert provide guns and ammunition, the steam engineer build mighty engines, and admirals and commodores, generals and colonels fulminate orders, but the blood and brawn and brains that are to fight the battles, operate the guns and animate the vessels are due to the professional presence of the military medical officer, colleague and co-equal of the others.

The handsome volume of "Proceedings of the Seventh Annual Meeting of the Association of Military Surgeons of the United States," held at Columbus, Ohio, May 25-27, 1897, which has just been issued, demonstrates the manifold functions of the military medical officer. The papers contributed, without concert and on random topics, by officers of the Army, Navy and National Guard, from all parts of the country, have naturally fallen under certain heads, under which they have been appropriately grouped by the secretary-editor, Captain JAMES E. PILCHER of the United States Army, and these need only be enumerated to show the wide range of the medical officer's province: naval medicine, surgery and hygiene; mili-

tary personal identification; clothing and accoutrements; military physical training; the proper type of the military medical officer; sanitary work among troops; transportation of the disabled; medical service in the field; the service of aid to the disabled; military surgery; military medicine; military medical problems, etc. The address of the President of the Association, Medical Director GIBON of the United States Navy, on "The Status of the Medical Officer in the Military and Naval Establishment," in terms lucid and unmistakable in intent, defines the place among military men to which these officers are entitled. By a happy coincidence the address in surgery at the sixty-fifth annual meeting of the British Medical Association, held at Montreal, Canada, September, 1897, by W. MITCHELL BANKS, M.D. Edin., on "The Surgeon of Old in War," in the words of the speaker, set forth "some of the most notable work done of old by a body of members of our profession, who have never received their due reward." After brief notices of Roman military and naval surgeons, of AMBROISE PARE, ROBERT CLOWES, PETER LOWE, JOHN WOODALL, RICHARD WISEMAN, and Baron LARREY, of whom Napoleon wrote in his will made at St. Helena: "I bequeath to the Surgeon-in-Chief of the French Army, LARREY, 100,000 francs. He is the most virtuous man I have ever known." Dr. BANKS referred to that enemy which assails fleets and armies, and against which only the medical officer is competent to lead and combat, "the pestilence more deadly than the sword," by which in the naval battles of the Seven Years' War as stated in the "Annual Register" for 1763, "it appeared there were but 1,512 sailors and marines killed, while 133,738 had died of disease or were missing." After narrating instances of conspicuous military courage on the battle-field in recent years by medical officers, who have been contemptuously designated "non-combatants," "brave civilians" and the like, Dr. BANKS stated, "of the 118 wearers of the Victoria Cross, fourteen are surgeons, nearly 12 per cent. of the whole number and in the proportion of 9.5 per cent. of all the officers of the army." Despite all this, he concluded, "today Her Majesty's government can not induce candidates to come forward for the medical service of the Queen's army. And why? Because it has persistently treated the army medical department meanly and shabbily." Qualified medical graduates will not enter the British army, because the medical officer is not accorded the same status as to pay and precedence as officers of other corps. A similar reluctance to enter the medical department of our own Navy is indicated in the "Annual Report of the Acting Chief of the Bureau of Medicine and Surgery," just received, who states that there are "fifteen vacancies at the present time, nor does there appear to be any immediate prospect toward filling the corps."

It is not strange that civilians can not understand

why, especially under a republican government, unfounded claims of inherent superiority of any one branch should operate to the extent of impairing the efficiency of the actual service. In fact, there is no tenable reason why there should be any lack of harmony in the composite organizations called the army and navy, in which each corps has well-defined equivalent duties, alike honorable and distinctive. The gist of Dr. GIBON's presidential address was a definition of the terms *grade*, *rank* and *title*, which indicates a seemingly practical basis of settlement of the vexed question of rank and precedence. "*Grade*," he says, "is that something the law has conferred upon all commissioned officers, which serves to show each officer's place, position or status in a military organization." Grades are the steps, one above another, upon which the entire body of officers is grouped, irrespective of their special duties. *Rank* means simply seniority or precedence in the several grades, and depends solely upon the date of the officer's commission; thus one officer ranks another in his own grade. Grades are generic distinctions, and are practically the same all over the world. *Rank* is the relation of the individual officer to others of the same grade and naturally as well to those of other grades, so that in fact no two officers of the same service can have absolutely the same rank. Properly there is no name for rank, but custom has led to the identification of the name of the grade as rank. *Title*, the third of the terms used in the designation of officers, is the specific definition of their particular duties. Thus, surgeon-general in the army is the distinctive title by which an officer of the grade of brigadier general, who belongs to the medical department, is distinguished from brigadier generals of other departments. It is not desired nor would it be expedient, that specific corps titles should be abolished. Major SMITH of the medical department does not wish to be confounded with Major SMITH of the artillery, while he does wish it distinctly understood and admitted that he is as much a major in dignity, privilege and precedence as any other major. And herein lies the solution of the lamentable disputes which have estranged the staff, and it is, of course, the medical staff with which we have concern, and the line. Let the fact be distinctly understood that the military surgeon is not a mere make-believe soldier, an imitation officer, parading in borrowed plumes, seeking to hide his professional identity under distinctively military titles, nor that he is accorded by courtesy a quasi-status in military life to which in strict justice he has no legitimate claim. The honor and dignity of the profession of medicine require this and make it the duty of every physician in the United States to demand that the just recognition of the equivalent importance of military medicine, surgery and hygiene shall be made in the statutes, and this done, the Congress will be relieved of the importuni-

ties of those who charge on the one hand staff assumptions, and on the other line persecutions. When one or the other trenches upon statutory enactments, it is easy enough to punish the infraction. Physicians are law-abiding men, and it is certain that the military lawbreaker will find no more sympathy among his civil confrères than other offenders, but it will not do to assert that because a man is a "doctor," he and his field of work are not as honorable, as important, as responsible and as indispensable as those of other vocations inside or outside the military service. In our army, at least, if not in the British, the question is practically settled. In the rearrangement of the navy, it is hoped that the officers of the medical corps shall be placed on precisely the same footing as those of the army, in pay, privilege and precedence. If this be done, we predict there will be five applicants for every one of the fifteen vacancies which the chief of the medical bureau now laments.

PROFESSORS.

"I want a professor," cries the patient, and the ordinary every-day doctor who has no title must obey and call in consultation "Herr Professor." Of course, the patient does not know how professors are created; he does not know that any half dozen "scrubs" can start a medical school and dub themselves professors; he can have no knowledge of medical politics as they really are and therefore he insists on having a professor.

To the patient a professor means one who by years of study and experience has made himself so proficient in his special line that his fellow practitioners have deemed him worthy of appointment as a teacher and adviser. True, often a man has served a long apprenticeship as instructor, assistant, demonstrator, adjunct professor, etc., before he attains to the title of professor; but, too often, it is the man with the most "pull" who "gets there," the man who can obtain the best endowments for the college who is created professor over and above the faithful quiz-masters, privat-docents and clinical instructors.

About every large medical school is clustered a small army of assistants waiting for promotion, lobbying like ordinary politicians whenever a vacancy occurs, and as servile to those above them as a fourth-rate postmaster to his Senator.

What is there in the title of professor, that makes it so much to be desired?

It can not be altogether honor, since neither wisdom nor great deeds are necessary to attain to it; the unworthy are as often made recipients of this "honor" as the worthy. It is not the salary usually connected with the office, since we know that many professors go so far as to endow their own chairs, and many others are at considerable outlay in keeping up their positions, and some have actually bought their professorships. We fear that quite a number are moved

to compete for a professorship because indirectly there is money in it. A professor can command larger fees, because the layman thinks he has superior knowledge, and for the same reason those who can afford it prefer to visit the professors.

Certainly this can not apply to the teachers in such subjects as chemistry, pathology, anatomy and physiology, and most often there is some salary connected with these positions to compensate the incumbent. Indeed, in some schools the professors of so-called "practical" branches forego their own salaries for the sake of supporting these professorships. There was a time when medical colleges had only six or seven professors in their faculty; today the average is twenty-five. In one large Eastern city 7 per cent. of the medical profession have professorships in the colleges, and a great many more occupy positions as instructors and demonstrators.

But any one can become a professor of any subject providing he has the proper amount of influence. If no vacancy exists a new chair is created for his benefit. It does not matter whether he can teach or not; that is a minor consideration. All he needs to do is to compile a text-book, tell the students to buy it, and require daily recitations from this book. A book is very easily compiled; buy a few German and French books, translate them, or ask others to run over two or three late English and American books, get plenty of illustrations, change a word here and there and the book is complete. If the publisher own a medical journal, favorable reviews and plenty of advertising finishes the job, and the title of professor helps to sell the compound.

The publishers have not been slow to perceive this source of revenue, and by concentrating in one volume the products of many professors they produce a "text-book" which must be sold in many schools. No matter what the quality of the material, the profits are larger in this way, and the risk is nothing, for the student must buy this syndicate text-book *volens volens*.

It is not always the men who compile books and occupy professorships who are the most learned or best trained physicians; and it is the great mistake of the medical profession that they put too much trust and faith in the words of men who possess such titles because they possess them. The character and standing of the school where he is professor should be taken into account. The ordinary medical man is too ready to advise his patient to go to some professor, instead of consulting with some honest, well balanced fellow practitioner.

In every city are earnest, studious and efficient medical men who do excellent work, and yet are but little known to the world at large because they do not *advertise*. Advertise is the word. They do not hang about the college waiting for a stray case, they are not

given to writing about wonderful cures obtained from strange remedies and reading reviews of other people's work before societies. They are not to be found in dispensaries, misunderstanding the poor patients who go there to receive relief, and because they do not do these things they are not invited to fill college chairs. But they are known to their patients, of whom they frequently possess more than many so-called professors. They are the men who keep alive the ethical spirit of medicine. They keep abreast of the times, even if they are silent. They are doing the heavy work, and the results they obtain, often amidst most unfavorable circumstances, are amazing. A time is coming when men who are prominent in the profession will not covet the title of professor, a time perhaps when the teaching of medicine will be a specialty in itself, and not merely a dodge to acquire practice.

When no medical schools shall be founded until there is need for it, and when all will put themselves on a scientific basis and look about them for teachers, for men who are qualified to instruct, the title of professor may have a real meaning, which at present it too often lacks. Let the general practitioner call the specialist to his aid because he is a specialist, and not because he is a professor.

CORRESPONDENCE.

Leprosy in Norway.

VIENNA, AUSTRIA, NOV. 12, 1897.

To the Editor:—I was much surprised while visiting Norway during the last summer, to find that among a population of less than two million people, there existed three special hospitals for the confinement and treatment of lepers, and that in these institutions were domiciled over one thousand unfortunates, afflicted with this terrible disease.

By far the largest of these institutions is situated at Bergen, and while there I availed myself of the opportunity to visit it. The superintendent, Dr. Hansen, was away on a vacation, but his first assistant received me cordially, and answered all my queries in the politest manner possible.

Naturally, where a fish diet forms so large a part of the food of the population of this country, one asks the question whether this may not act as a strong causative factor in the production of the disease. I was told that this was not the opinion held by those most competent to judge; but that it was probably on account of the small, unhealthy and crowded habitations that the people occupy during the long cold winters in this rigorous climate, that the disease had gotten such a foothold.

Speaking to my host in a congratulatory tone of our almost entire exception from the disease in the United States, he answered me warmly and decidedly, saying: You have plenty of lepers in your country, but your physicians do not recognize the disease, and allow the patients to run at large, while here in Norway we diagnose the malady in its early stages and isolate the patients.

In a late visit of Dr. Hansen to the United States, he told me that the Doctor found three cases in the hospitals in Chicago, and twice as many in New York, as well as encountered several cases of true leprosy upon the streets of each city, all of whom were being treated for lupus, syphilis or some other form of skin disease. I asked why the disease did not spread if we allowed lepers to run at large. "Because," he replied,

"where the hygienic conditions are favorable the disease is only very slightly contagious. None of the attendants in this hospital ever contracted the disease."

To fortify his position, the Doctor had me examine several cases where the disease only involved the skin, and asked me if these cases had consulted me at home, if I would have recognized the disease as leprosy; and I had to acknowledge that I would not have been able to have made a correct diagnosis if his was a correct one.

I have related this interview to a number of American physicians and all of them, except Dr. Moyer of Chicago, poohed at the idea what we could not correctly diagnose a case of leprosy. The latter related to me the case of a boy whom he used in his clinic to illustrate what he supposed to be one of syringomyelia, but which on further investigation he found to be one of true leprosy.

Medicine in Scandinavia.—Everywhere in Norway and in Sweden I find, both in medicine and surgery, everything to the savor of a most distinctly German type. The physician speaks German, his medical books are largely German, and his surgical technique is often the fashion that one sees carried out in Berlin and Vienna.

Small children in Norway have a habit, it seems, of drinking a strong alkaline solution that their mothers use in washing clothes. This is likely to be followed by a stricture of the esophagus. I saw a case operated on in Christiania for the relief of this trouble, and there were two more cases under treatment for the same difficulty in the same hospital. If the case be a bad one a gastrotomy is first done, the walls of the stomach are united with the parietes of the abdominal walls, so that an external gastric fistula remains. A piece of rubber cord of suitable size has sewed to each end a thin piece of tape, so that when pulled upon, the rubber cord has a much smaller diameter than when not upon the stretch. A small bougie is fastened to one of these cords and is passed, via the esophagus, down through the stomach and out at the fistulous opening in the stomach. The rubber cord, now being put upon the stretch by means of the two pieces of tape, is drawn down into the esophagus in a condition where its caliber is greatly reduced. The traction upon the cords is now loosened and the rubber cord assumes its original size and thus expands the restricted esophageal tube. These rubber dilators are changed every three or four days, a larger one being used each time.

The patient is nourished for the first few days, per rectum, and after that through the gastric fistula. At Christiania I saw a number of cases of prostatic enlargement treated by a super-pubic cystotomy, and permanent drainage of the bladder through this incision.

The surgeon has devised an ingenious appliance for the after management of these cases, which allows the urine to pass off into a rubber bag, with little inconvenience to the patient and allowing him at the same time to be on his feet without being annoyed by being wet from the urine as it passes off.

At Odessa in Ruesia, I met Dr. Mariachell, a bright man who devotes his entire attention to the diseases of the male genitourinary organs. He is one of the surgeons of the general hospital in that city, and has an abundance of material at his disposal. He tells me he has castrated fourteen times and operated on the vas deferens thirteen times for enlarged prostate, with the result of benefiting none of his patients, and sending two victims to the insane asylum as a result of his interference.

He is bitterly opposed to the operation and says that the better character, and is brought about solely by the patients being confined for a time in a horizontal position.

I was surprised to find on the table in the reading room of the general hospital at Odessa the latest medical journals in a half dozen different languages, and a set of men who seemed in all medical matters to be fully up to date.

To physicians who visit Sweden I can most warmly recommend that a few days be spent in the hospitals of the modern and thriving city of Stockholm, especially if you have some knowledge of German. Prof. Akermaun, I believe, is one of the brightest men for his years I have ever heard teach or seen operate as a surgeon. Dr. Josephson does a large amount of abdominal work and is a great advocate of using buried silk sutures in closing up abdominal wounds, thus, he believes, avoiding the hernias that often follow these operations.

The surgeons here (I found the same thing in several other places) have abandoned catgut as a ligature, and are using fine silk in its stead, claiming that thereby they avoid suppuration and, if the silk used be fine, that it is absorbed without the manifestation of any local irritation.

Everywhere in Scotland, in Scandinavia, in Russia, in Turkey, in Greece and in Austria, I have found typhoid prevalent, and have been trying to do some missionary work as a Woodbridgeite, with what success I will tell the readers of the JOURNAL in my next.

W. S. CALDWELL, M.D.

The Leprosy Question.

Translated from the French in *Janus* (July and August, 1897).

COPENHAGEN, June 26, 1897.

To the Editor (of *Janus*):—I see today with a certain displeasure that three of the publications, as numerous as they are little important, of Dr. Albert S. Ashmead, have been inserted in the sixth issue of your paper (May and June).

One of these publications, that entitled "Leprosy Overcome by Isolation in the Middle Ages," is absolutely useless. The author is pleased in this to attribute to me an opinion which I have never professed, *vide*, that the isolation of the lepers would be useless. *One will never find that opinion expressed in my works.* I am for isolation according to the Norwegian system, that is, the isolation of the diseased, who are incapable of taking care of and supporting themselves, and whose presence among other persons constitutes a real danger for the well. But I am not an admirer of the barbarians of the Middle Ages, who burned and imprisoned with horrible ceremonies the poor lepers, separating them from their families and their friends.

I know that Mr. Ashmead fights for the wholesale isolation of the lepers (even the 100,000 lepers in the English Indies), but I have the firm conviction that he will remain isolated himself with such a demand. The hygiene of our days does not act in the same manner as that of the Middle Ages.

Will you "kindly" ask Mr. Ashmead to quote in future the passages from my writings to which he refers, in order to avoid writing perfectly useless notes and attributing to me opinions which I do not have. I avail myself of this same occasion to interdict him, the copying without quotation of source, of photographs of my Icelandic lepers. These photographs were mine. I paid for them with two voyages, both perilous and disagreeable. Mr. Ashmead has inserted one of my photographs on the third page of his last pamphlet in the *Magazine of Medicine*, April, 1897, where he publishes, always without authorization of the correspondents, a number of letters, of which his own contains trifles, without interest, and also rude abuse of the leprologists of London, of Asmauer Hansen and myself. You will no doubt excuse me if I wish no longer to dispute with Mr. Ashmead, agree, Mr. Editor, the assurance of my perfect consideration.

DR. EHLERS.

NEW YORK, DEC. 6, 1897.

To the Editor of *Janus*, Amsterdam, Netherlands.—Dr. Ehlers says (*Janus*, July and August) I attribute to him opinions which he never professed.

Whether or not Dr. Ehlers stands for isolation was not the point at issue; it was, should isolation as a principle be promulgated by the Berlin Lepra-Conference? That was the important question. He stood an obstacle to our obtaining

official delegates, claiming that governments *had always neglected the holy name of hygiene*, le saint nom de l'hygiène, in all countries and in all times. *It was not, in his opinion, the way that leads to the goal to try to stir up the governments. It is a congress which takes place between known leprologists and not a congress of leprology.* Our goal was not so much a congress of leprologists, which I have taken the liberty to call very frequently a congress for talk only. What we wanted with absolute singleness of purpose was a congress to take practical measures against a disease against which talk, disputations of leprologists, etc., had availed nothing, that is to do everything possible, in order to obtain universal measures of isolation. Therefore it was our object to stir up the governments. Although he does not speak against isolation in his works, his acts in opposing the call upon governments to take part in the Congress were against isolation. Some shadow of this government representation was nevertheless obtained, but it was due to *our* initiative, to the fight we made, not to Dr. Ehlers, and not even to *Asmauer Hansen*. Especially was it not due to the non contagion clique of London.

One word as to the photograph of which he interdicts the publication without quotation of source. Dr. Ehlers would seem to like such pleasant expressions as *interdict*, though he reproaches me with being *grossier*: but it is only fair to attribute the strength of his expressions to his imperfect knowledge of the delicacy of the French language. I published a photograph of an Icelandic leper woman, with his permission, giving him due credit in "Suppression and Prevention of Leprosy." I copied it as an instance of melancholia of leprosy, which is my own interpretation of it, in the *Magazine of Medicine* subsequently. His name did not appear in that second publication; it was simply forgotten. There is certainly in this no justification for such tremendous trumpeting about the world of the wrong done to his photograph, which he had paid for by two perilous and disagreeable voyages. I think it would be a useful exercise for Dr. Ehlers if he tried to insert the following truth into his brain: Dr. Ashmead had a perfect right to use subsequently without any ceremony a photograph which he had once published in the regular way, with permission and quotation.

Let me say to Dr. Ehlers that the mixed system of isolation of Norway has driven to the United States 17,000 Norwegian emigrants of *leprous families*, and thus served only to transfer the leper problem from Norway to America. *International government laws*, which I stand for, would prevent that.

If he considers this duly and seriously he will surely find that it is (though he says my publications are *inutiles*) more important, more useful to meditate upon than anything he has ever written in any of his works, published after such perilous and disagreeable voyages.

With a pleasant felicity, which is rare with Dr. Ehlers, he observes that it is I who shall be *isolated with my demand*, not so entirely isolated, however; for, as I said above, there was, in the presence of some government representatives, at Berlin something like a foreshadowing of international leper law.

We Americans are interested, I mean directly, not in our own leprosy, for we have none; we are interested in the leprosy of Norway, Japan, China, Hawaii and South America, to prevent the disease from being brought by emigration, which would easily be done by international arrangements, by stirring up the different governments. Even from the 159 lepers which Dr. Ehlers so successfully saw in Iceland, four have since escaped to this country, and almost while Dr. Ehlers gave himself up to the charms of the congressional, leprologist, non-international conference, these four contaminated Manitoba!

ALBERT S. ASHMEAD, M.D.

License in Germany.

TOLEDO, OHIO, Dec. 10, 1897.

To the Editor:—Dr. Blech's answer to the inquiry as to the admission to the practice of medicine in Germany is not quite correct.

To be matriculated as a student of medicine, one must be a

graduate from a gymnasium covering a classical course of nine years. These graduates are 20 years old on the average. After four semesters, usually during the fifth, the medical student passes the *tentamen physicum*, an examination in physiology, anatomy, physics, chemistry, physiologic chemistry, botany, mineralogy. Before passing the *tentamen physicum* the student is not admitted to the clinics. The candidate for *State examination* must have studied medicine and the allied branches for at least eight semesters, of which not more than three are allowed to be passed at a recognized foreign university. While eight semesters are the required time, it is by no means the average, which may be put at ten semesters.

A foreign physician, who wishes to practice in the German Empire, must furnish satisfactory proofs that his preliminary education is equal to the one required for matriculation from the German student of medicine. From the American physician the college degree of A.B. or A.M. is considered as equivalent. Upon the further proof that he is legally entitled to the practice of medicine in his native country, he will be admitted to the German State examination without attending one hour clinics or lectures or anything at the German school.

At this occasion I wish to correct the erroneous statement which is frequently heard, that the diplomas from a few American schools, like Ann Arbor, Harvard, Johns Hopkins, and some others, are recognized in Germany. It is not so! Their diplomas do not entitle to practice in Germany. Quite a number of foreign physicians are practicing in Germany, especially at watering places and similar sanitary institutions, and they had to fulfill the requirements as described.

Another class of foreign graduates in the German Empire is formed by professors at the universities, who not infrequently receive calls from one European State to another. These men only receive the State diploma without passing any examination. For instance: Billroth was a German graduate, but he received and accepted calls as professor to Zurich in Switzerland and to Vienna in Austria. Ziegler, the well known pathologist, is a Swiss graduate, and now in Germany. A number of Germans are professors in Switzerland, etc.

The requirements are about the same in all the different States in Europe. In whatever empire one wishes to practice medicine he has to procure the State diploma.

This explanation shows that Germany lays the most stress upon the preliminary education. The reasons are obvious.

B. BECKER, M.D.

Appendicitis.

EVANSVILLE, IND., Dec. 3, 1897.

To the Editor:—The alarming mortality rate following operative measures for the cure of appendicitis in this city has caused considerable comment of a questionable nature, recently and in the daily papers this morning the Board of Health has taken the matter into consideration. A recent case of operation during convalescence, and the patient's death in less than thirty-six hours, has opened the way to adverse criticism. In the case mentioned the operation seems to have been done through jealous rivalry, with a large fee as an incentive, which only too plainly demonstrates the fact that the surgeon above all others should be a man of unbiased mind.

During my twenty-six months of hospital work in Louisville, Chicago and this city, I have carefully observed the medical and surgical diagnosis and treatment of this disease and noted the difficulty in differentiating between it and typhlitis, perityphlitis, para-typhlitis, volvulus and intussusception and all forms of intestinal obstruction, and have arrived at the following conclusions;

1. An operation for appendicitis is usually demanded the moment the diagnosis is absolute, the condition of the patient and other indications justifying, provided the case is of the progressive type with the bowels locked, and treatment seems of no avail.

2. If the temperature is not high, the pulse is not irregular and not weak, if the pain is not intense; if the patient rests moderately well without, or with very little anodyne and the case seems to be of a moderate type and at a stand-still, then every effort should be made to move the bowel, reduce the inflammation and tympanites, soften down and carry out the inspissated feces, flush the bowel and keep it open, use intestinal antiseptics, tone up and sustain your patient and carry him through without surgical intervention.

3. If, after recovery, there still remains a sickening pain of a radiating character in the region of "McBurney's point," increased by the administration of strychnia or other agents stimulating peristalsis, denoting plastic adhesions and future trouble, a coated tongue and torpid constipated bowel, then tone up and build up your patient. Remove all offending material from the sigmoid colon and cecum by high enemas and hydragogue salines and remove the crippled disturber. Break up all adhesions under anti- and aseptic precautions, and your patient will stand every chance of a speedy and permanent recovery.

4. Do not as too many supposedly good surgeons have done, operate on a patient afflicted with appendicitis too soon after the crisis is over, and thereby stir up an inflammation afresh that is practically past.

Many a man's life has been lost by an operation performed at this time, when the patient was slowly but surely convalescing, with the bowel open, the pulse only slightly accelerated and temperature 99 or 99.5 degrees, and in fact when operative interference of any nature was strictly contra-indicated.

W. F. STERMAN, M.D.

"Edema Universalis."

NEW YORK, Dec. 10, 1897.

To the Editor:—Such little blunders, as forgetting that a word ending in "a" is not always a Latin feminine, but may be, and very often is, a Greek neuter, are exceedingly unpleasant and it takes a deal of philosophy to overcome the bitterness of being corrected. Yet, let me tell you of an instance whose mention must pour balsam into any such grammatic sore. When Victor Cousin published his Plato, he wrote the title thus or about thus: *Platonis Opera Omnia Victor Cousin Recollexit*. The book with that title was spread all over Europe, over all the world, in fact, causing everybody to ask how it could be that such a great man did not know the tenses of *recolligo*.

M.D.

The Word "Os."

SAN DIEGO, CAL., Dec. 11, 1897.

To the Editor:—Were I an editor I should not object perhaps to read the Old English *thou*, but I should draw the line as do you at the too common substitution of "orem" for the classic and correct accusative of that old neuter noun, *os*.

Truly yours.

F.

PUBLIC HEALTH.

Control of Quarantine.

GOVERNOR BLOXHAM OF FLORIDA WRITES A LETTER ON THE SUBJECT.

GOVERNMENT SHOULD CO-OPERATE WITH THE STATES.

REASONS FOR A NATIONAL DEPARTMENT OF HEALTH GIVEN.

FLORIDA'S SYSTEM AN EXAMPLE OF EFFICIENCY.

TALLAHASSEE, Fla., Dec. 3, 1897.

Upon the request of the publishers of that journal, Governor Bloxham has written the following letter to the *New Orleans Picayune*:

T. G. RAPIER, Esq., Manager *Picayune*, New Orleans, La.
Dear Sir:—I have the honor of acknowledging your favor of recent date requesting an expression of my views upon the

question of State, interstate or Federal control of quarantine against the future invasion of disease. Never having worshiped at the shrine of Esculapius, it will be impossible for me to present anything of a scientific character, but simply such thoughts as have been engrafted upon my mind by the experience of the last ten years in Florida and enforced by the views of the health authorities, in whose judgment I place great confidence. Were those thoughts summarized, they could be condensed in one expression:

Government co-operation with State control.

Our health authorities have frequently placed themselves on record in the matter of public health regulations. The State Board of Health of Florida is a unit upon the necessity of Federal legislation looking to the creation of a Department of Public Health with a recognized head. The members of the board at an annual meeting a year or two ago adopted a strong memorial to our State Legislature and our Congressional delegation, earnestly recommending concerted action in this direction. Could a cabinet officer be invested with a more responsible duty than looking after the health of seventy millions of people? Then why not create a Department of Health with a cabinet officer at its head, with ample power and authority to render assistance, when needed, but whose principle line of action and basis of union with the ideal public health system shall be co-operative and contributory to the several State boards of health?

NATIONAL DEPARTMENT OF HEALTH.

Let there be a "Secretary of Public Health," with State boards as his coadjutors. Let him formulate a uniform maritime quarantine and domestic or internal sanitary code to be enforced and operated by the several States.

The AMERICAN MEDICAL ASSOCIATION has embodied this idea, carried out in all its details, in a bill, which has received the indorsement of many of the leading sanitarians and public health organizations of the several States, and which I presume will be called to the attention of Congress with the indorsement of the great mass of the medical profession of the country. The country, and no portion so urgently as the Southern States, needs such a measure, or any course that will relieve a small bureau of the Treasury Department of the necessity of taking care of the lives of millions of people.

By what decree of Providence of common sense is it ordered that the financier of the Union—the Secretary of the Treasury—burdened with care beyond endurance, by environment and education harnessed to a most potential and engrossing charge—made the arbiter of matters of life and death to the countless thousands? Who more unfitted to deal with the great issues of public health than the steward of the nation's wealth? And why relegate to a mere departmental division a responsibility second to none, and one which should be confided to no care but that of the ablest and most experienced?

At present, Governmental health affairs are administered through and by the Marine-Hospital Service—an organization for the care of sick seamen, though nominally committed to the Secretary of the Treasury, who, perforce, both by reason or stress of other matters and the necessity of some medical culture, has to foist them upon a subordinate. And what record is attributed to this Marine-Hospital Service? It is claimed by those in a position to know that inadequate measures upon the part of this service not only admitted, but almost contributed to the infection at Key West and Tampa in 1887, which was followed by the epidemic of 1888. Who, then, was responsible for the epidemic of 1888?

Who was responsible for the entrance of yellow fever at Brunswick in 1893? Was there not mismanagement at that port? And who was in charge of its maritime quarantine?

Who is responsible for the introduction of the recent plague in the first instance, through Ship Island Quarantine Station, near Biloxi? Was anything accomplished by this service to prevent a further spread of the disease after its careless introduction? Was confidence established, without which the country may always expect the barbarities of the shotgun quarantine?

The answer to these inquiries, which are not aimed at individuals, but at the system, must necessarily have weight in determining future legislation. Let us have a Department of Public Health, most assuredly, but let it be advisory and co-operative, and upon lines that will be an earnest of satisfactory and successful administration. Florida has been virtually free from yellow fever for eight years, and what few cases have appeared have been promptly stamped out.

What more striking lesson than that presented by Florida's health record during the months of September, October and November of this year, when intercourse between the cities and towns of the neighboring States was hampered, when not

totally inhibited, by local quarantines? While within this State no embargo of any description rested upon freight or passenger intercourse, and you came and went at will without even the suggestion of quarantine.

The reason is not obscure. Florida, after its experience of 1888, like the people of the whole country at this time, had its attention directed to a future invasion of the disease, and called into existence a system which its years and successes have demonstrated to be thoroughly efficient, and which has so won the confidence of the people that it has been enabled throughout the exigencies of the past summer to at once allay apprehension and suppress excitement.

To the student of the matter, Florida's part in the yellow fever history of this year evidences not only the capacity of our health officials, but the wisdom of our system, and arouses a desire for a similar condition in other States.

Should a co-operative and contributory system, as suggested, ripen into proper legislation, those in charge should be well qualified to take into consideration your inquiry as to the best means of preventing a recurrence of the epidemic, and at the same time minimizing the embargoes of commerce.

Very truly yours, W. D. BLOXHAM.

The Bubonic Plague still furnishes items to the press. Its ravages, according to a Bombay dispatch dated December 6, are still unabated at Poonah.

The War Against Typhoid Fever Germs is brisk in many centers of the milk supply in New York and New Jersey. The sources are found in the dilution with polluted water and the careless cleansing of cans. The Health Boards are to be hardly blamed for a want of vigilance, certainly not in this summary waste of the materia morbis.

Health in Chicago.—The report for October shows that the total number of deaths were 1,716 or 1.05 per 1,000; the rate for the same period in 1896 being 1.06 per 1,000. Of these 1,716 deaths, 419 were persons under 1 year old, 180 between 1 and 5 years old; 191 were due to acute intestinal diseases, 208 to nervous diseases, 193 to consumption, 134 to pneumonia, 96 to diseases of the heart, 61 to typhoid fever, 61 to diphtheria and membranous croup, 60 to bronchitis and 58 to cancer.

Health in Michigan.—Reports for November show consumption, remittent fever, typhoid fever, intermittent fever, pneumonia and erysipelas less prevalent as compared with the average for November during the 11 years, 1886-96. Consumption was reported in 172 places, typhoid fever in 111, diphtheria 66, scarlet fever 57, measles 37, whooping cough 18, and smallpox one place, this being a decrease from the October reports as to consumption and typhoid fever and an increase as to diphtheria, scarlet fever, measles, whooping cough and smallpox.

NECROLOGY.

JOHN BERRIEN LINDSLEY, M.D., Nashville, Tenn., died December 11. Dr. Lindsley was graduated from the University of Nashville in 1839, afterward taking his Master's degree there in 1841, in which year he began the study of medicine. He received the degree of M.D. from the University of Pennsylvania, Department of Medicine, in 1843. He devoted the years 1845 to 1850 to the study of natural science and in 1859 took courses of instruction in European institutions. In 1850 he began teaching medicine at Nashville, Tenn., where he has passed his life as a practical educator. From October, 1850 to April, 1873, he was Professor of Chemistry and Pharmacy in the Medical Department, University of Nashville, and was Dean of the Faculty until 1855, having been one of the founders of that institution in 1850. Largely through his influence was brought about the creation of a normal school, which has been in successful operation since 1875. From 1877 to 1879 he was Secretary and Executive Officer of the State Board of Health of Tennessee, and again since 1884, President of the Board from April 1 to July 1, 1884, and Professor of Chemistry in the Medical Department, University of Tennessee from 1889.

The Doctor was a prominent member of many societies, among them the Tennessee State Medical Society, AMERICAN MEDICAL ASSOCIATION, American Academy of Medicine, American Association for the Advancement of Science, American Public Health Association, etc. He served at Nashville during the cholera epidemics of 1849, 1854, 1856 and 1873, and in 1878 was in charge of the yellow fever refugees to that city. Dr. Lindley edited the reports of the Nashville Board of Health for 1877-79, reports of the Nashville Board of Health 1880 to 1884, and the *State Board of Health Bulletin* 1889 and 1890 to 1894. Other works from his pen are numerous. In the reports of the American Historical Association, 1889 to 1892, twenty-nine titles of papers from his pen are mentioned. In addition to his medical and sanitary work, Dr. Lindley devoted considerable time to ecclesiastic labors, being ordained in 1846 by the Presbytery of Nashville and for several years thereafter acting as minister to country churches and slaves connected therewith. The College of New Jersey (Princeton University) conferred the degree of S.T.D. on the Doctor in 1858, and since 1894 he has been Lecturer of Sociology in the Theological Department of the Cumberland University, Lebanon, Tenn. The Doctor was born at Princeton, N. J., Oct. 24, 1822, being a direct descendant from one of the earliest English settlers of the New Haven Colony.

CHARLES HARVEY QUINLAN, M.D., D.D.S., Evanston, Ill., December 6, aged 76 years. Dr. Quinlan had been a resident of Chicago and its suburbs since 1846. He came from Albany, N. Y., where he was born Feb. 19, 1821. Immediately after his graduation from a dental school at Buffalo he opened an office in Chicago. He at once became one of the most prominent men of his profession in the city. The introduction here of sulphuric ether as an anesthetic brought him fame. It was in the fall of 1846, when the method of application was discovered in Boston and full instructions for its manufacture and use were sent to Dr. Quinlan by his uncle, Dr. Harvey of Buffalo. Ether was then known as a letheon, and Chicago is the first city west of the Alleghanies where it was given a practical test. This test was given in a public clinic at Rush Medical College, where an amputation was to be performed. Dr. Quinlan was asked to be present and administer the anesthetic. Wide publicity was given the test, and the result was entirely satisfactory. The newspapers of the country teemed with accounts of the experiment and Dr. Quinlan was given great praise. Shortly after this, chloroform was discovered, and the formula was immediately procured by Dr. Quinlan. He was the first to distill this anesthetic in Chicago. Dr. Quinlan took the degree of M.D. from Rush Medical College in 1865, and practiced in Lake Forest until his removal to Evanston in 1875. Since then he has lived a quiet life at his residence, 1619 Chicago Avenue. He built the Avenue House, Evanston's fashionable hotel in 1882. He was one of the founders of the Lake Forest University, being one of four men to give \$1,000 each to start that school.

ALEXANDER W. STEIN, M.D., New York University, 1864, died at his home in New York from cirrhosis of the liver, December 5. He was born in Buda-Pest, Hungary, fifty-seven years ago, and when 4 years old was brought to this country by his father, Louis Stein, surgeon-general of the revolutionary army and a friend of Kossuth. As a lecturer on surgery, professor of physiology in the New York College of Dentistry and a writer he was well known to the profession. He was delegate or attendant at most of the medical congresses here or in Europe.

J. HARVEY MANNING, M.D., Chicago, December 6, aged 38 years. He was educated at Cornell College, Iowa, and graduated from the College of Physicians and Surgeons in 1890. He afterward took a two years' course in Columbia College of Physicians and Surgeons, New York, graduating in 1892. He spent a year in St. Elizabeth's hospital, and later a year in the Iowa State Insane Asylum. He began regular practice in Chicago in 1895.

MARK H. LACKERSTEEN, M.D., Chicago, December 7, aged 62 years. The Doctor was a professor in the Post-Graduate Medical College. In his early years he took an active part in

the famous Sepoy mutiny in India, besides holding high positions under the British government.

JOSEPH F. EDWARDS, M.D., Atlantic City, N. J., December 6. Dr. Edwards was born in Philadelphia, Dec. 8, 1853, and was a graduate from Georgetown College and the University of Pennsylvania and practiced medicine in his native city for sixteen years. He was formerly a surgeon of the Second Regiment, N. G. P. Dr. Edwards was the founder and former editor of the *Annals of Hygiene* and the author of *Edwards' Journal of Health*. He was a member of the Board of Managers of the Trenton Inane Asylum, also of the New Jersey Board of Health. He was formerly of the Pennsylvania Board of Health.

G. PERRY REYNOLDS, M.D., New York University Medical College, 1852, medical examiner for Guilford, Conn., died December 9, aged 68 years.—Robert N. Short, M.D., Miami Medical College, Ohio, 1871, died suddenly of cardiac disease at his home in Mechanicsburg, Pa., December 1, aged 66 years.—Mark Van Winkle, M.D., College of Physicians and Surgeons, New York, 1855, died in Little Falls, N. J., aged 73 years.—James F. Murray, M.D., Albany, 1866, of Gloversville, N. Y., died from abscess of the liver December 5, aged 52 years.—Dr. Jacquemet, *agrégé* professor in the medical faculty of Montpellier, aged 72 years.—Dr. Poisson, Professor of Surgical Pathology in the Medical School of Poitiers.—Dr. J. B. Bottero of Turin, editor of the *Gazzetta del Popolo*, and the oldest journalist in Italy, aged 81 years.—Dr. A. Jazenko, some time privat docent of surgery in the University of Kieff, aged 55 years.—Dr. Cristino Cebrían, Professor of Anatomy in the University of Salamanca.—Dr. Arthur Schaffer, some time Professor of Chemistry and Physics in the University of Moscow, aged 65 years.—Dr. A. Gadaud of Périgueux, Senator for La Dordogne, and for some time Minister of Agriculture, aged 56 years.—Dr. Paul Guterbock, privat docent of surgery in the University of Berlin, and Dr. Zinn of Eberswalde, for many years one of the leading medical psychologists of Germany, aged 72 years.—W. M. Anderson, M.D., Charles City, Iowa, December 2, aged 63 years.—J. Spofford Hunt, M.D., Chicago, December 10, aged 63 years. During the war the Doctor served as surgeon of the Third Illinois Cavalry.—R. H. Johnston, M.D., Cromwell, Iowa, aged 61 years.—R. A. Kirkpatrick, M.D., Montreal, aged 34 years.—George A. Munro, M.D., Providence, R. I., a veteran of the Civil War, December 3, aged 60 years.—George Q. Orris, M.D., Seymour, Ind., December 3, aged 47 years.—John M. Small, M.D., Lewiston, Maine, December 4, aged 80 years.—R. T. Worley, M.D., Baton Rouge, La., of yellow fever, November 29.—James H. Pooley, M.D., Toledo, Ohio, December 10, Dean of the Toledo Medical College, suddenly.

BOOK NOTICES.

The Peritoneum. By BYRON ROBINSON, B.S., M.D. Chicago. Part I. Histology and Physiology with 247 illustrations. Chicago. 1897. Svo. Cl. C. V. Waite & Co., 70 State Street.

Books of this character have not been very common in this country, but we are developing a class of students that by earnest plodding and scientific work will eventually bring our work up to a level with the best literature abroad. There are many expressions that we do not admire in this book, there are some specimens of the misuse of words and some mistakes of proof reading, but when the whole work is fairly examined it will be seen to be comprehensive, thorough, honest and creditable. We fear that Dr. Robinson will hardly receive the great credit he deserves for his hard labor, but let the reader of this handsome volume stop for a moment to reflect what great industry was required in its compilation alone, to say nothing of the vast number of original experiments undertaken. It is, we believe, safe to say that a very large percentage of practitioners have a quite imperfect knowledge of the peritoneum, and especially its histology and physiology. The work under consideration will greatly aid in acquiring the knowledge so generally lacking in the text-books, and will be welcomed as filling a distinct gap in modern medical literature. The illustrations are well executed, the paper is good, and the type is large.

Pictorial Atlas of Skin Diseases and Syphilitic Affections, in Photographs from the models in the museum of the Saint Louis Hospital, Paris. Ernest Beurier, A. Fournier, Tennyson, Hallopeau, Du Castel, physicians to Saint Louis Hospital, Paris, with the co-operation of the Honorable Henri Feulard, Curator of the Museum and L. Jacquet, former House Physician. Edited by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, London. Part 12. London: Rebman Publishing Company. Philadelphia: W. B. Saunders; W. T. Keener, 52 Randolph Street, Chicago agent.

This part, which completes the set, contains five plates with seven illustrations, pictorial representations of the unrivaled models of Barreta, the original of which are in the museum of the St. Louis Hospital. The explanatory text accompanying these magnificent plates is the work of professional masters and therefore needs no special comment.

Plate 46 contains the hypertrophic form of syphilitic chancre of the nostrils. The diphtheroid form of syphilitic chancre of the tonsils by Alfred Fournier.

Plate 16 in the accompanying text, Xeroderma Pigmentosum, by R. Du Castel.

Plate 48, Impetigo Contagiosa, by Lucien Jacquet.

Plate 49, Urticaria Pigmentosa with Atrophic Spots, by H. Hallopeau.

Plate 50, Syphilitic Chancre of the Lip: 1. Scabbed form; 2. erosive form, syphilitic chancre of the tongue (ulcerative form) by Alfred Fournier.

The practitioner is fortunate who can secure for his library these beautiful reproductions of the collection of models in the famous Paris hospital.

Index Catalogue of the Library of the Surgeon General's Office, United States Army, Officers and subjects. Second series, Vol. 2. B-Bywater, Washington: Government Printing, 1897, pp. 954.

This volume, according to Dr. Huntington's statement, includes 15,732 author-titles, representing 6,383 volumes, 14,802 pamphlets; it also contains 5,774 special titles and special books and 21,725 titles of articles in periodicals.

This magnificent index, which has reflected more credit on American medical literature than almost any other work, and has done more to make the medical literature of the work available than any other, is progressing at the rate of two volumes a year, and in the same careful and accurate manner characteristic of the preceding volumes.

We extend our congratulations to General Sternberg and Deputy Surgeon-General Huntington on the successful continuation of the work, and thanks to the wise Congress which by timely and liberal appropriations made possible this great undertaking.

Archives of the Roentgen Ray. We have received the July number of the "Archives of the Roentgen Ray," formerly Archives of Skiagraphy, London. Edited by W. S. HEDLEY, M.D., and SIDNEY ROWLAND, M.A., and the Editorial Committee. London: Rebman Publishing Company. Chicago agent, W. T. Keener, 52 Randolph Street.

The *Archives* has been modified in form and greatly increased in size from the former publication, and its scope is very materially broadened. By careful following of the pictures and studies of Roentgen one will be able to prevent the mistakes into which he otherwise would be liable to fall. The progressive surgeon can scarcely afford to be without the *Archives*.

Vade Mecum of Ophthalmological Therapeutica. By Dr. LANDOLT and Dr. GYGAX. Pages 138. Philadelphia: J. B. Lippincott Company. 1898.

This handbook is arranged in alphabetic order so that an index is not required, and is intended to give the essentials of ophthalmic medicine to the practitioner and students preparing for examinations.

It is a handbook for immediate reference. Translation has been well made by Dr. E. H. Neyman of Milwaukee with the

consent of the author. Formula given in both decimal and English terms.

Lectures on Physiology. First Series. On Animal Electricity. By AUGUST D. WALLER, M.D., F.R.S. Pp. 144. London, New York and Bombay. 1897.

This work contains part of the material of course of twelve lectures on animal electricity delivered by the author at the Royal Institute during the spring of 1897.

There are six lectures giving the results of various experiments on animal tissue. These lectures are fully illustrated and are intended for advanced workers in the field of animal electricity. It also shows very fully how the modern lectureships depend more upon the laboratory than upon the lecture theater.

About Children. Six Lectures given to the Nurses in the Cleveland General Hospital in February, 1896. By SAMUEL W. KELLY, M.D. Cleveland Medical Gazette Publishing Company. 1897.

These lectures constitute a pretty successful attempt to bring technical information within the reach of nurses. Pupils at nurses' training schools generally will find the book full of information and therefore very useful to them, not only in acquiring necessary knowledge, but after graduation as a book of reference.

A Handbook of Midwifery. By W. R. DAKIN, M.D. Four hundred illustrations, pp. 629. London, New York and Bombay: Longman, Green & Co. 1897.

This work is intended for students and junior practitioners. The subject is arranged in two divisions, those of physiology and pathology. The author has intended to make the work of high practical value without introducing any unnecessary details.

The printing is good, the illustrations are excellent and the work is very full and complete. By using fine type the publishers have succeeded in introducing as much matter as is usually found in the larger text-books.

Lippincott Company's Pocket Medical Dictionary; Including pronunciation and definition of twenty thousand of the principal terms used in Medicine and the allied sciences, together with many elaborate tables. Edited by RYLAND W. GREEN, M.D., Editor of Lippincott's Medical Dictionary. J. B. Lippincott Company, Philadelphia and London: 1897.

This is a pocket medical lexicon, handy in size, convenient, accurate and full, and contains more words than are to be found in most pocket lexicons, although it has omitted antique and obsolete terms. It will be found very useful.

MISCELLANY.

Medicine and Pharmacy in France.—The law which at present governs the practice of medicine in France, forbids the simultaneous practice of medicine and pharmacy, even by a person who may be in possession of diplomas in both subjects.

Bathing in London.—Foreign ideas of the British sense of propriety will receive a shock from the recent order of the London county council that men and boys bathing in public ponds must wear drawers. Hitherto they have bathed naked, and the minority in the council opposed the innovation as an "undemocratic step."

Pulmonary Phenomena of Hysterical Origin.—E. Leoni describes, in *Il Morgagni*, No. 6, a puzzling case of apparent pulmonary tuberculosis, with fever, râles and other symptoms of pulmonary trouble. They changed their position from one day to the other; sometimes on the right, the next day on the left, or absent altogether. Moral persuasion, suggestion and electricity resulted in rapid and complete recovery.—*Gazz. d. O. e. d. C.*, August 15.

Clonic Movements in Syringomyelia Exclusively of Medullary Origin.—Marinesco has been studying, with various registering

apparatus, the clinic movements in this disease, affecting mostly the fingers. They sometimes assume the character of a partial epileptic attack of cortical origin, and have been attributed to the motor zone of the brain. He finds, on the contrary, that they are convulsive attacks resulting solely from the medullary irritation, independent of any cortical intervention.—*Bulletin de l'Acad. de Méd.*, August 17.

Pathology of the Lachrymal Canaliculi.—Mitvalsky describes the cystoid protuberances that develop in these canaliculi, and states that besides those in which the actinomyces are found, he has observed a case in which the contents were the empty shells of starch grains, the starch having been removed by chemie action.—*Wien. Klin. Rund.*, October 31.

The Theory of the Toxic Effect of Extensive Burns is confirmed by the results of Tommasoli's recent experiments with dogs, to which he administered the serum or meat extracts of other dogs that had been burnt. The invariably fatal effect was averted however, if, at the same time, he injected artificial serum, which he considers the logical treatment for extensive burns. He reports one very severe case saved by injections of artificial serum and another which showed marked improvement after each injection, although the patient finally succumbed to his injuries.—*Cbl. f. Chir.* from *Monatsheft f. Prakt. Derm.*, Vol. xxv, No. 2.

Delay in Mailing.—For the first time since the fire, our mail was delayed last week. We had purchased at considerable expense a cutting machine known as Sheridan's "Auto." For the last three weeks the "Auto" failed to work when wanted by reason of breakage, breaking down when just in the midst of the edition. The Sheridan Company having received their money have taken little interest in its working, and left the office to fix up its machinery as best it could. We are sincerely sorry to have the delay inconvenience our members, but it has been unavoidable.

Construction of Medical Practice Act.—While some attack was made on the New Mexico statute "to regulate the practice of medicine," etc., approved Feb. 27, 1895, the supreme court of New Mexico assumes it to embrace a rightful subject of legislation. It also holds, in re *Roe Chung*, Aug. 25, 1897, that there is nothing unconstitutional in the provision of the statute that the penalty denounced is to be recovered in an action of debt, which is converted into a fine proceeding to enforce its collection. And it holds that a justice of the peace has jurisdiction of an action to recover the penalty for a first offense, which is \$100. In this, it holds that a statute of 1889, providing that for all fines and costs imprisonment may be suffered at the rate of \$1 per day until the days amount to the fine and costs, should be read into the act of 1895.

Can Refuse to Sell Coffins.—Not only may a heartless grocer refuse to sell a starving man provisions, but an undertaker can refuse to sell a coffin for the burial of a dead person and can refuse to accept employment in his capacity of an undertaker. Such is the decision of the court of appeals of Kentucky in the case of *Brewster* against *Miller*. More particularly does the court decide here that an undertaker is not bound to accept employment or furnish articles necessary for burial where the person asking for same is indebted to him for previous services. The court says that one has the right to decline to enter into a business undertaking with anyone. It also holds that to afford mutual protection against such persons, it is not unlawful for the undertakers of a community to associate themselves together and agree to refuse to render a like service to one who has refused or failed to pay such expenses in the past to some member of the association.

The Solubility of Gallstones in Oil.—To determine the solvent power of various oils on gallstones, Scott (*British Medical Journal*, No. 1917, p. 798) exposed in a warm chamber at 98.1

degrees, beakers containing from 20 to 50 c.c. of oil, the quantity varying according to the size of the stone used in the experiment. After immersion the stones were removed from time to time, gently dried with filter paper and weighed. The oils employed were pure olive oil, pure almond oil and the odorless and tasteless purified petroleum oil known as parolein. The stones used in the first experiment were passed by a patient in whom treatment had been employed with olive oil with some success. They were about the size of dried green peas, faceted, friable, and dark greenish brown in color. As they dissolved, they showed a thin outer brownish layer of pigment, a thick middle layer light yellow in color consisting largely of cholesterin, and a small dark nucleus of pigment. They dissolved with about equal readiness in the different oils, losing approximately one-quarter of their weight in twelve hours, one-half in twenty-four hours, and three-quarters in forty-eight hours. After thirty-six hours' immersion, little was left but the nucleus. The stones used in the second experiment were removed from the gall bladder by operation. They were considerably greater in bulk than those of the first experiment, being somewhat larger than cherry stones. They were hard in consistence and appeared to dissolve uniformly, maintaining their original brownish yellow color. In the process of solution they exhibited no well defined layers. They seemed to contain a larger amount of pigment and salts than the other stones and lost a much smaller percentage of their weight during corresponding periods of immersion in the oil. After four days those immersed in olive oil had lost rather more than half their original weight, those immersed in almond oil exactly half, and those immersed in parolein less than one-third. The stones used in the third experiment were obtained from the same source as those used in the second. They were of enormous size, being as large as filberts. Although they commenced to dissolve in one hour, the loss of weight per cent., as time went on, was not nearly so great as in the previous experiment. At the end of the twenty-five days, those immersed in olive oil had lost rather more than half their original weight and those immersed in parolein rather more than one-quarter.

Earth Worms as Propagators of Disease.—Dr. Halsted Boylan of Paris has recently presented some ideas concerning the cause of yellow fever, charbon and tetanus, and he claims that the worms coming to the surface of the earth from the bodies of those buried who have died of these diseases frequently act as propagators of the germ or poison. The earth itself becomes contaminated and the poison is inhaled by man, eaten by cattle or infects the water, which afterward becomes a fruitful source of disease propagation. Verneuil has called attention to the fact that tetanus is most frequent among those coming in any way into contact with horses, it only being necessary for men under these conditions to have upon their hands a small cut, scratch or wound inadvertently brought into contact either with the manure containing the bacillus or with the ground infected thereby. The first experiment of this kind was made by Nicolaier, who demonstrated that the subcutaneous inoculation of earth taken in the fields, gardens and streets determined in mice, rabbits and guinea pigs, at times septicemia by septic vibrios and at others tetanus. The contamination from below the surface is two fold; miasma and emanations from the soil in paludial districts or when particles of organic substances rise to the surface in different states of alteration, coming from the tissues of decomposing animal matter and by the ordinary rain worm. W. Theobald in a recent lecture claimed that in 1850 yellow fever appeared in the Valley of the Amazon where it had been previously unknown, and a careful investigation traced its origin in that locality to the burial of a man from Jamaica who had died from the fever and had been landed at Para for burial. The soil on the surface was found to be charged with the microbes of yellow fever. The question now rises whether typhoid and malarial fevers may not be also disseminated in this manner. The one has its bacillus of Eberth and the other its hematozoon of Laveran. Both are very resistant and the worms may swallow particles of them and deposit them on the surface with the same facility as the bacilli of yellow fever, although this method of transmission

of typhoid and malarial fevers is not generally admitted. Pasteur has found the germs of charbon in the superficial layers of the earth over ditches where sheep that had died of the disease several years previous had been buried. The earth worms are the first carriers. In the depths of the soil they swallow minute particles of earth containing the spores formed around the cadavers of men and animals, for the purpose of extracting from them what nutritive substances they may contain and rendering them on the surface in the form of little twisted cylinders of a dark brown color. The practice of cremation is strongly urged to destroy these dangerous elements of both the bodies of those having died of the contagious and infectious diseases and the soil surrounding their place of burial.

Telegraphy Without Wires by the Marconi and Rubens Methods.—The *Consular Reports*, September, has a communication from Consul General DeKay, at Berlin, regarding the present status of the above subject-matter, interesting to the profession. The latest work in this direction appears to have been done by Rubens of Frankfort who is an instructor in electric physics at the Berlin Policlinic. Marconi experimented from the British mainland to an island four marine miles distant. He used a generator of electric waves invented by the late Professor Herz, which generator throws the waves of electricity in all directions, as the rays of light emanate on all sides from a flame. The problem was to concentrate these waves of electricity in one direction, namely, toward the island. This he did by placing a concave mirror behind the Herz generator, by which the waves were reflected and made parallel in the required direction. On the island he placed what is called a "coherer," that is to say, a tube filled with particles of metal of just the right size and quality for the purposes now to be set forth. The coherer was set before another concave mirror, so placed that it would catch the electric waves coming parallel across the water from the concave mirror and Herz generator on the mainland. The coherer was set exactly at the focus. Imagine that the Herz generator on the mainland is a flame whose light rays are caught by a concave mirror, thrown over to the island, caught there in another concave mirror and focused on the coherer. Now, the metal particles in this coherer are so adjusted as to size that the whole may be likened to a violin string which vibrates when a certain sound is made by the voice. As one can tune a violin string to a certain note, so one can find the metal particles that will vibrate to an electric wave of a certain size. Try to pass an electric current through these particles at ordinary times and there will be no result; but when the waves generated by the Herz generator, coming from a distance, fall on these particles, a vibration is set up in them, they touch each other, and a charge of electricity applied to the tube is allowed to pass through and can be registered in the usual way. Thus, the coherer, being supplied with an ordinary battery and Morse electromagnet, permits the circuit to be closed when the electric waves from the mainland reach it. The click is registered only when the rays or waves from the Herz generator are reflected on it. The electric waves are not believed to be vibrations in the air itself, but rather in the ether between the particles of air. As compared to light waves, they are of enormous relative size. It will be noted that the electric current on the island sent through the coherer has no other office than to strengthen and register the effects of these waves or rays caught by the concave mirror and focused on the coherer. Professor Rubens, a young German of Dutch extraction, recently delivered an address at the Polytechnicum in Charlotten-Berlin, before a number of instructors, in the course of which he said:

"Since Herz's death in 1888, much progress has been made in reducing the size of the electric-wave generator. As the size of the apparatus has a relation to the length of the electric waves, and as it was desirable to shorten these waves, the decreased size of the apparatus has been of use in making air telegraphy more practicable. Shorter electric waves are more

approximate in their action to waves of light, and go further. Up to the present, the shortest are those of the Russian experimenter Lebedew, who has produced them from 6 to 7 millimeters long. Professor Rubens showed a thermo-element or heat catcher, invented by himself to take the place of Marconi's coherer, which catches, like the coherer, the refracted and focused electric rays. The spark, he observed, was not at all a necessary phenomenon in electricity. He then made many curious experiments to show the similarity in action of waves of light and waves of electricity, and also drew attention to the very different way in which electric and light waves pass through different substances. Thus he reflected electric waves like light, refracted them with prisms, and diffracted them with a wire grating of parallel wires, as light is diffracted by Langley's grating. He then showed the polarization of these rays—freely, through the fibers of wood longitudinally; and badly, across the fiber; easily, through closed books with the leaves; and with difficulty, across. Thus a pile of books or sheets of glass showed polarization like crystals under light. He showed, also, that on account of the length of these waves, their energy was absorbed differently by different substances: thus, 1, water absorbs all the energy; 2, metals absorb all the energy; 3, glass absorbs nearly all; 4, paraffin absorbs hardly any, and 5, hard rubber absorbs hardly any. Thus they move through hard, black rubber and paraffin as light moves through air, glass or water, that is to say, with hardly any resistance, while glass lets very little of them through, and metal and water are impervious to them. Professor Rubens imbeds his Herz generator in petroleum for better isolation, and, as a handy concentrator of the electric waves or lens, uses a round glass bottle filled with petroleum. By placing in turn the glass prism, wire grating, block of wood, pile of books, water, paraffin and hard rubber in the line of the unseen electric waves pouring from the generator and concentrator toward the wave catcher, he showed on an indicator the passage, easy or retarded, of the unseen flow or its entire interruption."

Detroit.

THE REGULAR MEETING of the Wayne County Medical Society was held December 2. Dr. W. T. Corlett of Cleveland, Ohio, read a paper on "Recent Researches in Ringworm." The paper was illustrated with lantern slides and microscopic specimens, showing the different clinical varieties of the disease and the microscopic features. The doctor, who is a disciple of Sabouraud of Paris, gave as the divisions of ringworm, *tinea tonsurans*, *tinea sycosis* and *tinea circinata*. He divided the fungi which cause ringworm into the trichophyton microsporon, trichophyton megalosporon endothrix and ectothrix, each of which produces a distinct clinical variety of ringworm. The first produces ringworm of the scalp in children of from 2 to 15 years of age. It is extremely rebellious to treatment except on hairless surfaces. The second produces nearly all cases of *tinea circinata* of the body, eczema marginatum and sycosis without folliculitis. It is much less contagious than the first variety and yields very readily to treatment. The third fungus is supposed to be of animal origin. In childhood it gives rise to kerion and in men to sycosis accompanied with deep suppurative folliculitis. The clinical features of each variety of the disease were minutely described, together with the microscopic features of the hairs involved. For the treatment, thorough cleanliness, epilation of the hairs, chrysophanic acid, oleate of mercury and of copper and boracic acid were recommended, and the specific treatment for each variety was thoroughly discussed.

A MEETING of the physicians of Detroit was called by the local board of health on Saturday afternoon, December 4, to discuss the necessity of placing tuberculosis and whooping cough in the same category with diphtheria, smallpox and such diseases, placarding the houses where tuberculosis and where whooping cough exist and isolating the patients infected with such diseases as proposed by the State Board of Health. There were about forty of the representative physicians of the city present. After discussion, the following resolution was unanimously passed: "That it is the sentiment of this meeting that it is unnecessary and inadvisable to placard, isolate, or in any way make public the fact that any person has consumption, but that it would be advisable to educate the public through the physician by suitable literature from the Board of Health. Further, in assisting the physicians, it would be advisable for the health board of the city to institute bacteriologic examination of sputum." Whooping cough was then taken up, and it required only three minutes to discuss and

pass a motion discountenancing the proposal to include it in the list of contagious diseases.

HEALTH REPORT for week ending December 4: Births, male 39, female 36. Deaths 69, of which 25 were children under 5 years of age. Contagious diseases: Diphtheria, 13; scarlet fever, 64; deaths from diphtheria 4, none from scarlet fever.

Dr. C. B. EGGEMAN of this city died on November 30. He was the son of the late Dr. Rudolph Eggeman, and was born in Detroit, March 23, 1857. He was a graduate of the Detroit College of Medicine, class of 1879. After taking his degree he went to Philadelphia and attended the Ophthalmic College, and then began the practice of his specialty of diseases of eye and ear in Detroit in 1881. He was a member of the Masonic fraternity and of several other local societies.

THE 44TH SANITARY CONVENTION OF MICHIGAN was held in Detroit under the auspices of the State Board of Health, December 9 and 10. President Thomas W. Palmer addressed the convention. Papers were read by Prof. Frederick G. Novy, M.D., of Ann Arbor, "Germs, What they are and how they Produce Disease;" by Hon. Frank Wells, President State Board of Health, Lansing, "Statement of the Objects of the Convention;" by Guy L. Kiefer, M.D., Detroit, "Isolation and Disinfection of Persons and Things;" by Miss Harriett Marsh, Principal of Hancock School, "Popular Education in Sanitary Science;" discussion of the subject by Prof. S. Emory Whitney, principal of Cass School, Detroit, and Prof. Delos Fall, member of State Board of Health, Albion; by Charles T. McClintock, M.D., Detroit, "From the Purely Scientific Standpoint;" by Chas. G. Jennings, M.D., Detroit, "From the Physician's Standpoint;" by Oscar Le Seure, M.D., member of Detroit Board of Health, "From the Standpoint of the Local Board of Health;" by John McVicar, president of the Board of Public Works, "Streets and Alleys and Their Relation to the Public Health," discussed by Mrs. L. H. Trowbridge, Dr. J. E. Clark and Dr. Longyear.

Washington.

HEALTH OF THE DISTRICT.—The report of the health officer for the week ended December 4 shows the total number of deaths to have been 83, of which number 41 were white and 39 colored. The principal causes of death were: consumption 11, heart disease 5, pneumonia 14, typhoid fever 2.

MEDICAL SOCIETY.—At the recent meeting of the Medical Society Dr. Deale read an essay entitled the "Climatic Treatment of Pulmonary Tuberculosis," and presented specimens of fibrosarcoma of the uterus. Dr. Stone presented specimens of extrauterine pregnancy and appendicitis. Dr. Allen read a paper on "Senile Epilepsy." Dr. Caldwell presented a specimen of cancer of the stomach, and Dr. Acker presented a specimen of tubercular tumor of the brain involving the cerebellum and pons.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 27th meeting of the Society was held on December 3. Dr. Acker read a report on two cases of acute purulent peritonitis in infancy.

Hospitals.

ST. LUKE'S HOSPITAL, Borough of Manhattan, New York City, at the annual meeting in December showed that the death rate from all causes for the year was 10.3 per cent. In the medical department 1,201 cases were treated, and 1,243 in the surgical department. In the patient or dispensary department, which was opened on Nov. 4, 1896, 2,608 new patients have been treated and 9,930 visits made. The total house expenses for the year were \$153,299.04. A report made by the building committee stated the cost of the new buildings to be \$1,749,605, which, added to \$530,000, the cost of the land, brings the total outlay up to \$2,279,605. The deficiency of income as against expenses for the year ending Sept. 30, 1897, was \$57,499.25.

Societies.

The following meetings are noted:

Connecticut.—New Haven Medical Association, December 2.
Georgia.—Athens Medical Society, December 2.
Illinois.—McLean County Medical Society, Bloomington, December 2.
Indiana.—The Perry County Medico-Surgical Society, Tell City, was organized December 4.

Iowa.—Iowa Central Medical Society, Marshalltown, December 14; Polk County Medical Society, Des Moines, December 7.

Maine.—Portland Medical Club, December 2.

Massachusetts.—Eastern Hampden Medical Association, Springfield, December 2.

Minnesota.—Hennepin County Medical Society, Minneapolis, December 6; Minnesota Academy of Medicine, Minneapolis, December 1; Minnesota Valley Medical Association Mankato, December 6.

New York.—Glens Falls Medical and Surgical Society, December 2.

Ohio.—Cuyahoga County Medical Society, Cleveland, December 1; Logan County Medical Society, Bellefontaine, December 5.

Pennsylvania.—Harrisburg Academy of Medicine, December 3; Lebanon County Medical Society, Lebanon, December 1; Luzerne County Medical Society, Wilkesbarre, December 6; York County Medical Society, York City, December 2.

CHANGE OF ADDRESS.

Archieby, T. E. W., from 226 Summit Ave to 48 E. 4th St., St. Paul, Minn.
Bullard, W. M., from Wickes, Mont. to Fall Brook, Cal.
Fisk, F., from Chicago, Ill. to Waterloo, Ind.; Friedel, A. H., from 27 Wave City Pl. to 328 W. Monroe St., Chicago, Ill.
Hanna, C. U., from Palakala to 46 So. 6th St., Zanesville, Ohio.
Langdon, F. W., from 65 W. 7th to 6 Garfield Pl., Cincinnati, Ohio; Litvin, A., 638 So. Halsted to 568 W. 14th St., Chicago, Ill.; Lagorio, A., from 65 Randolph St. to 228 Dearborn Ave., Chicago, Ill.
Moody, H. A., from Bailey Springs to 938 Government St., Mobile, Ala.; Miner, A. L., from Ponsford, Minn. to Bellows Falls, Vt.
Pomeroy, H. M., from 200 W. 113th St. to 222 W. 23d St., New York, N. Y.
Rugg, D. F., from Hartland, Vt. to Adirondack Cottage Sanitarium, Saranac Lake, N. Y.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from December 4 to 10, 1897.

Capt. Madison M. Brewer, Asst. Surgeon, is granted leave of absence for four months from the date of his departure from Ft. Keogh, Mont.
Capt. William O. Owen, Asst. Surgeon (Ft. Bayard, N. M.), is granted leave of absence for one month.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending December 4, 1897.

P. A. Surgeon S. S. White, detached from the "Concord" and ordered to the "Wheeling."

EXTRA-UTERINE PREGNANCY, WITH REPORT OF CASES.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY M. PRICE, M.D.
PHILADELPHIA, PA.

In considering the condition of extra-uterine pregnancy there are very many questions of great professional interest, some not yet finally settled, all relating to the condition; giving light upon its treatment is of vast importance to the practitioner. It is important that he should be familiar with all the more prominent symptoms of an accidental misplacement or deviation from lines of normal pregnancy.

All cases of suspected pregnancy in women who have had a longer or shorter period of sterility, should be carefully watched in the early months for symptoms of tubal gestation. I do not know of a single case of rupture, or the history of rupture with well marked symptoms of loss of blood, that the rupture did not take place before the twelfth week.

All these cases must of necessity first pass through the hands of the general practitioner, and are lost or saved through their appreciation of the symptoms and their ability to make a diagnosis.

If the real character of the accident goes unrecognized, the great majority of these cases of extra-uterine pregnancy perish; death is almost certain and in very many instances sudden.

They perish in the majority of instances because of the failure of the physician to make a diagnosis; they perish of hemorrhage, septic peritonitis, obstruction of the bowel, etc.

That there are instances of recovery in ectopic pregnancy, without surgical interference, we are not prepared or disposed to dispute, for there being instances of recovery we have the testimony of men who by their wide experience are entitled to speak with some weight of authority. Numbered among these are the eminent English surgeons, Tait, Greg Smith, Taylor and others. Recoveries are reported by a number of American surgeons.

Our earlier gynecologic literature, that antedating our advances in abdominal surgery, abounds in the reports of cases where symptoms and conditions, the entire clinical history, could only be interpreted in our present light as ectopic pregnancy.

These cases augmented the statistics of every practitioner's mortality. They were classed under the head of hematocele. There has been very considerable useless groping around by surgeons in settling the nomenclature of this trouble. We are gradually settling into a common sense simplicity of terms. The symptoms, the actual perils of the condition bother us more

than those confusing, misleading or obscure names under which too many things medical and surgical pass or, to speak more accurately, stay. With names as with operations, the more simple and intelligible the better. Because exceptional cases recover, we can not afford the risks involved in delay, the long suffering, if not death, to which the patient is exposed. We can not determine in any given case the probability of recovery. We know this condition kills, that the only certain relief is good clean surgery and that in the hands of men with a prolonged surgical experience few die.

The word "variety" used in connection with ectopic gestation has very little practical interest to those of us whose sole object is to save life. Speaking for myself, from my own experience and observation, whatever may have been that of others, I have never seen in my own work, nor in that of Dr. Joseph Price (numbering together more than 175 cases), but one variety, that of tubal pregnancy. And I have seen them in all stages from the first to the tenth month, and have yet to see the first case developed in the broad ligament. I have seen the ovary stretched over and part of the capsule enveloping the child, which by some would probably have been called an ovarian pregnancy.

The symptoms of extra-uterine pregnancy are almost infallible. It is rare indeed for the symptoms of this condition to be taken as evidence of some other trouble, but it is not an infrequent occurrence for other conditions to be taken as extra-uterine pregnancy.

Lawrence Tait has made this subject one of such thorough investigation, and has taught us the lessons of his wide and successful experience, that it would seem that little aside from what he has said is worth saying. We can not do better than to follow his teaching and record as successful experiences. We can offer very little excuse for making mistakes in diagnosing this condition. There can be but two, ignorance or carelessness. It may occur repeatedly; it does occur that the practitioner recognizes the condition, but is without that surgical experience which would enable him to surgically deal with the condition. In this situation the duty is plain, that of promptly calling in the assistance of one as expert in the surgery of such cases as is at command. The duty is equally imperative upon the surgeon to promptly respond. Where the issue is one of life, no mere personal prejudices or questions of loss or gain should restrain or influence professional action.

As to those cases which go to term I will give my own opinion, deductions of my own experience. The possibility of these cases going to term is not disputed. Conclusions from my own observations may not accord with those of others of the profession. I have seen three cases at or near term. In each case the child was encapsuled in an amniotic sac and not in the broad ligament. My reasoning is that the fetus is

forced through the rent in the tube encapsuled in its amniotic sac. And if the placenta has sufficient attachment to continue the life of fetus until the placenta has made new attachments, the child continues to develop in its sac surrounded by the abdominal viscera, coming in contact with it, forming adhesions and in this way materially aiding and strengthening the walls of the sac. I am of opinion that the reason why we so often find the fetus absent in undoubted cases of tubal pregnancy is not only that the tube has been ruptured, but also the amniotic sac, and the fetus is forced into the general peritoneal cavity where a few days will suffice for its digestion.

As to just how soon the fetus can possibly be protected by the amniotic sac I am unable to say. I have found the fetus not longer than a Lima bean, but it was in those cases where the primary rupture and the operation for the relief followed immediately. It is rare indeed to find a child where there has been several attacks or several severe hemorrhages, but you find everything else, the ruptured tube, placenta and all that pertains to a ruptured tubal pregnancy save the fetus. I have seen a number of cases, from the second month on, where it could be clearly demonstrated that the child was within the amniotic sac. In this connection Tait uses the following language: "I have at the present moment lying in these very rooms a fetus of the full term which I removed from among the intestines, and round which nearly complete amniotic membranes were to be seen." I do not deem it possible that a child could live long at any period of gestation free in the peritoneal cavity. My conviction is that it would be encapsuled by the omentum or protected by an inflammatory barrier in some way. There are a number of cases on record, but there is very little to explain or show how long they had been so placed or how protected. Very many of the recorded cases give a very unsatisfactory clinical history and few of those interesting phases characteristic of these cases.

My case at term, reported some five years ago where both mother and child lived, was in the tenth month of gestation and in the amniotic sac. When the nurse attempted to wash the child she found that by the slightest rub of the wash rag she would take the skin off. The child would bleed from every point so touched, showing that the child was already being digested alive. The mother and child are today both living and well, the child a beautiful little girl. I will be pardoned here for a moment's digression. This case is reported in Gregg Smith's system of abdominal surgery as operated on by one Dr. Eastman, no one of the name known to belong to the profession of Philadelphia. This goes to illustrate the worthless character of the statistics of even eminent authority. This case is stated by Smith to be the only one in America where mother and child both lived. As to the manner of dealing with the placenta, where it is possible the placenta should be removed. Where it has not contracted adhesions outside of the pelvis, and involving bowel and mesentery in its attachments, there is probably less danger in its immediate removal than to treat it in any other way. It is only rarely that you can obtain a pedicle and control hemorrhage by ligation. The gauze pack is probably the only method in many cases by which hemorrhage can be controlled. Up to the beginning of the fourth month there is no trouble in controlling hemorrhage by ligation. From the fourth month on, hemorrhage is the

most serious complication. The second method of dealing with the placenta is what is called the open method of treatment, the one used in my case of term with the result of saving both mother and child. In this case, for thirty-five consecutive days, this woman with an abdominal wound six inches in length, with the amniotic sac stitched to the wound, endured daily the packing of the wound with from four to five yards of bichlorid gauze, this over the face of the placenta, covering a space as large as the rim of a man's hat. It was attached to everything from the left cornu of the uterus, descending colon and part of the transverse colon and over the entire face of the left kidney. The placenta was black and gangrenous in appearance and owing to the desperate condition of the patient, three determined efforts were made to remove the placenta. These efforts had to be abandoned on account of the frightful hemorrhage. Gauze packing in each instance stopped the hemorrhage at once.

On the tenth day, when the first attempt at removal was made, her temperature dropped to 96 degrees. The temperature chart indicated variations of temperature from 96 to 105 degrees; this for thirty-five days. At this time the whole left side of the body seemed to contract just as the uterus does in labor, with free discharge of blood. I at once removed almost the entire placenta, cutting it loose with the fingers just as we do from the uterus in a partially detached placenta, meeting with about the same amount of difficulty. There was free hemorrhage which was controlled by gauze pack. This immense opening had almost entirely closed in a week's time. I am positive that after my experience with hemorrhage, sepsis and other accidents incident to this manner of treating the placenta, I would not again resort to the practice of the open method and leave the placenta to slough away. It is out of the question to talk of removing the placenta in these cases at time of the operation, for the patient would beyond doubt perish from hemorrhage. I believe it to be better to cut short the cord, thoroughly clean the face of the placenta, remove all loose membranes and clot and close the abdomen, trusting to absorption, or later, when the condition of the patient indicates the necessity for a second operation. This impresses me as the safer procedure because it can not possibly offer any poorer chance for the patient than the open treatment. When the placenta is placed in the pelvis and is attached to either ovary, tube, uterus or pelvic wall, and it may only be slightly to abdominal viscera, the entire uterine mass can and should be removed at the time of operation at any cost, but when the placenta has formed attachments to vital organs and over a large surface, the patient would perish if removal of the placenta was attempted. These questions can only be decided by those who have many times dealt with such cases; it is nonsense to say that any surgeon can deal with the complications always possibly involved in this condition. He must be an abdominal surgeon trained by many experiences, with a knowledge of all the varying conditions met with in these cases and the surgical confidence to grapple with any possible emergency. The reference of these cases to those trained by special study, long clinical experience and observation brings no opprobrium upon the general practitioner, whose care is of the general public, the treatment of the more general ailments. His time and study are too much taken up for him to become expert in major operative procedures. The common diseases of women and children,

and obstetrics, one of the most important branches of medical practice, open a wide field for usefulness and honor. The wounded patient, whether by disease or accident, is entitled to the best skill.

In the report of nine cases in the London hospitals, in the later months of extra-uterine pregnancy, five perished, certainly a large mortality. These cases were probably in the hands of some of the best general surgeons in the world, but we should infer from the mortality that they were men not specially trained in abdominal surgery. In extra-uterine pregnancy there is no time for the discussion of symptoms, easy chair deliberations, for consulting the books or literature of the subject, collecting an armament of instruments—there is always urgency and there should always be readiness. Ninety-nine times in a hundred the operation is to save life from hemorrhage. Usually sufficient time has already elapsed to leave the patient pulseless and in collapse. This collapsed condition results from two causes: 1, from direct loss of blood; 2, from intraperitoneal pressure on the abdominal sympathetic nervous system. The urgent indications are the immediate stoppage of the hemorrhage. The only way to do this is to open the abdomen and tie the vessel; *no matter what condition of collapse the patient is in, so she is not actually dead.*

More than half the cases I have operated on have been pulseless at the wrist, and to all intents and purposes almost at their end. In many of these cases, as soon as the abdomen was opened and the ligature applied, the hemorrhage stopped, and after the great quantities of free blood in the peritoneal cavity, in many cases amounting to two or three quarts, was removed, there would be a moderately good pulse at the wrist. A statement made by Dr. Hobart A. Hare of Philadelphia may have some bearing in this connection. In a discussion, he called my attention to experiments he had made by forcible injections of water into the peritoneal cavity of a dog, and that it would kill him much quicker and with a very much smaller quantity of water than if injected into the bowel. I believe this goes to explain the quick recovery from the grave symptoms of ruptured extra-uterine pregnancy after operation. The hemorrhage is stopped and the pressure removed from the sympathetic nervous system. If the practitioner has not or can not diagnose a case in hand correctly, it is criminal for him to permit his patient to go on suffering while he refuses or neglects to call in advice. It is to be presumed that when a man operates for extra-uterine pregnancy, that he has made a diagnosis. There can be but little shock in an operation that involves only two inches of the abdominal wall, the delivery of the specimen and the application of the ligature. How is it possible for any one to justify delay when we compare this procedure with the actual condition of the patient, hemorrhage and intraperitoneal pressure, with everything pointing to speedy dissolution. Later, in the surgical treatment of this condition, say from the fourth month to term, before operation, there are questions to be considered more important than that of hemorrhage. We have then to consider the dangers during and after operation and how to deal with them. It is these very dangers and how to deal with them that have interested the profession. The later months with the attendant risks are anxious months for the patient and attending physician if real conditions are realized. The profession is not of one opinion as to the plan of surgical procedure and after-treat-

ment in cases of extra-uterine pregnancy when they have passed the fourth month.

I am of the opinion that no matter at what period of gestation a woman may be in, an effort should be at once made to end the pregnancy by surgical means, for there is not an hour that the patient is not in danger, and every day that the fetus is allowed to remain the risk to the patient is increased, and for that reason there should be prompt, unhesitating interference to terminate it.

The united surgery of the world has only been able to save from eight to ten children where these cases have reached term, with a mortality to the mother and an amount of suffering that by no possible argument, with the simple claims of humanity in the balance, could justify.

If the peritoneum can be left with everything removed, with a well-placed glass drainage at the lower point of the wound, the result will be perfect. If the hemorrhage can not be controlled without a gauze pack we should then depend on gauze drainage, which, while it will save life, greatly prolongs the after-treatment. The toilet of the general peritoneal cavity should be perfect. It should be faultlessly clean and kept so. If there has been contamination from any source there should be thorough cleansing with clean boiled water.

Case 1.—Mrs. Y., operated on Jan. 20, 1896, for extra-uterine pregnancy, supposed to be in the tenth week of pregnancy. About two quarts of liquid and clotted blood were removed at the time of operation. The child was partially digested. The patient made a good recovery.

Case 2.—Mrs. L., patient of Dr. Burroughs, Trenton, N. J. Operation April 19, 1896. Tube ruptured near its end. The placenta and about a quart and one half of blood obtained. Glass drainage for three days. Patient made a good recovery.

Case 3.—Mrs. S. S., patient of Dr. Edwards of Williamstown, N. J. There was not a very large quantity of blood, probably about a quart. Rupture had taken place several weeks before I saw her. Liquid portions of the blood had been absorbed. Fetus was not found. Placenta and tube were removed. Irrigation and glass drainage. Tube removed on the third day. Satisfactory recovery.

Case 4.—Mrs. T., patient of Dr. Hubler, Pittston, Pa., Dec. 5, 1896. Operation. A moderate quantity of blood, irrigation and drainage. Placenta, tube and ovary all removed. Recovery.

Case 5.—Mrs. W., patient of Dr. Shea. Extra-uterine pregnancy; about the twelfth week. The contents of sac suppurating. Patient septic. The sac, placenta and tube were removed. Irrigation. Glass drainage for four days. Recovery.

Case 6.—Mrs. L. G., patient of Dr. Nock, Philadelphia. Mrs. G. is a thick-set woman, twice married, and during her first marriage had a number of provoked miscarriages, some of which must have left the tube in condition favoring extra-uterine pregnancy. After her second marriage both she and her husband desired children, so were much pleased when the wife developed symptoms of pregnancy. They had been married three years when, as they supposed, this much to be desired accident happened. She missed her period on Jan. 11, 1897, followed by sick stomach and severe pain in the abdomen on or about February 15. She suffered with very severe pain in the abdomen followed by a weak faint feeling which sent her to bed. This condition was followed by a slight bloody discharge which continued to increase until March 16. During this time she had a number of these attacks of pain followed by a weak faint feeling, with constant tenesmus and desire to go to stool, but could not accomplish anything. On March 16 I was called to see the patient by the following note from her attendant, Dr. Nock: "I have in my opinion a case of tubal pregnancy with rupture. Can you come at once and operate?" I operated at once and found the conditions as stated by her attendant correct. The woman made a beautiful recovery. In this case no fetus was found; the rupture probably had forced the child into the peritoneal cavity and it was there digested. The placenta was living and adherent to the end of the tube.

Case 7.—*Extra-uterine pregnancy.*—Mrs. M. C., age 34 years; one child 5 years old, a boy; always a strong, healthy, robust woman; had one miscarriage; last menstrual period on

Nov. 28, 1896; December period missed. On Jan. 28, 1897, while washing her feet, she felt some little pain in the abdomen. After going to her room the pain increased, accompanied by symptoms of fulness in the bowels with severe tenesmus. She went to the water-closet feeling that the bowels must be relieved at once. Nothing passed from the bowel. The fulness and tenesmus increased. She made ineffectual efforts to relieve the bowel; this is the last she remembers. Her husband found her in a dead faint on the floor, very pale and pulseless. A physician was called who said she was suffering from peritonitis. The severe pain and distension of the abdomen he said all indicated peritonitis. From this time on until March 14, when I first saw her, she had a number of paroxysmal attacks of great pain accompanied with great weakness. There was a slight bloody discharge almost continuous after the first rupture in January. She had all the classic symptoms of extra-uterine pregnancy: Sterile for a number of years; a missed period; sick at the stomach; pains in the breast; intense pain with collapse and symptoms of hemorrhage, in the constant slight discharge of blood as in miscarriage, and at the end of the twelfth week a shedding of an entire cast of the uterus. At the end of the fourth month I was asked to take charge of her. Her condition was desperate. A weak thready pulse, a peculiar nervous condition so often found in these cases, bordering on insanity. She could not sleep and could not be persuaded but that death was impending. The physical examination revealed a tumor extending to the umbilicus, hard and tender and almost as a fibroid. The uterus was pushed back and fixed in the pelvis. The cervix was soft, open and bleeding as in miscarriage. The entire pelvis was filled up with the pregnancy and blood clot. She was at once sent to Dr. Joseph Price's hospital and, as soon as she could be prepared, with Dr. Price's assistance I removed the entire mass, capsule, baby, placenta and all.

I do not know whether the baby was alive when delivered. I rather think not from the appearance of the child, and it was the opinion of those present that it was dead. I do not know that the placenta was very much alive. Some bowel stitching had to be done and hemorrhage controlled by the gauze pack. The placenta was in front of the uterus and over the left tube and filled up the left side of the pelvis. No ligatures were used. The appearance of the gestation sac was that of muscular tissue adherent to everything it came in contact with; it had no connection with the broad ligament except at those points where it came in contact with it, as it did with other pelvic contents. I have seen three pregnancies at term and many others at different stages of pregnancy, and I have the first one to see that was located in the broad ligament, but I have seen a number that had the appearance of being so located.

The capsule had much the appearance of the thickened broad ligament. In many cases of operation for the removal of extra-uterine pregnancy, it has to be removed from under the broad ligament and not from within its folds. I have now had half a hundred of these cases in all stages of their development and have never found one in the folds of the broad ligament. This has been the experience of my brother in now nearly 150 of these cases, with many of which I assisted him; nor have either of us ever seen a case of hematocele in all our work.

This patient has made a most satisfactory recovery. As she recovered from her accident and the operation, her mental condition constantly improved so that at the end of ten days her mental condition was restored. I have seen the symptom of anxiety and fear amount to terror of approaching death so that some one had to be at the bedside to constantly assure them that all was going well with them. I had one case that this condition lasted for ten days, with every other symptom the most favorable. This patient cleared up as if a veil had been removed, and was as bright and happy as she was before miserable and unmanageable.

The child in the case just reported was in its own amniotic sac. I have seen three extra-uterine pregnancies at term, or so nearly that no one could say they were not. The children were all delivered alive but two of them only lived for a short time and the other is living and now over 4 years old. They were all in the amniotic sac and the head of one was wedged up under the ribs. I do not believe that an extra-uterine baby can live any great length of time in the free peritoneal cavity. Those that do and go on developing have been forced through the rent in the tube and encapsuled in the amniotic sac with sufficient attachments. If the rupture in the tube ceases to bleed, the pregnancy goes on to term or operation to the death of the child or the mother, or both, more frequently both.

THE VAGINAL ROUTE IN OPERATION FOR RUPTURED TUBAL PREGNANCY.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY J. WESLEY BOVÉE, M.D.

GYNECOLOGIST TO COLUMBIA AND PROVIDENCE HOSPITALS, AND CLINICAL PROFESSOR OF GYNECOLOGY IN COLUMBIAN UNIVERSITY. WASHINGTON, D. C.

Ruptured tubal pregnancy has been so forcibly kept to the front during the past fifteen years, that many of the profession have been led to think it is a condition in which, without exception, the life of the individual suffering from it is in great danger. We are obliged to believe it is not so dangerous in many cases, and that quite often it escapes attention either from the little discomfort caused by it, or from the physician failing to realize the condition and procrastination allowing the absorption of the escaped blood. This latter variety can not include a very large percentage of cases however, or it would more often be found as a complication of other forms of pelvic disease. We have reason to think also, that occasionally Fallopian tubes are ruptured by over-distension from blood, not due to pregnancy, but mistaken for that condition. We have recently had such a case in our own practice.

It is not the purpose of this paper to deal extensively with the general subject of ruptured tubal pregnancy, but to mention particularly the variety best operated on through the vagina. It is that special variety in which the hemorrhage has not been the most severe, has been stopped by the outer pressure of the lost blood and in which the omentum, either alone or with other structures, has formed a barrier to its progress upward into the abdominal cavity, that we think can be best operated for through the vagina.

It manifestly would not be available to select the vaginal route to control hemorrhage from an ovarian artery, or to remove from the abdominal cavity a large amount of free blood. But for those cases in which hemorrhage has stopped and the free blood has remained in the pelvis and is retained there by a petition from nature, no other route is as safe, quick and efficient as the incision through the roof of the vagina behind the cervix. While this is not the only variety of ectopic pregnancy in which this route is satisfactory, we wish to limit our remarks to this one kind.

The clever work of Howard Kelly, Miller of Utica Reynolds and others in this operation, is well known and leaves very little to be said concerning the technique of the operation. The paper that Kelly read

before the American Gynecological Society last year, mentions thirteen cases operated on in this manner with but one death, and that one not due to the operation *per se*. He has given in his paper the precise details and steps of the operation as well as the dangers of it, and we can only endorse his description. We have not found it necessary to continue the gauze packing as long as he recommends, and our patients have been allowed to sit out of bed about two weeks after operation, and to walk about a week later.

The difficulty concerning this method of operation is in differentiating the cases to which the vaginal route is applicable from others that demand abdominal section. We must be quite certain the loose blood is in the pelvis only. Of this we can never be absolutely certain, and for that reason we should be prepared for abdominal section in all cases of diagnosed ruptured tubal pregnancy that are to be attacked through the vagina. Lest valuable time be lost by attempting the vaginal operation first, in cases requiring laparotomy, considerable care is necessary in the physical examination of the cases. A careful examination through the abdominal walls is not sufficient. Vaginal and rectal explorations are also necessary. By all these methods we can be very certain as to whether a complete operation through the vagina can be made. And yet, in our last case of ruptured tubal pregnancy we made the mistake, and had the chagrin of being unable to remove the larger part of blood through the bulging cul-de-sac of Douglas, and had to do a section above. Kelly has called attention to the absence of hemorrhage during and after the vaginal operation. He has also invited us to notice that removal of pelvic viscera is not so common in the vaginal as in the abdominal operation for ruptured tubal pregnancy. This may or may not be advantageous. It is quite possible that Fallopian tubes that have produced tubal pregnancy and have ruptured, may be of future benefit to the patient. *Per contra*, may not their retention be a source of danger to the life of the individual, either of repeated tubal pregnancy or of sufficient diseased condition to cause future prolonged misery of that life, or even worse. This matter is still *sub judice*. On the whole, the writer feels that it is better to favor the course of leaving as much of the pelvic organs as possible, and to allow these organs an opportunity to be restored to a functioning condition.

Nature sometimes does wonderful things in this direction and we should allow her the necessary opportunities. We can feel sure the tube has recently been permeable else it could not have been pregnant. The writer has done six cases by the vaginal route, all of which have promptly recovered, and in none of them has any severe pelvic trouble followed. We should also bear in mind that many of these patients are in a condition so bad that they stand mutilation very badly, and therefore should not be made to bear any traumatism that can possibly be avoided.

The histories of the writer's cases are as follows:

Case 1.—Mary, colored, 23 years old, was referred to me and sent to Columbia Hospital Sept. 17, 1894. Her history was as follows: She had been married two years and was said to have had two abortions, the last of which had occurred Aug. 15, last, and was of a fetus of six weeks' development. As her menses were regular she was sure she had been pregnant in August, but the doctor told me, after careful questioning, that he had been called after the fetus was supposed to have been passed, and she was yet having considerable low and pelvic soreness. She had not been well since the so-called miscarriage, and had been flowing at intervals during the interim.

An examination revealed a slightly enlarged uterus, high and

fixed anteriorly; abdomen prominent, a firm swelling in the right inguinal region that extends down behind the uterus to half way down the posterior vaginal wall; here it is boggy to touch and has the feel of an abscess pointing to open; the lowest point of the accumulation is thought to be most fluid. From the history, ruptured tubal pregnancy was diagnosed, but the physical examination led us to also suspicion the presence of pus; this was added to by the patient telling us she had been having chills and sweats.

Three days after admission the abdomen was opened and dense adhesions to the abdominal wall found; the pelvis was filled and the color of the tumor indicated blood rather than pus; closed incision and placed patient in lithotomy position. The soft lowest point of the mass was opened through the vagina with scissors, and through the opening escaped a quite large quantity of dark, fluid blood. The opening was enlarged and about two quarts of blood clot, fetal membranes and fluid blood removed. The cavity thus made extended behind and to both sides of the uterus and up to above the sacral promontory. It was irrigated freely and drained. Both appendages were found enlarged and in the adhesions, but were not interfered with in any respect. Menstruation occurred normally two weeks later while in the hospital, and on October 25, a small mass was yet present on either side of the uterus. However, as she was feeling very well and had no pelvic pain whatever, she was sent home to return if trouble occurred. The husband of this patient during the past winter told us she has had no pelvic trouble since.

Case 2.—Mrs. B., white, mother of two children, the youngest being 5 years old, was seen in October, 1895. She had not missed a period, but from various symptoms she suspected pregnancy and abortion, as she passed some membrane from the uterus, accompanied with great pain and some hemorrhage ten days before. An examination found the uterus slightly enlarged and softened and the cervical canal patulous. An examination demonstrated the presence of a slightly movable and nodular mass behind the uterus and ectopic pregnancy was diagnosed. The same day she was etherized and the uterus explored. It was found empty, but three inches in depth. The pelvic mass was now opened by a small transverse cut through the vaginal wall behind the uterus and its contents evacuated. It was principally coagulated blood and a small amount of membranes; a tubal cast of blood was removed; no fetus was found. As both appendages were high and adhered, I did not attempt to loosen or remove them. The sac was irrigated with boiled water and packed firmly with iodoform gauze.

The packing was removed next day and the cavity irrigated; no evidence of hemorrhage was present and no packing was inserted; vaginal douches of 1 to 5,000 corrosive sublimate solution were daily employed for nearly three weeks, when she was considered well.

Case 3.—Mary C., white, single, 23 years old, was seen at her home June 8, 1896. She had missed one period but seemed to attach no significance to that fact, pretending to have gotten her feet wet during her last period. She was very pale and suffering from severe pain in the pelvis and rectal tenesmus. It was only after considerable difficulty that her consent to a vaginal examination was secured. Upon introducing the finger into the vagina it was found to be quite capacious and the cervix slightly lacerated on the right side. Behind the slightly enlarged uterus was a boggy tumor that did not seem to extend much above the symphysis and was most marked on the left side. Upon withdrawal of my finger it was found to be covered with blood. She then acknowledged she had been treated instrumentally by an abortionist, fearing she was pregnant. This had occurred a few days before, after which, on reaching home she had gone to bed on account of severe cutting pains through the pelvis; this was soon followed by a gush of blood from the vagina, and bleeding had continued at intervals nearly all the time since.

Next morning she was chloroformed and a small opening made into the mass behind the uterus through the vaginal vault. A few ounces of thin blood and some clots poured out through this opening and a finger removed more of the same material, together with some shreds that resembled fetal membranes, and felt a roof to the cavity. The left tube was found to be low, about an inch in diameter, and in its wall was found a small opening, through which was felt protruding thin membranes. These were pulled out, and as no bleeding seemed to be going on the sac was washed out and packed gently with iodoform gauze. She made a perfect recovery and was out of bed on the fourteenth day. No fetus was found, but to the naked eye the character of the membrane was unmistakable.

Case 4.—L. L., colored, 22 years old, married, admitted to Columbia Hospital Sept. 20, 1896; had had two children, the last two years before and no abortion; menses began at 18

years of age, were regular, of fair quantity and slightly painful. The last two periods had differed however, the first being very scant and of short duration, while the last had been continuous during the four weeks previous to admission. She complained of severe pain in the lower part of the abdomen and of great weakness. An examination revealed blanched mucous membranes, great emaciation, a very frequent and small pulse and rapid respiration. A mass was found extending from the pelvis behind the uterus, upward about 7 cm. above the pubes, very sensitive to the touch and slightly fluctuating. The uterus was found to be slightly enlarged, fixed anteriorly and above its usual plane. The lower part of the mass was quite soft and encroached on the vagina.

September 24 vaginal puncture was made and two liters of solid and fluid blood with fetal membranes evacuated. Free irrigation of the cavity was done and as no bleeding was present, nothing further was deemed necessary. The left appendage was found very much enlarged and ragged, but was not disturbed but packed for a few days with iodoform gauze. Two weeks later she sat out of bed and was allowed to go home one week later, though the left tube was still enlarged.

Case 5.—Mrs. — had had four children and one abortion, but during the four years previous to this illness had not been pregnant. She had missed one period but did not consider herself pregnant, as no symptoms of her former pregnancies had been present and menstruation had not been regular. She had been working very hard one day arranging furniture, and was uncomfortable on going to bed. During the night she awakened with great pain in the pelvic region and felt very faint. Thinking she had worked too hard and that it was necessary to rest, she did not arise in the morning. Later in the day she felt cold and chilly and sent for the writer. I was absent from the city for the day and she did not call another physician, and did not send again for me until two days later. On Sept. 28, 1896, an examination revealed the uterus to be high in the pelvis and to the front; behind this in the cul de sac was a mass, that resembled a pus tube ready to rupture into the vagina. This sac was mistaken for a pus collection, and later in the day, with the assistance of her husband, she was chloroformed and the sac opened through the vagina. To my surprise no pus came away, but instead about eight ounces of fluid and coagulated blood. As the top of the sac seemed to be firm and the appendages could not be easily palpated, they were left undisturbed and the cavity emptied of clots and a material resembling early fetal membranes. The cavity was quite firmly packed, as there was a slight tendency to hemorrhage. The cavity was again emptied on the third day and lightly packed. She made a good recovery.

Case 6.—Mrs. H—, white, 27 years old, seen in consultation at Chevy Chase, Md., January 7, 1897, with Dr. E. A. Sellhausen. History: Married one year, menstruated regularly until November 15, when flow not appearing at time took a box of Chichester's pennyroyal pills, twenty in number, during three days, and on the 24th of that month began flowing profusely and with extreme pain. This was the first painful menstruation she had ever experienced. The pain was so severe that she collapsed, and it lasted all night and well into the next day. She remained in bed several days, suffering with vomiting and great exhaustion. At the time I saw her the pulse rate was but 96, and feeble, and the temperature 102. The uterus was slightly enlarged and pushed high to the left and front by a mass to the right that was slightly movable and fluctuating; it was rounded and, according to Dr. Sellhausen, gradually increasing in size. Its contents were thought to be blood from a ruptured tubal pregnancy, or pus. Advised operation, and as conveniences were not at hand it was thought best to move her to a hospital, which was done the next day, after her temperature was found to be 103 degrees. January 9 opened through vaginal wall into tumor and evacuated the cavity that extended across pelvic cavity. Still higher to the right was found a cyst about three inches in diameter that was thought to be an ovarian cyst and was evacuated as well. Irrigated with normal salt solution; after removing considerable debris that was thought to be fetal structures, packed with gauze. The pulse fell from 118 on the morning of the operation gradually to normal on the fourth day, and the temperature took a similar course from 103.5 degrees. She made an uneventful recovery and left the hospital within three weeks.

Conclusions.—In concluding we would urge:

1. That the vaginal route is preferable for operation for ruptured tubal pregnancy when the hemorrhage has ceased or is slow, the escaped blood limited to the pelvic excavation, and especially if a limiting diaphragm has formed above it.

2. That the vaginal route is freer from shock, is less liable to permit infection and furnishes better drainage.

3. That there is less liability to the removal of the adnexa than when the abdomen is opened.

4. That the period of convalescence is shorter and devoid of many of the usual complications of abdominal section.

1404 H Street.

VAGINAL SECTION.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LEWIS SCHOOLER, M.D.

DES MOINES, IOWA.

By the term section is meant an ample opening for the extraction of the fetal membrane, as well as the fetus itself, if present. To Recamier is awarded the priority, although unintentional on his part. He, no doubt being impressed with the teaching of the day with reference to a hematocele, which was, but a short time ago, the same as the teaching in regard to peritoneal and intraperitoneal affections. To see why this should have been so one has but to recall the unfavorable statistics with reference to many surgical affections. Lister had not then promulgated the advantages of asepsis and antisepsis. Bacteriology had not then become a science. In fact, the profession was far more ignorant regarding the causes of disaster than they are now.

The science of diagnosis of pelvic troubles was crude in the extreme. Crude for lack of accurate pathology; and while the strides toward accuracy in this respect have been great and rapid, the student of twenty years ago must often feel chagrin when he recalls how much of what he then called knowledge but now knows that it was not in reality useful knowledge, for the advancement of the age has forced him to discard it for the reason that all of our pathology was obtained from the dead subject. Today clinical observation with operations during all stages of inflammatory processes, from the earliest to the latest, has furnished the pathologist with an abundance of material and has also familiarized the operator with the microscopic aspect, which of itself is of untold value.

Two thousand years of empiricism and conservatism had accomplished little or nothing. Human suffering and surgical advancement demanded something more radical and more definite as well as more successful.

Working along these lines, in a variety of cases, principles were evolved that have completely revolutionized the practice of the older gynecologists. The gain to mankind in general and to womankind in particular can not be computed. That errors have been committed by ambitious and unqualified persons is apparent, and may have retarded scientific work in some quarters; in others it had but helped to emphasize the need of well-defined principles.

Most of us were taught that diagnosis of extra-uterine pregnancy was an impossibility and as there was no treatment the diagnosis was no great loss. Today we diagnose with remarkable accuracy, operate without fear and save the lives of many women. We have learned how to prevent sepsis and to control hemorrhage; we have learned that the evacuation of

clotted blood does not retard, but with proper precautions hastens recovery.

Having arrived at this point it would seem that the remainder of the distance to be traveled by the gynecologist was not beset with many difficulties. The route, however, divides right here, and what may be the proper course in one case may be decidedly dangerous in another. The infected and the uninfected, the complicated and the uncomplicated, each requires investigation. Two avenues are open, neither is safe, absolutely, as a routine. The advantages of the vaginal route are to be found in the cases where pus abounds, and where contamination of the abdominal viscera would most certainly occur were the collection attacked by that route. The pus is easily evacuated without the risk of shock, hemorrhage or contamination, and with the minimum of mutilation. Danger of infection from irrigation or mopping is not even a possibility. Breaking up of adhesions, causing bleeding, necessitating clamps or ligatures, is greatly lessened, as in the great majority of cases no foreign body is left in the wound except temporarily. In well-marked uninfected collections, with the membranes adhering to the ruptured tube, it is also possible to remove them with little or no trouble by this method, and when so done the operation, even here, possesses advantages, although it is in these cases that the abdominal method is frequently to be preferred for the reason that when the abdomen is opened the placenta may be safely removed and the hemorrhage controlled. The ligation of all bleeding vessels is done under the guidance of the eye. The operation is short and should not be followed by shock or secondary hemorrhage. The latter is an accident which sometimes occurs after the vaginal operation, requiring a laparotomy at a later date, as happened in one of my own cases. Circumstances of this kind have induced operators to recommend and to practice being prepared to make a laparotomy in the same case where the vaginal method fails or is unsatisfactory. It may be said, however, that where the vaginal wall is incised and irrigation and drainage used nothing is sacrificed by the operator. That the generative function is unimpaired, save in so far as it is interfered with by the cause which requires surgical interference; whereas by the abdominal method laceration and ligation may necessarily cause the sacrifice of an ovary or a tube.

Adhesions of intestines to uterine tube or ovary may be greatly enhanced, while by the vaginal method it would not be at all influenced, this being, in some cases, of inestimable value afterward. It is urged by some that hernias are equally as frequent in the vagina as in the abdomen. This I do not believe: though it would not be strange should it occur oftener than it does. Healing by first intention and accurate approximation of incised tissue are not to be thought of in the vagina. Healing by second intention is alone expected and is often delayed and hindered in order to be sure that all the cavity is drained and obliterated, while in the abdomen in all properly selected cases the edges of the wound are carefully approximated and closed without drainage. The peritoneum and the different layers of tissue may be sutured separately, if deemed of advantage, though to my mind it is far from being essential. It is in these cases that we expect the greatest strength in the wall after a section. Where infection already exists or accidentally occurs at time of operation or where drainage

is a necessity, a portion of the wound usually heals by second intention, just as does the wound in the vagina; and here my observation teaches me that the abdominal hernias exceed the vaginal. Ligatures themselves, when of silk, sometimes fail either of absorption or encystation and become a source of infection, locally causing abscesses and sinuses, necessitating an operation for their removal, an operation, too, no less formidable than the first and sometimes with greater danger of infection.

It is within the experience of every operator that the virulence of pus differs within the widest limits governed by age and the character of the germ. Few are there who have not opened the abdomen and found pus in abundance, which after its removal seemed to leave no deleterious effect behind, while *vice versa*, a small or recent collection was possessed of such virulence that no amount of asepsis, by irrigation or otherwise, seemed to lessen its force in the least. Could we determine this in advance it would in many instances be the governing factor in not only the cases we are now considering but with many others with which we have to deal.

The strongest objections urged against the vaginal operation are that it is not a definite operation, that damaged tissue is necessarily left behind and that bleeding vessels are unseen and may produce disastrous results, that the conception does not take place in the tube and that the product is not always found between the folds of the broad ligament, and when found free in the abdominal cavity may even glide beyond the reach of the operator, or if within reach is found to have reached too great development to permit extraction through so limited an opening.

Again, it is claimed in pus cases (and it is certainly admissible to consider them here, as pus sometimes present is a complication and again through mistakes in diagnosis, is found to be the identical condition with which we have to deal), that a cure is not effected and that abdominal section is at last the only source of relief. This is claimed to be the observation of many able operators of large experience.

In other cases it is claimed that a small amount of relief is obtained and the woman suffers on in silence rather than undergo another operation, while the operator classes the cases among the cured. How much of this is true is difficult to estimate. That in some cases palliation is the only result is doubtless true. The same may, however, be said of abdominal operation, not only when performed for this but for many other afflictions. While the more radical operation has the advantage, so far as definiteness is concerned, it is too radical sometimes. Important organs are too frequently sacrificed. The swing of the pendulum is already more conservative and the assertion that it is cowardice instead of advancement will have to be supported by argument and by facts capable of demonstration before the position taken by able and experienced gynecologists will be yielded. Since human happiness is the end sought by all it behooves us all to lay aside all prejudice and carefully record our observations only after a sufficient length of time has elapsed to insure their reliability. Preconceived theories are of no value unless supported by facts, and beliefs are of no value unless they are capable of demonstration.

If after the lapse of time the vaginal operation for extra-uterine pregnancy is found to relieve a large percentage of cases, with safety and dispatch, it will

take its place as a legitimate life-saving operation. If not it deserves no better fate than to be forgotten by gynecologists, and the sooner the better.

Byford has recently reported 162 cases of vaginal section with only five deaths, and three of these cases should not have been operated upon by this method.

DISCUSSION ON THE PAPERS OF DRs. PRICE, BOVÉE AND SCHOOLER.

Dr. J. HENRY CARSTENS of Detroit—These papers cover the ground of extra-uterine pregnancy pretty thoroughly, although Dr. Bovée and Dr. Price do not seem to agree. I think they are really both right. I would not like to say that we should do one operation always. Dr. Schooler and Dr. Bovée admit that when we have acute cases with active hemorrhage, the best thing to do is to open the abdomen, ligate the artery and then we have no trouble. When we have a case like Dr. Bovée speaks of, where the active symptoms have ceased, where the tube has dropped down, has become firmly adherent everywhere, it is reasonable that we should puncture the cul-de-sac, let out the blood and allow the placenta to gradually dissolve and come away with the discharges without much shock or danger to the woman. That is my method of practice. I wish to most emphatically dissent from the doctrine advanced by Dr. Price, that in case of extra-uterine pregnancy which has advanced to the fourth or fifth month, we should not take away the placenta at once. I hold that this is very dangerous and serious and very bad practice. If we have a case of pregnancy only three months advanced, we can shell out the whole thing without trouble, ligate the pedicle and close up the abdomen. When we have a six months' pregnancy with a large sac adherent to the left side of the diaphragm, the hemorrhage we get in such cases is frightful, and the woman is in great danger, in the hands of an ordinary man at least. She would not perhaps be in such danger in a hospital in the hands of Dr. Price, where he has all the facilities, but in the hands of a less experienced man and in a private house, it is dangerous practice, and it has been so proven over and over again. If the records of cases of this kind where men attempted to do too much could be collected, we should find that the mortality is frightful. I know of a number of cases that have not been placed on record. We hear only of the cases that recover. It is better practice in my judgment in cases of extra-uterine pregnancy at the sixth or seventh month to simply open up the sac, take out the fetus, stitch the sac to the external abdominal wall and let the placenta dissolve. If it is done aseptically you will have no trouble. This is the best practice for the average general practitioner who has to do this operation in emergency cases. In exceptional cases the experienced surgeon may safely take out the sac.

Dr. L. H. DUNNING of Indianapolis—In reference to ectopic gestation, I am very much of the opinion expressed by Dr. Carstens, that there is a great deal of truth in the statements of those gentlemen who oppose each other in their methods. Yesterday I stated that it was my privilege to see two old cases which ruptured early, and I saw them four or five weeks after rupture. The history was clear, yet months had elapsed since rupture had taken place. A large hematocoele had opened through the vagina, and the patient made an excellent recovery.

I want to say a word here relative to the experience of Dr. Price regarding broad ligament pregnancy. I believe he has made the statement that he has never encountered a case of broad ligament pregnancy, and that he disbelieves in the existence of this form of pregnancy. I do not believe that he wishes to convey such an idea, and yet we should have this thought in our minds in dealing with every case at full term. Here are two cases which demonstrate beyond peradventure, that broad ligament pregnancies do occur. In the first case, because the picture of dissections made from the frozen subject shows the placenta was attached beneath the abdominal walls between the muscular coat and peritoneal coat. I have myself encountered one case which I operated on two and a half months after labor and enucleated the fetus and sac without rupture, the same as we would enucleate an intraligamentous cyst retroperitoneally. The placental attachment was in the tube. It was three quarters of an inch thick, distinctly separated from the broad ligament covering and might have been removed without trouble. As it was we enucleated the fetus and sac without hemorrhage two and a half months after labor. The only point I contend for is that we must recognize the fact that there is such a thing as broad ligament pregnancy.

STUDIES IN GYNECOLOGY FROM THE SERVICE OF THE WOMAN'S HOSPITAL OF PHILADELPHIA.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY ANNA M. FULLERTON, M.D.

PHILADELPHIA, PA.

My paper does not pretend to be a contribution to the most interesting and valuable subject of surgical gynecology but rather a plea for what may be termed preventive gynecology, to which perhaps we have given too little heed in the past.

Not that I would in any way decry the brilliant and skilful results attained by surgical gynecology in this day, for it is too true that diseased conditions affecting the pelvic viscera very frequently result in the production of organic lesions which induce chronic invalidism and render the functional activity of the generative organs a menace to the health and even the life of the patient. Too often, however, the operator himself realizes that in the removal of diseased pelvic organs he is but cutting away, as it were, dead twigs and branches from a plant which has a worm at the root. It is not a matter of surprise, therefore, that when the same social conditions must continue which have originally caused disease, a speedy recurrence is found of the manifestations of ill health. It has not been uncommon in my experience, after having removed pus tubes for a patient, to have her return suffering from an acute attack of gonorrhoeal cystitis, endometritis or vaginitis. To insure against the recurrence of an endometritis, at least, it is always best I believe in such cases to amputate the uterus at the same time that the appendages are removed.

Practically, the performance of these very radical operations upon the pelvic organs unfit a patient for the marital life, and since two-thirds of all patients operated on for pelvic diseases are women who are or have been married, the decision as to the absolute necessity for any operative procedure is one requiring a very careful judgment.

So largely is the health of a woman affected by her emotions that any cause for unhappiness induced by the changed conditions of her life may seem to make her last state worse than the first. For these reasons it is my ardent hope that we may look in the future to the fuller development of the constructive processes of our art, the making of healthy women.

How rarely do we find in the special hospitals for the treatment of the diseases of women, any tolerance of the so-called palliative measures for the relief of the pelvic disease! Yet there is a time in the development of many of these when they are not beyond the pale of hope. There is no better vantage ground for a study of woman's needs than that afforded by such a hospital as that with which I have been connected for many years, the Woman's Hospital of Philadelphia, with its large obstetric and gynecologic service. Here opportunities for careful study may be obtained, the constitutions and habits of life of patients observed and such investigations made as to cause and effect in the production of disease as can not fail to bring much enlightenment.

In reviewing the records of the Woman's Hospital of Philadelphia, during the time of my incumbency as its physician in charge, from September, 1886 to September, 1896, I found that among nearly forty

thousand cases treated in its wards and dispensary over 41 per cent. were inflammatory disorders of the pelvic organs, mainly septic in origin, puerperal or gonorrhœal; 27 per cent. were displacements with their attendant complications; 14 per cent. were functional disturbances, mainly due to constitutional causes and arrest of development; 7 per cent. were neoplasms and over 10 per cent. lacerations resulting from child-birth.

In making a study of the conditions which might be regarded as causative factors in the production of the graver forms of pelvic disease I analyzed 236 cases of major operations occurring in my own service. Forty-two being hysterectomies, twenty-one ovariectomies, twelve cases of extra-uterine gestation and the remainder chiefly cases of diseased appendages, including thirty-three cases of pyosalpinx.

In 40 per cent. of these the morbid condition seemed to be directly traceable to a puerperal origin; in 15 per cent. there was a hereditary predisposition to tuberculosis; in 12 per cent. a specific taint; in about 14 per cent. simple inflammatory conditions appeared to be the result of exposure or trauma; in 5 per cent. there was imperfect development of the pelvic organs; in 5 per cent. also, persistent uterine displacements; in another 5 per cent. anemia appears to have been the most prominent factor, and in 4 per cent. malignant disease. The facts connected with these figures are in themselves suggestive of the measures to be taken which might obviate much of the suffering. Hospital experience constantly goes to prove that the woman of modern times is inferior in physical resistance to the women of primitive times.

This physical deterioration, although in part the result of the process of evolution by which nature decrees that like shall produce like and that the sins of the fathers shall be visited upon the children, is also the result of an unnatural environment and habits of life which threaten, if persisted in, to result in the extermination of the human race.

The especial manifestation of this inferiority in the growing girl consists in a condition of nerve and muscle atony which greatly weakens her powers of resistance. The pelvic maladies resulting from this condition are arrest of development, displacement and inflammatory involvement to which all weakened tissues are liable on slight cause. Necessarily these conditions tend to disorganize the menstrual life of the young girl and sow the seeds of future calamity. A condition of post-menstrual subinvolution is commonly found which is aggravated after each period of menstrual congestion and results in changes of structure in the tissues of the pelvic organs. The indications, therefore, are for a radical and rational treatment of these abnormal tendencies. I do not agree with the teaching that there should be little local treatment given such cases, nor have I found treatment properly carried out to be demoralizing. The relaxation of the vulvar and vaginal tissues induced by a catarrhal condition of the mucous membranes, as a rule, renders local treatment easy and painless. The use of cocaine in any case renders it quite manageable.

Local treatment is only a temporary aid to the restoration of normal conditions. The most vigilant and pains-taking effort requires to be directed to improving the tonicity of the uterine supports as well as of the muscular system generally, improving the quality of the blood and combating any especial dyscrasia.

The usual tendency to inactivity of the bowels, bladder and skin must be overcome. Before beginning any treatment I insist on such arrangement of the clothing as shall entirely remove all pressure from the chest and waist. This can be done perfectly well without rendering the clothing unsightly or unattractive and is absolutely necessary to the attainment of satisfactory results. In an article written some time ago by Dr. Kellogg on "The Relation of Modern Dress to the Pelvic Diseases of Women," he has admirably shown, by a series of experiments, the effect produced by constriction of the waist upon the mobility of the pelvic organs and on the tonicity of the abdominal muscles and uterine supports. The round ligaments he has demonstrated to be the chief agents concerned in the maintenance of the uterus in its proper position, their power being dependent on the muscular fibers which they contain. Any fixation of the pelvic organs tends in time to produce loss of contractile power in these uterine supports, and as a result we have displacement of the organ or the beginning of a series of ills. The clothing should always be worn sufficiently loose to enable the patient to exercise the abdominal muscles. The removing of all waist bands and the adjustment of the skirts in such a way that their weight is borne by the shoulders facilitates this purpose.

After the matter of clothing has received proper attention I teach the patient how to practice abdominal breathing and give her a series of exercises for strengthening and developing the abdominal muscles. The judicious use of the bicycle is a great aid to overcoming loss of nerve and muscle tone. Even when marked uterine displacement exists I do not prohibit this exercise, but only permit it while the uterus is maintained in proper position by means of tampons or a soft rubber pessary, the presence of which even in the case of falls would have little or no ill effect.

Should a marked catarrhal endometritis exist, it is sometimes well to precede all other treatment by a curettement of the uterus under proper precautions. Such treatment as the above, carried on for weeks and even months with the growing girl has, in my hands, proved fruitful of most excellent results, and has been of great advantage when persisted in even after this period.

The weight of the patient's trunk being borne by the saddle of the bicycle, she can take much more exercise with less exertion than she could if she attempted to walk. In older women, with relaxed vaginal outlet, I have found that I have gained much by teaching them how to introduce a sponge daily into the vagina in such a way as to lift the uterus into proper position. A soft silk sponge of proper size is selected and made into a tampon having a string fastened to it, by which it may be withdrawn. The patient is instructed to keep this over night in carbolyzed water, after having thoroughly washed it out after its withdrawal, with castile soap. Before its introduction, it is anointed with boroglycerid, and as it needs to be carried up in the pelvis to a point farther than the finger can reach, she is instructed how to use a thick glass rod, such as may be obtained at any drug store, to carry it well into the hollow of the sacrum and behind the cervix uteri. The knee-chest position facilitates its adjustment.

The same sponge is only permitted to be used two weeks, when a new one must be obtained. Patients unable to wear pessaries because of peri-uterine inflam-

mation or tender ovaries have found this treatment very acceptable. It is only permitted to be carried out under strict medical supervision.

Unhealthy conditions of the pelvic organs brought about previous to marriage illy fit a woman for child-bearing, and as a consequence, we find the following perversions of the normal phenomena associated with child-birth:

1. During pregnancy, a tendency to the early loss of the product of conception, owing to a diseased condition of the endometrium.

2. When this does not exist, a tendency to the prolongation of the period of gestation, the result of the atonic condition of the uterine tissues and of the abdominal walls, which thus more readily submit to overdistension.

During labor we find dystocia caused: 1. By physical exhaustion, the result of neuromuscular atony, which renders uterine contractions inefficient.

2. By the mechanical hindrances to the progress of labor produced by undue size and ossification of the fetal head, this being undoubtedly attributable in large part to the physical inactivity of women in civilized life during pregnancy.

During the lying-in period we have: 1. The lengthening of the time required for the process of involution, also frequent subinvolution. This condition of puerperal subinvolution, as does that of menstrual subinvolution, predisposes the uterus, upon the action of all causes of pelvic congestion, to take on structural change. A second perverted phenomenon of the lying-in is the imperfect performance of the function of lactation. A third is what may be termed a subinvolution of the abdominal muscles. The effect of this relaxation of the abdominal walls upon intra-abdominal pressure and its relation to prolapses and displacements of the pelvic organs is a matter of great importance.

All these conditions may be averted or modified by judicious treatment. Without dwelling unduly on the methods to be followed, I should like to mention the effect of bicycle riding as persisted in by two patients during their pregnancy. The one who had always suffered considerably from delay during labor, had the shortest and easiest delivery she had ever experienced and a more satisfactory convalescence. The other is still riding her wheel during the last month of gestation. Fearing she might injure herself by a fall I tried to dissuade her from doing so, but after a few weeks she begged me to allow her to resume the exercise, saying that it tired her so much less than walking and prevented her from getting melancholy. Both patients live in a suburban place and hence are not subjected to the accidents so common in crowded streets.

When a contraction of the pelvis complicates the condition of things in a patient of weakened muscular power I give especial attention to aiding the first stage of labor. In the maternity wards of the Woman's Hospital I found about 14 per cent. of the patients to have contracted pelves. Including among abnormal cases those of faulty inclination, the number reached fully 20 per cent. This is perhaps owing to the large proportion of foreigners delivered in our obstetric wards. The generally contracted pelves were found to almost double the number of simple flat pelves. The average contraction was not of a high grade. In the simple flat pelves the conjugata vera varied between 8 and 10 cm; in the generally contracted between 6½ and 10 cm.

The management, *par excellence*, of moderately contracted pelves is, to my mind, the induction of premature labor. The advantages of premature delivery to the mother are owing to the diminished head pressure; hence the rare occurrence of lesions of the genital canal. I have rarely found it necessary to induce labor before the thirty-sixth week. The aid of the *couveuse*, or hatching-cradle, is very appreciable in the management of premature infants in our maternity. The fetal mortality from all causes during the period covered by my investigations was 4.3 per cent. On the occurrence of uterine inertia during labor, when it could not be overcome by suitable tonics, artificial delivery was resorted to, the presenting part not being permitted to remain stationary at any one point long enough to endanger the maternal tissues by pressure.

During the lying-in, when the lochia rubra persisted for a longer period than was normal, I made an examination to discover the cause. Was there a tendency to uterine malposition, this was kept corrected. A possible hypertrophied condition of the endometrium treated by gauze packing or gentle curettage, which served also to stimulate uterine contractibility. Hot douches were employed and the patient kept in a reclining position longer than was usual. Difficulties with regard to lactation can largely be met by a judicious management of the patient, especially with reference to diet during pregnancy.

The methods just described have proved most satisfactory in our hands in the management of the obstetric work of the hospital. The maternal mortality was less than 1 per cent. About 19 per cent. of the cases required operative interference at full term. The operations included Cæsarean section, the Porro operation, symphysiotomy, forceps deliveries, versions, the management of breech deliveries, craniotomy, embryotomy and the induction of premature labor. I have found in my work that whenever I was able to reach a woman's understanding, getting her to co-operate with me in the measures intended for her relief, I have had little difficulty in carrying such measures into effect. I therefore believe that it is in the education of women to a proper appreciation of physiologic laws and of the virtue and dignity of true wifehood and motherhood as controlled by these laws, that we will find the most powerful factors in the work of reform which we hope may result in her physical restoration and in the production of a healthier generation of human beings as her offspring. At the close of a lecture given by myself recently on the subject of personal hygiene, to a large class of young ladies in one of our fashionable schools, I had a striking illustration of this. One young lady among several grouped around me said most earnestly: "Doctor, if you have been doing everything all wrong before the age of 20 is there any chance for you to be set right afterward?" I would close with a query addressed to the members of this Section of the AMERICAN MEDICAL ASSOCIATION: Do we as conservers of the health of women so influence the education of the young men and the young women of our day as to teach them how to live for healthy parentage.

DISCUSSION.

Dr. HOWARD A. KELLY of Baltimore said in regard to the contagious diseases, such as typhoid fever, diphtheria, etc., that we have learned a great deal in the way of prevention, and could readily prevent these diseases if matters were entrusted to physicians entirely, but politics entered here and our municipal authorities made scientific discoveries more or less

futile in this country. In the matter that Dr. Fullerton had brought before the Section today, it was in the hands of physicians to mold very largely the future generation, to carry out those plans which we know will result in the prevention of disease, and in producing better women and a better race in the next decade. This subject had for a long time been prominently before his mind in connection with gynecologic work. It was a question which confronted him almost every day of his life. Prevention might be classed under two heads. In the first place, prevention which anticipated disease. In the second place, prevention which attacked disease in its earlier stages and prevented graver consequences, such as death, or the necessity of graver operations later. Under the head of anticipation he classed the treatment of the young girl, saying her education began with her mother or in the cradle. The education of our girls was in his opinion largely wrong. They were confined too much; they did not get sufficient exercise, and at the developmental period the abdominal corset came in. He has difficulty with his patients on account of wearing corsets. The corset prevents proper expansion of the chest, and in doing this it likewise prevents the proper development of the abdominal walls. Then, too, in the line of prevention he would urge on the profession at large painstaking attention to all symptoms. Physicians in general were too apt to pass over what seemed to be slight symptoms in women. Anything which did not cause a great deal of discomfort they readily overlooked, and sooner or later the woman came back, when the physician was forced to examine her. Discharges should be carefully investigated, notably excessive hemorrhage or lochial discharges, and if serious, treated. Pain, if persistent, should be investigated and a minute painstaking examination made under an anesthetic, if necessary. Another important means of prevention was cleanliness in caring for obstetric patients. The physician could not do better than to go to every case of obstetrics with a white suit on, not that the suit itself did anything in particular, but it impressed on the physician that the attitude toward the patient was different from that which he holds to any of his other work. Furthermore, it was of the utmost importance to observe greater caution in personal cleanliness, in scrubbing and cleaning the hands, etc., and in this connection the kind of scrubbing brush used in most clinics in Philadelphia and other cities was little better than a wash rag. Soft scrubbing brushes were worse than useless, and surgeons were deluded into the idea that they were doing something with nothing. With reference to gonorrhoea, which is a frightful source of many ills, we needed better morals among men; we wanted the same rules for men as for women. Both should be treated on the same principle. When we give our sisters the same rights of license and indulgence that were given men we would have less ills to complain of and fewer diseases to treat in married women. An important preventive, then, of disease was morality.

Dr. WILLIAM A. FISHER of Philadelphia said that Dr. Fullerton's paper indicated that the gynecologist should be a good all-around practitioner. Disordered conditions of the pelvic organs did not always depend on diseased conditions of those organs, but in some cases on disordered conditions of the liver, of the blood, of the heart and so on, so that it was necessary to bear in mind as regards the future dependence of organs the fact that in woman the pelvic organs dominate her whole being. We should consider in the study of symptoms connected with the pelvic organs the temperament of the patient, whether or not she is of the lymphatic, nervous or plethoric type. All these had an important bearing on symptoms in pelvic troubles. One woman with a slight retrodisplacement of the uterus might suffer excruciating pain, while another with a decided retrodisplacement would suffer but little, simply because of the difference in the nervous organization of the two women. Exercise is very important in the treatment of disordered pelvic conditions. By judicious exercise we cause an increased amount of blood to the surface and body and relieve congestion of internal organs. The circulation in the pelvis is largely carried on by respiration and inspiration, and during the act of each respiration and inspiration we have a rise and fall of the pelvic diaphragm and with it maintenance of the pelvic structure. In order to keep up proper pelvic circulation it is necessary for women to have their clothes loose about their waists. Furthermore, in so far as the uterus is concerned, we know that women are unwell about one-fifth of the time and they do not take extreme care of themselves at this particular time. I refer to the time of menstruation. They expose themselves to cold and damp. This brings about chilling of the surface and internal congestion, and at the time of menstruation may give rise to dysmenorrhoea, and this frequently repeated may result in the production of pelvic disease. The skin, as a very

important excretory organ, is often forgotten by practitioners in general. The skin in its active condition throws off excrementitious products, and when it is in an inactive condition we have the accumulation of toxic materials that should be thrown off by it. If there is pelvic disease existing or a tendency to it we may have a localized expression of this want of activity of the skin in certain conditions of the pelvic organs, etc.

Dr. MILO B. WARD of Kansas City, Mo.—I would like to ask Dr. Fullerton the effect of bicycling on girls.

Dr. FULLERTON—Unless there is considerable pelvic disease I consider bicycling a great aid to the development of the muscular structures of girls.

Dr. WARD—How do you account for the fact that women who ride bicycles can not walk: that is, they are too weak to walk?

Dr. FULLERTON—I do not think this would obtain after they have used the bicycle for some time. There is really less fatigue from using the bicycle than in active walking. After the muscular system has been developed, I believe a woman who learns to ride a bicycle can walk farther than her sister who does not ride a wheel.

Dr. A. H. TUTTLE—I would like to ask Dr. Fullerton if she prescribes any regulation dress for young ladies who use a bicycle?

Dr. FULLERTON—Always. I do not permit them to ride a bicycle with a corset.

Dr. A. E. MILLER of Boston—I would ask Dr. Fullerton if she has ever met any bladder difficulties arising from bicycle riding, as for instance, irritable bladder?

Dr. FULLERTON—Only in those cases where the women have not selected and adopted a proper saddle. If they use an improper saddle it will cause discomfort in more than one way. If proper attention is given to the performance of the functions, to evacuation of the bladder and bowels, to dress, etc., I do not believe any injury can result from bicycle riding.

THE INJURIES OF PARTURITION, THE TIME, METHOD AND REASONS FOR THEIR REPAIR.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY A. H. TUTTLE, M.D., S.B.
CAMBRIDGE, MASS.

In May, 1893, I was called to Milford by Dr. Wm. J. Clarke, to repair a complete rupture of the perineum, which occurred in the practice of a neighboring physician one week before. I found the levator ani and both sphincters torn, with liquid feces coming from the rectum, while pus flowed from the wound. The condition was such as seemed to render primary union impossible, but by means of washing, scraping refreshing and defining the ragged edges of the skin and mucous membrane and bringing the denuded surfaces into close apposition with buried sutures, the result was perfect with first intention throughout. The long delay after the accident, combined with the condition of the wound and the subsequent perfect result of the treatment, brought up a line of thought which I have since pursued with advantage in the primary repair of the injuries of parturition.

The immediate repair of the perineum has been laid down imperatively as the best procedure, and at present is the practice of competent physicians; in fact its neglect is considered almost criminal. But no one knows better than the operating surgeon and gynecologist the incompetency of the average obstetrician to make a satisfactory repair of the injuries peculiar to parturition, except where they are of minor degree. Their imperfect results are perhaps due to the indifference for careful technical work, often arising from a tendency to make light of an injury that they assume may cast a reflection on their ability as an obstetrician. The patient is rarely moved from her bed; the

parts often only seen by bad light or not at all; disinfection is imperfectly carried out, and the work is faulty: that is, the edges of the skin may be brought carefully into apposition, but no attention whatever is paid to the mucous membrane, the various muscular structures, or the more deeply situated and perhaps most important injuries of the case.

In my opinion a primary repair of the parts requires greater skill and better surgical technique than a secondary operation. If the injuries are extensive, it is worse to do an imperfect operation than to leave the case alone, as it opens up the road for severe infection.

It is not common practice to make an inspection of the cervix until ready to discharge the patient, and primary repair of its injury, although it has been advocated and executed for several years by J. Price of Philadelphia, is not the usual custom.

If a deep cervical tear is not repaired it is a cause of infection, and a common means of subinvolution of the uterus with subsequent displacement and catarrhal inflammation.

With neglect of the cervix comes also an indifference for the treatment of deep vaginal tears, and in the majority of cases they are entirely overlooked.

Unless one is in the habit of examining the tears of parturition carefully, they can little realize their extent and the possible dangers they afford. The pelvic cellular tissue and the region of the broad ligaments are exposed to external infection in two direct ways, both of which are common. One is by a deep tear of the cervix passing beyond the cervicovaginal junction; the other is by a tear of the vagina which extends from a point in the roof or side and runs parallel with the urethra close to the neck of the bladder, to terminate internally near the cervix. These tears are often bilateral, with one side a little greater than the other. I have seen this particular vaginal tear so extensive that it reached the outside of the vagina, where it ended in the prepuce of the clitoris, thus running the full length of the vagina. If an inspection is not made in a proper manner this injury is entirely overlooked, and unless a careful repair is made the wound heals by secondary intention. This injury I believe is one of the most frequent causes of a form of pelvic inflammation represented clinically or by comparatively simple phenomena, but which becomes a source of great after-trouble owing to the adhesions about the ovaries and a tendency to anchor the uterus in an immovable manner and in an unnatural position. In a number of ovariectomies I have found the adhesions so great as to make the removal of the ovaries extremely difficult, yet there was absolutely no sign of tubal disease, and I have been at a loss to account for their development. In most of these cases there was a history of difficult labor and generally the use of forceps. After careful examination of many of these deep tears, through which I have passed my finger into the pelvic cellular tissue as far as the peritoneal covering, I feel that these tears offer the most rational explanation for the adhesion so common about the pelvic organs. The adhesions of the uterus in the vagina so frequently found during the repair of the cervix where the organ is placed high, can not be drawn down to the outlet but is firmly fixed to one side with a mass of hard scar tissue, are formed from the improper or neglected treatment of these tears. The form of puerperal septicemia which arises from these tears should be carefully distinguished and the fact recognized that the infection in the peritoneal

space is direct and not by the way of or involving the uterus.

The perineal tears usually extend upward through the vaginal membrane that lines the lateral sulci, are rarely medial, owing to the thickness of the membrane in this region (the posterior vaginal column), and if the tear is bilateral, the corrugated membrane or raphe is raised in the form of a thick flap with the base *upward*. The tear along the lateral sulcus often reaches to a great depth. Emmet has described a tear where this posterior column is torn across in a deeper situation near the cervix and the lateral tears arising from within and extending outward, make a flap of the floor tissues with the base *downward* near the outlet. This flap curls up and heals in the form of a crumpled mass, which from its situation gives the appearance of a rectocele. I have seen but one example of this tear and believe it must be a rare accident.

Besides the tears in the vault already mentioned, are those which involve the bladder and urethra. They are very infrequent. The accidents of this sort, which in times past came from pressure necrosis, are now very rarely seen owing to the timely use of forceps. I believe that most of the cases of vesicovaginal and vesico-urethral fistulae occurring at the present time are the results of forceps extraction of an occipito-posterior presenting head or breach, although my experience in these cases has been very limited. The perineum is usually well torn, and there is a median tear of the vagina above involving the deeper organs, which has a clean appearance as if cut by a blade of the forceps. The involuntary and constant flow of urine with every change in position very soon attracts the attention of the patient to the accident, and the physician is informed of it without any great delay.

The skin tear of the perineum is more or less straight, sharply defined and regular, extending in severe cases from the fourchette or hymenial ring to the mucous membrane of the rectum.

The rectal tears are rarely deep. Both sphincters are at times torn, and in all important lacerations the levator ani is injured. Frequently the sphincters are partly torn from their sheath and appear as a nipple-like projection half an inch in diameter and about an inch in length. There is a temptation to cut off this protrusion of muscle at the time of repair, but I think it unwise; it should be restored intact.

Beside the above tears, which I believe constitutes all that are of any magnitude, there are often innumerable smaller ones like a crack in the tissue, short and superficial, and rarely severe enough to require special attention.

From a practical experience with all the injuries of parturition above briefly described, I believe that I am justified in making the statement, that it is absolutely wrong for the obstetrician to attempt to repair the injuries of a severe labor, where the lacerations are extensive, without competent assistance and the proper means at hand as regards instruments, disinfection, etc.; or to do the work in an incomplete manner by simply sewing the muscles and outside skin together so as to give a fair temporary appearance exteriorly, which is foul within.

As I know from experience, that the parts can be satisfactorily treated within several days from the time of the accident, then the question of time is no excuse for indifferent treatment, nor the fact that the attending physician is worn out by an exhausting

labor and perhaps very nervous about the issue. The fact that a primary repair will prevent a great many conditions which later require operative treatment, often of a capital magnitude, is sufficient reason why one should treat the case carefully from the beginning. The mere fact of a difficult labor condemns the patient to a period of lying-in, which is equivalent at least to the period of repair, and is a period which, in the lifetime of many women, is the most opportune for the treatment of her trouble. It is a positive fact that in many cases the period of convalescence would be greatly shortened by complete primary repair. In consideration of the above facts, I will propose the following deviations from the established custom, as giving a most satisfactory result immediately and as a preventive measure for many of the pelvic troubles of women.

When the injuries of a labor consists of more than a simple tear that does not involve the sphincters, the placenta and blood clots should be expressed from the uterus; a full dose of ergot administered; a pad rung out of bichlorid solution applied to the perineum; and then the patient should be given time for rest, unless it so happens that every measure for a repair of the parts has been previously arranged, competent assistance is at hand, and the patient is already under the influence of an anesthetic that was administered during her delivery. If it is a simple tear, a few stitches taken immediately is all that is necessary.

The duration of time that the surgical repair should be delayed will depend upon the different circumstances peculiar to each case. At least one hour should be given for the rest of the patient, and for the reason that by this time the full effect of the ergot will be realized, which may be of some use in counteracting any tendency of the anesthetic to relax the uterus. If the injuries have occurred at night, it will be better to wait until the next day, when there will be good light to work in, and if the obstetrician is incompetent to cope with the case, or his patient is far removed from help as in the country, it may be necessary to wait longer until the proper assistance is procured. I have been unable to discover any special advantage in the time of operating within the first ten hours after the injury. The retraction of the uterus is greater at the tenth hour than at the end of the first, but a little more care is requisite in refreshing the parts. The repair of the cervix is easier at the end of ten hours.

The preliminaries for the operation should be made in a careful manner: antiseptic solutions should be prepared for sterilizing the wound, the hands of the operator and his assistants, and an irrigator should be filled with the same; the instruments should be sterilized; a table covered with clean linen should be arranged where there is a good light for operating; a smaller table for instruments should be placed near it; a Kelly pad, or similar contrivance, with a pail for catching the irrigation, should be set in their proper places, and means for supporting the legs with the patient in a dorsal position should be at hand. For the repair of the multiple injuries of parturition I am in the habit of using animal sutures entirely, kangaroo tendon and fine catgut. This should be perfectly aseptic.

The etherized patient is placed upon the table so that the parts are exposed to good light and the legs are well supported. The hair about the parts is shaved off and the skin and vagina are carefully cleansed with

soap and water, and finally with a solution of bichlorid. The rectum is dilated and also cleansed in a like manner. Clots of blood, which are usually present in the uterus, should be removed. The parts can now be satisfactorily examined and the exact nature of the injuries determined. The fingers are usually efficient retractors, but metallic ones can sometimes be substituted to advantage. With pressure of the hand of an assistant on the fundus of the uterus the cervix can be readily exposed and the tears, which are usually bilateral, extending toward the region of the broad ligament are easily recognized. They are repaired by closure with an over and over, or an interrupted suture, after scraping the raw surface with a sharp curette to insure union. The suture is exposed on the outside of the cervix but not in the canal, as it is passed just below the mucous membrane. With the closure of each stitch the blood should be carefully washed away with the irrigator and the corresponding parts adjusted with the help of dissecting forceps. In holding the cervix during repair I have found Pratt's rectal forceps of much help.

In closing the vaginal tears there is a simple rule to be carried out: viz., carefully bring together the torn edges of the mucous membrane and muscles that correspond to each other and unite them with sutures firmly and in close apposition, so that the raw surfaces are in contiguity and their exposure along the line of tear reduced to a minimum. This is the principle of the treatment in the case of a simple incised skin wound. The deep tears through the vault can be closed with an over and over stitch taken with a fine ligature, but all the remaining repairs can be easily manipulated and are best treated with buried sutures. If the repair is not immediate the raw surfaces should be scraped clean with the edge of a scalpel or sharp curette. A suture is taken in the tears of the mucous membrane that extend up the lateral sulci, beginning at the deepest point. There is no muscle to be united in this region as many suppose. If the tear is double then use one suture for each tear, which closes the vagina in the shape of a letter W. These sutures are not drawn tight until the other parts are united, because there would be less room for manipulation. The rectal tear is now closed in a similar manner, using very fine tendon and needle, the suture passing only through the muscular coat of the gut. The first suture is taken at the internal angle of the wound and should be placed sufficiently deep that no opening will be left which would admit a leakage of the contents of the bowel into the perineal wound. This line of suturing is carried to a point just above the junction of the skin with the mucous membrane of the rectum, and is fastened so that it is entirely disconnected from the other lines of suturing. By having each line of sutures entirely separate from the other, should infection occur in the region of one it will not necessarily be transmitted to that of another. The deeper layers of the torn levator group of muscles and the transverse perinei are now brought into apposition with a figure of 8 suture and the internal, and later the external sphincters are repaired by simple suturing. As the value of the perineum depends on the perfect condition of these muscles great care should be exercised to bring the torn edges back to their normal position so as to make a good fibrous union. All of the deep sutures having now been placed, the ends of those that close the tears in the mucous membrane which were left unfastened, are

seized and carefully drawn tight. Thus the wound is closed from infection by way of the vagina. If the ends of these sutures are brought out at the upper and outer angles of the tear, in the region of the caruncles then by tying the two ends together the closure of the wound, at the most dangerous point for gaping, is completed in a most thorough manner and at the same time the sutures are fastened. This applies of course to a bilateral tear. There is nothing now left to be done but an apposition of the remaining outer torn portion of the levator ani and transverse perinei and the union of the skin wound, which is easily performed with two or more layers of buried sutures.

If there has been a tear in the neck of the bladder or urethra, the opening in the mucous membrane of these organs should be closed with a fine buried suture of kangaroo tendon passed by the help of a sound in the urethra and bladder, and with great care that no part of the suture extends out upon the mucous surface. The loose submembranous connective tissue can be gathered up with a line of sutures over the first layer to reinforce the wound from leakage. The vaginal tear is now closed in the manner already described. The repair of the bladder and urethra should be done immediately after that of the cervix while there is yet plenty of room to work in.

After the injuries are all repaired the urine is drawn, parts irrigated and a protective suture is passed just above the lower angle of the vaginal introitus through the labia of either side. The two ends of the suture are tied together, bringing the surfaces of both labia into close juxtaposition above the seat of injury. By thus pinching the two lips together the top of the perineal wound is greatly protected from the secretions in the vagina, which can not flow over the line of repair, but must rise higher to pass over the protective suture; and in case the nurse is obliged to catheterize, should she depress the inserted instrument, it would be prevented by the double strand of the ligature from bearing down upon and prying open the top of the perineal wound, one of the weakest points in the repair. This suture can be removed in two or three days and has nothing to do directly with the closure of the perineal injury. In bladder and urethral injuries a catheter should be passed and fastened *in situ*. It is kept here for three or four days.

Results.—If the case is done in a skilful manner, healing will occur by first intention throughout and there will be no constitutional disturbance of the patient except a slight fever of reaction, which is rarely greater than 100 degrees F. It may be criticised that a technical error would lead to a severe infection with great sloughing and danger where so much buried material is used. I must say that the worse sloughing of the perineum that I have ever seen was in the practice of a physician who closed the wound with external sutures, the infection coming by way of the vagina. In my own experience I have had but one complete failure and, recognizing it was inevitable by the fourth day, I again etherized the patient, opened up the wound, cleansed it thoroughly and reunited the parts as before. The case healed after the second operation with primary union. In a number of cases where the work was performed under trying conditions, a small abscess formed in the center of the perineum. This forced an opening and discharged spontaneously, sometimes into the vagina, and at other times through the skin. These cases have all healed

kindly leaving a satisfactory perineum without complications, but the convalescence was slower. The technique must have been faulty in these cases. My worst cases, including vesical and urethral fistulae, have all healed by primary union, probably because the greatest care was taken to obtain an aseptic operation. I have never had a failure in the union of the sphincters.

In my earlier operations on the cervix I practiced the introduction of some foreign body into the uterus for the purpose of draining that organ and in cases of secondary repair where there was extensive removal of tissue to help establish a patent canal. I found the custom an evil one in cases where there was simultaneous repair of a complete perineal location. The cervix in its natural position rests against and is supporting the rectal wall of the vagina, usually an inch and a half to two inches above the introitus. The pressure is received upon the posterior column or raphe, which from peculiar construction is well fitted for the purpose. When the parts are repaired the cavity of the vagina is closely occupied, and any foreign body tends to disturb the natural relation, which in a case of uterine drain produces pressure upon the lateral sulci, where the mucous membrane is very weak and the partition between the lumens of the vagina and rectum thin. In deep tears, a foreign body in the vagina will tend to open the internal ends of the wounds of the rectum and vagina behind the sphincters, making a vaginorectal fistula. This has twice occurred in my practice. In these cases I removed the drain early, as soon as I discovered the accident, kept the vagina clear by douches, and the fistula closed spontaneously. Since giving up this mode of draining I have had no further trouble.

Conclusions.—In my opinion, the obstetrician who today boasts that in his practice he has no lacerations of the cervix or perineum, proclaims to the world his ignorance of this branch of his profession. It is as much the duty of the obstetrician to his patient to see that she is properly repaired, as to see her safely delivered. The public should be educated to the fact that injuries to the soft parts of the parturient canal are often inevitable, and that such injuries only cast a reflection on her professional attendant when their after-treatment is neglected. The physician in whose practice a severe laceration of the parturient canal has occurred, can protect himself in no better way from a legal attack on alleged malpractice, than by calling in assistants, who serve as witnesses, within twenty-four hours of the time of the accident, and repairing properly, or offering to, the injuries which his patient has sustained. There is no better time to repair the injuries of parturition than within twenty-four hours of the time of their occurrence; such immediate repair of the injuries will often hasten convalescence and prevent in many cases, severe pelvic complications. The obstetrician should be educated to do this part of his work in a more careful and thorough manner. The injuries already sustained by a multipara in previous labors should be an incentive, rather than an objection, for the careful treatment of the lacerations of her present delivery, because a repair of her total injuries can be accomplished at the same time.

An early symptom of carcinoma of the esophagus is afforded by decreased flexibility of one of the vocal cords. An instructive instance is related in the *Deutsche Med. Wochenschrift* of November 4.

REMARKS ON THE RELATION OF THE UTERUS TO DESCENT OF THE PELVIC FLOOR, AND TO GENITAL PROLAPSE.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GEO. ERETY SHOEMAKER, M.D.
GYNECOLOGIST TO METHODIST HOSPITAL,
PHILADELPHIA.

As the title implies, it is not intended here to formally cover the field of genital prolapse but to remark upon one phase of it, and to emphasize the fact that the uterus is not the sole offender, but that, in greater or less degree, all the other pelvic organs and tissues are involved to such an extent in some cases that even after the uterus is completely restored to its position, the prolapse of vagina, rectum, bladder and tissues of the pelvic floor continues.

There seems to be, in the minds of some, an idea that the uterus descends alone through a normal tube, the vagina, because of some relaxation of suspending supports above. This idea leads to attempts to cure prolapse by shortening round ligaments alone, by fixation (literal) of the uterus alone to the abdominal wall, or even to the performance of hysterectomy followed by fastening the cervical stump to higher pelvic tissues, while the relaxation, sliding and stretching which have occurred in the pelvic diaphragm are left untreated. Ultimate failure to cure must be the result of this policy. The truth is that in varying degree in different cases, the uterine prolapse is only a part of a vast hernia through the inferior pelvic strait of the pelvis; that in this hernia are involved bladder, rectum, peritoneal pouches in front and behind the uterus, with or without bowel contents; also the muscles and fasciæ of the pelvic floor. All of these structures do not descend to equal degree, but there is a gradual sliding in different planes. The uterus is often forced furthest down by intra-abdominal pressure and gravity, the posterior bladder wall less so, the anterior bladder wall still less so, and so on with each succeeding plane of connective tissue until the bony pelvis is reached. By thrusting up the uterus, this whole prolapsed mass may be made to telescope back, partly into position, but not wholly. No operation can be permanently successful which aims to deal with the uterus alone and does not take into account the sliding planes of stretched tissue and the telescoping movements when the cervix is thrust up or down.

This is best illustrated by the following case, which shows that the uterus may be even higher than its normal place in the pelvis and yet the bladder and much of the vagina be outside the vulva.

Mrs. X., a young and healthy multipara, was referred to me for operation by her physician because her "womb came out," giving rise to chafing and various discomforts. He had made no careful examination, but saw simply a large pinkish mass, the size of the fist, protruding from the vulva, and sent her to me without further investigation. Upon examination I found, indeed, a large genital prolapse outside the vulva, larger than the fist, but it was made up of anterior vaginal wall and bladder in front, and rectocele behind. The uterus so far from being an element in the case was, to the surprise of patient and physician, found to be pregnant six months. It was within the abdominal cavity, having risen normally above the snpe-

rior strait. The cervix was normal in size and high up. Here was a case in which Nature by pregnancy had restored the uterus temporarily to its normal position in the body without dragging up enough of the other elements of the genital hernia to attract the patient's attention. In fact, the prolapse continued. A hundred diagrams or theories could not better demonstrate the position that any effort to cure this woman by any operation for suspending or removing the uterus would be futile unless something were also done to the pelvic floor. The case aborted shortly afterward and is now awaiting operation. What shall this be? First a serious attempt from below to restore, not the perineum but the integrity of the pelvic floor, of the whole pelvic diaphragm. By operating within the vagina, to endeavor to reach with stitches and take up the higher and deeper planes of pelvic fascia and muscle. When the uterus is large and the cervix long or hypertrophied, amputation of the cervix from below is a great help as it is preceded by dissecting off the vagina from the cervix, while the method of sewing shortens materially the vagina and implants it higher upon the uterus, virtually at the same time taking a reef in utero-sacral attachments. In addition I believe that uterine suspension should usually be done, or in very rare cases of enlarged uterus, hysterectomy, but the main effort must be concentrated upon the vagina.

It is of interest, in passing, to note the curious tolerance of this patient to septic influences, no doubt owing to long protrusion of the uterus from the body. She aborted, as has been said, at six months. Her physician found, a few days later, to his horror, that finding herself unable to pass her urine owing to protrusion of the bladder she would take her hands and push everything within the vulva, when the husband with unwashed hands would catheterize her with an instrument which he had bought for that purpose. No harm resulted!

THE INFLUENCE OF OUR SCHOOL SYSTEM ON THE HEALTH AND DEVELOPMENT OF THE CHILD.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. STUVER, M.Sc., M.D., Ph.D.
Member Colorado State Medical Society (Vice-president 1894),
American Medical Association, International Medical
Congress (Berlin); Active Member National
Educational Association.
RAWLINS, WYO.

(Concluded from page 1252.)

Answers to No. 6.—To most persons it may seem that such a question as this is entirely superfluous; that the dictates of humanity and common sense would make such a practice an impossibility. From my personal experience as a member of a school board and as a practicing physician however, I am sorry to say that the practice is more prevalent than I would have believed it to be without a thorough investigation of the subject. Indeed, I am satisfied that even superintendents and principals of schools do not fully appreciate how frequently teachers err in this matter. This can probably be explained, in part at least, by the fact that it is a delicate subject, about which parents do not like to make complaint, and which does not receive the attention and discussion in teachers' meetings that its importance demands. Whatever may be the cause of the practice it certainly exists to a

greater or less extent and exerts a most baleful influence, both morally and physically, on the pupils subjected to it.

If teachers would take the golden rule or Charles Reade's title, "Put Yourself in His Place," for a text and then imagine how they would feel under similar circumstances, in a company of fifty of their fellow teachers, they would be able to appreciate the humiliation and moral degradation caused by such a restriction, and understand the resentment and disregard of authority which the practice produces.

As every one should know, the disregard or failure to attend to nature's calls promptly is the source of many physical ills and may be the cause of lifelong disease and misery. In the first place it may produce chronic constipation, which, as every physician knows, is a regular Pandora's box of evils and may lead to the gravest consequences. The toxins produced by the retained fecal matters are absorbed into the circulation and penetrate to the most remote cells of the body; they poison the blood, poison the brain, lower the vitality of the body and weaken the mind. This poisoning causes headaches, neuralgias, lassitude and malaise, which make work a drudgery and life a burden. It is even asserted by Dana (*vide* JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Jan. 9, 1897, p. 62) "that organic changes in the central nervous system are doubtless due to the absorption of toxic substances produced by microbic processes in the alimentary canal." By clogging the system with effete matters digestion is impaired, nutrition rendered imperfect, and growth and development retarded. The strain on the bladder caused by efforts at retention may lead to paresis, incontinence of urine and chronic inflammatory conditions of the bladder and the irritation and congestion thus produced may cause irritation of the sexual organs and lead to secret vices, thereby not only wrecking the child physically, but morally.

Answers to this question were received from about one hundred respondents. While many could give no definite opinion as to the existence or prevalence of the practice, and many state that they do not believe it to exist, or if at all to a very limited extent, still a large number assert that it does exist, and nearly all are very emphatic in their opinion as to the moral and physical evils resulting from the practice. The following answers indicate some of the views expressed:

Prof. J. J. Allison, A.B., of Boise City, Idaho: Extensively, I think.

Prof. Joseph Baldwin, LL.D., of Austin, Texas: Practically general. Pupils should visit closet at will. Asking is one of the relics of a cruel barbarism.

Prof. J. E. Brate, A.B., of Fostoria, Ohio: Possibly in the majority of schools. *a.* Hurtful, as it leads him to disrespect authority. *b.* Disease of organs involved, constipation, urinary troubles, etc.

Prof. Fred Dick, A.M., of Denver: To too great an extent. *a.* Causes disobedience and frequent loss of self respect. *b.* Sexual weakness, etc.

Hon. A. L. Emigh of Denver: It is pernicious.

Prof. C. C. Emigh, of Fort Collins, Colo.: I can not say, but it exists and is dangerous to moral and physical health. *a.* Engenders anger, deceit and malice, poisoning the mind and soul of the child.

President Chas. W. Eliot, LL.D., of Cambridge, Mass.: I think such barbarous practices are not common. Frequent recesses obviate almost entirely necessary withdrawals from the school-room between recesses. *a.* The child experiences a sense of injustice.

Supt. J. M. Greenwood, A.M., Kansas City, Mo.: Does not exist in any form here. Children can not be turned out to the water-closets like ponies to a watering trough. *a.* Very injudicious, as well as injurious. *b.* Intestinal and urinary diseases.

Joseph W. Mauck, LL.D., of Vermilion, S. D.: If such a monstrous practice is in vogue I am happily ignorant of it. *a.* It would justly beget a contempt for authority. By creating disorder of the physical organs. I should fear it would lead to carnal vices. *b.* General derangement of the system, with special seats of disease in the weakened points of the body. Who can anticipate what ills may not be developed?

Prof. E. B. McElroy, Ph.D., of Eugene, Oregon: In my opinion, there is an oversight in this important particular in 20 per cent. of our schools and I fear there is more of this vicious and ignorant practice on the part of teachers than superintendents and supervisors are led to suppose. *a.* The moral effect is always bad; no exception to this.

Prof. Wm. H. Smiley of Denver: Not at all to my knowledge; a teacher who should do such a thing would deserve instant discharge. *a.* It would certainly encourage lying and deception.

President Irwin Shepard, A.M., Ph.D., Winona, Minn.: I do not know of its existence. I would instantly discharge a teacher guilty of such barbarity.

S. Henry Dessau, M.D., of New York City: I do not know positively, but it does exist. *a.* Bad in every sense. *b.* Constipation and subsequent secondary digestive disturbances and enuresis.

Prof. C. H. Hughes, M.D., of St. Louis: To far too great an extent. Pupils should not be subjected to the ignorance or caprice of teachers in this matter. *a.* Children are often compelled to soil themselves with urinary discharges and are unfit to study when depressed by reflex irritation from bladder and rectum. *b.* Distension of bladder; damage to nervous system; constipation habit; incapacity to study well.

Prof. Thad. A. Reamy, M.D., LL.D., of Cincinnati: Don't know; have never known teachers to presume this way. It would be awful to do so. *a.* Very bad. *b.* Disease of bladder, kidneys, and serious nervous troubles would ensue. Digestion and nutrition would be interfered with.

W. H. Short, M.D., of La Grange, Ind.: It exists to quite an extent here. *a.* Humiliates, causes lack of self-respect, habits of uncleanness, loss of respect for teacher; many effects which might be traced to this as a primary cause. *b.* Incontinence of urine, irritation of bladder, constipation. Children under such circumstances can not think well, and attempts to study lead to bad mental habits. They are apt to have reflex troubles of various kinds. Many mothers attribute colds or catarrhal ailments to child thus deprived of such privilege, owing to chills caused by damp clothing.

Henry Ling Taylor, M.D., of New York: *b.* Constipation and attendant evils, dyspepsia, anemia, piles, incontinence of urine, nervousness, interference with general health.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: I do not know. All calls of nature should be attended to at once, "nor pause, though e'en the king passed by that way."

Prof. Augustus P. Clarke, A.M., M.D., of Cambridge, Mass.: To a considerable extent and much more than is realized by our public benefactors. *a.* It depresses or weakens the moral sense of the child and

serves to implant in him doubts as to the teacher's ability to instruct him aright. *b.* Constipation, headache, eye strain, and in girls anemia, neurasthenia, chlorosis, cystitis and, in some cases, perversions of the sexual system as in amenorrhea, dysmenorrhea and their sequelæ.

Prof. Leonard Freeman, B.S., M.D., of Denver: I do not know. It should not exist at all unless real deception be exposed. *a.* May lead to masturbation through irritation of the neck of the bladder by accumulated urine. *b.* Irritation of the prostatic urethra with coincident nervous phenomena.

Pres. Alfred Holbrook of Lebanon, Ohio: I do not know that any teacher is so unreasonable anywhere. Hourly recesses make restraints unnecessary. *a.* Being entirely unreasonable, it makes all restrictions seem unreasonable and unjust.

Elizabeth K. Matthews of Des Moines, Iowa: Am sorry to say it, but it exists to a very great extent.

Prof. J. A. Larrabee, M.D., of Louisville, Ky.: Does not exist to any extent in our schools. Personal and private hygiene concerns the home training and teachers so instruct our pupils. *a.* Neglect of personal hygiene, either in the schoolroom or at home, is equally deleterious to the moral status of the child. When necessity demands, a modest signal should be given. *b.* The physical effect of delayed defecation or urination concerns all the functions of the body and results in imperfect cerebration, hemorrhoids and, in females, in retroversion of the uterus and chronic indigestion in both sexes.

Answers to No. 7.—This is a very important question and one about which there is a great diversity of opinion. There can be no doubt but that if children could have plenty of outdoor exercise in pure air, surrounded by moral safeguards, and the time now devoted to entertainments, parties and other social dissipation were largely spent in sleep or devoted to healthful recreation or a judiciously selected course of general reading, children would enjoy better health and be better off in every way.

Whether home study will be beneficial or hurtful to a child depends much on the surrounding conditions and the motives or incentives which prompt it. If done through enthusiasm or a love of truth for truth's sake, the results will likely be beneficial; if, on the other hand, the child is impelled to study by the slave-driver's lash or threats of failure and disgrace, the effects will in all probability be injurious. Unfortunately, under our cramming, high pressure methods of education, with its frequent examinations and grand stand plays for public show and approval, truth is lost sight of and children are spurred on and incited to cram, memorize and fill themselves up for examinations and public exhibitions regardless of the permanent effects of such a course. This sort of work keeps the child in a constant state of excitement, worry and anxiety; the brain is irritated, the vitality lowered, the mind weakened and the importance of truth and honesty lost sight of. Under such a system even the brightest and best pupils will lie awake nights and worry over their grades, their examinations and their promotions, when never a thought or care on such matters should disturb them. Nor is this confined to the higher grades of the schools, but also applies to many pupils in the primary grades.

The period of puberty is one of rapid development and growth and makes great demands on the strength and vitality of the child, who as a consequence should

be very carefully protected against undue excitement or anything that will divert the vital forces from the great work which they have to perform.

Dr. Miller (*vide Cincinnati Lancet-Clinic*, Feb. 6, 1897, p. 159), very clearly depicts the condition of the child as follows: "The child fatigues much more readily, that is, his organism is much more quickly depleted and poisoned during the periods of most rapid growth. The average boy has the most rapid growth between the ages of 14 and 16. In these two years he increases in weight by as much as he did during the entire six years preceding the age of 14. At this period of most rapid growth, the period of pubescence, the brain loses considerable weight because of the fact that the usual blood supply is lessened by a portion being withdrawn to nourish the viscera and other organs undergoing revolutionary changes during this period. While the weight of the brain is only one forty-fifth of that of the whole body, it requires one-eighth of all the blood to nourish it. At no time in his whole school career is the boy so deserving of sympathy as at the time of most rapid growth. In all learning, two great features are involved; proper presentation of material by the teacher and proper attitude of mind on the part of the pupil. Seldom, if ever, can the latter condition be supplied by the boy or girl in the midst of the physical and mental revolutions and evolutions of pubescence. The great curse of the age is the demand for rapid education. Parents and teachers crowd the children through a long year's work. Health is sacrificed for promotion. What is learned while the child is fatigued is soon lost, the mind's force being equally dissipated. Vital force is required faster than it is generated. The work of today is done on tomorrow's credit and the system of a child is wholly at a loss to protect itself against disease and accident."

Reuben Peterson, M.D., of Grand Rapids, Mich. (*vide JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, Dec. 19, 1896, p. 1269) writes as follows: "The growing girl who should spend most of the time in the open air with never a care in the world, is closely confined in a schoolroom the air of which is so vitiated as to be scarcely capable of supporting life. Here she may be found, ambitious to excel in her studies, poring over her books with back bowed and chest contracted. If the remainder of her time were spent in recreation the evil effects of overcrowded schoolrooms might be counteracted, but such is not the case. The parents are ambitious that their daughter shall take high rank in her studies, and that accomplishments such as music and painting be acquired at an early age. Hence the girl is urged to still greater mental efforts. Thus the nervous force so needful at puberty for the establishment of the menstrual function is wasted in the acquisition of what may be considered trifles compared with perfect health. He (the family physician) should demand that the hours of recreation in the open air should be lengthened and the school duties be lightened."

Fifty-three educators and thirty-four physicians answered this question more or less fully. While there is a wide divergence of opinion from absolute condemnation to warm approval of the practice, still all insist that the work should be carefully guarded and not carried to extremes and that the health should be properly cared for at the same time. When these conditions are fulfilled and the pernicious habit of attending parties, keeping late hours and indulging in

the various social dissipations and excitements which are so prevalent and injurious, is done away with, the majority believe that a moderate amount of home study, ranging from a half-hour to two hours in grammar grades (No. 8 A) to from one to three hours in high school grades (No. 8 B), or a judiciously selected course of general reading, will not prove harmful. Quite a number insist, however, that this work should be regulated by the parents and no tasks should be imposed by the schools.

Following are some of the opinions expressed:

Prof. J. J. Allison, A.B., of Boise City, Idaho: Very bad. Makes them nervous and destroys vitality; should not be allowed.

Sarah A. Arnold of Boston: There is too much tension.

Prof. Joseph Baldwin, LL.D., of Austin, Texas: Reasonable amount does not hurt.

Henry S. Baker, Ph.D., of St. Paul: School hours are long enough. It hurts brain cells.

Prof. Edwards Brooks, LL.D., of Philadelphia: It is much less injurious than most of their usual habits of life. Properly guarded it has not any bad effects.

Pres. John E. Bradley, LL.D., of Jacksonville, Ill.: Quiet and helpful if not excessive.

Pres. Chas. W. Eliot, LL.D., of Cambridge, Mass.: Ordinary mental work during puberty has not been shown to be harmful except in the case of some girls during the catamenial periods.

Supt. Aaron Gove of Denver: No harm reasonably directed.

Supt. J. M. Greenwood, A.M., of Kansas City: Study affects them but little, society a hundredfold more.

Prof. O. P. Kinsey, B.A., of Valparaiso, Ind.: Never thought it advisable if they were good students in school.

Prof. F. V. Lester of Westport, N. Y.: It must be very judiciously arranged or it will be very injurious.

Prof. Geo. L. Osborne, LL.D., of Warrensburg, Mo.: If a school is well managed there is little use of it. When the proper interest is kept up in school there will naturally be considerable home study but this matter parents should control. Tasks for home are not to be assigned.

Wm. H. Payne, LL.D., of Nashville: Home study is a great evil.

Col. F. W. Parker of Chicago: There should be very little home study in the lower grades; seventh and eighth grades may do an hour's work outside of school.

Prof. Albert Salisbury of Whitewater, Wis.: It is far less injurious than street roaming and other social dissipations so common.

Pres. Irwin Shepard, A.M., Ph.D., of Winona, Minn.: A large question. Home study is a far less serious evil than social customs and consequent late hours.

Prof. E. R. Axtell, M.D., of Denver: Conduces to hysteria and neurasthenia.

Prof. J. C. Culbertson, M.D., of Cincinnati: Do not believe in home study as a requirement but an encouragement to read suitable books, such as history, biography, travels, and some fiction, the latter carefully selected; none obligatory but made attractive as far as possible.

Jesse Hawes, M.D., of Greeley, Colo.: I believe home study a necessity.

Prof. J. N. Hall, M.D., of Denver: Overtaxes nervous system, I think.

Prof. C. H. Hughes, M.D., of St. Louis: Generally detrimental, tending both to dwarf body and impair development of the brain, nerve power and tone, and to produce precocity and cerebro-spinal irritability.

Prof. Frank Parsons Norbury, M.D., of Jacksonville, Ill.: I advise against it and consider it especially detrimental to adolescents both to physical and mental health.

Wm. Jay Youmans, M.D., of New York City: Would abolish it altogether. It is a convenience of the schools not an advantage to the pupils.

Elizabeth K. Matthews of Des Moines, Iowa: I argue that all study should be done during school hours. It is the business of the school.

Examinations.—The question as to the benefits arising from or the injuries that follow the present methods of conducting examinations in many schools, is one of great importance and deserves careful consideration.

There can be no doubt but that where pupils are subjected to an everlasting grind of monthly examinations, term examinations and annual examinations and are continually being reminded that if they do not do this, or do not accomplish that, they will fail to pass and not receive their coveted promotions, great injury is done. I believe when pupils are subjected to such a system and in addition have the misfortune to be under teachers who failing to realize or appreciate their true needs, give them puzzling problems or work that will mystify them or is too difficult for them to perform, the examination becomes a menace rather than a help to the pupils. They are worried, annoyed and kept in a constant state of mental excitement from the time they enter the primary department of the public schools until the doors of the university are closed against them. Frequently insufficient or no time is given for careful original observation and investigations, for that calm deliberation, serious reflection and earnest thought so necessary to make thorough students, ripe scholars, good citizens and the best type of ladies and gentlemen. And for what are these things sacrificed? In order to give place to facts and details which will make a brilliant show before the public, that will convert pupils into smoothly working machines which turn out highly ornate and elaborate work, to dazzle the dear people and impress them with the wonderful things that the educators are doing.

This kind of a system; especially when conjoined with the pernicious practice of awarding prizes, not only impairs or ruins the health of pupils but has a very degrading effect upon them from a moral standpoint, because instead of imbuing them with a love of truth for truth's sake and impressing them with the fact that truth, justice and honesty are the grandest possessions in the world, a high grade, class standing or a prize is made the *summum bonum*, often regardless of the manner in which it was obtained.

Everyone knows that in order to pass good examinations and win coveted prizes, many pupils will resort to cheating and all sorts of dishonesty and that large numbers of teachers become so myopic in detecting these evils and so presbyopic in looking out for their own interests by having their pupils make a dazzling show before the public, that the honest, conscientious workers do not receive justice, and they either become discouraged or resort to similar means

to make a good showing. Any teacher, by a careful system of grading recitations and a systematic preservation and inspection of the work done by the pupils, together with a general review of the subject matter gone over, say three times a year, can arrive at a much and better knowledge of the *capability* of pupils and the *progress* they have made than can be obtained by continual examinations.

What we most need in educational work is a symmetric development of all the powers, physical, intellectual and moral, of the child; a more thorough appreciation of the fact that in its development the child is an epitome of the development of the race, with many of the impulses and passions incident to the savage, barbarous and semi-civilized phases through which the race has passed, and that in order to attain the best results, instruction must be carefully adapted to the ever changing, ever varying needs of the child; a more thorough and intimate knowledge of the laws of mental development; a better understanding of educational methods and the best means of imparting instruction; better pay for the rank and file of teachers, who as a rule should have a more thorough education and more careful professional training and preparation for their work; more enthusiasm and less routine; more original investigation and search after truth for truth's sake, and less cramming for examinations; less talking and lecturing on the part of teachers and more time devoted to training pupils in systematic and logical analysis, and in clearness and accuracy of expression. Then, too, not so many studies should be pursued at the same time, but more thorough work should be done and a stronger grasp of the fundamental principles on which all true education depends should be secured. More attention should be given to implanting correct moral and ethical principles, because it is better to inspire the heart with a noble sentiment than to teach a fact of science, and because truth, honesty, nobility of character, good manners and a proper regard for the rights and feelings of others are of much greater value to the child than all the book knowledge in the world.

It ought to be needless for me to suggest that the personal actions and behavior of the teacher are of supreme importance in moral training. No teacher who calls pupils, liars, fools, sneaks, and uses similar choice epithets in the schoolroom (and I am sorry to say some still do these things), can exert any but a most pernicious moral influence in the schoolroom. Teachers who are not perfectly truthful infect their pupils with falsehood and deceit: those who can not control themselves and disregard reasonable rules and regulations, destroy the regard for law and order in their pupils and help to increase the army of anarchists.

Particular attention should be given to physical development because this is the foundation on which the whole structure must be built and unless this part of the work be done in accordance with correct hygienic and physiologic principles, the result must inevitably be a failure.

The inculcation of the value of proper food, pure air, plenty of healthful exercise and the avoidance of stimulating and narcotic poisons is of much greater importance to the pupil than the mere formal routine and in many cases machine work of the schoolrooms. Unfortunately, however, the matter is greatly neglected in many of our schools, and pupils are crowded

together during long sessions. The foul atmosphere of the rooms and the deadly poisons formed within and exhaled from the bodies of the pupils, cause an accumulation of toxic materials in the system of every child; these poisons, or toxins, poison the blood, poison the brain, poison every cell and tissue of the body, and when long retained may cause kidney and bladder diseases, chronic constipation, and lay the foundation for general ill health. Nor is this all. The general toxemia thus induced leads to mental weakness and moral degradation, because impressions made on a tired brain do not last and pure and noble thoughts can not long exist in a foul body.

In conclusion, I desire to thank the ladies and gentlemen who so courteously answered my inquiries and thereby furnished much of the material on which this paper is based, and from which its conclusions are drawn.

DISCUSSION.

Dr. LONDON of Massachusetts—It is very difficult for me to keep my seat when the matter of educating the child is under consideration. My first child was left in my hands at the age of four weeks. I was recently from the college of New York at that time and I thought I understood the proper care of the boy. Without a mother and without a nurse I proceeded on the milk and water diet, which was then prescribed by the instructor at New York and also by the books. I continued with the milk and water until I found that the child began to lose weight, and then changed to whole milk. He is now 30 years old and far away from here, so I can talk of it with freedom. He reached a full development of six feet or more, and good physique, so I was very well satisfied with the method I pursued. He also had plenty of air. Two windows were open 365 days in the year, and the boy grew 365 days in the year, and without a cold. He did have one childhood disease, mumps, and he did stay in the house then for one day. That is the only time he was ever kept in the house. His training field was in my strawberry field, because I did not like to see the little one kept away from home so long. Part of his time was spent in reciting to a chosen teacher. The children now are being spoiled in the schools. I have been a superintendent in the school and for several years a schoolmaster, and it seems to me we are aiming at everything above this point and we are spoiling everything at this point. The doctor is called upon to supply bone and muscle and heart, and the teacher is called upon to supply grammar.

The child is kept in school from five to fourteen years and as much longer as they desire to stay, without regard to health. A 15 year old boy coming from the country is more promising than a city boy who stays in school until he is 20 years of age. I was so much disturbed by this that at one time I inquired whether the parents had not done as much damage as the saloon in the past decade. After this they passed me by for a while, but afterward they came to me and asked how I could say such a thing. Later I challenged the educators to discuss the matter, but they did not respond.

Dr. JEFFRIES of Chester—I came here this afternoon to hear some specific direction as to the care of the children in the public school. Both as an old director and a school teacher of long standing, I have been deeply interested in this subject. We have, in our town, some school houses as near right, so far as the heating, ventilating and the seating are concerned, as we know how to build them. They are entirely modern. It has taken a good many years of my life to get to this point. A few months ago I began to study the inside workings of the school. I happen to have in my pocket a copy of programs, taken for an entirely different purpose, which may I think throw some light upon the want of health and the generous nervous debility and weakness which is so common in our school children. In this State children enter school at 6 years of age, and in our town the 6 year old child studies every day, the following curriculum: Drawing (otherwise called form study), writing, nature study, reading, spelling (with special reference to diacritic marking), physical culture board work, music, physiology and hygiene (with special reference to the dangers of intoxicating liquors, etc.). They do that at 6 years of age in our school today, and we have schools that are entirely up to date. I was afraid we had nothing more. We have not gotten as far as the ninth grade. After they have been in school six years they study arithmetic, grammar, geography, spelling, hygiene, writing, drawing, music, reading, physical culture, and history.

Now, if that does not account for a good deal of the trouble we have in our public schools, then I do not know anything about public school education.

Dr. ELLIS—I would like to say just one word with reference to the correction to special deformities in the gymnasiums. I think we have reached a point now in the care, especially of the orthopedic cases when it is time for the physicians to take a stand and not send the abnormal cases into the gymnasiums. I do not think we have any more right to send these cases to the gymnasiums than we have to send cases to the druggists and ask them to prescribe for a given disease. The gymnasium, as I understand it, is for the treatment of normal and not of abnormal children. I am practicing in the specialty of orthopedics and I have had several cases made worse by gymnasium work. We should put these cases in the hands of people who do this work, especially not in gymnasiums.

Dr. T. C. MARTIN of Cleveland—The subject of the noon lunch is certainly of great importance. In passing through a crowd of school children we find very often a candy sack, and usually, there are grocery stores and similar stores in close proximity to the schools, where many children go with five, ten, fifteen or twenty-five cents and buy so many pickles, some candy and perhaps a piece of pie. That is the sort of a lunch that they partake of before returning to the school, and then they are asked to apply themselves directly to study. Those of us who are in large cities as a rule have to get a very light lunch. In college I could work better when I had hardly anything for lunch, perhaps only a cracker and some milk or something a long that line. If I had a pretty substantial lunch I could not do as much work. It seems to me a lunch provided by the school would be an excellent thing, for we could then regulate the quantity and especially the character of the food. It is difficult to work hard directly after a heavy meal, and it would be well if we could control the kind of food. We can not depend on the mothers and children to call on the family doctor and follow out the physical care of the children, nor can we depend on the gymnasium as such to develop the child properly. I have had some connection with the Young Men's Christian Association. Several of my classmates have been directors in this line of work and, while they are medical men and have direction of the classes and can examine the heart and general physique as a physician can, they can get some result. But that the gymnasiums are doing much harm I know from my conversations with these directors. Most of the pupils are not examined by the doctor. It is the same way in the schools. The child should be examined by the physician before taking up any study or systematic exercise. But parents are careless and as long as the child is not ill they will not send for the doctor, and so we must extend the public school system along this line. In New York we have made some advance in this way, inasmuch as all children must be examined.

Dr. J. A. LARRABEE of Louisville—The subject I consider the most important is the co-relation of physician to teacher. As Professor Bartlett has said, we are going in the right direction, but in meantime many valuable lives will be sacrificed. As a matter of fact, growing out of our public school system, while we have ostensibly fine buildings and everything in the curriculum that could be desired, we are having wrecks about the period of puberty that might be prevented. These disastrous effects fall most heavily on the female sex and, at that, about the time when nature is struggling to make developments essential to the organism and the educator is struggling to make developments essential to the graduation of his pupil. There is in fact a perfect cyclone to the system at the time of the establishment of menstruation. I suppose it is in your experience, as it is in mine, that we have frequently to interdict, although with great regret on the part of the parents, the further progress of the student.

I am not at all surprised that Philadelphia should be the first city in the Union to take an advanced position in regard to luncheons. My experience since I have been in your city is that it is luncheon all the time. It is constant with the treatment we have received here and I am prepared to understand why the school luncheon system should begin in the city of Philadelphia, the city of philanthropy. In regard to gymnastics, I would say that, not including the cases of deformity, I do not suppose in many instances children will be put on the rack. With reference to rhythmic systematic gymnastic exercise as a relaxation after study, my idea is opposed to a systematic or rhythmic exercise by any plan which does not let the mind rest. If you have a plan or a rule to go by, the mind is constantly exercised and you will not get the mental rest and distraction that you should have, and such as we do have in an outdoor free roll and tumble exercise. I do not believe rhythmic exercise in the schoolroom should supplant the outdoor free exercise.

Now as to overstudy. Here we have ten studies, which it is

impossible for a student to do justice to. If there is any fault in the present system of education, from the common school through the high school and into the colleges, it is the destruction of the individuality of the student. Students are educated until they can not find what they want when they want it, and they become educated imbeciles.

Dr. SIGDOWSKY of Philadelphia—I have two children, whom I have watched since they were 5 years old. I find that the number of studies is not oppressing and difficult when the schoolroom is bright and airy and the school teachers humane and congenial. They come home with half the lessons learned. But I find when they convene in a class where there is not sufficient light and air and the teacher is bent on making it very disagreeable for the children, they do not get along as well and do not eat as well, and altogether they are in a worse condition. The studies may be numerous, but they do not get so much at a time but they can master it. There is one thing to be said about the schools in the poorer sections of the city. Those schools are in a less sanitary condition and the children have neither proper surroundings at school nor at home. I think it would be well if we as physicians would think of that and try to recompense the children in the schoolroom for the deficiencies at home. In this city we have advocated the means of having at the schools some matron and a room set aside for washing the children's faces and hands and combing their hair, and for giving them a bath at least once a week. I am now speaking especially of the poorer part of the city. I have watched the progress of affairs there and we certainly need active work for the good of the children. I think they need a great deal of our consideration.

Dr. KANE of Kane, Pa.—There is a little too much effort to find fault with the forcing of instruction at schools and too little effort made to look after the scholars outside of schools; at least, it has seemed so to me in the country district I come from, a town of about 6,000 inhabitants. There the children are allowed to have their own way. Many children 8 or 10 years of age are out until 8 or 10 o'clock at night, about the streets, doing just as they please. They often come into the house and go to bed without the parents knowing anything about it. When they are engaged in places outside of the school there is also very little attention paid to them, and in this way they acquire many bad habits and get a great deal of ill health that is attributed to the school life. For instance, cigarette smoking is very common among many children, as is tobacco chewing. It is an actual fact that intemperance is to be found among these children. It is said that these children can not get liquor, yet the fact of the matter is there is always somebody to buy liquor sufficient for them, and on two occasions last summer as many as eight or ten children were seen intoxicated at ages varying from 8 to 12 years. Then, these little secret societies are extremely injurious to the nervous system of the children, and their morals generally. I had occasion to treat two children last year, one 12 and another 9 years of age, a boy and a girl, for gonorrhea contracted in a secret society of about fifteen members, children varying, I think, from 7 to 18 years of age. Most of these secret societies are not what they ought to be, and parents never seem to look into the matter to ascertain what is going on in them. It is impossible for the school teachers to look into all these matters.

Dr. EDWIN ROSENTHAL of Philadelphia—I began my education at the age of 4 years, and when I was 12 years old I entered the Central High School of Philadelphia. When I entered the College of Pharmacy I found that much I had learned was of little use to me, and I found that my right and left sides were not alike. So I thought there was, perhaps, something wrong in the public schools. Therefore, I placed my child under Professor Bartlett. The first two years she had only two hours daily, the next four years she had three and a half hours daily, and then until maturity four hours study daily. She practices calisthenics and has a daily lunch, and she has what I did not have, that is a love for the school. The gentleman in his paper laid considerable stress on whether or not the child thrived, determining whether or not the school was doing good. My little one has a good appetite, sleeps well and I have her in as perfect a school as there is in this city or any other city.

Dr. I. N. LOVE of St. Louis—I feel the subject is one of vital importance, and I have been impressed every day since I have had children, and even before, that the physician does not do his full home duty in instructing the mother in her duty to the children and school. The physician comes in closer contact with the child than anybody else, save the mother. The physician should represent the highest type of manhood. The parents should be instructed in the manner of teaching their children and they should take an active part in the selection of the school boards. I believe the father shirks his duty too

much in his efforts at bread winning, for, in my opinion, the father should be a mother just as far as conditions will allow. I feel that the doctor should impress the father with that fact, for the doctor is placed in a position to be of more service to the parents than anyone else. The clergyman is not in it for one minute compared with the doctor. We as physicians should explain to the parents that they should talk with their child as to its duties to the teacher. The child comes home with its little tale of woe, and too often the mother listens to it sympathetically and does not realize the duty they bear to the teacher. I have been in the habit of instructing the children that they owe a debt to the teachers and I tell them that I must hear from the teacher that they are good children, and they must learn to love their teacher. If the child comes home with a criticism of the teacher he should be corrected at once. He should be taught to respect as well as love his teacher, and that it is his duty to make a friend of his teacher and that if he can not make a friend of his teacher he is to blame. If the child is taught in this way he will have a good time in his school, he will love his school and love his teacher. The parent having done his duty in the question of co-operating with the teacher, then if there is anything wrong he may investigate the teacher.

Dr. S. E. WOODY of Louisville—I have only one criticism on the subject. Everybody is jumping on the school boards and school teachers, but it seems to me we should be thankful for what we have. When I think of the wonderful advance made since I sat in the schoolhouse, with vitiated air except when it was relieved by numerous drafts, sat there from early morning until dewy eve, sat there bound down by a stupidity that was inimical to all advances—contrast that to the great variety of study and the beautiful surroundings children now have. I think instead of jumping on these men we should thank those who are making teaching an art instead of what it was a few years ago, a trial of main strength and awkwardness.

Dr. JEFFRIES of Chester—The Doctor is looking back and calling our attention to the deplorable condition of the schoolhouse when he was a schoolboy. I am sorry he did not compare the average young man then. I would call the attention of the audience to the average young man today as, after the receipt of his diploma, he goes seeking for health and after seeking from the East to the West he comes back on the check forwarded from the East to bring him home.

Prof. J. HENRY BARTLETT of Philadelphia—No more serious indictment could be brought against our school system than that it interferes with the health and development of the child. Fortunately, we live in an age when an intelligent co-operation of forces makes the reverse of this charge true, and our schools may be, in fact as well as in theory, what Dr. Stanley Hall calls them, palaces of health. Even a false regimen of hours and diet in the homes is measurably overcome by the regularity of the school life; if combined with this regularity there is a measure of preventive and corrective physical environment. Educators owe much to the medical profession for pointing out lines for the hygienic treatment of the child in schools. I am here today to submit some evidence of practical experience in these lines in one of the schools of the city. It were impossible, however briefly, to touch all the lines that aid, directly or indirectly, in efforts for the health and development of the children. The medical profession has indicated many lines of work and most of these today are bearing fruit. My remarks are confined to two subjects, but the progress in them is measurably typical of all. City conditions at home and school reflect the tension of business life and the tendency of the age to extreme specialization, so that very great effort is needed to prevent a one-sided development. Business arrangements for instance control the habits of our people (in too many instances including the children) in the important matter of the midday meal. Many of our larger financial and even mercantile institutions recognize the effect of this circumstance, and as a measure of economy in securing working ability provide their employes with a dinner. Ideal conditions for children would include a substantial luncheon with the family circle near the noon hour, but in a large percentage of cases this is quite impracticable, and it remains for the school as a matter of self-protection, if for no better reason, to invade the domain of domestic economy and add a kitchen and dining-room to its equipment. In varying degrees this necessity is recognized. In Boston all the high schools have arrangements for luncheon; in Brookline there are ample accommodations in the magnificent high school building, and in Philadelphia a considerable variety of arrangements, from the basket of pretzels at the school gateway to the attractive dining-room of a modern restaurant, may be seen. Speaking for the latter, I may be permitted to remind you that even in matters of this kind the law of development is operative.

Parents and children, as physicians well know, need to be educated as to when to eat and what to eat. The stage of sweet buns and fancy cakes precedes the stage of cocoa, milk and nutritious soups. At no distant future our more progressive schools will have all children sit down at midday to an inviting repast. Let us be encouraged that the matter is growing and let our medical men believe that their labors in this direction are bearing fruit. On the direct efforts for physical development in our schools, volumes have been written and the gymnasium is amply justified as a necessary adjunct of a good school. It would be out of place for me to deal with this question in its larger bearings. I can but submit to you in a form of a report a very brief chapter of results from a school gymnasium for the last year.

The particular record to which I call your attention deals with 108 girls of 12 years and upward. Seventeen of these at the year were distinctly abnormal in their development, and these have all been "materially helped in all parts"; 68 of the 108 have gained in chest expansion, 58 in flexibility of the waist and abdominal muscles, 41 in depth of chest, 50 in increased breadth of shoulders, 74 gained in lung capacity, 56 in strength of back. Of the 108, 67 had shoulders and hips uneven in the autumn; 33 of these were made even and 34 were improved. Eleven of the 108 had spines distinctly curved; 5 of these were made straight and 6 much improved. These figures have reference to school gymnastics taken in two half-hour periods each week, but they reflect also the effect of a pretty faithful effort to overcome defects by free movements prescribed for home work. This is more apparent from the fact that 10 of the total 108 have losses of development recorded and these 10 are those who have not been interested in carrying out the prescriptions or fulfilling the conditions of the class work as regards dress and other circumstances.

I have said enough and reported enough to indicate how our school system can meet the exactions of hard conditions and make an environment in which development shall not be retarded nor health sacrificed. It is not a simple problem, it involves many elements and study and labor along many lines.

I adopt the words of a recent résumé of the results of child-study in one of our educational journals, as a further acknowledgement of the service of the medical profession to education as well as to indicate how far reaching the efforts are to correct the defects of our school system: "The physician is becoming interested in the schools, as at one time was the clergyman. As the physical basis, or at any rate the physiologic concomitants, of intellectual deficiencies and moral defectiveness are coming to be more clearly understood, the physician's function as an instructor of teachers and as an examiner of children as to sight, hearing, touch and symptoms of fatigue or illness, as to temperamental characteristics and 'nervous' peculiarities, as to differentials in age and sex, are being in turn more fully apprehended. School hygiene, not only as related to problems of heating, lighting, ventilating and sewage, but also to the manner of seating, length of sessions, frequency of recess, size of playgrounds, modes of recreation, as well as to individual 'health,' nourishment, cleanliness and raiment, and finally a more rational instruction of the children themselves in the structure and functions of their bodies, their use and abuse, not to mention the application of gymnastics, all these matters have come to be of vital concern jointly to mothers, teachers and doctors."

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 1266.)

XIX. DISEASES OF THE URINARY AND GENITAL ORGANS AND OF THE RECTUM.

Lithotomy; Catheterism; Ischuria (strictures, swelling of the prostate); Cystotomy; Hematuria; Nephro-lithotomy, extirpation of the kidney; Hydrocele; Sarcocoele; Castration; Varicocele, testicles in the groin; Phimosis; Amputation of the penis; Symphysectomy; Vesico-vaginal fistula; Atresia of the vagina; Dropsy of the ovaries; Fistula ani; Hemorrhoids; Atresia and strictures of the rectum.

"There are few operations to which surgeons have turned so much attention and which they have performed in so many ways and with so many kinds of in-

struments as *lithotomy*. . . . The operation deserves the preference over internal remedies; it relieves certainly and quickly. In recent times it has been so perfected that one can be almost certain of a fortunate result if it is performed in time by a practiced hand and with a certain precaution." Thus wrote Richter. Lithotomy united the surgeons of all nations in the effort to wrest this operation from the hands of the itinerant lithotomists, with their unsavory secret traffic, and to restore it to science. They distinguished four methods, the major and minor apparatus, the suprapubic and the lateral lithotomy. In order to better locate the various modifications of the operation let us group them according to the direction of the internal incision, as urethra incision, prostate incision and bladder incision.

The urethra incision, or the method of the major apparatus, was originated by Giovanni de Romanis (1525) and made known by his pupil, Mariano Santo (Mariano lithotomy). By this method only the urethra was opened and further enlarged. A grooved bent probe was inserted in the bladder, and in the middle of the perineum between the scrotum and the anus everything up to the bulbus was separated, then by means of a dilator the urethra was enlarged and the stone extracted with tweezers. If the stone was of any considerable size the urethra and prostate were so bruised and lacerated by these manipulations that urethral infiltration was unavoidable. Almost half of the patients operated on died. This method, the traditional secret of the Colot family since 1556, was made public (1727) by the last of the family, Franz Colot, and was brought into prominent use by the lithotomists of Norcia. Maréchal and le Dran perfected it, the latter especially improved the bandage after the operation. Schmucker also operated according to his directions, but with a somewhat larger incision, from fear of laceration, and out of twelve lithotomies which he performed during his lifetime, he lost only one. He never needed more than two or three minutes and "could almost maintain that not a single patient need die in this operation if the operator performed it with sufficient skill." The method of the major apparatus, however, was soon displaced from lithotomy and at the end of the century was almost entirely discarded. Morand had reckoned that out of 812 lithotomies performed in Paris within eight years with the major apparatus, 255 proved fatal.

The prostate incision, by which only that gland was cut through and the bladder not injured at all, or only at the neck, is classed with the lateral incision. Franco had originated it in the middle of the sixteenth century. He introduced a grooved probe into the bladder and had it pressed obliquely backward by an assistant in order to force the urethra somewhat to the left. Then he made an oblique incision which began two centimeters in front of the anus and ended in the middle of a line from the anus to the tuber ischii. The urethra was slit up the probe, along whose groove the knife was pushed obliquely through the prostate to the neck of the bladder. The lithotomist, Frère Jacques, first brought the lateral incision into practice. Rau received the operation from his hand and Heister learned it from Rau (see chapter ii). Heister recommended Rau's modification, while Camper rejected it, because not only the body of the bladder but also the neck and the prostate and urethra were affected; it was also dangerous on account of a possible injury to the rectum and to the seminal vesicles.

The operation received a further improvement from Cheselden, who really first led the educated surgeons to accept the lateral incision. The number of unfortunate results which he had at first and acknowledged (three times he performed a lithotomy and found no stone) drove him unceasingly to improve his method. In the first, where the incision fell behind the prostate into the body of the bladder, frequent urine infiltration ensued; in the second the urethra was cut behind the bulbus and the prostate was cut straight through to the bladder; in the third, which he retained as the best, a grooved lithotomy probe was introduced into the bladder and adjusted with the groove toward the left side of the perineum. Then, left of the raphe an incision was made which began behind the scrotum, ran obliquely downward and ended in the middle of the anus opposite, a half an inch from its edge. The left forefinger inserted in the wound pressed the rectum back and guided the small, slightly convex and pointed knife attached to the groove of the probe. Directed upward and forward, it cut the urethra together with the prostate, whereupon the tweezers were introduced on a broad gorget. The fortunate results of which Cheselden boasted from that time on (six fatalities among eighty operations) were the reasons for Morand being sent to London (1729) to learn this method and introduce it into France. He himself, in the following year, had seven successes out of eight lithotomies, and later six fatalities out of eighteen operations. In the Paris Charité in five years (1731-1735) seventy-one cases were operated upon according to Cheselden's method with thirty-one deaths; in the Hôtel Dieu within eight years, 604 cases with 164 deaths. Sharp and Bromfield, who devised some four-bladed tweezers, la Faye and Bertrandi, all recommended Cheselden's incision; in Germany Senff and Henckel especially advocated it, so that in the middle of the eighteenth century this method displaced all others.

They endeavored to lessen the difficulty of it by the invention of a host of new instruments. Richter's criticism in this connection says: "The least which one can say of most of them is that they are useless and superfluous, since one can, at all events, make this little incision with any long narrow scalpel." The lithotome caché of Frère Cosme raised the greatest renown. This knife, four inches long, narrow and somewhat curved, was covered by a sheath attached in front, and could be released by means of a spring. Attached to a grooved probe and inserted, they touched the spring and in this way cut through the neck of the bladder. For very large stones Frère Cosme used tweezers provided with iron teeth, with which he thought he could break the stone. Among the advocates of Cosme's method were Acrel (five deaths in twenty-two lithotomies), Steidele and Richter, who described it as the model of lateral incisions.

After it was made known through dissections that by this method, received so favorably in France, the rectum might be injured and the bladder pierced entirely through, it found many opponents. Frère Cosme defended it and declared that of seventy-eight patients upon whom he had operated with his instruments only six had died. In general, Le Cat, and with him the whole academy, opposed the lithotome caché. As a pupil of Morand, Le Cat had at first employed Cheselden's method, but discarded it after 1742. While the Englishman advocated slitting the

prostate to a considerable length, Le Cat announced the principle of cutting through the gland to a less extent, rather risking its laceration in case of large stones and of making the external incision much larger than the internal. Le Cat went to Paris and operated publicly before the Académie de Chirurgie with great success; while once for a period of six years, and among thirty-eight operations, he did not lose one patient. Later he had six fatalities out of nine cases in a single year. At the time of his death (1768) he had performed 310 lithotomies. Günz, Pajola and C. C. von Siebold in particular, brought Le Cat's method into use in Germany. C. C. von Siebold once performed a lithotomy twice upon the same patient in one year, and with success. On the contrary, Richter, whom one of his critics reproached with a lack of observations, since he, with the rarity of cases of stone in Göttingen, had never operated or at most very seldom performed the operation, advocated the principle of Frère Cosme, namely, to always fit the incision as far as possible to the size of the stone so that it could be extracted without force instead of making a small incision, according to Le Cat, and giving it the proper size by extension. To him the danger of a long hemorrhage did not seem so great as that of a forcible extension of the wound. On the other hand, Pouteau adhered rather to the principle of Le Cat. Pouteau ascribed his fortunate results to the fact of gradually extending the wound, in which of 120 patients only 3 died in consequence of the operation. For the incision in the perineum Richter recommended the urethrotome of Le Cat; for the incision in the prostate and the neck of the bladder, the lithotome caché. Besides the latter, as really a perfection of Cheselden's method, a new instrument was devised, which was said to guard against the danger of a possible slipping of the point of the knife; it was the cutting gorget of Hawkins, a surgeon in George's Hospital in London (1753). It protected the rectum and served to introduce the lithotomy tweezers. The gorget raised great applause and displaced, especially in England, the lithotome; Bell and Cline modified it. Desault, who first employed it in France, gave the cavity a stronger surface and shortened the blade; however, he preferred to operate with the lithotome. His results were very varied; once in the Charité fourteen of his patients who had been operated upon died one after another, while twelve others who were operated upon at the same time by one of the monks all recovered; on the contrary, he had in the Hôtel Dieu only two deaths from twenty-two lithotomies. To remove the stone only after a few days after the operation, had already been advocated by P. Franco, and it now found defenders in Maret and Louis. The latter attributed the unfortunate result of the operation chiefly to the fact that it had been completed immediately and he asserted that he had not lost a single patient. Camper, Richter and Loder also favored this method.

We have hitherto had in mind only the usual method of the prostate incision (*sectio lateralis*); there was besides an incision on the median line and one on both sides. For the former, Vacca Berlinghieri devised the method of making the incision on the median line, behind the bulbus urethrae, to the pars membran.; then a knife was forced into the neck of the bladder and the prostate slit exactly in the middle. But in this way the rectum and seminal vesicles were exposed to injury. In regard to the

sectio bilateralis, le Dran recommended the division of the prostate on both sides, but Dupuytren first developed the method further and introduced it into practice.

By the third main course, the bladder incision, the body of the bladder was opened directly by various methods. Celsus had already briefly described an operation from the perineum outward, which later received the name "minor apparatus," or Guy de Chauliac's method, because this surgeon recommended it anew and apparently was the only one in his time who practiced lithotomy. According to Celsus the operation should only be performed in the spring and in case of boys between 9 and 14 years of age, because only with them could the stone be felt through the rectum. For the extraction nothing further was necessary than a scalpel and perhaps a pair of dressing forceps. An assistant took the child upon the lap so that he sat almost vertical; another held the strongly flexed legs as far apart as possible, and at the same time fastened the open hands at the knuckles. The operator inserted two fingers of the left hand high up in the rectum while an assistant pressed the stone against the perineum with the hand laid above the pubis. The operator endeavored to seize it with his fingers, pressed it to the left and forward, and cut it out. If the stone did not come out of the wound of itself it was extracted with the fingers or with a spoon. In the treatment according to Celsus, Heister first showed how disadvantageous it was to be willing to operate only in the spring, a rule which was pretty generally followed; although the method was confined almost exclusively to the charlatans, yet he advocated it in case of children and for small stones. In adults it was only permitted if the stone was wedged solidly into the neck of the bladder or the pars membr. and it was contra-indicated in case of angular stones and for large strong persons. As an injury to the rectum or the seminal vesicles was easily possible, this method was almost entirely discarded by the end of the century. A second operation from the perineum was that of Frère Jacques previously mentioned; a third, that by Foubert of Paris (1727). He would thrust a grooved trocar between the urinary passage and the neck of the bladder into the previously filled bladder, allow a part of the urine to run out through the groove and then insert a long knife into the bladder. This method produced no good results. It was too difficult to find the right place for the trocar puncture and the bladder with certainty, and a swollen prostate might be injured.

In spite of all the improvements of the lateral lithotomy, it was impossible to remove very large stones without causing various injuries (P. Camper), inasmuch that attention was attracted anew to the suprapubic method. P. Franco, the originator of it (1561), operated upon a 2-year-old boy in Lausanne, according to the method of Celsus, although he would not remove the stone. But from the rectum he would lift the stone (as large as a hen's egg) so high with his fingers that he could distinctly feel it near the linea alba, above the pubes; he thereupon made an incision and extracted it. Although the child recovered, yet Franco cautioned against a repetition of this operation on account of the possibility of an effusion of urine into the abdominal cavity. Although Rousset set forth the advantages of this method, defined it in a rational manner and laid the greatest stress upon

previous filling of the bladder (1590), yet the suprapubic lithotomy only came into favor in the eighteenth century. Indeed the contest with the lateral incision continued, but the suprapubic was generally recommended for large stones, while for callous bladder and in case of children and fleshy persons it was disapproved of. Douglas and Cheselden in England, Morand, Winslow, le Blanc and Frère Cosme in France, Boretius and Heister in Germany, interested themselves in the matter. Douglas, of the Westminster Hospital in London first performed the operation anew; he syringed the bladder with barley water, made an incision along the linea alba, opened the bladder with a curved scalpel and removed the stone with the fingers. Cheselden and Morand, who first performed the *sectio alta* (1727) in France, operated in a similar manner. There came to the knowledge of the two Englishmen and two other surgeons, within a few years, thirty-one suprapubic incisions with only five fatalities. In Germany, Pröbisch, regimental surgeon at Königsberg, first accomplished the operation (1726); Senff of the Berlin Charité followed him in 1728. Frère Cosme devised a special modification of the operation (1779) in that he, in the suprapubic lithotomy, bandaged the urethral incision from the perineum in order to conduct the urine and pus off freely, to which he ascribed the entire success of the operation. Without previously expanding the bladder by injections, he severed the *pars membr.* as in the *sectio lateralis*, as far as to the prostate. He then cut through the soft parts over the pubis to the linea alba, and perforated this with a so-called *trocár-bistoury*. Through the opening of the urethra into the perineum a somewhat curved silver tube, in which a pointed needle lay, was introduced into the bladder, which was raised by the mouth of the tube and the needle thrust through. The peritoneum and intestines were held back by the hand. A bistoury fixed in the groove of the needle enlarged the bladder, whereupon the stone was removed with the fingers, which Morand had already extolled as a great advantage over extraction by means of tweezers. Frère Cosme reported eighty-two operations, for the most part successful, and he found many supporters until Ev. Home and Loder entirely discarded the simultaneous incision of the perineum. In the suprapubic lithotomy the surgeons especially feared the entrance of urine into the abdominal cavity. To avoid this Frère Cosme applied an elastic catheter from the perineum outward; Deschamps made the puncture of the bladder through the rectum and Richter adjusted a small bandage to the wound in the bladder. They were also apprehensive of injuries to the peritoneum. To guard against this the bladder was previously distended by means of injections, although Morand protested against such a procedure. Richter at first thought that in opening the empty bladder a particular difficulty of the suprapubic lithotomy was removed, but in later years he laid great stress upon filling the bladder and advised an injection of about a pound or a pound and a half of lukewarm water. B. Bell, on the contrary, preferred that the patient should retain the urine, since the sudden distension of the bladder by injections is painful and dangerous. Heister pressed the peritoneum, with the finger, backward and downward from the symphysis. After the operation he applied adhesive plaster, while B. Bell joined the upper part of the abdominal wound by means of a twisted suture.

The opening of the bladder through the vagina was

indeed successfully accomplished a few times (Gooch), but it was not general because of the persistence of the fistulae, etc. C. L. Hoffmann of Münster suggested the rectovesical incision (1779) after he had twice seen a bladder stone removed through an abscess induced in the rectum; this first gained credit through Sanson (1815). Lithotrity as a method of operation did not yet exist.

Condensed in a few words, the judgment of the surgeons in the second half of the century agreed that the lateral lithotomy should always have the preference, with the single exception of cases in which the stone was very large; then the suprapubic incision was necessary. If in a lateral incision the stone was found to be large, contrary to the supposition, one should rather try to break it up, than to draw it out whole.

Knowledge as to the nature of the stone was first brought from darkness by Scheele. He found (1776) that it consisted of a special acid, lithic acid ("Steinsäure"), and contained no lime. Later, phosphate of lime was discovered in it. Then Fourcroy, who distinguished twelve kinds of stones according to their composition, and Vauquelin (1799), found lithate of ammonia, oxalate of lime, silica, phosphate of ammonia and magnesia, and an animal matter which was regarded as a "glutinating mucus," which held together the constituents of the concrement. Pearson changed the name lithic acid to uric acid. Water rich in calcareous earth and selenite in connection with humid air among other things, was announced as the genesis of bladder stone (Saucerotte) and the basis of every bladder stone was sought in small renal stones (Schmucker).

Surgeons were not inexperienced in *catheterism*. Heister considered the silver catheter as the best and thought that a thick one slipped into the bladder more readily than a thin one. His variously formed instruments were very similar to those of the present day, only the apertures on both sides were larger and longer. In cases of suppression of the urine and paralysis of the bladder, to make possible a longer retention in the bladder he used a flexible catheter, which consisted of a spiral-formed silver wire, an idea of Solingen, which later came into use through Flurant, but which was not favored by Richter. Petit recommended a catheter which, when open, could be closed by means of a button situated at the end of the wire, and gave it an S-shaped curve corresponding to the course of the urethra. For injections the posterior end was enlarged in a funnel shape, in order to accommodate the mouth of a syringe (Garengot and Brambilla). Theden has the merit of the introduction of the elastic catheter into surgery. He had a fine gold wire insulated with silk, wound in a spiral around a thick wire and washed with a solution of caoutchouc. He said in favor of these flexible instruments that they were easily inserted by unskilled hands and could be left in position for a considerable time. Richter at first praised them, but later made the discovery that they were too easily worn out, inasmuch that one patient with suppressed urine, for example, found ten necessary within eight weeks, therefore at the price of six thaler each, the expense was too great. They were displaced by the catheter of Professor Pickel of Würzburg (1783), which consisted of silk cylinders which were woven over a probe and covered with a varnish. These lasted longer and were cheaper (five for a louis d'or). The rules for

the insertion of the catheter, as Richter gave them, are still valued. According to him the most important was, never to apply force. The master turn (*tour de maitre*) arising from the charlatany of the lithotomists of the Middle Ages, to conceal from the bystanders, under complicated manipulations, the introduction of the catheter, he regarded as injurious, but if the catheter would not come out over the prostate, recommended one whose point was bent farther, to the length of about an inch, hence the model of the Mercier instrument.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated meeting, October 15, 1897.

(*Concluded from page 1270.*)

Dr. G. FRANK LYDSTON in the Chair.

REST CURE IN HYSTERIA.

Dr. H. C. B. ALEXANDER—The value of the rest cure in hysteria will turn entirely on the organism attacked. In a degenerate organism or in one with an acquired neuropathy due to traumatism or secondary to constitutional disorders, infections and otherwise, hysteria under the strict Weir Mitchell type of rest cure (especially as conducted by trained nurses without medical supervision) does not do well as to ultimate mental outcome. With the rest cure modified as far under medical supervision as to introduce a healthier mental tone, even this type may improve very decidedly. Improvement in general nutrition without mental improvement is often mistaken for cure of hysteria. As the disorder is practically accepted by the vast majority of neurologists as a psychosis with nervous expression such "cures" are physiologically illogical and do much to injure medical science in popular estimation since they support the claims of the faith healers and other charlatanic enthusiasts. The hysteric inhibitions need strengthening, and unless this be done nothing is permanently accomplished. The hysteric, in my experience, is peculiarly susceptible to suggestion so far as individual symptoms are concerned. Of this, the case of blistering by suggestion which I reported to the Academy some years ago¹ was an excellent illustration. This element of suggestion constitutes at once one of the dangers and the benefits of the "rest cure." Too frequent concentration of the patient's mind on a symptom or group of symptoms tends, under the most simple principle of association, to produce exaggeration or fixity of these symptoms through suggestion. The opposite course has decidedly beneficial effects. This constitutes one of the dangers of the "trained nurse" in this method of treatment. Her desire for objective symptoms due to methods taught as to so-called precision leads to the frequent suggestion of new symptoms to the nosophilic mind of the hysteric. The same fact should rule diet and medical treatment. In the type of hysteria developing upon a nervous adynamia or brief neurasthenia the rest cure gives undeniably good results but, as in the deep neuropathic or degenerate types, its essential principle of seclusion from improper sympathy, medical or otherwise, must be rigidly carried out. The defects of the rest cure largely arise from the violation of this essential principle. The "cure" should always be under the care and supervision of a physician. "Trained nurse," "rest cure," are no less quackish than other practices of medical principle by laymen. To them are due the disrepute the rest cure has obtained with many excellent practitioners. Removal of the patient from the morbidity-manufacturing atmosphere of home is a necessity, but it is no improvement to fling the patient into a lay atmosphere which will manufacture a similar atmosphere by the showy lay use of instruments of precision in the search for symptoms which will undoubtedly be furnished abundantly under such conditions by the hysteric. Diet, medicine, etc., during the rest cure must be suited to each case.

SUGGESTION IN HYSTERIA.

Dr. W. X. SUDDUTH—I was not here early enough to get Dr. Bannister's definition of hysteria; I shall therefore, take the liberty of giving one of my own. Hysteria is a pathologic mental state in which there is increased suggestibility accompanied by lack of emotional control. This being the case, the hysteric state should be very amenable to suggestion: and that

is the trouble with it. It is so amenable to suggestion that we get little or no permanent results in the treatment of the disease by suggestion alone. The Charcot school held that hysteria was one of the manifestations of hypnotic suggestion and that necessarily all good hypnotic subjects were hysteric, but I find in the use of suggestion that hysteric patients are the very worst, so far as permanent results are concerned. I would rather treat any other patients than hysteric ones so far as permanent results are concerned, because these patients are amenable to suggestion from all sides. Anything that stands for an idea in the mind of a patient is a suggestion. Whether it be verbal or physical, external or internal, that is suggestion given by some one else, or auto suggestion.

In the treatment of hysteria I find that I get much better results where I couple physical exercise as a basis for the administration of suggestion, putting the patient through a course of "psycho-physical culture." If he will carry out the breathing and physical exercises to be given, the results obtained by these exercises are more permanent than when suggestions are given in any other way. In fact, where emotional prodigality exists, as it does in hysteria, one of the surest ways of controlling it and redeveloping the will power is through a series of physical exercises, muscular training, rhythmic breathing, systematic habits, and a regular military discipline, such as I put my patients on. Accompanying these exercises suggestion is used from which, to my mind, we may confidently expect benefit in proportion to the thoroughness of the system employed.

The statistics given by Dr. Coolidge justify suggestion, if applied in this way, in the treatment of nearly all forms of hysteria. Hysteric cases are difficult to handle, and it requires a great deal of patience to get good results. The very amenability of patients to suggestion is apt to give rise to a recurrence of hysteria. Unless the patient follows out some such line of psycho-physical culture you need not expect permanent benefit to be derived from the use of suggestion in the treatment of hysteria.

GENERAL REMARKS ON HYSTERIA.

Dr. JAMES G. KIERNAN—In dealing with the question of hysteria, the diagnosis is of necessity the first factor requiring consideration. My experience leads me to doubt whether clearly defined demarcations can be made between hysteria, neurotic states and neurasthenia, yet upon such demarcations must turn the questions of treatment and prognosis. In my opinion a neuropathic state may be either an expression of hereditary defect or of some systemic shock from traumatism, or secondary to the great systemic disorders. If nerve tire and resultant neurasthenia be grafted on such a neuropathic state, either inherited or acquired, the resultant will be a condition which in many instances neurologists can not demarcate from hysteria even when this last occurs in a scion of a degenerate stock. Hysteria is not the clear cut symptom-complex of favorable prognosis which many practitioners and neurologists accept as a type. Globus hystericus and unstable emotionalism have not the pathognomonic symptoms that popular medical opinion assigns to them. Either or both may be an expression of an attempt to suppress a deep emotional state and have nothing pathologic about them at all. Usually these two symptoms represent all that there is in the popular conception of hysteria and the gravity of that disorder is thus beloccluded into a triviality. From this standpoint it is not difficult to see how hysteria comes to be regarded as due to civilization. Unrestrained shallow emotionalism is characteristic of a lower grade of culture. Civilization tends to restrain emotional expressions, but this implies increased evolution of inhibitions. The absence of these inhibitions would therefore imply a lower grade of culture not due to civilization, but survived in it from savagery with whose sine civilization is so often charged by a certain school of pessimists. Sexual perversion, like hysteria, was said even by Krafft Ebing to be a product of civilization, but an American physician, A. B. Holder, showed that it had existed from time immemorial among the Indians of the Northwest, and that each tribe had its own term for the practice, showing that it had originated within the tribe. If it had been otherwise the practice would have been denominated by a loan word. On the Indian reservation in the interior of New York are both civilized members of the Six Nations whose daughters play pianos as well as those who perform fetichic rites at the feasts of the "White Dog." Hysteria is more common in the women of these last than the first. The dances at the feast of the "White Dog" are marked by hysteric phenomena closely akin to those of the dancing mania of the Middle Ages. In the nineteenth century, speculative changes often lift the lower classes, intellectually speaking, into the plutocratic classes. It is hence not surprising to find hysteria ex-

ceedingly common among the "higher" classes so constituted, but civilization does not manufacture this hysteria, free from it.

Dr. Butler brought out an excellent point in referring to the case of the eighteenth century servant girl, who had hysterics which might be emulated by some of our fine women of today. She, like hundreds of others were, might be raised to wealth, but civilization and culture would not cause her hysterics. Hysterics I find come from all the nations of Europe, and in the main from the lower stations in life rather than the upper.

A Bohemian general practitioner once insisted that hysteria was rare in Bohemia. I got an explanation at one consultation why, in his opinion, it was rare in Bohemia. He asked me to see a girl of 16 years, whose mother would not let her go to work, but wanted to keep her at school, whereupon the girl had a typical hysteric convulsive attack. She later became paralyzed and anesthetic on one side and had hysteric mutism. On inquiring into the family history I found the mother was similarly affected during her girlhood by the same exciting factors, and that the grandmother had been likewise affected. When the girl was allowed to go to work the convulsions and hysteric hemiplegia disappeared. The practitioner had looked upon these from his ordinary conception of hysteria, which means emotional irritation, globus hystericus, etc. After that he saw a number of cases of hysteria. His opinion in the matter was in marked contrast with that of another general practitioner who had a large clientele among a very hard working class of people, and who observed many cases of hysteria with varied manifestations. He brought me, on one occasion, to see a woman suffering apparently from gallstone colic. She had jaundice and a slightly elevated temperature; but when her husband promised her a new dress the condition disappeared. That woman had worked in the fields in Germany. She had a good many of these attacks. To attempt a demarcation on the ground of apparent difference in the sex or social condition as a method of diagnosis is futile. As regards sex I must confess I would like to find out the difference between neurasthenic cases which have been built upon a pathologic basis and hysteria: when it occurs in the man, and when in the woman. I can not make the diagnosis. I get the anesthesia, the visual field disturbance, and every now and then hysteric ptosis in the man. In attempting to draw this line we are drawing it rather on older ideas than on data that are more obtainable. We are too apt to look at the man who is a neurasthenic as a pure hypochondriac. The subjective results are more frequent than the objective, and they do not vary one iota in my experience from typical hysteria. I have never been able to do much with the so-called hysteric zone, although I have tried repeatedly to do so. One man had a notion which started with his testicles. A grave hysteric condition could be set up from that source.

With reference to the question of traumatism in these cases it is a grave condition, and one that is not easily recovered from. There is often a marked change of character in previously healthy people, which does not subside on receipt of payment of certain damages, as we are frequently informed by gentlemen who devote themselves to railroad interests. The condition continues a long time after. I have seen a marked case manifesting true symptoms of hysteria in a man who fell into the hands of an official surgeon for these four years after injury. This man could not be accused in the slightest degree of desiring damages. He was a builder of bridges on the Mississippi. He had been knocked into one of his own boats by his own derrick, had sustained a fracture of the scapula, and it was also suspected that he had sustained some spinal injury. Among the symptoms that were decidedly marked after the accident were retention of urine and anesthesia on one side. The urine, before I saw the man, had been drawn with a catheter. I made a careful examination and my opinion was against spinal injury, but in favor of general traumatic shock. I told the man he would be able to pass his urine that night without a catheter, and he did it. But that man's character completely changed. He improved for a while. That man is now an hysteric, and I doubt if he will ever return to the original condition he was in at the time of the injury.

With reference to the mental condition of the hysteric, he exhibits one of the characteristics of degeneracy, namely, anesthesia of moral sense.

I had hoped Dr. Moyer would be here to take up the forensic relations of hysteria, because hysterics sometimes commit acts with extreme cold-bloodedness, and without apparently sufficient motive. I remember the cases of a girl who poisoned four members of a family. She was a hystero epileptic. She committed this act with the utmost coldness, without any apparent motive except a slight scolding, and she was only detected by accident. Another phase of the mental state with which physicians are familiar is hysteric accusation, and

this has more than once landed many an innocent person into a penal institution or State's prison. In our State we had a case where a hysteric came near landing four men in prison. The community was very much excited over the supposed assault, but the story was too much even for a country jury in its final contradiction. It is the safe rule in an accusation of criminal assault to take into account the possibility of the accusation. With regard to the minor forms of hysteric mental disorder, they are characterized by emotional instability, by emotional irritability and by a large number of hallucinations and other conditions that are in no small degree the product of suggestion. In the grave disorders there are mixed religious and erotic symptoms; women who have seen the Virgin and angels and have talked to them are in a number of cases hysteric.

There is one work in pathology that might be read with advantage, namely, the hagiology. St. Theresa, for example, was a most magnificent case of hysteria. She used to have one part of the time a divine ecstasy which made her have a convulsion and kick everything out of bed. Then she used to faint and her soul would mount up to heaven. She had seen her celestial spouse and would give the usual mixed story of the hysterics. This grave hysteric condition does not tend to pass into dementia, but it is nevertheless a destructive condition as far as the mental state is concerned.

The visual field side has been much discussed and needs little further reference. Charcot claimed, in 1888, that all so-called hysteric unilateral paralysis of the facial, lingual and oculomotor muscles are in a reality hemispasms. This view of Charcot was later abandoned by him and his followers. A case of mine observed some four years ago tends to justify this abandonment. The patient, since this case was first observed, has repeatedly come under my observation for the like condition, which has remained "cured" for a longer time than usual after the correction of certain errors of refraction by glasses. The case is as follows: The patient, a 33 year old married multipara, comes from a family rife with neurotic taint. Neuroses of various types are frequent in this family for three generations. One sister has periodic attacks of nymphomania, whose morbid nature she recognizes and is therefore able to control. The other children suffer from cerebral phenomena from very slight causes. One brother has had infantile hemiplegia with athetoid phenomena. There have been numerous children for three generations, the greater proportion of whom died in infancy. The present patient has visceral neuroses, simulating at times peritonitis and gallstone colic and attended by pyrexia followed by apyretic states, when the temperature falls from 103 to 90 degrees in a few hours without corresponding constitutional disturbances. Paralysis and local anesthesia are easily produced in this state from suggestion.

On one occasion discolorations of the skin resulted from an accidental suggestion that the skin looked slightly reddened at the seat of a paresthesia. The patient had an attack of "visceralgia" simulating gallstone colic. This left her much exhausted, and in this state the suggestion was made by a neighbor that her eyes looked weak whereupon slight amblyopia resulted, followed by double ptosis. The "visceralgia" disappeared under what was chiefly moral treatment, but the ptosis persisted for some weeks. One day while the patient was relating her symptoms a window fell and she passed into a hypnotic state. While in this state the suggestion was made that her ptosis was under full control of her will and that she would hereafter be able to control it. On awakening her from the hypnotic state the ptosis and amblyopia disappeared.

The last attack occurred under the following circumstances: The patient while East had been treated for a headache by the correction of refractive errors through glasses. Soon after her return to Chicago she suffered with a very obstinate sub-occipital headache. Through much talk by her friends she was persuaded that this headache was of optic origin and that the glasses had been improperly fitted. She was found to be badly constipated. The persuasion, however, that the eye had been improperly fitted with glasses continued. She finally had a recurrence of the old symptoms of ptosis and amblyopia. This condition, however, disappeared with the disappearance of the headache, which yielded very rapidly to dietetic treatment and cathartics. Since this time (nearly a year ago) there has been no return of the ptosis and the patient has not complained of either eye strain or headache.

If I were to discuss the subject from a therapeutic standpoint I should be exceedingly careful in giving anything but a very guarded prognosis in cases of traumatic hysteria, and some of the graver forms of the affection. I should also use a great deal of care in giving a prognosis from the results of the rest-cure treatment in either one of the two forms of the disease. There is no doubt that the rest-cure has done good in cases of hys-

teria, but most physicians who have seen cases find that it has likewise done a great deal of harm, and has given patients a chance to brood and form fixed illusions and ideas when carried out in routine fashion.

As regards the question of epilepsy, there is one point that puzzles me, namely, the differential diagnosis between the epileptic state in which hysteria occurs and hystero-epilepsy. In well defined cases there is no difficulty experienced in this regard. But take the average text-book and the only diagnostic point is drawn between a grave hysteric attack and a grave epileptic attack, and the hundreds of minor epileptic disturbances that simulate hysteria on the one hand and the hundreds of hysteric disturbances on the other are ignored. The difficulty is further enhanced by the large number of epileptics who have entirely hysteric attacks. I had a case under my care, an undoubted epileptic, and yet of the three attacks he had while under my observation, two were genuine hysteric attacks, the third was a true epileptic attack. For a long time I was puzzled about certain beneficial therapeutic effects, until an explanation was found in the hysteric condition.

With regard to the diagnosis, the temperature may be of some avail, but the physician who watches epileptics in an insane hospital will find temperature disturbances that closely simulate those observed in the hysteric.

A point that may be covered by some of the subsequent speakers, one which is now being raised by certain neurologists, is as to whether the presence of certain tests, like the aukle clonus, are purely characteristic or indicative of organic disease. There have been two or three cases that look very suspicious in that direction. This raises another point to which a number of neurologists are opposed, but on which I am inclined to believe with Charcot, namely, that secondary to prolonged localized hysteria we may have local spinal or cerebral pathologic changes set up. Two-thirds of the secondary changes which occur in certain acute psychoses are due to biochemic lesions. I see no reason for doubting the cases Charcot has published. He published his first case in 1867, in which the spinal lesions found were not changed to hysteria, nor did he attribute hysteria to them, but he believed that they were the secondary results of disease consequent on hysteric contractions.

Dr. Kuh made a statement regarding epileptics which I have heard made quite frequently, that the epileptic pathologic findings are primary. Spitzka and myself made quite a series of careful examinations, examining brain after brain of persons not demented, and found teratologic lesions due to a degenerative condition, but no microscopic or macroscopic lesions.

I can not fully agree with Dr. Sudduth as to suggestion. As to its effect on the disease hysteria itself I admit his position, but suggestion has a most potent effect on causing and removing symptoms. The literature of hysteria is full of such instances.

OPHTHALMIC RELATIONS OF HYSTERIA.

Dr. C. P. PINCKARD—As we all know, eye symptoms may be very prominent in the clinical history of hysteria. They may be briefly divided into disturbances of motion, disorders of secretion, disorders of sensation, disturbances of sight, and abnormal sensations.

1. Strange to say, paralyses are not at all common, while spasms, on the other hand, are very frequent. An exception may be made, however, in the levator palpebræ, which is frequently paretic and not associated with other pareses. According to Charcot, it is particularly frequent in children. The next most common symptom in the muscular apparatus is a paresis of the abducens, or more probably a spasm of the abducens. Of the internal muscles, pareses of the ciliary occur, but the diagnosis is difficult. Paresis of the iris is rare. Blepharospasm is often observed, and a rhythmic twitching of the lid is said to be very characteristic. Variation in the size of the pupils is frequent.

2. Among the disorders of secretion, epiphora is frequent: edema and sweating also occur. They begin and disappear very suddenly, and may be transferred from one side to another by means of the contact of magnets, acids, etc.

3. Of sensation, anesthesia of the skin of the lids, temples, conjunctiva and cornea are very frequent, with or without retinal anesthesia. Paresthesias are also often observed, such as hyperesthesia of the lids, conjunctiva and cornea, with or without photophobia. Pain is very common, especially those pains beginning in the eye and radiating toward the forehead, temple, teeth, etc. These may occur with or without efforts at accommodation. At times tenderness is present in the ciliary regions.

4. The most important class, however, is the disorders of sight. According to Charcot, a pathognomonic sign of hys-

teria is the concentric narrowing of the field of vision with more or less impairment of central vision and of color perception. This, as a rule, is associated with anesthesia of the conjunctiva and cornea. This disturbance of the sight is usually unilateral, but if it be bilateral it is more marked on one side. Unilateral amblyopia is much more common than complete blindness, but double amblyopia is still rarer. The boundaries of the field for the different colors may be entirely abnormal, so that the curves of the different colors may cross each other, or the order be reversed. Charcot has said that hemianopsia does not occur in hysteria, but others, as Landolt and Glorieux, have denied this. Diplopia or polyopia, either unilateral or bilateral, is a rare symptom, but occasionally occurs. Complete blindness is much more common in one eye than in two, but bilateral blindness is not so rare as it would seem. Within the past three months I have had two cases of bilateral complete blindness, one in a woman 36 years, the other in a child of 14 years, in both of which cases the attacks came suddenly and disappeared as suddenly upon suggestion.

5. Of the abnormal sensations the most important one is the so-called *audition colorée*, that is, certain tones or words produce a coincident vision of color. Still rarer, where certain colors perceived cause coincident tones.

The case of ptosis, reported by Dr. Kiernan, without other symptoms in the eye, is very characteristic. As was said before, this symptom occurs more often in children than in adults.

A diagnosis of hysteric symptoms from symptoms simulated is at times very difficult, and can only be positively made by association with other symptoms in other parts of the body.

PRACTICAL NOTES.

Incompatibility of Hydrochlorate of Cocain and Nitrate of Silver.—

If cocain is to be used with nitrate of silver, the nitrate must be used, instead of the hydrochlorate, as the latter causes an insoluble precipitate of silver to be deposited.—*Nouv. Remèdes*, November 8.

Sterilization of Catgut.—Rajewski recommends that the catgut be sterilized while it is being manufactured with a 1 per cent. solution of formaldehyde. This sterilizes the interior, and superficial sterilization is sufficient after this. He considers chemie methods of sterilization more reliable than physical.—*Cbl. f. Chir.*, November 6.

Painful Dentition in Infants can be relieved by frequently washing out the mouth with a 1 per cent. solution of chloral hydrate, which is antiseptic as well as analgesic. Rub the gums to soothe the pruritus with the following: Cocain hydrochlorate 15 centigrams; chloroform, 1 gram; glycerin, 20 grams; essence of roses, 6 drops.—*Presse Méd.*, October 20.

Prophylaxis of Chapped Hands.—After washing the hands with non-irritating soap, rub in the following lotion and allow it to dry on the hands. It is especially recommended to physicians and surgeons. Alcohol, 80 grams; glycerin, 35 grams, rose-water, 30 grams; salol, 2 grams; tincture of musk, 2 drops.—Morel-Lavallée in *Gaz. Méd. de Liège*, August 22.

Mother Solution of Formol for Surgical Antisepsis.—The disagreeable odor of formol is disguised if prepared as follows: Alcohol solution of formol at 40 per cent., 25 grams; tincture of eucalyptus, 5 grams; ethyl alcohol, q.s. to make 200 c.c. Each teaspoonful contains 25 centigrams of formic alcohol; 1 to 4 teaspoonfuls to the liter of water.—A. Reygasse, in the *Semaine Méd.* of November 24.

Oxygenated Water in Psoriasis, Otorrhea and Plugs of Cerumen.—E. Luton reports a severe case of psoriasis cured with injections of an oxygenated serum as follows: 10 per cent. solution of sodium phosphate, 75 grams; oxygenated water, 20 volumes. 25 grams. Local applications of oxygenated water assisted the cure, which was surprisingly prompt and complete. A small quantity of oxygenated water dropped in the ear will soften the hardest wax plugs so that they can be syringed out without difficulty. The efficacy of oxygenated water in purulent chronic otitis, with or without mastoid complications, has

already been proclaimed in America and Belgium. Buys and Lebarre had only three negative results in sixty cases treated with it.—*Semaine Méd.*, October 27, November 10 and 17.

Treatment of Epidemic Cerebrospinal Meningitis with Injections of Sublimat.—Nineteen recovered in twenty-seven cases, all treated with a daily subcutaneous injection of sublimate, varying with the age from 5 decimilligrams to 1 centigram. Improvement was observed after the second or third injection; the pain was relieved so that the patient could sleep; consciousness returned after the fifth or sixth, and the fever gradually subsided. Four to twenty-four injections were required.—B. Angyan of Budapest in the *Semaine Méd.*, October 20.

Abortive Treatment of Influenza with Calomel.—Freudenthal has been successful in aborting influenza with 10 centigrams of calomel twice a day (men) and 5 centigrams three times a day (women), administered in the first or second day of the attack in epidemics of grip. The temperature falls in six to eight hours, the neuralgic pain subsides and the cure is complete in forty-eight hours, or in a week when the treatment was not commenced until the third day. He combines antipyrin or phenacetin with it if there is much pain, wet packs of the thorax if the fever does not subside, and sodium iodid if there are respiratory complications.—*Presse Méd.*, November 6.

Treatment of Chilblains with Chlorinated Lime.—This substance passes through the epidermis and soothes the inflammation beneath, applied in a salve gently rubbed in for five minutes at bedtime and covered with an impermeable bandage (Rp. Calcar. chlorat., 1.0; Unguenti paraffini, 9.0; M. f. unguent. subtiliss. D. in vitro fusco. For external use). This salve has often cured the obstinate and disfiguring redness of the tip of the nose in women during the cold weather. The chlorinated lime must be fresh and effective and the salve smell strong of lime, otherwise it is worthless. C. Binz, *Therap. Woch.*, October 24.

Compression of the Nerves to Relieve Whooping Cough.—A. de Miranda announces in the *Semaine Méd.* of October 20 that compressing the vagus at the neck checks the vomiting in this disease, and that compression of the superior laryngeal rapidly calms the paroxysms of coughing. The family can be easily instructed how to perform the compression. In the early stages of the affection the bronchi are full of mucus and the cough must be allowed its course, but later the compression will be found practicable and effective. He also reports the cure of one case of uncontrollable vomiting in pregnancy by compression of the cervical portion of the pneumogastric.

Protargol.—Prof. A. Neisser states that he has never obtained such certain and permanent cures in gonorrhoea as since he commenced to use protargol. It is a fine yellow powder, a combination of 8 per cent. silver with a protein, dissolves readily and is not precipitated like the other silver salts by albumin, diluted sodium chlorid, hydrochloric acid or sodium. Its general disinfecting power is not yet established, but its efficacy in gonorrhoea is beyond question. He uses a 0.25 per cent. solution, increasing to 0.5 and 1 per cent and makes three injections a day, the patient retaining the fluid five minutes after the first two injections and thirty minutes after the last, soon reducing the treatment to the one long retained injection a day. This treatment is so little trouble that it can be kept up three to four weeks and ensures a permanent cure.—*Therap. Woch.*, October 24.

Hernial Tuberculosis is the subject of an extended study by Barozzi reproduced in the *Jour de Méd. et de Chir.*, of October 25. In the twenty-two observations on record the diagnosis was usually uncertain, and the operation alone, which is the only treatment, cleared up the question. The existence of a liquid effusion, the thickening of the sac and the presence of indurated points, are the guide, as the subjective symptoms

vary from severe functional disturbances, much pain and edema to merely slight discomfort. Left to itself the termination is always fatal, and the fourteen cases on record have a mortality of 21.4 per cent. Jonnesco advocates herniotomy: the resection of the diseased intestine seems risky to him in such cases. Koenig also asserts that the circumscribed lesions of the intestine have a tendency to spontaneous recovery, but the writer, Terrillon, Routier and others, consider laparotomy indicated, especially when the bacillary lesions have invaded the large peritoneal serosa.

To Disguise the Taste of Cod-liver Oil.—R: Cod-liver oil, 400 grams; syrup of tolu, 200 grs.; tincture of tolu 12 drops, essence of cloves, 2 drops. Do not emulsify. Shake well before using. Dose: a tablespoon two or three times a day.—Bricemoret, *Rev. Méd.*, November 10.

Dangers of Arsenic in Cutaneous Diseases.—Brocq states in the *Jour. de Méd.* of September 10, that arsenic should only be administered in dry dermatoses, never in the moist kinds, as it makes them worse. He even ascribes some of the keratoderma accompanying Dürhing's disease, to the arsenic treatment exclusively, also pigment patches.—*Therap. Woch.*, November 14.

Eudoxin in the Gastro-intestinal Troubles of Children.—Recommended by Rosenheim for chronic diarrhoea in adults, Ladniewski has been testing this bismuth salt of nosophen in fifty-eight cases of diarrhoea, and announces that he found it effective in some cases with mucous or purulent discharges that had resisted the usual remedies, bismuth, nitrate of silver, etc. He gives as many centigrams as the child is months old; limit, 50 centigrams, repeating the dose two to three times a day. In other forms of diarrhoea it is counter-indicated, particularly in cholera infantum.—*Semaine Méd.*, November 10.

Pyramidon.—The antipyretic and antineuralgic properties of pyramidon, dimethylamido antipyrin, have lately been proclaimed by several who consider it a valuable acquisition. The temperature is gradually lowered from one-half to two and one-half degrees during the two hours after the dose (0.2 to 0.6 gram), and slowly rises again in four to six hours. It has also a marked soothing effect. Horneffer tried it in forty-five cases of phthisis, also in pneumonia and typhoid, and states that there are no inconveniences from its use, which can be kept up for months without injury or lessening of the effect. It proved ineffectual in ischias, but cured trigeminal neuralgia and headaches, the latter in one dose. (*Berl. Klin. Woch.*, No. 35). Two cases of trigeminal neuralgia cured with it were reported at the Congress of Naturalists and Physicians. Feuerstein has found it possible to prevent fever altogether in pulmonary tuberculosis, by the administration of 0.6 gram during the hour in fractional doses. He confirms its harmlessness. No benefit seems to have been derived from it in rheumatism. *Therap. Woch.*, Nos. 41 and 44.

Reduced Mortality from Pulmonary Tuberculosis.—Good effects have already begun to show themselves in New York City as a result of the compulsory notification of cases of pulmonary tuberculosis to the Board of Health. In a report to Mayor Strong, this Board declares as a result of three years' special effort to stamp out pulmonary tuberculosis that the disease is a distinctly preventable one; that it is not directly inherited; and that it is acquired by transmission from the sick to the healthy. Deaths due to pulmonary tuberculosis are now 30 per cent. less than they were twelve years ago. The Board recommends that the law should be amended so that all cases of pulmonary tuberculosis shall be reported to it; that rooms of a patient dying from the disease shall be disinfected; that special care be used in transporting tuberculous patients on railroads, steamers, etc. The general dissemination of a knowledge of the foregoing fact, in conjunction with an application of the principles of an enlightened hygienic will do much not only to further diminish the mortality from tuberculosis but also to restrict its general prevalence.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, DECEMBER 25, 1897.

IS THE APOTHECARY SHOP DOOMED?

Industrial evolution, as well as professional evolution, is constantly changing the relation of individuals to each other. The apothecary shop was originally the medicine-room of the physician. Galen himself is supposed to have used the word, deriving it from the Greek *apotheka* meaning a store or magazine. It was not until the time of Henry VIII. that apothecaries were recognized as distinct from the medical doctors. They were incorporated in 1606 together with the grocers, but later on had a separate organization, and since then have become more and more specialized. Today another change seems to be taking place among them. The manufacturing pharmacist with his large factories and hundreds of workmen, is assuming here and there the duties of the dispensing apothecary.

On the one side the physician has his medicines ready made; his pills, tablets, coal-tar combinations, organic compounds, elixirs, etc., are used as they come from the manufacturer. The apothecary dispenses them as the grocer sells baking powder and soap. No skill is necessary to fill a prescription for "Aunt Martha's Soothing Syrup" or "Roberts' Elixir of New Life." On the other hand, the science of therapeutics is becoming simplified; no twenty-ingredient mixture as in old times; not so much dosing; more expectant treatment; and the pill manufacturer is putting up cough syrups and tonics and fever mixtures to please the taste of the most fastidious.

Where is the apothecary to go? Is he to become a vendor of toilet articles and fancy crockery? Is he to be the commission agent for the pill manufacturer?

Or is he to set up a medical advice counter and revert to the old surgeon-apothecary of the Middle Ages?

In the cities, many druggists study medicine and advertise *advice* and drugs for a nominal fee, and, on the other hand, many doctors buy a case of tablets and mixtures and dispense their own drugs. The manufacturing pharmacist in all probability is going to stay and to enlarge his domains. His agents will become more obtrusive, physician's samples will be left in greater numbers, and he will have his retail agents on every corner. Perhaps this is not bad; perhaps it will insure greater uniformity in quality. The large manufacturer can afford to test all the drugs he purchases; he can command the best skill in manufacturing; he can obtain greater accuracy; his pharmacists are not bothered by retail customers, or talkative friends; they need not be overworked and underpaid.

The corner drug store with its boy and one clerk and its thousand and one things requiring attention its soda water counter, window cleaning, unpacking of goods, etc., is not in a position to fill prescriptions accurately. The large factory with its labor divisions is surely in a better position.

In the evolution of the trade, the manufacturing pharmacist must supplant the small drug store just as the department store supplants the small dry goods shop.

Even at present very few pharmacists do more than act as agents for the wholesale druggist. They buy their tinctures and extracts, pills and plasters already made. Their infusions are water-diluted extracts their waters are mixtures of essences. They have not the time nor the means to make their own preparations, and the chances are that the crude drugs they would make them from would be beneath the standard.

And then they must load their shelves with a dozen makes of pills, a hundred and more new remedies that the physician tries once and abandons. Surely the lot of the apothecary is not a happy one. Can the doctor do anything for him? We hardly think so. Economic reasons are at the bottom of it, and the druggist must go the way of the tailor, the shoemaker and the cigar-maker. His education must fit him for the laboratory of manufacturing apothecary and not for the corner drug store.

THE DISINFECTON OF BOOKS.

It has long been recognized by boards of health and others that the disinfection of school books and library books was a peculiarly difficult problem. We therefore note with pleasure that Dr. J. S. BILLINGS of New York City has taken the problem in hand, especially that which relates to the sanitation of libraries.

Attention has been called to this matter so repeatedly that many of the boards of health of the different

States have taken action and caused the State legislatures to make a criminal offense for persons coming in contact with contagious diseases to borrow books from circulating libraries. But the act is often done so unwittingly that some other means seem necessary in order to combat the evil.

Be this as it may, future borrowers from New York's great library can rest assured on this head, for the trustees have already formulated a plan by which means every book that leaves the library shelves will be submitted on its return to a process of sterilization and disinfection that will free it from all its pathogenic properties. Several months ago, when the idea of the consolidation of the free libraries was but yet in its infancy, the officers of the library commissioned Dr. JOHN S. BILLINGS, the future director of the library, to make experiments with a view to determining how such a process could best be carried out, and it is the result of Dr. BILLINGS' investigations that will prevail when the new library is opened.

The agent that Dr. BILLINGS will employ is formaldehyde gas. In actual practice each book as it is returned will be placed in a double-walled box of Russian or Swedish iron, the inner wall of which is perforated, and which has a double-walled door, which will tightly close and inside of which is a false door of glass. In this box are shelves on which the books are laid, the bottom shelf being perforated and opening into a generating box. The books are allowed to remain in this box for a period of two hours, at the end of which time not a trace of live organism can be discovered. Not only does the method not injure the books in the slightest degree, but it actually rids them of the small parasites that infest morocco and calf bindings and which prove such a source of annoyance to those who treasure up old and musty volumes.

THE TEACHING OF MEDICINE.

Medicine can be readily separated into two distinct portions; the scientific and the practical or art. The science of medicine, or better, one should say the sciences used in medicine, can be taught by the specialist whose knowledge of the practice of medicine may be very limited. Chemistry, physics, biology, physiology, anatomy, microscopy, histology, pathology, bacteriology and materia medica are capable of being taught in the class-room and laboratory without the aid of the living human subject.

These branches of science so virtually necessary to the practice of medicine should be taught by men thoroughly trained and competent, and as this requires time for which no recompense is to be had out of practice, and as the knowledge can not be acquired in practice as other specialists such chairs should pay their occupants sufficiently well to permit them to give most of their time to the study.

There would then be a goodly number of anat-

mists, physiologists and medical chemists who could devote themselves exclusively to these sciences, and who would be scientists pure and simple.

The study of the application of the above science to the cure of disease must necessarily be demonstrated on the human subject, and by persons sufficiently acquainted with the manifestations of disease by actual clinical experience to be able to do so completely.

The hospital, dispensary and private practice is the laboratory of the clinician. Every addition to his knowledge can be put to use among his patients for his own material benefit. The position of teacher is in itself a positive benefit, as it brings to him the consultations with his former pupils, and increases his importance in the eyes of the individual who might require his services.

The man who is called to teach one of the clinical specialties of medicine should, if anything, be compelled to endow his own chair, since the advantages to be derived from such a position are quite considerable from a material standpoint. In former times great men gathered about them young students to teach them the art of medicine, or some particular portion of it. And schools were often known as the school of this man or that. Such teachers may have been filled with a desire to impart knowledge, or a love of authority, or only with the hope of gain, but whatever the end, they fully realized the advantage of teaching.

Medical schools in our country are too much concerned about the practice of medicine and too little about the science. The laboratories and scientific branches instead of being relegated to the young men who regard them merely as stepping-stones to some clinical position, should be in the hands of well-paid specialists who will aim to make the subject interesting and complete, so that the student will not shirk them as disagreeable tasks to be gone through with as superficially as possible.

There will be no difficulty in filling the practical chairs without pay if it is generally understood that a consulting practice comes through the collegiate position, and the money so saved should be used to strengthen the other side of the school.

MORE MEDICAL PSEUDO-SCIENCE.

It is not very long since there was reported in the daily papers that a Washington professor, apparently not connected with any of the scientific Government bureaus, had made some remarkable discoveries in microscopic technique which were likely to revolutionize our method and greatly enlarge our range of microscopic vision. His own account of his achievements is contained in the two latest issues of the *New York Medical Times* and is of a character to perhaps deserve notice if not unqualified belief. He claims amongst other things that by inserting the objective of one microscope into the place for the eye piece

another he is able to increase the magnification of objects to a most wonderful extent; that he is able to photograph with an infinitesimal amount of light, less than the one-hundred thousandth part of that formerly necessary; that he can make sections the thickness of one-hundredth of the thinnest section heretofore produced and can thus divide a single cell into hundreds of separate slices. To appreciate these claims one has to realize that they apparently mean that he is able to magnify the image in the first of his two connected microscopes to the extent of the magnifying powers of the second; and that his sections, assuming that the thinnest heretofore made were two microns in thickness, would be less than one millionth of an inch in thickness, or less than the wave length of the shortest visible ray of light. We would be justified in some incredulity of these pretensions, were they far less extravagant, and if not prepared to reject them *a priori* from our acquaintance with the physical laws of matter and the laws of optics one could judiciously leave them in his suspense account until such actual and verifiable results were demonstrated as would amount to something more than claims. As it is, however, it is hardly possible to do more than to charitably assume self-deception and nothing more actual than faulty reasoning and imperfect and misdirected observations.

This would be the natural and proper mode of view were these assumed discoveries all that were announced. The author of the papers in the *Medical Times*, however, goes on to lay down at length his theories which one can best describe as a mind-cure system worked up in a pseudo-scientific way. He adopts the theory that mind and vitality are one and that physiologic processes are purely mental phenomena, an old notion that has been revived as a basis for a therapeutic system possibly many times, and notably by STAHL in the beginning of the eighteenth century, but one which requires too many assumptions and too much ignoring of difficulties to meet successfully any truly scientific tests. Plausibly stated, however, and with an abundance of pseudo-scientific verbiage it may easily gain adherents, and its appearance in a respectable medical journal, of homeopathic antecedents it is true, but with a broader and less sectarian tendency than is common amongst such publications, is a matter to be regretted.

In these times when faith cure and Christian science are so much in vogue, it is not surprising that some one should seize the opportunity to bring out a system practically identical with these but without the religious auxiliaries that contribute so largely to the success of these delusions. Such have indeed their disadvantage with a certain class of minds; the liability to medical delusions is by no means confined to church goers, or the religiously inclined. A system of hysteric therapeutics that starts out

like this one with the claim that vitality and physiologic processes are simply mental processes, and that the laws of health and disease and crime are therefore all made manifest "not by faith or through mysticism and symbolism" but professedly by verified facts ascertained by asserted scientific researches, will attract a large class who would reject the same methods offered under the guise of Christian science or a faith cure. Practically it is Christian science for non-Christians, a pseudo-scientific jargon taking the place here of the religious phraseology that characterizes the other; the element of credulity is alike predominant in both.

The whole performance is simply a revival of an antiquated psychologic theory as a basis for a sort of suggestive therapeutics, supported by extravagant statements of alleged discoveries and a few commonplace but misinterpreted experiments and observations.

CORRESPONDENCE.

Department of Health Bill.

CHICAGO, Dec. 18, 1897.

To the Editor:—I was greatly interested in reading Governor Bloxham's communication in the current issue of your JOURNAL (see pages 1284 85) regarding the proposed Department of Public Health having at its head a "Secretary of Health," etc.

Permit me, therefore, to introduce briefly as I can the following additional argument as it occurs to me at this moment, in addition to what has been stated by the Governor of Florida, why such department should be created. Twice within the past five years, namely, during the summer of 1892 and the year following, the commerce of this country was materially disturbed and the lives of the people greatly endangered by a threatened invasion of *supposed* Asiatic cholera, and that more recently, yellow fever has gained entrance to the United States, namely, in 1893 and during the early autumnal months of the present year (as has already been ably stated), wherein many cities throughout the Southern States became infected with the germs of this oftentimes very fatal though *preventable* malady. Such being the case as the *status præsens* conditions exist, it is to my mind not impossible that a repetition of these and kindred diseases of pestilential origin and character may in future invade the United States from foreign shores, and its ravages again result in the loss of many precious lives, a panic among the living (*refugees*), as well as a serious menace and great financial loss to the commercial welfare and industrial interests of our country.

It appears to me, therefore, that every medical society, and perhaps other scientific bodies throughout our land should heartily approve and give their unqualified indorsement to the Department of Public Health bill that has been prepared by the special committee of the AMERICAN MEDICAL ASSOCIATION, and as such was unanimously adopted at the semi-centennial meeting of said ASSOCIATION at Philadelphia in May last, and which was subsequently unanimously *accepted* at the twenty-fifth anniversary (annual) meeting of the American Public Health Association held in the same city in October.

As many associations have already placed themselves on record "by endorsing this bill," the profession as a unit is certainly *uniting* in its manifestation of having the utmost confidence in the ability of this special committee into whose hands this matter was intrusted, and I will go farther by stat-

ing that any additional amendments to said bill should meet our hearty approval so long as the purport of its original intent and meaning shall remain unchanged and the amendments are germane to the bill, for we may not be able to get the bill enacted exactly in its present form and it may become necessary to make some minor changes, etc.

I am also reminded that the holiday season is approaching, and that many of our Senators and Representatives will "go home" on a visit at this time. This will afford "us" a splendid opportunity to personally respectfully request of our friends, our National legislators, that they carefully consider "our" Department of Public Health bill, with the view that favorable action will be taken by them toward passing this already too long delayed measure. And why should there not be a Medical Secretary or a Commissioner of Public Health, to be on a parity and rank with equal dignity as the various secretaries of the other departments of the Federal Government?

Why should the Secretary of the Treasury be longer expected to (nominally) remain at the head of the hygienic welfare of this nation? The answer is, We are too great and have outgrown such ideas.

In conclusion, I trust that Congress, during the present session, will legislate upon this question for the "welfare of the people" as provided in the Constitution of 1787, adopted in 1788, and that every physician throughout the country who has not already personally interviewed his Representative or United States Senator and discussed this topic with him, will do so, by correspondence or otherwise, within the near future, and appeal to him to vote for said bill.

With best wishes for our JOURNAL also in its efforts in this (the right) direction, and for its future prosperity, and a very merry Christmas and bright New Year to all its readers, I beg to remain,

Very sincerely yours,

LISTON H. MONTGOMERY, M.D.

Concerning Rates to the Denver Meeting.

SIoux FALLS, S. D., Dec. 16, 1897.

To the Editor:—Dr. J. F. Jenkins in the JOURNAL of December 11, thinks that if the Committee on Transportation could obtain the same rates to the meeting of the AMERICAN MEDICAL ASSOCIATION that other less important bodies get, we could have at least five thousand physicians present at the Denver meeting next year. Now, we have been informed that the doctors formerly had all they could ask for in the way of rates, until they abused their privileges. The railroad companies finally kept tab, and discovered that in one year, free transportation to the amount of about \$60,000 had been called for and used to go to places other than the ASSOCIATION, over and above that actually used in good faith. The railroads thereupon cut off free transportation over each other's lines to their surgeons, thereby punishing the innocent with the guilty.

Hence, the doctors have some of their own numbers alone to blame in that direction. If the committee could induce the railroad companies to grant transportation to their surgeons, under such restrictions that the companies could not be imposed upon, hundreds of railroad surgeons would attend who could not otherwise afford to do so.

The incidental expenses outside of transportation amount to quite an item to the average country doctor.

Our experience with railroad companies is that they appreciate good, honest service, and are liberal with those who do not abuse their privileges. It is certainly to their advantage to have their surgeons use every available means to improve themselves professionally.

It is true, the AMERICAN MEDICAL ASSOCIATION includes all regular physicians in good standing who wish to join, and is in no way intended more for one branch or class of the profession than another: yet the existence of two national

associations of railway surgeons, besides numerous smaller ones, demonstrates that that class of physicians are active and progressive; men who would not only be glad to avail themselves of the benefits of the AMERICAN MEDICAL ASSOCIATION but would make valuable members as well.

Yours respectfully,

A. H. TUFTS, M.D.

PUBLIC HEALTH.

Prophylaxis of Yellow Fever.—Lacerda states that the epidemics of yellow fever in Rio de Janeiro are due to the periodic revivification of the germs of yellow fever in certain permanent foci in the interior of houses and the holds of ships, where they propagate, favored by dampness, darkness and filth. They can not live any length of time in sewers nor in open water nor anywhere exposed to the sun. His conclusions were adopted by the Academia de Medicina, which proclaimed that the extinction of these foci in Rio de Janeiro is practicable and necessary.—*O Brazil Médico*, October 22.

Sanitation of Railways and Steam Vessels.—The *New Orleans Medical and Surgical Journal* states that the State Board of Health of Louisiana has adopted resolutions calling attention to the present lack of sanitary measures in vogue on public carriers, notably steam vessels and railroad sleeping cars. The necessity for reform in this particular is too glaring to need defense. No one who travels fails to observe the offence to health and ethics which exists on the steamship or sleeping car. The wash-basin is used by the porter for his own toilet and it is not an infrequent thing to see the cuspidors washed out at the same font. From the standpoint of health, it is familiar to all that no provision is made for those suffering with tubercular affections or with other ailments. We have seen the syphilitic, in acute eruptive stage, use the common drinking-glass, the toilet articles and eating from the buffet crockery. Not long since a lamentable instance was related to us of a woman dying of tuberculosis, on her way to New Orleans making the car uncomfortable by her spells of coughing and rendering the atmosphere unbearable by the emanations from the decomposing lungs. The Pullman conductor relating the incident, deplored the fact that no provision was made for the separation of such cases. Resolutions can only direct intelligent thought at the remedy, but persistent effort in directing attention to the necessity for some remedial measure must result in its application. State legislatures have it in their power to compel sanitary measures through their State Board of Health, and there is no reason why the legislative action should not go farther in compelling provision for the hospital accommodation in transit for such cases as the above.

Fumigation of the Domicile by Corrosive Sublimate, followed by Sulphur.—The October number of *Public Health* contains the following annotation regarding the disinfection of rooms after contagious disease. Professor Koenig of Goettingen, in a recent article, says that at one time, while he was practicing medicine in Hanau, he suddenly discovered that his bed-room was thickly inhabited by obnoxious insects. A friend assured him that he could easily get rid of the pests and proceeded to fumigate the apartment with corrosive sublimate. The success of this measure was most gratifying, and when the room was opened the dead bodies of various kinds of insects were seen strewn about the floor. This incident led the professor to hope that the same means would be effectual in destroying the infectious elements of contagious diseases, and a trial in private houses after scarlet fever or measles, and in hospitals after erysipelas or pyemia, gave most satisfactory results. Since adopting this method he has never seen a second case of contagious disease which could be attributed to infection remaining in the room in which the patient had been confined. The mode of procedure is very simple. From one and one-half to two ounces

of corrosive sublimate are put on a plate over a chafing-dish, and then the windows and door of the room are closed. At the expiration of three or four hours the windows and doors are opened and the apartment is thoroughly aired. The person entering the room should take the precaution to hold a sponge or cloth over the mouth or nose in order not to inhale the vapor. The following day the windows are again closed and some sulphur is burned in order to neutralize any of the mercurial fumes which may linger about the furniture and other articles. The room should then again be aired and cleaned, when it will be ready for occupancy.

Slaughter-House Ordinances in Early England.—In Richard II.'s time we find an act for "the punishment of them which cause corruption near a city or great town to corrupt the air" (12 Rich. II., C. 13, A. D. 1388), the preamble of which notes that so much filth "be cast and put in ditches and other waters and also within many other places . . . that the air is greatly corrupted and infect and many maladies and diseases do daily happen." A century later we find an act under the heading "Butchers shall kill no beasts within any walled town or Cambridge" (4 Henry VII., C. 3, A. D. 1487). The preamble of this speaks of the "Corruptions engendered by reason of the slaughter of beasts and the scalding of swine," the "unclean and corrupt and putrified waters," and adds "that in few noble cities and towns, or none within Christendom, the common slaughter-house of beasts should be kept within the walls of the same, lest it might engender sickness unto the destruction of the people." It was nearly four hundred years later when the 317 slaughter-houses scattered promiscuously in New York City below Eightieth street, were driven out and the work concentrated in clean abattoirs outside. When London was to be rebuilt after the great fire, a law was passed for "the cleansing and scouring of vaults, sinks and common sewers" (19 Ch. II., C. 3, A. D. 1667), and in 1670 another was passed for the better paving and cleansing of the sewers and streets in and about the city of London.

Hospital for Consumptives at Paris.—A part of the large estate of the late Madame Boucicault will be directed to the establishment of a hospital for the treatment of tuberculosis. The hospital is only one of the many objects of charity for which Mme. Boucicault left money, but it is the most important. The buildings have cost with furniture, about \$650,000 and a sum of \$1,500,000 was left for its maintenance, the interest of which will amount to about \$45,000 a year. Any expense not covered by the gift will be liquidated by the Assistance Publique, which, besides receiving money from the city, receives yearly large bequests from private charity. This institution which bears her name, is upon the point of opening, in the charge of Professor Maurice Letulle, who has had marked success in his treatment of tuberculosis at St. Antoine. The new hospital has an ideal situation in the comparatively open quarter of Paris known as Javel, which is on the south side of the Seine opposite Auteuil. The building is isolated, even the four streets inclosing it being wide and little traveled. Although the building is large there will be but 160 beds, as the great object is plenty of space and ventilation. Of these beds only thirty-two will be devoted to consumptives at the beginning, but it is believed that the hospital will eventually become one for such cases only, and the buildings have been planned with that end in view. Sixteen beds are reserved for employes of the Bon Marché; otherwise the hospital will be absolutely free. The main improvements to be noted are in the condition relative to the housing of the consumptive patients. The two wards to be devoted to them exclusively from the start occupy separate pavilions. The wards themselves are glass-roofed galleries, the sides of which may be made entirely open. This is for the air treatment, which is a method constantly growing in favor. The patients will, practically, eat, sleep and live out of doors, without draughts and protected by the glass roof. Only in stormy and very cold

weather will the galleries be closed. The flooring is of polished hard wood, the furniture of enameled iron, and there is no curtain or drapery of any kind. The object is to be able to disinfect the entire apartment by means of steam and hot water. The mattresses are made of wood fiber, sterilized and unflammable, and the system of spittoons is entirely new. The matter of instant sterilization of all discharges from the patients' mouths and throats is to be carefully looked after. Finally, the clothing of patients, nurses and servants is to be specially fashioned, and is to be kept constantly disinfected. The patients, also, are to be graded as to the stage of the disease in which they may be. Incurable patients are to be isolated in smaller rooms away from the wards.

ASSOCIATION NEWS.

Section on Laryngology and Otology.—A bound reprint or volume of the Transactions of the Section on Laryngology and Otology at Philadelphia will be prepared; after publication in the *JOURNAL* and furnished to subscribers at \$1 per volume, provided seventy five subscribers can be at once received. Those wishing the volume and who have not already entered, therefore, will please send their names without delay to Dr. W. E. CASSELBERRY, Chairman, 34 Washington Street, Chicago. It is urged that as many subscribe as possible as the valuable papers contributed at this meeting will thus be preserved in book form, and the custom of issuing an annual volume established.

BOOK NOTICES.

The Physician's Visiting List for 1898. Leather. Philadelphia: P. Blakiston, Son & Co. Seventy five cents to \$1.25.

This visiting list contains calendars for 1898 and 1899. The metric system of weights and measures, a dose table giving both the English and metric systems to correspond with the U. S. P., a table for converting apothecaries weights and measures into grams, and other data. The list is published in three styles, all containing special memoranda pages.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Paper, 90 pages. Baltimore. 1897.

This volume of transactions covers the ninety ninth annual session held at Baltimore, April, 1897, and the semi-annual session held at Hagerstown, Md., November, 1896. The contents comprise reports of various boards, committees, etc., lists of presidents, vice-presidents and members, the presidential address on "The Functions of a State Faculty," by Wm. Osler, M.D., and the annual address, "Does Medicine Advance?" by David W. Cheever, M.D.

Transactions of the South Carolina Medical Association. Paper 129 pages. Walker Evans and Cogswell Co. Charleston, S. C.; 1897.

This volume contains the transactions of the forty seventh annual meeting, held in Union, S. C., April 28 and 29, 1897. The following papers appear: Ectopic Gestation; Observations on Continued Fever; Carbolic Acid in the Treatment of Hemorrhoids; Graves' Disease; Oxygen Gas as a Local Therapeutic Agent; Remarks on Otitis Media and Otitic Syphilis; Up-to Date Treatment of Cataract; Kangaroo Tendon as a Ligature and Suture in Ovariectomy; Dr. Paquin's Antitubercle Serum; Removal of Pus Tubes and Appendix; Acute Opium Poisoning; Trephining for Traumatic Epilepsy; Leucocytosis on Element in Diagnosis and Prognosis.

Transactions of the American Surgical Association. Vol. xv. Edited by DEFOREST WILLARD, A. M., M. D., PH. D. Printed for the Association. Philadelphia: William J. Dornan. 1897.

This volume contains the usual number of interesting papers by members of the Association, and necrology reports on Sir Thomas Spencer Wells, Sir John Eric Erichsen, Sir George Humphry, William Hunt, William H. Pancoast, Perry H. Millard and J. Edwin Michael. The addresses and ceremonies on

the occasion of the presentation and unveiling of the Gross statue are given, an excellent half-tone showing the statue itself with the Army Medical Library in the background. Altogether one of the most notable volumes of this series yet published, especially from a historic point of view.

The JOURNAL has heretofore published an account of the meeting (see JOURNAL, May 15, 1897, p. 947), and commented at length upon the character of this session.

An abstract of the papers can be found in the JOURNAL, May 29, 1897, page 1025.

MISCELLANY.

Errata.—In "Some Practical Points on Infant Feeding and Infant Feces," *vide* JOURNAL, December 11, page 1197, at the end of Formulas 2, 3 and 4, the amount of milk sugar should read 6¾ drams instead of 6¾ ounces.

The Pasteur Prize offered by the "Circulo Med. Argentino," was awarded to Dr. José Sanarelli, for a communication describing his experimental work in the line of immunization against yellow fever. As his article was the only one received, Dr. Sanarelli refused to accept the prize.

The Necessity of Aseptic Cushions for the operating table is urged by P. Klemm of Riga, who recommends for the purpose bags made of stout linen, of the required shape, filled as needed with excelsior (Holzwolle), and sterilized with steam, or the bag and excelsior can be sterilized separately. He has found these cushions convenient, cheap, absolutely aseptic and superior to rubber cushions for several reasons.—*Cbl. f. Chir.*, November 16.

Hay-fever at Carlsbad.—M. Müller reports in the *Wien. Klin. Rundschau* of October 31, his opportunity to observe several cases of hay-fever among Americans at Carlsbad. After describing in detail the familiar symptoms, he mentions that he succeeded in abating them to such an extent that the patients were enabled to return home and not wait for frost as usual. His treatment was a full course of the waters and local applications of a 20 to 30 per cent. solution of argentic nitric., with which he touched the nasal mucosa, following it with a spray of Carlsbad water.

Dystrophia Muscularis Progressiva.—A case was recently observed by E. Bonardi, described in the *Gaz. d. O. e. d. C.* of August 15, that combined the more common picture of facio-scapulo-humeral dystrophia of Dejerine-Eandouzy with the rarer Brossard femoral dystrophia with pes equinus, etc. Both affections were typical manifestations, non-symmetric, with a functional lesion of the left eye, like a mist constantly before it, which the specialist was unable to remove. The first symptoms appeared at 19, with weakness of the limbs and inability to step on the heel.

The Conductibility of the Nerves in Both Directions is not demonstrated by physiology, but pathology and therapeutics confirm it in many ways, especially by the phenomena of electricity, catalepsy and suggestion. . . . The production and cure of morbid conditions by psychic stimulation appear in an entirely new aspect when viewed by the light of double nerve conductivity. . . . The fact is too often forgotten that the excitations originating in diseased conditions of the nervous system are usually propagated according to entirely different laws and in different directions from the physiologic stimuli. To correct the false deductions we have made in this respect, will be the task of the next generation. . . . Orschanski states that the nervous system is constantly in a condition of activity, which he calls nerve tonus, in its efforts to maintain the temperature and the general economy of the organism. It is probable that this tonus requires centripetal stimulation of the motor nerves and centrifugal of the sensory. From Prof. M. Benedikt's address in the Phys. Section at Moscow. *Deutsche Med. Woch.*, October. 7.

Spontaneous Sediment; Formation in the Blood a Method of Scientific and Clinical Investigation.—E. Biernacki has established the fact that the sedimentation of the blood is by no means a purely mechanical process, but depends upon certain factors which render it a valuable aid in scientific and clinical investigation along different lines from the hematokrit and centrifuge. The rapidity of the sedimentation is an indication of certain alterations in the blood which no other method is able to detect. It depends upon the amount of fibrinogen in the blood and varies with it. Another fact established by it is that the fibrinogen is in direct proportion to the capacity of the blood for oxygen, and the amount of oxygen contained in it, forcing the conclusion that fibrinogen is an albuminoid involved in oxidation, and hence that the variations in the amount of fibrinogen indicated by the rapidity of sedimentation point to abnormal processes of oxidation. His numerous experiments and the standards he has adopted for comparison are given in full in the *Deutsche Med. Woch.*, of November 23.

Fsüre's Method of Total Abdominal Hysterectomy is described and illustrated in the *Presse Méd.* of October 19. The abdomen is opened, the surgeon at the left, and the fundus is seized with forceps each side of the median line. With a scissors it is then cut down straight on the median line into the vagina, applying forceps half way down and again to the two stumps of the cervix. Each half then shells out from below upward, like a ripe nut, held only by the utero-ovarian vessels, which are then severed after seizing with forceps. The operation is surprisingly simple and easy. The only disadvantage is the opening up of a possibly infected uterus, but the danger from this is slight and can be prevented by touching the lips of the incision with the thermocautery. It is also an easy matter to disinfect the small pelvis afterward if necessary. The method is especially adapted to suppurated adnexa, as they are removed intact and all danger of infection from this source is avoided. It also avoids approaching the lesion from the periphery, which is frequently laborious and dangerous. He considers it applicable to all uteri of normal or slightly more than normal size. Cut in two from above down, the two halves, freed from their lower attachments, roll out from the vagina upward and can be enucleated with remarkable facility.

A Medical Man Honored.—Dr. Alexander Hill has been elected to the honorable position of Vice Chancellor of Cambridge University. This is the first time in history, says the *Lancet*, that the highest executive office of one of the two leading English Universities has befallen a medical man. John Caius, who, like Dr. Hill, was a student of St. Bartholomew's Hospital, ruled over the College, which he refounded and endowed, from 1559 to 1573, but he did not fill the office of Vice Chancellor. John Harvey was appointed Warden of Merton College, Oxford, in 1644, but lost his office six months later on the fall of Charles I. Of other medical men, if any, who have filled headships of colleges there is, we believe, no record. Dr. Alexander Hill's mastership of Downing alone excepted. Of late years medicine has made great advances at the universities, and we must look upon the election of Dr. Hill not only to the mastership of Downing but to the Vice-Chancellorship of the University as a proof of the increasing influence of our profession at Cambridge, and also as one of many recent indications that medicine is rapidly stepping into a position of equality with the sister professions of theology and law. Dr. Hill holds the office of Lecturer in Advanced Anatomy to the University. He was for some time Hunterian Professor of the Royal College of Surgeons of England. He is the author of many papers on the anatomy and physiology of the nervous system, the translator of Obersteiner's "Central Nervous Organs," and the author of the "Physiologist's Note Book" and other works. Last year he succeeded Sir William Broadbent as President of the Neurological Society and it is as a neurologist that he is chiefly known to the profession.

Treatment of Putrid Abortus, Hemorrhagic Endometritis, etc.—

Pincus considers steam almost a specific for these conditions. He uses a wooden speculum and injects a stream of steam at 100 degrees C. for two minutes (*Wien. klin. Rundschau*, October 10). This treatment is enthusiastically endorsed at Prague, where it is extensively applied. The technique there is described in an article in the *Presse Méd.*, of October 2. Schick prefers a boiling water, which he injects into the uterus for one minute, never more than a minute and a half. To prevent burning the vagina, he injects a constant stream of ice-water into the vagina at the same time. The uterus is first dilated and the patient put to sleep; she is also kept in bed until the eschar falls, which requires about three weeks. The wick of gauze in the vagina is changed every four or five days, and the vagina irrigated occasionally. No accidents nor inconveniences were observed at any time. In rebellious hemorrhagic endometritis, hemorrhage after curettement of uterine cancers or after abortion, and the metrorrhagia of the menopause, this treatment has proved a perfect hemostatic. In the first named, two cauterizations at an interval of a month or six weeks, have sometimes been required before the cure was complete.

Holothyrus Coccinella; a New Parasite.—M. Mégnin recently showed before the Paris Academy of Medicine a parasite of a fairly large size which had been sent to him from the Mauritius by Dr. Charmoy for the determination of its zoologic position. It is the holothyrus coccinella of Gervais. Its popular name is "trouille canard," and poultry farmers know its noxious properties so well that they have given up breeding birds in those elevated and damp regions of the island where this parasite abounds, lying hidden during the day under the moss and stones. Even children have often fallen victims when, having found a "trouille canard," they have put their fingers in their mouths after having touched it, for the tongue and pharynx become affected with an exceedingly painful swelling so that they are in danger of asphyxia. With his last consignment of these parasites M. Mégnin tried some experiments to verify the existence of these unheard-of properties. If one is applied to the skin and kept there by a bandage, a burning sensation is felt, which after a time becomes very disagreeable, although the skin is only slightly edematous and exhibits no change of color. Upon mucous membranes the effect is very much more pronounced.—*London Lancet*.

A Simple Regimen for Obese Persons.—Dr. Cathell reports that he has had more than ordinary success during several years with a plan of treatment outlined below. In his view, obesity is due to one or more of the following causes: Congenitally small lungs with a defective oxygenating capacity; eating excessively of all kinds of food; want of lung-expanding exercise; using alcoholic drinks to excess. Many of the drugs which have a known fat-reducing power exert an injurious action on the other tissues of the body, and if used persistently for any length of time, or in efficient doses become dangerous to health. While the various obesity cures are so rigorous that few carry them out conscientiously, the treatment of the author is very simple. The patient has only to drink after each meal a glass of the artificial Kissingen water to be found at drug stores and soda water fountains, and on the succeeding day, a glass of artificial Vichy water also half an hour after each meal. This is to be continued week after week until the patient comes down to a normal degree of stoutness, and the waters are then discontinued. While taking the waters the person should keep a weekly record of his weight, always using the same scales, and wearing the same clothing, and should also, for his own satisfaction, record his chest, waist and hip measurements. If the loss in weight exceeds two pounds a week, the amount of each water should be made smaller; and if the loss has not equaled two pounds a week, a few teaspoonsful of lemon juice should be added to each glass of the Kissingen water to increase its acidity, and a teaspoonful of aromatic spirits of ammonia to the Vichy to increase its alkalinity. The diet should be light and contain only small amounts of fat, starch, sugar, and alcohol. Moderate outdoor exercise should be included in the day's program. The mode of action of these waters taken in the manner described, is not clear, but their efficiency is too well established to admit of doubt.—*Maryland Med. Jour.*

Denver.

THE DENVER AND ARAPAHOE MEDICAL SOCIETY.—At the regular meeting, December 14, Dr. S. G. Bonney reported "An Unusually Successful Result of Thyroid Treatment in a Case of Myxedema." The patient was a woman aged 54 years, whose father died of cerebral embolism, mother and one sister of cancer. Previous history was good. On July 31, 1897, the patient presented the characteristic symptoms of myxedema; features enormously swollen; nose flattened; lips bluish, the lower somewhat everted; eyelids full and distended; constant watering of the eyes; pronounced lemon discoloration of hands and neck; tongue much swollen; speech slow and hesitating; very apparent mental hebetude. Subjective symptoms: Prickling of skin, coldness of feet, frequent sharp burning sensation in extremities; skin dry, hard and fissured; hair dry and coarse; nails brittle; vision and hearing impaired. Temperature by mouth at 2 P.M. 96.4. Pulse 60, weak, compressible. Treatment was instituted, August 3, which consisted of complete rest, and a 2 grain tablet of desiccated thyroid extract, prepared by Armour & Co., two hours after breakfast. After the second dose the temperature had risen to 97.2. On the third day temperature was 97.4, with diminished lachrymation, improvement in quality of voice and for the first time in many months she began to feel the return of strength.

The improvement continued steadily, and on September 3, after one month's treatment, all the above enumerated symptoms have disappeared. She has diminished about one third in size; lost nearly thirty pounds in weight; feeling of vigor, almost buoyancy; pulse 86; temperature normal, and an apparent complete return to a normal condition has been secured. Only once during the treatment did the patient feel badly, which was attributed to the administration of an additional tablet of the thyroïdin. The administration of the drug was suspended for two days and again resumed, without any further trouble. Dr. Bonney in summing up the case, made the following practical deductions: 1. The remarkably short period of treatment. 2. The brilliant results obtained from unusually small doses of the thyroïd. 3. The danger attending the indiscriminate and injudicious administration of larger doses especially with the patient not under competent observation.

Dr. J. T. Eskridge, in opening the discussion, gave a short historic résumé of the treatment of the thyroid gland. He highly complimented the work of H. Gideon Wells, Ph.G., of Chicago, for his elaborate and excellent paper on the "Physiology and Therapeutics of the Thyroid Gland" which was published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, October 30, November 6 and 13, 1897. The treatment of cases of myxedema, he said, is divided in two stages. The first is for the relief of symptoms, and the second to maintain the degree of health secured. He usually begins with the administration of two to five grains daily. Rapid action and palpitation of the heart, slight dyspnea, pains in the legs, headache, etc., indicate that the dose should be diminished or that the agent should be discontinued for a few days. He had employed the animal extract in ten cases of obesity with failure to reduce the weight in one. In three of the nine cases thirty pounds each were lost, while the strength and general well-being of the patient seemed decidedly increased. In a number of cases he found it necessary to give strychnin and spartein to sustain the heart during the most active period of the thyroid treatment. The loss of fat is permanent. Dr. Eskridge also made a résumé of the literature on the thyroid treatment in ununited fractures (*British Medical Journal*, Sept. 12, 1897); pelvic congestion (Twelfth International Med. Congress "Gynecologie"); skin diseases (*N. Y. Med. Jour.*, Nov. 20, 1897); mental diseases (*Journal Mental Science*, January, 1895; *Dublin Jour. Med. Science*, August, 1895; "Practical Therapeutics," vol. ii, p. 292). He thinks it probable that it might be used with advantage in some of the depressive states of the nervous system, and in cases of retarded development both mental and physical. He is at present trying the treatment in a few cases of infantile cerebral palsies. Drs. Edson, Freeman and Rothwell each reported a case of myxedema in which the thyroid treatment was successful.

Dr. CHAS. DENISON read a paper entitled "Passing Consideration of the Antitoxin Treatment of Tuberculosis, Wayside Remarks on the Direct (tuberculin preparation) Versus the Indirect (animal serum) Method of Immunization Against Tuberculosis." He prefaced the paper by the following remarks: "From the absurd advertisement of a Swiss barber, 'Tuberculin injections given here,' and the equally preposterous belief which at first prevailed that a means to destroy tuberculosis has been discovered, as easy of use as a household remedy, we have come to learn that if cure it will, it must be

by a concentration of skilled effort, and by a technique involving as much discrimination in diagnosis and care as does the differentiation of a complicated eye refraction, the microscopic determination of blood changes due to disease, the endoscopic study of internal organs or any other delicate field of professional work." He divided the tuberculin products into two classes: A. Those which are supposed to work by their toxin, creating or stimulating the production of an antitoxin in the blood of an affected person. B. When the antitoxin has already been produced in an animal's blood, preferably one already immune, and then through its serum made available in the treatment of tuberculosis.

To the first class belong: 1, the crude original tuberculin of Koch; 2, tuberculoidin, Klebs' first modification of the former; 3, antiphthisin, practically the same product as Klebs manufactured in this country; 4, tuberculinum purificatum of Dr. Karl von Ruck of Asheville; 5, purified tuberculin of Dr. Whitman of Los Angeles; 6, oxytuberculin of Dr. Hirschfelder of California; 7, Koch's new tuberculin (T. R.); and 8, Dr. Karl von Ruck's watery extract of the bodies of the dead bacilli.

To the second class belong: 1, antitubercle bacilli of Paul Paquin; 2, Professor Crandal's (St. Louis) serum; 3, the serum prepared by the H. K. Mulford Co. of Philadelphia, and the antiphthisic serum (T. R.) made by the John T. Milliken Co. of St. Louis according to the formula of Dr. Carl Fisch. This serum is peculiar in that the selected horses from which it is taken have been strongly immunized, charged with Koch's new tuberculin (T. R.), the process usually taking four months and the serum being drawn fourteen to twenty-eight days after the last injection. When it is considered that for a last dose 150 c.c. are given the horse, we can get some idea of the enormous load of tuberculin these animals are carrying in their blood, by remembering that according to Koch the initial dose of tuberculin (T. R.) should be one five hundredth of a milligram. Dr. Denison gave in brief the results of the various experiments of Dr. Fisch, and the histories of seven cases which he himself treated with the last named serum. Dr. Denison has obtained good results in all his cases, and has not met with any untoward effects so frequently encountered in the use of the other tuberculin preparations.

Dr. BANE reported a case of an "Animate Body in an Ear." The patient, a woman, was exposed in a storm in Arizona and for several days the cold wind blew against the right side of her face. A day after she experienced a peculiar sensation in her right ear. The ear became very painful, swollen, tinnitus constant, with severe pain in the salivary glands upon taking liquids or doing anything that would excite the flow of saliva. On looking into the right canal he noticed a greenish substance that almost filled the membranous portion, which he easily removed. It was found to be a lively insect 4 by 6 mm. in diameter, and 2 mm. thick. It lived for two days and was identified as a wood-tick, *Ixodes*.

Louisville.

HEALTH OFFICE.—It has been announced that the new Board of Public Safety appointed by Mayor Weaver will remove Dr. W. P. White from the office of Health Officer and appoint as his successor Dr. M. K. Allen. Dr. White has had the endorsement of the Louisville Medico Chirurgical, the Clinical, the Surgical, the Falls City Medical Society and the Practitioners' Club, besides the private endorsement of the majority of the practitioners of the city; yet in spite of this the removal of Dr. White has been decided upon. From present indications it was decided upon before the election. Dr. White has made a most excellent record as a health officer and it is a great disappointment to all that this office has been made a political gift.

FALLS CITY MEDICAL SOCIETY. At the last meeting of this Society Dr. Albert Muench read a paper entitled "The Treatment of Acute Urethritis."

REPORT.—The seventy-third annual report of the Eastern Kentucky Asylum for the Insane has just been issued by its superintendent, Dr. Edw. M. Wiley, for the fiscal year ending Sept. 30, 1897. The Board of Commissioners in their report, embodied in it, ask for an appropriation of \$10,000 for the purpose of constructing an adequate artificial sewer. This will be referred to later in speaking of the superintendent's report. An adequate hospital and a gas plant is also asked by the commissioners. Several thousand dollars will be needed for the necessary repairs to the buildings, which is not to be wondered at when it is remembered that this asylum is the oldest one west of the Allegheny mountains. It is urged by the commissioners that the appointment of the superintendent be taken from the Governor's hands and placed in the commissioners', thus removing it from politics entirely. The census at the

close of the year showed 817 inmates, 1,027 being treated during the year. The place is in a most deplorable sanitary condition, with a sewerage system which overflows, damming the refuse back until it has contaminated five cisterns, the typhoid bacillus being found in two of these and sewer gas in the rest. As a result of this there have been forty-two cases between August 12 and October 31 of typhoid fever. The report goes on to say that there is no provision for examining patients or their care beyond the public wards and the rooms in which patients are confined, and as a result of this ten attendants requiring treatment during the typhoid fever epidemic had to be sent outside the building. The provision for the erection of a suitable hospital is earnestly urged. There were a total of 103 deaths during the year. As to the age of those admitted during the year it is interesting to note that thirty-four of the 236 admitted were between 20 and 25 years and thirty-five between 25 and 30 years. Fifty-eight of the females admitted were domestics. Thirty-three of the males were farmers and forty six farm laborers. The remarkable number of insane among the farming class was called attention to on a previous occasion in these columns. Consumption caused seventeen deaths and pneumonia twenty-six. The cases of pneumonia occurred at the time of the overflow of the sewer. Farm and garden products to the value of \$12,827 were produced on the lands of the institution during the year.

CHANGE OF ADDRESS.

Atwater, M. B., from Marysville to 107 Grand St., Helena, Mont.
Becker, E. C., from Riverside to 1753 Milwaukee Ave., Chicago, Ill.
Drake, G. W., from Chattanooga to Nashville, Tenn.
Davidson, S. S., from Mercer to New Castle, Pa.
Holmes, W. F., from 341 Ogden Ave. to 240 N. Kedzie Ave., Chicago, Ill.
Lebau, J. W., from Chicago, Ill. to Alexander, Ia.
Pressey, A. J., from 841 E. Madison Ave., to 900 Fairmount Ave., Cleveland, Ohio.
Prather, D. J., from Little Rock, Ark., to Los Angeles, Cal.
Reynolds, J. F., from Louisville, Ky., to Mt. Sterling, Ky.
Scherer, O. A., from 404 Jefferson Ave. to 106 Miami Ave., Detroit, Mich.
Schultz, W. C., from Lomira to Mayville, Wis.
Stout, J. C., from Los Angeles to 911 Laguna St., San Francisco, Cal.
Storer, W. D., from 1402 Wrightwood Ave., to 485 E. Fullerton Ave., Chicago, Ill.
Tugle, S. P., from 302 Stockton St. to S. E. corner Geary and Stockton, San Francisco, Cal.
Welcome, J. W. B., from Sleepy Eye, Minn., to 620 Jefferson St., Los Angeles, Cal.
Wysor, J. C., from Charleston, W. Va., to Clifton Forge, Va.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from December 11 to 17, 1897.

Capt. Isaac P. Ware, Asst. Surgeon, ordinary leave of absence granted, under orders for duty at Benicia Bks., Cal., is extended one month on account of sickness.

Major Louis Brechemin, Surgeon (Ft. Sherman, Idaho), is granted leave of absence for one month, to take effect about Dec. 15, 1897, with permission to apply to the Adjutant General of the Army for an extension of two months.

First Lieut. Guy C. M. Godfrey, Asst. Surgeon, will be relieved from duty at Ft. Sheridan, Ill., and will report in person to the commanding officer of the detachment of troops at Finn's Point, N. J., for duty at that place and at Ft. Delaware.
